Splanchnic hypoperfusion results in a decrease in gastric intramucosal pH (pHi). Gastric pHi of less than 7.32 has been correlated with increased morbidity and mortality in shock patients (42). Measurement of gastric pHi may be useful in assisting with the estimation of disease severity (43). A 50% mortality has been demonstrated in critically ill patients with a pHi less than 7.32 obtained 24 hours after initial insult, compared with 11% mortality in those with pHi greater than 7.32 (44). Gastric intramucosal acidemia may be an early indicator of hypovolemia.

### Hematological System

The hematologic system is widely affected in shock; in addition to anemia, WBC activation, platelet activation, and coagulopathies are commonly seen. Red blood cells, platelets, and coagulation factors can be diminished by both dilution and consumption. Consumption can result from disseminated intravascular coagulation (DIC), or more rarely, adverse drug reactions such as heparin-induced thrombocytopenia (HIT). Functional platelet dyscrasias can also occur without thrombocytopenia secondary to hypothermia, uremia, and sepsis. Blood products are commonly required in trauma patients with shock. The transfused blood products can themselves cause reactions that mimic or exacerbate shock.

## HYPOVOLEMIC SHOCK

Hypovolemic shock often results from uncontrolled hemorrhage, and is the most common form of shock occurring

in the acute trauma patient. External hemorrhage is usually easily detected following large lacerations, gunshot wounds, and open fractures, but these are not always easy to control. Thoracic and abdominal trauma are additional sources of blood loss that are usually apparent on chest radiograph and objective evaluation of the abdomen [e.g., focused abdominal sonography for trauma (FAST), computed tomography (CT) scanning, or diagnostic peritoneal lavage (DPL)]. However, concealed hemorrhage can be more problematic to diagnose. Common etiologies of concealed hemorrhage include long bone fractures, pelvic fractures, and other sources of retroperitoneal hemorrhage. Nonhemorrhagic hypovolemic shock can also result from diminished intravascular volume from etiologies other than hemorrhage. Causes of nonhemorrhagic hypovolemic shock include major burns, third space losses from crush injury, or major blunt trauma. Other sources include GI losses such as diarrhea and vomiting, and urinary losses such as DI or excess diuretics.

### Pathophysiology

Hypovolemic shock is characterized by intravascular volume loss. The pathophysiology of hypovolemic shock can be revealed as a decrease in venous return, SV, Q, BP, central venous pressure (CVP), pulmonary artery pressures, and pulmonary artery occlusion pressure. A compensatory increase in resorption of fluid into the capillaries decreases interstitial volume in an attempt to maintain intravascular volume. At some point, this compensatory mechanism may become inadequate and frank microcirculatory derangements (increases in capillary permeability, WBC plugging with no-reflow phenomenon, inflammatory mediator release, etc.) may occur.

### Clinical Presentation

The patient's clinical presentation is dictated by the degree of hypovolemia along with comorbid conditions. The worse the premorbid state, the less the body tolerates the hypovolemia. The acutely volume-depleted patient has cool, moist, pallid, and/or cyanotic skin, especially at the extremities. Typical physical examination reveals diminished pulse pressure, rapid pulse, cold clammy integument, and flat neck veins. ⚡ **Because of compensatory mechanisms, there may already be as much as 30% to 40% blood volume loss by the time hemodynamic changes occur (Table 2).** ⚡ The greater the quantity and rate of volume loss, the greater the degree of shock sustained. Initial patient evaluation includes estimating blood volume deficit (Table 4), estimating rate of additional blood loss, completing a primary and secondary survey according to ATLS principles, evaluating cardiopulmonary reserve, and evaluating coexisting hepatic or renal dysfunction (45).

**Table 4** Estimation of Blood Volume Deficit in Trauma

Unilateral hemothorax	1000–3000 mL
Hemoperitoneum with abdominal distension	2000–5000 mL
Full-thickness soft-tissue defect 5 cm <sup>3</sup>	500 mL
Pelvic fracture	1500–2000 mL
Femur fracture	800–1200 mL
Tibia fracture	350–650 mL
Smaller fracture sites	100–500 mL

## Management and Monitoring Priorities

✦ Major goals in resuscitation include controlling blood loss, repleting intravascular volume, and restoring adequate tissue  $\dot{D}O_2$ . ✦ Management and monitoring priorities in the acutely bleeding trauma patient target oxygenation and ventilation, BP measurement, electrocardiogram (ECG) monitoring, pulse oximetry, and capnography. The treating physician must establish or verify adequate intravenous (IV) access for infusion of normothermic fluids. Measurement of temperature, urine output, ABGs, hemoglobin, hematocrit, electrolytes, and parameters of coagulation is routine in severely injured patients. Arterial catheterization and monitoring is usually warranted once basic management priorities are fulfilled. Placement of invasive monitors (e.g., CVP, pulmonary artery catheter) and/or transesophageal echocardiography (TEE) may be considered, but should not delay definitive care.

A lag in restoration of normal organ perfusion may be present even after it appears the hemorrhagic shock patient has been adequately resuscitated (46). Despite recent suggestions that delayed fluid therapy may be preferable in isolated penetrating trauma, the current recommendation remains to optimize intravascular volume to prevent organ hypoperfusion. ATLS recommendations call for an initial bolus of 2000 mL crystalloid to determine hemodynamic response (Table 5).

Patients with higher preload, initially, after shock presentation maintain higher preload, demonstrate less intramucosal gastric acidemia, and have lower mortality (47).  $\dot{Q}$ , BP, and perfusion of oxygenated blood flow to vital organs are important determinants of outcome. A byproduct of massive volume resuscitation is tissue edema, in part, due to increased capillary permeability and perhaps decreased plasma oncotic pressure. Patients with comorbid cardiac dysfunction may be at risk for congestive heart failure (CHF) with even moderate volume overload. These patients may benefit from early placement of central monitoring to guide therapy.

## Fluid Options

The choice of IV solutions for fluid resuscitation in all forms of shock remains controversial and is fully discussed in Volume 1, Chapter 11. Initial fluid resuscitation is most commonly performed with crystalloid solutions. Blood products are reserved for replacement of significant red blood cell loss, thrombocytopenia, or coagulopathies due to factor deficiency. Nonplasma colloids are generally used in low albumin states or when hypovolemia is so pervasive that crystalloid administration is not capable of resuscitating the patient.

## Isotonic Crystalloids

Lactated Ringer's (LR) solution or isotonic 0.9% normal saline are given intravenously to replenish intravascular and interstitial volume (48). One-fourth to one-sixth of the isotonic fluids administered remains in the intravascular space. LR is a balanced electrolyte solution containing lactate, which is converted to bicarbonate by a functioning liver (49,50). This is useful in trauma patients with metabolic acidosis, as LR solution does not elevate circulating lactate levels in patients with a functioning liver (51). Because LR solution contains calcium, and can theoretically precipitate clotting when infused into blood products using citrate phosphate dextrose (CPD) as an anticoagulant, it should not be used with blood product. Rather, 0.9% normal saline is the solution of choice to dilute packed red blood cells. It is an acceptable alternative for fluid resuscitation; however, large volumes result in a hyperchloremic metabolic acidosis (Volume 2, Chapter 45), which may complicate patient care (49,52). Glucose solutions are avoided, as hyperglycemia may aggravate CNS injury (53,54).

## Colloids

Colloids increase plasma volume to a larger degree than do crystalloids per unit volume infused, and remain intravascular for a longer period of time (55,56). However, several studies suggest worse outcomes in trauma patients receiving albumin (see Volume 1, Chapter 11). Trauma induces a state of inflammation which results in damaged endothelial integrity and altered microvascular permeability, promoting the extravasation of fluid and large molecules such as albumin into the interstitium (57), which may actually worsen interstitial edema (58).

Albumin is the least likely of the colloids to induce a coagulopathy, but both albumin and hetastarch can increase the risk of coagulopathy (59–62). In view of these concerns along with the expense of colloid compared to crystalloid, routine use of colloids in trauma patients appears unwarranted. Hetastarch doses greater than 1.5 L have been implicated in coagulopathy as a result of diminished factor VIII levels (63,64). Anaphylactoid reactions may also occur with colloid administration (65).

Hextend, a relatively new, physiologically balanced colloid plasma expander, does not appear to cause acidosis or coagulopathy following the infusion of up to 5 L in vivo and may be a promising colloid option (66). To date, no trauma outcome studies have been completed with Hextend.

**Table 5** Responses to Initial Fluid Resuscitation<sup>a</sup>

	Rapid response	Transient response	No response
Vital signs	Return to normal	Transient improvement, recurrence of ↓ BP and ↑ HR	Remain abnormal
Estimated blood loss	Minimal (10–20%)	Moderate and ongoing (20–40%)	Severe (>40%)
Need for more crystalloid	Low	High	High
Need for blood	Low	Moderate to high	Immediate
Blood preparation	Type and cross-match	Type-specific	Emergency blood release
Need for operative intervention	Possibly	Likely	Highly likely
Early presence of surgeon useful	Yes	Yes	Yes

<sup>a</sup>2000 mL Ringer's lactate solution in adults, 20 mL/kg Ringer's lactate bolus in children.

Abbreviations: BP, blood pressure; HR, heart rate.

### Hypertonic Saline

☞ **Hypertonic fluids can provide rapid volume expansion, improved hemodynamics, lessen tissue edema, diminish inflammatory response, lower ICP, and decrease brain water when compared with isotonic solutions (67,68).** ☞ Hypertonic solutions result in an osmotic translocation of extracellular and intracellular water. The intracellular half-life of hypertonic saline is similar to that of isotonic saline.

Despite the above described theoretical benefits, hypertonic saline has been associated with bleeding, hemodynamic deterioration, and increased mortality in some animal studies of uncontrolled hemorrhagic shock (69). A small study of septic patients demonstrated an improvement in cardiovascular parameters; however, patients receiving hypertonic saline had a higher incidence of bleeding, hemolysis, hypernatremia, and hyperchloremia (70). Hypertonic saline does not improve cerebral  $\text{DO}_2$  after head injury and mild hemorrhage in animals (71). However, hypertonic saline combined with 6% hydroxyethyl starch may improve neurologic function and cerebral perfusion pressure (CPP) in patients with traumatic brain injury (TBI) (72). Such hypertonic fluid solution is currently used in Austria for resuscitation of all head-injured and major trauma patients in the field.

### Blood Products

☞ **Blood products should be reserved for patients who are hemorrhaging briskly, and in more stable patients who are requiring transfusion due to dangerously low levels of red blood cells, platelets, or other factors (see Volume 2, Chapter 59) (73).** ☞ Blood products should not be transfused in stable patients for volume expansion without such deficiencies. Blood products are expensive, relatively scarce, and carry the risk for transmissible disease.

$\text{DO}_2$  is generally adequate with a hemoglobin of 7 g/dL in critically ill patients without underlying coronary artery disease (CAD) (see Volume 2, Chapters 54 and 59). A reasonable transfusion trigger in patients with significant CAD is a hemoglobin of 10 g/dL. Tissue oxygenation is maintained in otherwise healthy, normovolemic individuals, between hematocrits of 18% and 25% (74). Relatively restrictive transfusion triggers, maintaining hemoglobin between 7 and 9 g/dL, in critically ill patients appears to confer no added risk to organ function or survival compared with a liberal regimen trigger of 10 to 12 g/dL (75). The rate and magnitude of blood loss, degree of cardiopulmonary reserve, presence of atherosclerotic disease, and oxygen consumption should affect the transfusion trigger for red blood cells (73).

Actively bleeding patients with large volume blood loss in class III or IV (Table 2) shock, however, require immediate blood administration (76). Type O-negative, type-specific, typed and screened, or typed and cross-matched packed red blood cells are options. The initial choice of product depends upon the degree of hemodynamic stability and the acuity of the need for transfusion. Type O-negative red cells have no major antigens and may be given to patients with all blood types (76). Only 8% of the population have O-negative blood; therefore, O-positive red blood cells are frequently used. However, O-positive blood will predispose Rh-negative females of childbearing age to hemolytic disease of the newborn and should be avoided in this population if practicable.

If type O blood has been given in volumes of 50% to 75% of the patient's blood volume (e.g., approximately 10

units of red cells in an adult patient), it is prudent to continue to administer type O red cells if further transfusion is required. If possible, the use of type-specific red cells, requiring five to ten minutes in most institutions, is preferred over O-negative (77). Temporizing measures may sometimes be employed to gain the necessary time, as a full cross-match requires 45 minutes.

Post-traumatic bleeding is primarily due to surgical causes, hypothermia, and dilution. Additional coagulopathies may present due to preexisting defects or DIC (78). Correction of coagulopathies to forestall continued bleeding is essential in the care of hemorrhagic shock. Point-of-care testing and rapid reporting of coagulation test results should be used to guide decisions regarding administration of fresh frozen plasma (FFP), platelets, or cryoprecipitate (Table 6). Microvascular bleeding in this setting can be treated with FFP (79). Typically, 30% of coagulation factors, provided by two units of FFP (10–15 mL/kg), are required to achieve clinically adequate levels. Cryoprecipitate may be used to correct specific factor deficiencies. Dilutional thrombocytopenia, or a platelet count reduced to  $<50,000/\mu\text{L}$ , is a cause of hemorrhagic diathesis after transfusion of 1.5 to 2.0 blood volumes (80,81), corresponding to approximately 15 to 20 units of red cells in an adult trauma victim (82,83). Platelet transfusions are indicated in the presence of clinical bleeding and platelet count less than 75,000 to 100,000/ $\mu\text{L}$ . One unit of platelet (50 mL) increases the platelet count in an adult by 5000 to 10,000/mL.

Activated recombinant factor VII, although not approved by the FDA, is a relatively new approach to assist in the control of massive hemorrhage (84). A number

**Table 6** Common Blood Components Used in Trauma

Blood component	Characteristics
Whole blood	RBC and plasma WBC and platelets not viable after 24-hr storage Labile clotting factors significantly decreased after 2 days of storage Hematocrit 35%
PRBC	PRBC with reduced plasma volume WBC, platelets, and coagulation factors as for whole blood Hematocrit 69%
Random-donor platelet concentrate	Platelets $5.5 \times 10^{10}$ Some WBC (i.e., lymphocytes) 50 mL of plasma Few RBC Hematocrit $<0.5\%$
Fresh frozen plasma	Plasma proteins All coagulation factors Complement
Cryoprecipitate	80 units of factor VIII Other plasma proteins Von Willebrand factor Factor XIII Fibrinogen (200 mg) Fibronectin

*Abbreviations:* PRBC, packed red blood cell; RBC, red blood cell; WBC, white blood cell.

of clinical and case reports indicate an improvement in hemostasis without the apparent activation of the coagulation cascade. Although no definitive dosing schedule has been determined, doses ranging from 40 to 221  $\mu\text{g}/\text{kg}$  have been reported (85,86).

### Hypothermia

✎ **Avoidance of hypothermia (Volume 1, Chapter 40) is another primary consideration in the resuscitation of hypovolemic trauma patients.** ✎ The patient's environment should be kept warm. Trauma patients often arrive to the hospital hypothermic. The subgroup of spinal cord injury (SCI) patients uniformly present with hypothermia. Detrimental effects of hypothermia include coagulopathies, cardiac dysrhythmias, and compromised immune function (87–89).

Standard coagulation tests are temperature corrected to 37°C and may not reflect hypothermia-induced coagulopathy (90–92). Hypothermia impairs coagulation due to decreased enzymatic rates and reduced platelet function. Hypothermia may also cause decreased myocardial contractility (93), cardiac dysrhythmias, and even cardiac arrest due to electromechanical dissociation, standstill, or ventricular fibrillation, particularly with core temperatures below 30°C. Citrate, lactate, and drug metabolism are impaired by hypothermia; increases in blood viscosity, impairment of red blood cell deformability, increases in intracellular potassium release, and a left-ward shift of the oxygen dissociation curve impairing oxygen offloading to tissues may also occur. One hundred percent mortality has been reported in trauma patients whose body temperature fell to 32°C (94), regardless of severity of injury, degree of hypotension, or fluid replacement.

Infusion of 4.3 L of room temperature crystalloid to a 70-kg trauma patient will result in a decrease of 1.5°C in core temperature (95,96). Similarly, infusion of 2.3 L of diluted red cells could result in a core temperature decrease between 1°C and 1.5°C. Thus, in addition to keeping the patient's environment warm, all fluids administered should be warmed.

The use of fluid-warming devices effective at delivering normothermic fluids to the patients at clinically relevant flow rates permit rewarming of hypothermic trauma patients; rewarming may be enhanced by an externally provided heat source such as a convective warming device (97). Fluid and blood resuscitation of the trauma patient is best accomplished with large-gauge IV catheters and effective fluid warmers with high thermal clearances (98). Counter-current water and other fluid warmers using 42°C set points provide consistently warm fluid delivery, maintain thermal neutrality with respect to fluid, and do not damage red blood cells (97).

### Pressors and Inotropes

✎ **Pressors and inotropes should be used only as temporizing measures in the setting of isolated hypovolemic shock.** ✎ Their use to maintain perfusion pressure within the range of autoregulation of the brain and the heart may occasionally be temporarily necessary while volume is being transfused. It must be recognized that such intervention will not necessarily provide adequate perfusion to other organs, and may worsen splanchnic and renal perfusion. In contrast to most pressors, vasopressin has shown potential in the early treatment of hemorrhagic shock without such compromise. The dosage for hemorrhagic shock is an initial bolus of 20 units followed by infusion of

0.2–0.4 units/min, increased up to 0.9 units/min as needed, per FDA guidelines. Vasopressin has an even greater role in the treatment of distributive shock (discussed further).

Calcium is also frequently required to restore hemodynamics in patients who have received large volumes of blood products. Packed red blood cells, FFP, and platelets are all stored in CPD with adenine or adsol at 4°C and may acutely decrease serum-ionized calcium levels (citrate-binding calcium) (99). Hypocalcemia decreases inotropy and vascular tone, and at severely decreased levels will exacerbate coagulopathy. Calcium administration is warranted during massive transfusion if large amounts of blood are transfused rapidly (50–100 mL/min) or if the patient is hypotensive and measured ionized calcium values are low. Ionized serum calcium typically normalizes when hemodynamic status is restored, so long as liver function remains intact.

## CARDIOGENIC SHOCK

Cardiogenic shock is common, occurring in up to 25% of myocardial infarction patients in the United States. Cardiogenic shock is associated with an increased morbidity and mortality, approaching 60%. Cardiogenic shock can also be seen in such conditions as acute valvular dysfunction, dysrhythmia, or myocarditis. In trauma, myocardial contusion or coronary artery injury can also precipitate cardiogenic shock.

### Pathophysiology

The pathophysiology of cardiogenic shock usually results from a decreased O<sub>2</sub> supply/demand ratio, and is characterized by a decrease in myocardial contractility. Consequently, SV, Q, and ultimately BP are all diminished. The CVP, pulmonary artery (PA) pressure, and PA occlusion pressures are generally all increased as blood returns to the heart but is not subsequently pumped out efficiently. Heart rate is variable, but often is increased in order to compensate for decreased SV, in an effort to preserve Q, and systemic vascular resistance (SVR) increases in order to preserve BP.

Among the more common etiologies of cardiogenic shock in trauma is myocardial contusion (100,101). Nonetheless, hemodynamic consequences precipitating shock from this etiology are not common. If myocardial failure occurs in the setting of blunt chest trauma, etiologies such as tamponade and cardiac rupture must be ruled out. Pulmonary artery catheter placement and/or optimally, TEE can discriminate between these diagnoses. Equilibration of pressures on pulmonary artery evaluation would indicate tamponade. TEE can quickly reveal or rule out tamponade, valvular dysfunction, contractility problems, and hypovolemia. The right ventricle (RV) is most frequently involved following blunt chest injury, demonstrating focal or general stunning.

### Clinical Presentation

The clinical presentation of cardiogenic shock demonstrates hypoperfusion with peripheral vasoconstriction. Ejection fraction (EF) is decreased. Cold and mottled extremities, cyanosis, hypoxemia, altered sensorium, and decreased urine output are typical manifestations. Signs of elevated intravascular volume such as jugular venous distension, rales on chest examination, and an S3 gallop may be present. A new murmur may also be present. Invasive monitoring is generally diagnostic, with elevated CVPs along with diminished

$\dot{Q}$  and SV. Chest X rays may demonstrate elevated pulmonary vascular volume with cephalization of vessels or frank pulmonary edema. TEE may demonstrate either global or segmental dysfunction with diminished EF or possibly an acute valvular defect. ECG may demonstrate ischemic signs such as ST-depression (subendocardial ischemia) or ST-elevation (transmyocardial ischemia).

In the case of myocardial contusion, it is rarely an isolated injury, and generally occurs in the setting of severe polytrauma. Abnormal ECGs and abnormal CK-MB and/or troponin values correlate with significant symptoms and the need for treatment, whereas normal ECGs and CK-MB and/or troponin values correlate with clinically insignificant complications. In patients with ECG abnormalities and/or echocardiographic abnormalities, cardiac troponin is not especially sensitive, nor specific for the diagnosis of myocardial contusion (102). Patients at risk for myocardial contusion who are younger than 55 years old, hemodynamically stable, without history of cardiac disease, and with a normal ECG have minimal likelihood for significant adverse events requiring subsequent intervention (103).

### Monitoring and Management Priorities

Management of cardiogenic shock centers upon improving cardiac performance, improving cardiac output, maintaining sinus rhythm, and restoring effective organ perfusion. A variety of means may be employed, depending upon the etiology of the insult. Inotropic agents, arterial dilators, venodilators, appropriate sedation, and intra-aortic balloon counterpulsation (Volume 2, Chapter 22) may be indicated. Emergent definitive therapy such as emergent revascularization or valvular repair may be life-saving. Thrombolysis in the setting of acute myocardial infarction with cardiogenic shock has not been demonstrated to improve mortality.

### Fluid Management

In the setting of cardiogenic shock, fluid administration must be judicious. These patients may be approaching the steep end of the Starling curve. Even moderate volume administration may place these patients at risk for CHF. Naturally, trauma patients with concomitant hypovolemia will require more aggressive fluid repletion. PA catheters and TEE monitoring can assist in guiding rational fluid therapy. For significant myocardial contusion, which is similar to other forms of RV failure, treatment requires adequate preload to maintain LV filling.

### Inotropes

Inotropic agents should be considered early in cardiogenic shock. Inotropic agents improve myocardial contractility. Normal patients have a  $\beta_1$ - to  $\beta_2$ -myocardial receptor ratio of 80:20. Patients with a failing myocardium have a decreased absolute number of  $\beta_1$ -receptors along with a global diminished responsiveness to  $\beta$ -stimulation (104). Initial  $\beta$ -receptor down-regulation may occur within several hours of initial insult. With increased clinical severity of heart failure, there is greater reduction of  $\beta_1$ -receptors (105). This consideration must be entertained when choosing inotropic therapy for patients with myocardial dysfunction. Phosphodiesterase inhibitors do not rely on  $\beta$ -receptors, and may be helpful in cardiogenic shock. Phosphodiesterase inhibitors act primarily through inhibition of phosphodiesterase fraction III, found predominantly in cardiac muscle, increasing cyclic AMP and intracellular calcium to

increase inotropy (see Volume 2, Chapter 17 for rational use of vasopressors in this population).

### Vasodilators

Vasodilators can be considered in the treatment of severe cardiac dysfunction when SVR is very high. Decreasing SVR and preload decreases myocardial wall tension and cardiac work, thus improving the myocardial oxygen supply to demand ratio. However, in the setting of concomitant hypovolemic shock with compromised BP, isolated treatment with vasodilators is not beneficial, as it will further diminish coronary artery perfusion pressure, and simultaneously decrease perfusion pressure to other vital organs such as brain and kidneys. Rather simultaneous volume repletion and inotropic support is a superior initial management plan. As intravascular volume is repleted, the SVR will tend to decrease some. If ongoing cardiogenic shock keeps SVR high, despite adequate fluid repletion, then inotropes with vasodilatory side effects can be employed.

Inotropes such as dobutamine and phosphodiesterase inhibitors provide a component of vasodilation along with improved inotropy and are the most commonly utilized vasodilators in cardiogenic shock. In the postacute cardiogenic shock phase, primary vasodilator drugs such as angiotensin-converting enzyme (ACE) inhibitors, nitrates, along with rate-control drugs such as  $\beta$ -blockers have been shown to improve long-term outcomes.

Caution must also be exercised when instituting nitrates in patients with decreased preload, as nitrates can cause further intravascular depletion resulting in increased hypotension, with a compensatory response of increased HR (increasing the risk of ischemia). Rate-related ischemia is often best remedied by initially controlling HR, using a cardioselective  $\beta$ -blocker, such as esmolol 10–100 mg IV, titrated 10–20 mg per dose, and augmented by small doses of pressors such phenylephrine 40–80  $\mu$ g IV during initiation of  $\beta$ -blocker therapy. As HR decreases, and MAP is maintained, ischemia often resolves. As ischemia resolves, myocardial performance typically improves. Systemic BP increases, organ perfusion improves, and the need for supplemental pressor support can be abated.

### Ensuring Adequate Analgesia and Sedation

A cornerstone of patient care is providing adequate comfort, including both analgesia and anxiolysis (Volume 2, Chapter 5). Adherence to these precepts is particularly important in patients with cardiogenic shock. Indeed, these patients are uniquely prone to ischemia and dysrhythmias when pain and/or anxiety are inadequately treated. Reducing the hyperadrenergic state by effective analgesia reduces myocardial oxygen consumption by decreasing sympathetic discharge, decreasing vascular tone, and decreasing cardiac work.

Opioids are a reasonable first-line choice. Once adequate analgesia is provided, additional anxiolysis can be added, if required. Benzodiazepines are an appropriate choice in this setting. The synergistic effect of benzodiazepines with opioids must be kept in mind when initiating their use, both in terms of hemodynamics and respiratory depression. In general, the peak respiratory depressant effect of morphine occurs 15 to 20 minutes following an IV bolus.

An additional consideration for sedation are the newer  $\alpha_2$ -agonists such as dexmedetomidine. Dexmedetomidine offers analgesia and sedation with minimal

respiratory-depressant properties. Dexmedetomidine also possesses potent sympatholytic properties, and directly produces both vasodilation and decreased HR.

### Mechanical Assist Devices

Intra-aortic balloon pump (IABP) counterpulsation may be life-saving for patients in cardiogenic shock. The IABP was developed and entered into clinical practice 40 years ago (106,107), and improves survival in patients with severe or intractable cardiac shock (108) due to various forms of LV failure (Volume 2, Chapter 22). IABP is not a definitive therapy, but can be a bridge until definitive therapy can be initiated. Inflation of the IABP during diastole augments diastolic pressure improving coronary artery perfusion, whereas rapid deflation during systole decreases “afterload” and myocardial work.

### Definitive Therapy

Definitive therapy, when appropriate, specifically addressing the underlying etiology of the cardiogenic shock should be instituted as soon as possible (Volume 2, Chapter 18). Thrombolysis for acute myocardial infarction is typically contraindicated in the setting of acute trauma. Alternative therapies such as percutaneous transluminal coronary angioplasty (PTCA) or surgery may also be contraindicated given the need for anticoagulation in such therapies. Surgical intervention, however, may be required as a life-saving measure in acute, traumatic valvular injury. Cardiac surgery and cardiology consultation should be obtained in such circumstances to access appropriate risk:benefit ratios.

## DISTRIBUTIVE SHOCK STATES

Distributive shock states comprise a spectrum of disease processes with vasodilated hemodynamic profiles. The most commonly considered forms of distributive shock are septic shock, anaphylactic and anaphylactoid reactions, neurogenic shock, and adrenal crisis.

Septic shock, SIRS, and anaphylaxis are characterized by release of mediators that induce vasodilation, increase microvascular permeability, and affect capillary leakage of plasma proteins. Neurogenic shock refers to hypotension following spinal cord injury and is characterized by vascular dilation secondary to a diminished sympathetic outflow. Systemic hypotension secondary to vascular dilation is the hallmark in distributive shock. SV is often normal or elevated.

### Septic Shock

Septic shock results of an infectious process (Volume 2, Chapter 47), cause an SIRS (Volume 2, Chapter 63) state. Because SIRS can result from either infectious or noninfectious etiologies (e.g., trauma, transfusions, pancreatitis) a wide differential should be initially considered. SIRS is characterized by tachycardia, tachypnea, hyperthermia (temperature  $>38.5^{\circ}\text{C}$ ) or hypothermia (temperature  $<36^{\circ}\text{C}$ ), leukocytosis (WBC  $>12,000/\mu\text{L}$ ) or leukopenia (WBC  $<4,000/\mu\text{L}$ ), or bandemia (elevation of immature WBC  $>10\%$ ). Should SIRS progress to involve failure of more than one organ system, it is termed MODS. Septic shock is characterized by hypotension not readily responsive to volume infusion, and dysfunction or failure of at least one organ system. It is the 13th leading cause of morbidity in the United States (109,110) with a mortality of more than 50%.

Bacteria, fungi, and rarely, viruses cause sepsis. Septic shock is a systemic inflammatory syndrome secondary to a suspected or documented infectious process accompanied by end-organ damage or refractory hypotension (111–113). Trauma and hemorrhage are the leading causes of noninfectious SIRS. Similar to sepsis, a neurohumoral cascade is initiated with major trauma or hemorrhage. Early changes are proinflammatory; inflammatory mediators such as cytokines are released and contribute to physiological changes of vascular dilation and impairment of intravascular integrity (i.e., leaky capillaries). Subsequent immunodepression may follow.

### Pathophysiology

The pathophysiology of septic shock results from both direct action of microbial toxins and the body’s response to the infection. Toxins such as endotoxin, peptidoglycan, and lipoteichoic acid (LTA) may trigger an inflammatory cascade. The body’s response to these stimuli may be overzealous and precipitate SIRS, septic shock, and MODS. Cytokines and a host of other circulating inflammatory mediators are involved in the process. Among those cytokines implicated include tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and the interleukins. These cytokines mediate such systemic responses as hyperthermia, tachycardia, increased endothelial permeability, DIC, and shock. Systemic vasodilators include NO, prostacyclin, and prostaglandin E<sub>2</sub>.

### Clinical Presentation

The presentation of septic shock results from hypotension primarily from vasodilation, but also from intravascular hypovolemia secondary to extravasation of fluid into the interstitium. In addition, direct myocardial depressants may be present, impairing cardiac performance. Therefore, although septic shock is commonly considered as secondary to vasodilation, that is, distributive shock, it is apparent that components of hypovolemia and myocardial dysfunction are common. Components of obstructive shock, such as decreased venous return with either ACS or elevated ventilatory pressures, may also contribute to the overall condition. In this setting, multiple organ systems are impacted. The CNS may be affected directly with toxins causing obtundation, but may also be affected due to cerebral hypoperfusion during severe shock.

The cardiovascular system is affected in several ways. The vasculature dilates causing an effective intravascular hypovolemia. Additional intravascular hypovolemia occurs secondary to toxically mediated endothelial injury, resulting in extravasation of fluids into the interstitium. Furthermore, direct myocardial depression may occur (usually later in the course of disease). The overall hemodynamics of this setting are typically that of increased Q, SV, HR, with decreased preload and SVR. TEE, early in the process, will demonstrate central hypovolemia with variable degrees of diminished myocardial performance.

The pulmonary system is also frequently affected in septic shock. The etiology of infection can be the lungs. However, even if the site of infection is distant from the lungs, pulmonary dysfunction is common. The body’s entire circulation passes through the lungs, exposing the lungs to circulating toxins and mediators. Extravasation of fluids into the lung interstitium may cause significant declines in oxygenation due to increased diffusion gradients. Further injury may occur with the progression of ALI to ARDS.

Renal dysfunction is also prevalent, ranging from mild oliguria to frank ATN. Typically, the hypotension of septic shock and renal hypoperfusion is the precipitating event of the ATN; however, additional injury secondary to sepsis-related cytokines and nephrotoxic agents such as antibiotics (aminoglycosides) and radiocontrast agents can also occur.

The GI system may be involved in the pathogenesis of septic shock. Gram-negative sepsis is the most common etiology of septic shock. Sepsis from GI sources may also be a result of shock from other etiologies. During periods of significant hypotension, such as during traumatic hypovolemic shock, splanchnic blood supply and GI perfusion may be compromised. In this setting, mucosal integrity may be compromised with resulting systemic transfer of vasoactive peptides, lipids, and eventually the translocation of gut bacteria, resulting in sepsis.

The hematologic system also develops derangements. WBC count is typically elevated early in sepsis (predominantly neutrophils) but may decline to precipitously low levels in later stages of sepsis as immune function is compromised. Thrombocytopenia due to either the dilutional effects of volume resuscitation, consumption of platelets with DIC, or microvascular thromboses may occur. Bone marrow suppression may occur in critical illness or secondary to medications. Anemia requiring red blood cell transfusion may be required.

### Management

Management of septic shock requires a multimodal approach. Care is not just focused upon the hypotension, but also must include treatment of the inciting infection (111,114,115). Appropriate antibiotic coverage should begin as soon as possible, with a goal of initiation of treatment within four to eight hours. Empiric broad-spectrum antibiotics may be a reasonable choice in the early period while definitive diagnosis and therapy is undertaken as reviewed in Volume 2, Chapter 53. Specific antimicrobial choices may be tailored to the suspected source of infection. Surgical management such as for bowel perforation or catheter placement for abscess drainage may be required. Additional care is supportive in nature, supporting the systems that may be affected by the septic shock. As in other forms of shock, initial therapy is aimed at maintaining adequate intravascular volume. Tissue oxygenation is dependent upon both supply and demand. During periods of excess inflammation, demand increases while supply must remain adequate to meet the increased demands.

Perhaps the best-known evidence-based publication for the treatment of sepsis and septic shock is the Surviving Sepsis Campaign Guidelines published in 2004 (116). Among the positive recommendations supported by at least one large randomized trial with clear-cut results is the use of "early, goal-directed therapy" (120). This method advocates aggressive optimization of hemodynamics and oxygen balance within six hours of diagnosis of septic shock.

The guidelines for sepsis and septic shock have been well articulated by the Surviving Sepsis Campaign. Recommendations were graded from A to E with category A representing evidence from two or more large randomized trials, and category E representing case series, uncontrolled studies, nonrandomized historical controls, or expert opinion. Here we review the findings of the Surviving Sepsis Campaign that were graded with an A or B (supported by at least one large randomized trial) (Table 7).

Volume resuscitation to replace fluids lost to leaky capillaries and decreased vascular tone is the cornerstone of therapy. Meta-analysis of sepsis patients shows no consistent benefit to crystalloid versus colloid use (117–119). In all forms of distributive shock, relative intravascular volume is depleted, whereas total body volume is usually elevated. It is common for infused volumes to exceed 5 L of crystalloid (120). An effective approach is to titrate volume until SV is maximized, typically at 100–150 cc/beat, while maintaining acceptable cardiac filling pressures, effectively defining the cardiac Starling curve.

Vasopressors are added when volume resuscitation is deemed adequate. They may also be used during early resuscitation to augment systemic BP while volume is being administered. Norepinephrine, phenylephrine, vasopressin, dopamine, and epinephrine are commonly used agents in the treatment of septic shock.

### Vasopressors and Inotropes

Vasopressors are instituted in septic shock when volume resuscitation alone does not restore adequate BP and organ perfusion. Phenylephrine is often the first pressor chosen. As a direct-acting  $\alpha$ -adrenergic agent, phenylephrine produces vasoconstriction without inotropic support. Phenylephrine has a rapid onset and a limited time of duration of less than 10 minutes following bolus. It may be given through a peripheral IV either in bolus or continuous infusion.

Norepinephrine is the pressor of choice in septic shock; it has both direct  $\alpha$  and  $\beta$  sympathomimetic effects. Supplementation with norepinephrine will provide a greater  $\dot{Q}$  and SV for a given systemic BP than phenylephrine alone. Norepinephrine is a potent vasoconstrictor and should be infused via central access to lessen the risk of local ischemia, should peripheral extravasation occur. Recent studies demonstrate that norepinephrine may indeed be the drug of choice for patients with a low-tone state when used to support hemodynamics in patients with normal to elevated  $\dot{Q}$  (121). Models of distributive shock treated with norepinephrine have shown an increase in organ perfusion pressure along with an improvement of splanchnic, renal, and glomerular blood flow, and may be associated with better prognosis than either epinephrine or dopamine (122–124). While there has not been a controlled outcome study in humans, many distributive shock patient series demonstrate an increased GFR and urine output when norepinephrine is utilized (122), presuming that adequate volume resuscitation has been undertaken. Norepinephrine is also less likely to raise ICP than dopamine (125), and may be preferred in head trauma patients requiring vasopressor therapy with modest inotropy.

Dopamine, traditionally, has been the drug of choice for cardiovascular support in septic shock. Dopamine exerts various effects based upon the dose range. Doses in the range of 2–5  $\mu\text{g}/\text{kg}/\text{min}$  have historically been used for as yet unproven "renal protective properties" (126), affecting predominantly the dopamine receptors located chiefly in the splanchnic circulation and renal beds. Doses in the 5–10  $\mu\text{g}/\text{kg}/\text{min}$  range are used for inotropic effects as  $\beta$ -adrenergic effects come into play. Doses 10–20  $\text{mcg}/\text{kg}/\text{min}$  are used for pressor effect as  $\alpha$ -receptors become affected. The utility of dopamine as first-line pharmacotherapy has been questioned recently. Norepinephrine and vasopressin appear to offer improved outcomes in distributive shock when compared with dopamine. Dopamine is further limited by its propensity for tachyarrhythmias.

**Table 7** Surviving Sepsis Campaign Guidelines

Category	Grade	Recommendation
Initial resuscitation	B	Resuscitation of a patient with severe sepsis or septic shock should begin at recognition. During the first 6 hrs, the following should be targeted: CVP 8–12 mmHg MAP >65 mmHg UOP >0.5 mL/kg/hr SvO <sub>2</sub> >70%
	B	During the first 6 hrs, if SvO <sub>2</sub> of 70% is not achieved with a CVP of 8–12 mmHg, then transfusion of PRBCs to a hematocrit of 30% and/or a dobutamine infusion should be started to achieve this goal
Vasopressors	B	Low-dose dopamine should not be used for renal protection as part of the treatment of severe sepsis
Inotropic therapy	A	A strategy of increasing cardiac index to achieve an arbitrarily predefined elevated level is not recommended
Steroids	A	Doses of corticosteroids >300 mg hydrocortisone daily should not be used in severe sepsis or septic shock for the purpose of treating septic shock
rhAPC	B	rhAPC is recommended in patients at high risk of death (APACHE II ≥25, sepsis-induced multiple organ failure, septic shock, or sepsis-induced acute respiratory distress syndrome) and with no absolute contraindications related to bleeding risk or relative contraindication that outweighs the potential benefit
Blood product administration	B	Once tissue hypoperfusion has resolved and in the absence of extenuating circumstances, such as significant coronary artery disease, acute hemorrhage, or lactic acidosis, red blood cell transfusion should occur only when hemoglobin decreases to <7.0 g/dL to target a hemoglobin of 7.0–9.0 g/dL
	B	Erythropoietin is not recommended as a specific treatment of anemia associated with severe sepsis, but may be used when septic patients have other accepted reasons for administration of erythropoietin such as renal failure–induced compromise of red blood cell production
Mechanical ventilation	B	Antithrombin administration is not recommended
	B	High tidal volumes that are coupled with high plateau pressures should be avoided in ALI/ARDS. Tidal volumes should be 6 mL/kg and inspiratory plateau pressures should be <30 cmH <sub>2</sub> O
	A	A weaning protocol should be in place and mechanically ventilated patients should undergo a spontaneous breathing trial to evaluate the ability to discontinue mechanical ventilation when they satisfy set criteria
Sedation, analgesia, and neuromuscular blockade	B	Protocols should be used when sedation of critically ill, mechanically ventilated patients is required
	B	Either intermittent bolus sedation or continuous infusion sedation to predetermined end-points with daily interruption/lightening of continuous infusion and retitration if necessary
Renal replacement	B	In acute renal failure, and in the absence of hemodynamic instability, continuous veno-venous hemofiltration and intermittent hemodialysis are considered equivalent
DVT prophylaxis	A	Severe sepsis patients = low-dose unfractionated heparin or low-molecular-weight heparin If contraindication to heparin = mechanical prophylaxis or intermittent compression device High-risk patients = pharmacologic + mechanical therapy
Stress ulcer prophylaxis	A	Stress ulcer prophylaxis should be given to all patients with severe sepsis

*Abbreviations:* ALI, acute lung injury; APACHE II, Acute Physiology and Chronic Health Evaluation II; ARDS, acute respiratory distress syndrome; CVP, central venous pressure; MAP, mean arterial pressure; rhAPC, recombinant human activated protein C; UOP, urine output; DVT, deep venous thrombosis.  
*Source:* From Ref. 116.

Care must be particularly exercised in this regard in patients at risk for heart rate-related ischemia. Dopamine also suppresses growth hormone, thyroid stimulating hormone, and prolactin. These additional detrimental effects in critically ill patients may induce immunosuppression and catabolism.

Epinephrine, similar to norepinephrine, is both a direct-acting  $\alpha$ - and  $\beta$ -sympathomimetic. However, norepinephrine has been demonstrated to be superior to

epinephrine in the treatment of septic shock, possibly partly related to its relatively greater  $\alpha$  effects. Care must be taken in the use of epinephrine due to its propensity for significant tachycardia and dysrhythmias, which, in the setting of cardiac disease, can cause myocardial ischemia.

Vasopressin is becoming popular in the treatment of septic shock. Patients with septic shock refractory to volume infusion and standard pressor therapy have demonstrated restoration of adequate BP with the addition of small-dose

vasopressin therapy. Septic shock patients have a relative vasopressin deficiency, and its exogenous administration can stabilize hemodynamics in advanced distributive shock (127–130). Septic shock patients require markedly smaller doses of vasopressin, in the range of 0.01 to 0.05 units/min, to improve BP (131). Vasopressin augments response to concomitant pressors, often allowing a reduction in other agents (132,133). Utilizing doses above 0.04 units/min in septic patients requires caution, as hemodynamics are not consistently improved in larger doses. Larger doses may compromise organ perfusion and contribute towards adverse events (134). A synthetic analog, terlipressin, has a longer half-life than vasopressin, and may be useful in potentially allowing intermittent dosing (135).

Inotropic support is frequently required given the myocardial depression secondary to the circulating toxins and mediators. Patients with supernormal physiology have been observed to have comparably improved outcomes. However, attempts to pharmacologically augment physiology to supernormal levels have not been shown to improve outcomes, and have indeed been shown to worsen outcomes. Pharmacological augmentation to normalize physiology is the current standard of care. Norepinephrine gives both vasoconstriction and moderate inotropy without significant tachycardia or dysrhythmias.

#### Corticosteroids

Steroids are sometimes utilized in septic shock patients in relatively modest dose replacement therapy to support hemodynamics. High doses of steroids (e.g., methylprednisolone 30 mg/kg) were given in the past for patients with septic shock, but were shown to have either no or detrimental effect on survival (136–139). A number of studies have explored the use of moderate steroid doses, in the range of steroid replacement therapy, and have shown improved outcomes (140–142). One effect may be to limit the systemic inflammatory response. Reduced HR, temperature, C-reactive protein, and phospholipase A<sub>2</sub> are noted (143).

Endogenous cortisol increases the pressor effect of catecholamines (Volume 2, Chapter 62). Cortisol increases  $\beta$ -adrenergic receptor cell density and synthesis by preventing desensitization (144,145), and its release from the pituitary is stimulated by stress and plays a role in homeostasis.

Half of the septic shock patients have relative adrenal suppression with serum cortisol levels less than 20  $\mu$ g/dL (146). Patients with pressor-dependent septic shock who are unresponsive to fluid resuscitation have a high likelihood of adrenal suppression. Those with an inadequate response to 0.25 mg cosyntropin (synthetic ACTH) stimulating test (147), that is, less than 9  $\mu$ g/dL increase over baseline serum cortisol level, had a 74% 28-day mortality when compared with 18% in those with positive response.

A follow-up randomized controlled outcome study showed 76% of patients with pressor-dependent septic shock unresponsive to volume replacement to have a nonresponsive cosyntropin stimulating test. In these nonresponders, patients who received steroid replacement therapy of 50 mg hydrocortisone as intravenous bolus every six hours along with 50  $\mu$ g fludrocortisone orally, once per day had a 53% 28-day mortality versus 63% in the placebo group (148). The patients who had a positive response to the stimulation test showed a slight, nonsignificant trend towards increased mortality if given the above steroid replacement regimen.

Based on these findings, a reasonable approach in pressor-dependent septic shock patients nonresponsive to

volume replacement, given that roughly three-quarters of the patients will be nonresponders, is to perform a cosyntropin stimulation test, and then start low-dose steroid therapy. If there is a positive response to the test (i.e., appropriate increase of >18  $\mu$ g/dL plasma cortisol levels), discontinue steroids. If the patient is a nonresponder, continue steroid therapy for seven days.

In an analogous fashion, noninfectious inflammatory syndrome patients and posthemorrhagic patients with shock have been demonstrated to have a high incidence of adrenal cortical suppression with abnormal response to corticotropin stimulation test (149). In this group of patients, there was an increased requirement for norepinephrine support, both in the amount of drug administered and in the duration of treatment required (149). Nonetheless, it has not yet been demonstrated whether steroid replacement therapy, similar to that described earlier in the septic shock, will be efficacious in this patient population.

#### Activated Protein C

Despite the general lack of apparent efficacy targeting specific mediators and toxins, recombinant activated protein C (APC) has shown promise in the treatment of septic shock. Infection causes a procoagulant, antifibrinolytic, and inflammatory state. A variety of therapies have been explored for septic shock, including high-dose glucocorticoids (150,151), cytokine antagonists (152–162), bacterial modulators (163–165), anticoagulants (166,167), nonsteroidal anti-inflammatory agents (168), and NO inhibitors (169), which have all proven ineffectual or detrimental in patient studies.

On the other hand, APC appears to play a critical role in achieving regulation of thrombosis, fibrinolysis, and inflammation with subsequent improvement of survival in septic shock. Native APC reduces activated factor VIII and activated factor V leading to a reduction in thrombin formation with a decrease in fibrin clot formation. APC also reduces neutrophil activation and margination, plasminogen activating inhibitor, tissue factor, and monocyte activation by, as of yet, unknown mechanisms. In addition, APC deficiency is seen in 85% of severe sepsis patients (170). In a large randomized, placebo-controlled study, administration of recombinant APC showed a significant, overall reduction in mortality of 6.1% (171). A follow-up, open label trial dosed at 24  $\mu$ g/kg/hr for 96 hours showed similar results with even sicker patients (172). The sicker the patient, the more cost-effective the treatment with recombinant APC appears to be; the chief benefit of APC appears to be seen in patients with greater than one failing organ system (173). The major adverse event with APC is serious bleeding, with a small minority exhibiting fatal intracranial bleeding; this may be exacerbated in the pediatric population secondary to an immature blood–brain barrier. Nonetheless, the decreased mortality seen with APC is eight times less than the risk of a fatal bleed (in adults). It may soon be that all patients arriving in sepsis receive APC by protocol, as acute myocardial infarction and cerebral vascular accident patients today receive thrombolytic therapy.

#### Anaphylactic Shock

♣ Anaphylaxis is an immunoglobulin E (IgE)-mediated allergic reaction, and requires an initial exposure with sensitization to an antigen with synthesis of IgE. ♣ On re-exposure, the antigen binds to specific IgE antibodies bound to mast cells and basophils, and triggers the release

of chemical mediators including histamine, tryptase, leukotrienes, kinins, and prostaglandins (see Volume 1, Chapter 33).

These immunological mediators produce the systemic signs and symptoms of anaphylaxis. Common early symptoms are urticaria, edema, wheezing, excess airway secretions, vasodilation, and cardiovascular collapse. Anaphylaxis may be life-threatening, compromising both respiratory and cardiovascular systems, and be confused with etiologies such as sepsis, cardiogenic shock, and asthma. The most threatening manifestations of anaphylaxis are airway edema, bronchospasm, and shock. Anaphylactoid reactions are similar to anaphylaxis but not mediated by IgE and thus do not require a previous exposure. Anaphylactoid reactions are clinically indistinguishable from anaphylaxis and treated in the same fashion as anaphylaxis.

Inciting agents for anaphylaxis and anaphylactoid reactions may be environmental agents or medications. The temporal relationship to a triggering event often provides a clue. Bronchospasm and hematuria are consistent with the diagnosis. Elevated levels of serum histamine, tryptase, and IgE confirm the diagnosis. Common inciting environmental agents include latex products, hymenoptera (bee) stings, crotalid (snake) venom, and antivenom. Medications such as penicillins, cephalosporins, protamine, dextran, and radiocontrast agents are commonly noted to incite anaphylactic and anaphylactoid reactions. Immediately upon recognition of anaphylaxis or an anaphylactoid reaction, an attempt should be made to determine the inciting agent. The inciting agent should then be removed, for example, latex catheters, bee stingers, or medications.

The presentation of anaphylactic and anaphylactoid reactions has classic symptoms. Fifty percent of the deaths from anaphylaxis occur within the first hour. Seventy-five percent of the anaphylaxis deaths are from asphyxia, the remainder from circulatory collapse. Upper airway obstruction may occur from tongue and glottic edema. Bronchoconstriction may produce dyspnea, wheezing, air trapping, and acute respiratory collapse. Hypotension and tachycardia are typically present. Histamine is the most important mediator, affecting both H1 and H2 receptors. Vasodilation and vascular hyperpermeability ("leaky capillaries") cause hypotension. This marked hyperpermeability may occur rapidly, producing a fluid shift from the vascular to the extravascular space. Rapid, profound loss of intravascular volume may occur. Up to 50% of intravascular volume may be lost within 10 minutes (174). Secondary mediators are stimulated with an increase in serum catecholamines and a conversion of angiotensin I to angiotensin II (175,176). The  $\dot{Q}$  and SV may be normal or increased, depending upon the patient's functional volume status and these compensatory mechanisms. Measurements of CVP,  $P_{PA}$ , and  $P_{PAO}$  are generally low. However, depending upon the effect of the toxic mediators upon the bronchial tree and pulmonary vasculature, the CVP and  $P_{PA}$  may be increased. Care must be taken not to interpret this as primary cardiac dysfunction.

Treatment of anaphylaxis and severe anaphylactoid reactions must be prompt and follow the ABCs (airway, breathing, and circulation) of patient management (177). Identify and remove the offending allergen. Supplemental  $O_2$  and airway management take highest priority followed by administration of epinephrine and intravascular volume. Intubation prior to severe airway edema should be considered, both to ensure an adequate airway and also to enable positive pressure ventilation given the probability of significant bronchospasm. Aggressive volume resuscitation

to correct the significant hypovolemia with infusion of 1000–2000 mL of crystalloid as an initial bolus to replete the intravascular volume, given the ongoing interstitial extravasation, is indicated.

Pharmacological therapy with epinephrine is the single most important specific therapy. Epinephrine is the ideal agent for the treatment of anaphylaxis and anaphylactoid reactions. Epinephrine increases vascular tone, increases cardiac output, stabilizes mast cells to prevent further deregulation, bronchodilates, and helps restore circulation. Initial dosing in early anaphylaxis is 100  $\mu\text{g}$  IV bolus, followed by subsequent infusion. Alternatively, 300–500  $\mu\text{g}$  should be administered intramuscularly (when an IV is not available). IM doses can be repeated several times at 10-minute intervals. Acute bronchospasm may be treated with 0.01 mg/kg IM epinephrine or SQ or, alternatively, with 0.5–0.1  $\mu\text{g}/\text{min}$  IV. In the setting of fulminant cardiovascular collapse, continuous epinephrine infusions titrated to effect should be instituted. More severe or prolonged symptoms may be treated with 100–500  $\mu\text{g}$  intravenous doses every five minutes as needed to maintain hemodynamic stability (177). Continue therapy with an IV infusion of 1–4  $\mu\text{g}/\text{min}$  as necessary.

When administering epinephrine, the patient should be closely monitored. Cardiac ischemia and myocardial infarction have been reported in the use of epinephrine in anaphylactic shock. In the event of cardiac arrest, Advanced Cardiac Life Support<sup>®</sup> (ACLS<sup>®</sup>) protocol should be followed. Secondary treatment with corticosteroids and antihistamines inhibit further immune response. Antihistamines are particularly useful in the treatment of cutaneous symptoms. Since both H1 and H2 receptors are involved, both H1 and H2 blockers should be utilized. Diphenhydramine (25–50 mg) should be given either intramuscularly or intravenously along with 1 mg/kg of ranitidine intravenously, or 4 mg/kg of cimetidine intravenously. Corticosteroids may be considered, but do not have an immediate effect. However, corticosteroids may play a role in diminishing inflammatory respiratory reactions. Corticosteroids may be given IM, IV, or PO. Options include hydrocortisone 100 mg IV or prednisone 60 mg PO.

### Neurogenic Shock

Neurogenic shock is caused by traumatic SCI. Neurogenic shock is characterized by an adrenergic deficiency characterized by vascular dilation and bradycardia. Higher SCI increases the incidence of significant bradydysrhythmias. If the SCI is above T1–T5 (level of the cardiac accelerator nerves), significant bradycardia, bradydysrhythmias, and even sinus arrest can occur.

The pathophysiology of neurogenic shock is hypotension due to loss of vasomotor tone. SCI ablates intrinsic sympathetic stimulus while allowing elevated or unopposed parasympathetic stimulus. Venous pooling occurs with decreased venous return and decreased cardiac output. Hypotension may ensue. Monitoring of BP, HR, and urinary output is necessary. Bradycardia may contribute to shock, and is a significant factor in post-SCI morbidity and mortality.

Neurogenic shock presents with significant vasodilation precipitating hypotension. The CVP,  $P_{PA}$ ,  $P_{PAO}$  are all typically low, but depend upon the overall volume status. Bradycardia is often present if the injury is at or above the cardiac accelerator nerves (T1–T5). On physical examination, patients will have evidence of peripheral vasodilation,

and may evidence signs of parasympathetic excess such as bradycardia, priapism, diarrhea, and bronchospasm. Evidence of neurologic injury should be explored in trauma patients with shock symptoms. The etiology is generally clear; however, other types of shock such as hypovolemic shock must also be considered. Significant hypothermia is often present given inadequate temperature regulation.

Management of neurogenic shock begins with supportive measures. Airway management may be required should innervation of muscles of respiration be disrupted. Fluid resuscitation is necessary given the significant vascular dilation and pooling. Temperature control is critical, as these patients uniformly enter the hospital hypothermic due to their inability to autoregulate their temperatures secondary to peripheral vasodilation.

Early steroid loading with methylprednisolone (30 mg/kg loading dose followed by 5.4 mg/kg/hr  $\times$  24 hrs) may improve recovery in spinal cord injured patients for patients treated within four to six hours of the SCI. Pharmacological support is also at times necessary. The constellation of symptoms in neurogenic shock must be considered. In view of this, care must be exercised in using phenylephrine as the sole medication for restoration of vascular tone due to the potential to worsen bradycardia. Dopamine and epinephrine both offer vasoconstriction and increased chronotropy. If hypotension is severe, norepinephrine may be useful. For acute episodes of bradycardia, boluses of atropine or glycopyrrolate may be necessary. In SCI above the cardiac accelerator nerves, significant bradycardic events may be present.

### Adrenal Crisis

Adrenal crisis (a.k.a. acute adrenal insufficiency or Addisonian crisis) is a medical emergency characterized by low serum cortisol and aldosterone with hypotension and tachycardia refractory to volume administration (Table 8). Prompt treatment with fluids, steroid replacement, and correction of metabolic derangements is necessary. A cosyntropin stimulation test (as described in the steroid treatment section for septic shock earlier) may still be utilized after a single dose of 2 mg of IV dexamethasone has been given (also see Volume 2, Chapter 62). Dexamethasone does not, however, offer mineral corticoid replacement. Therefore, in

**Table 8** Common Causes of Adrenal Insufficiency

Primary	Secondary
Autoimmune adrenalitis	Sepsis
Acquired immunodeficiency syndrome (opportunistic infections)	Pituitary damage or dysfunction (tumors, metastasis, traumatic lesions, surgery, radiation)
Tuberculosis	Drugs
Metastatic carcinoma	Long-term glucocorticoids therapy
Systemic fungal infections	Interference with cortisol synthesis (etomidate, ketocozazole, aminoglutethimide)
Hemorrhage; necrosis or thrombosis of adrenal gland	Increased metabolism of cortisol (phenytoin, phenobarbital, rifampin)

Source: Adapted from Ref. 189.

primary adrenal failure, subsequent dosing with IV hydrocortisone 200 mg infusion over 24 hours should be initiated. Tapering of the initial large-dose steroids may be considered after resolution of the acute crisis, aiming for simple replacement doses.

### OBSTRUCTIVE SHOCK

☞ **Obstructive shock is due to mechanical impediment to blood flow; that is, obstruction of venous return and/or arterial outflow from the heart.** ☞ Causes in trauma patients include PE, pericardial tamponade, ACS, increased intrathoracic pressure such as with tension pneumothorax, positive pressure ventilation and excessive PEEP (either iatrogenic or intrinsic). Obstructive shock is characterized by a diminished  $\dot{Q}$  and SV, with increased HR, CVP, and intracardiac pressures. The CVP,  $P_{PA}$ , and  $P_{PAO}$  can all become elevated to similar values, which is termed as equalization of pressures.

Signs and symptoms common to all forms of obstructive shock include hypotension, tachycardia, respiratory distress, cyanosis, and jugular venous distension. Classical findings of pulsus paradoxus and Kussmaul's sign are also seen in forms of obstructive shock. Pulsus paradoxus is a greater than 10 mmHg decrease in systolic pressure during inspiration. Kussmaul's sign is an increase in venous pressure with inspiration during spontaneous ventilation.

Management of obstructive shock primarily focuses upon supportive care until diagnosis and definitive therapy such as decompression of tension pneumothorax, pericardiocentesis for pericardial tamponade, thrombolytic therapy for PE, or abdominal decompression for ACS are instituted. Supportive measures may include volume resuscitation and inotropic support. Volume therapy provides temporary support by improving intracardiac filling. Although the central pressures are elevated in obstructive shock, they are reflective of transmitted pressures rather than due to elevated intracardiac volumes. Inotropic support with dobutamine and phosphodiesterase inhibitors may also be considered while diagnosis is being accomplished. Pressors are not generally required, as peripheral vasoconstriction is typically present from sympathetic stimulation.

### Pulmonary Embolism

PE is a common complication following deep venous thrombosis (DVT) formation after trauma. Virchow's triad of intimal damage, venous stasis, and a hypercoagulable state comprise the classically described conditions predisposing to thromboembolic disease (see Volume 2, Chapter 56), which exist in most trauma patients. Risk is reduced by utilization of both DVT prophylaxis and vena caval filter placement in patients unable to have anticoagulation. Mortality from PE increases in settings of significant comorbid disease, RV dysfunction, and age greater than 60 years. The risk of PE is further increased in TBI, SCI, pelvic fracture, and lower extremity fractures.

PE can present with classical symptoms of pleuritic chest pain and dyspnea (60–73% of the time). Apprehension is a common symptom as well, occurring in up to 60% of patients. Additional common symptoms include hemoptysis (20%), wheezing (9%), and palpitations (10%). However, syncope and sudden death may be the only signs at presentation. Examination is typically nonspecific. Tachypnea

(70%) is the most common finding, followed by crackles (50%) and tachycardia (30%).

Nonspecific ECG changes (50%) are common. The classically described pattern showing RV strain, right bundle branch block, and right axis deviation are present in less than one-third of the cases. Dysrhythmias, such as atrial fibrillation, premature ventricular contractions, and premature atrial contractions are present 5% of the time.

Radiographic imaging is helpful. Chest X rays are abnormal in 80% of patients. Parenchymal infiltrate (66%) is most common, followed by small effusions (50%), and atelectasis. The classic X-ray findings of Hampton's hump (a wedge-shaped pleural-based infiltrate) and Westermarck's sign (prominent pulmonary artery with decreased pulmonary vascularity) are seen infrequently, but, if present, are strongly predictive of PE. Although  $\dot{V}/\dot{Q}$  scans are often abnormal and useful in patients without other lung pathology, these are seldom useful in trauma patients due to the common presence of concomitant pulmonary infiltrates. Previously, pulmonary angiography represented the gold standard for diagnosis. ⚔ **More recently, multidetector spiral CT angiography has emerged as the diagnostic imaging study of choice for pulmonary embolism (see Volume 2, Chapter 56).** ⚔ Treatment is with systemic heparin, except for those with contraindications to anticoagulation (e.g., TBI) in whom placement of IVC filters is recommended.

### Abdominal Compartment Syndrome

The ACS can result in refractory hypotension and ultimately obstructive shock in trauma patients (Volume 2, Chapter 34). Patients at risk are those with direct abdominal trauma, massive volume resuscitation, burns, intra- or retroperitoneal hemorrhage, along with those who have had gut ischemia, such as peritrauma episodes of significant hypotension.

The most common method to measure intra-abdominal pressures is to instill 100 cc of saline into the bladder, then transduce, and measure the bladder pressure. The syndrome may be classified as grade I, II, III, or IV based upon the pressure (Table 9). Elevated abdominal compartment pressure is transmitted to the vasculature and thorax. Its primary effects are seen upon the cardiac, pulmonary (decreased chest wall compliance), and renal systems. At pressures of 20 mmHg, effects are already seen in the kidney, with decreased renal perfusion and urine output. At pressures above 40 mmHg, renal perfusion is minimal, and urine output is usually absent. As intra-abdominal pressures rise, venous return decreases and afterload increases. Cardiac output decreases, pulmonary artery occlusion pressure rises, and hypotension may ensue. Typical symptoms include a distended tense abdomen, unexplained respiratory failure, decreasing blood pressure

**Table 9** Intra-abdominal Compartment Syndrome

Grade	Intra-abdominal pressure (mmHg)	Recommended treatment
I	<15	Maintain normovolemia
II	16–25	Hypervolemic resuscitation
III	26–35	Decompression
IV	>35	Decompression and re-exploration

Source: Adapted from Ref. 190.

with increasing  $P_{PAO}$  and decreasing cardiac output, persistent gastric intraluminal acidosis, and oliguria (178).

Initial treatment is moderate fluid loading. If symptoms do not improve, or if the patient has grade III or IV pressures, consider surgical decompression as follows: pressures above 26 to 35 generally indicate that decompression is required. Those patients with compartment pressures >35 usually require decompression and consideration of re-exploration of abdomen if the prior surgery had occurred (179). Typically, symptoms quickly resolve after decompression. However, immediately after decompression, reperfusion syndrome is possible, with ensuing acute metabolic derangements, acidemia, and hypotension (see Volume 2, Chapter 34) (180).

### Tension Pneumothorax

A tension pneumothorax is seen in trauma patients secondary to a variety of causes, including direct pulmonary trauma, placement of invasive monitoring, and positive pressure ventilation. Tachycardia is common along with an abnormal chest examination. Chest examination usually reveals hyporesonance to percussion along with diminished breath sounds on the affected side. Additional symptoms include agitation, arterial desaturation, air hunger, increasing peak airway pressures, hypotension with shock, and pulseless electrical activity. Chest radiograph or chest CT would confirm the diagnosis of pneumothorax. However, in the setting of likely pneumothorax with significant hemodynamic compromise, treatment should not be delayed to obtain imaging studies. Initial therapy may be placement of a 16- to 18-gauge angiocatheter in the second intercostal space in the mid-clavicular line. Definitive therapy with chest tube placement should follow.

### Dynamic Hyperinflation

Dynamic hyperinflation, also known as auto-PEEP or intrinsic PEEP, occurs when a subsequent breath is initiated prior to complete exhalation of a prior breath. Auto-PEEP may be unrecognized by ventilator estimation due to frequent non-communication between some hyperinflated airways and site of airway measurement. Recognition of auto-PEEP is likely in the setting of failure to reach zero pressure at the end of exhalation. Dynamic hyperinflation may present with hemodynamic collapse due to decreased venous return and RV filling, increased RV afterload, and decreased LV compliance. When dynamic hyperinflation is suspected, the initial therapy should be to disconnect the patient from the ventilator, allowing the patient to fully exhale. Typically, hemodynamic effects readily resolve with such a trial. Should dynamic hyperinflation be confirmed, ventilator adjustments should be undertaken to administer bronchodilator therapy, and to ensure complete exhalation (i.e., decrease RR and increase exhalation time).

### Cardiac Tamponade

Cardiac tamponade may be seen in trauma patients. The pericardium isolates the heart and great vessels from the mediastinum. It usually holds approximately 50 cc of fluid. While over the long-term, the pericardium can accommodate 2–3 L, in the acute setting, hemodynamic compromise should likely accumulate more than 200 cc of fluid in the pericardium. Pericardial injury is common with chest stab wounds. As pericardial pressure increases, intracardiac pressures equilibrate, and cardiac output is compromised. Pulsus paradoxus is seen. Percutaneous or surgical drainage

is required to treat tamponade, should hemodynamics be significantly compromised.

## EYE TO THE FUTURE

Experimental therapies targeting toxins and mediators of shock have been at the forefront of critical care research for some time. Trials utilizing dialysis in an effort to “wash” the blood of inflammatory mediators have not yet demonstrated benefit (see below). Similarly, antitoxin/antimediator antibodies have not yet proven efficacious. Work continues in this arena with hope that targeted therapy will one day provide a “magic bullet”; however, it is becoming increasingly clear that multimodal therapies offer the most reasonable approach for effective therapies in shock.

Orthogonal polarization spectral (OPS) imaging is a relatively new method of imaging the microcirculation, which may have some utility in the diagnosis and treatment of shock. De Backer et al. (181) used OPS to examine the microcirculation under the tongue in both healthy volunteers and in patients suffering from septic shock. They found that the proportion of perfused capillaries was significantly less in severely septic patients, and that this decrease in proportion of perfused capillaries correlated with the severity of the septic process. Sakr and associates (26) prospectively observed the microcirculation in another group of septic patients and correlated improvement in microvascular perfusion with survival, whereas most systemic hemodynamic and oxygenation variables did not differ between the survivors and the nonsurvivors. OPS is a fascinating new technology, which, when validated, may play a role in the understanding and possibly treatment of shock.

One of the new strategies emerging from the biotech sector is the marriage of rapid analysis of large numbers of data streams with biological problems of interest, including combinatorial analysis and computer-aided drug design. An illustrative example of diagnostic testing now in use includes gene (DNA microarrays) and protein chips as well as other “lab on a chip” devices, where trays are plated with large numbers of candidate molecule ligands for assay analysis. Increasing numbers of putative target molecule probes [e.g., known (heat) shock proteins or genetic precursors] can be put on chips, allowing simultaneous evaluation of large numbers of molecules, either manually or through artificial intelligence or neural network-type processing (182,183). At present, this kind of mass data analysis approach is limited by cost and understanding of shock pathophysiology, but may become clinically practical as design refinements occur.

Important strides are also being made in the treatment of shock. Although it has long been acknowledged that shock is a systemic phenomenon with global organ involvement, it has become increasingly clear that the nidus for MODS following shock may in fact be the gut (184). Proteolytic cleavage at the intestinal lumen is implicated in systemic shock, be it circulatory or septic in nature, and intralumenally-given protease inhibitors are efficacious in ameliorating the inflammatory response and subsequent mortality (185,186). Interventional techniques to block proteolytic enzymes in the gut may prove to be a valuable intervention against the initial shock process.

Alternatively, it may prove that either multipronged downstream approaches to modifying individual inflammatory mediators [oxygen free radicals including

nitric oxide, prostaglandin derivatives and phospholipases, platelet activating factor, and other lipid mediators, TNF- $\alpha$ , high mobility group box 1 (HMGB1) as well as other cytokines, NF- $\kappa$ B and transcriptional factors, leukocytes, serine and metalloproteases, leukocyte integrins/selectins, protein activated receptors (PARs), lipopolysaccharides and Toll-like receptors (TLRs), the complement, coagulation, and kinin pathways, etc.] or inhibitors [heat shock proteins, nitric oxide, cytokines, growth factors (e.g., GM-CSF), erythropoietin, calcitonin, etc.] are efficacious. Thus far, all of the above candidate molecules have found some relevance in the preclinical arena but have not, in general, proven decisive in the clinical shock condition. This may be secondary to inadequate targeting, timing of intervention, or most importantly, the redundancy of the inflammatory response. As multiple therapies necessitate multiple toxicities and side effects, one method is to simply attempt to remove inflammatory mediators from the body (187). This assumes that mediators are circulating systemically (not merely locally diffusible molecules) and can be instrumented as an inflammatory “filter” that binds either nonspecifically or specifically via antigen-antibody complexing to mediators of interest. At present, prototype models are extracorporeal in the mode of continuous veno-venous hemodilution (CVVHD) (188). Their efficacy remains to be determined.

## SUMMARY

The key to trauma care is a prompt recognition that the patient has sustained serious injury. Severely injured trauma patients may either present in shock or develop shock as a result of their injuries. Shock is a syndrome of hypotension and hypoperfusion with a broad variety of etiologies. Shock may progress from one hemodynamic classification to another. It is not unusual that a single patient may be treated for any and all of the four broad categories of shock: hypovolemic, cardiogenic, distributive, and obstructive during the peritrauma period. Diagnosis and treatment of shock's underlying etiology is always the foundation of shock treatment. Neurohumoral mechanisms initially maintain vital organ perfusion, yet cannot compensate long term. Aggressive intervention is warranted; without intervention, systemic ischemia with organ failure ensues.

Trauma patients have an array of etiologies of shock, with hypovolemic and distributive shock the most commonly seen. Hemorrhage and sepsis are among the most common specific etiologies of traumatic shock, following CNS injury as most common etiologies of death in trauma patients (7–9). Success in caring for the bleeding trauma patient and adherence to ATLS standards require rapid evaluation and treatment to ensure adequate tissue perfusion by skilled trauma personnel. Thermally efficient fluid warmers, effective transfusion services, and rapid availability of coagulation tests are practical aspects of trauma resuscitation that deserve priority. Preventing hypothermia, recognizing other complications of massive transfusions, as well as following trends in vital signs, urinary output, CVP, ABG analysis, and mixed venous blood gas analysis are critically important in managing patients with hemorrhagic shock.

Septic shock requires similar aggressive therapy. There is a growing belief that there may indeed be a “Golden Hour” in sepsis as well as trauma. Early, goal-directed

therapy is rapidly becoming the gold standard in septic shock. Institution of appropriate antibiotics and optimization of hemodynamics through aggressive volume resuscitation and invasive monitoring, as early as in the emergency department, has been demonstrated to significantly improve outcomes.

Despite intensive research efforts in finding a magic bullet cure for shock, the foundations of management including airway, breathing, and circulation remain most vital in the care of the critically ill and injured trauma patient.

## KEY POINTS

- ✎ Shock is defined as inadequate perfusion of the tissue. This inadequacy can result from deficient oxygen delivery ( $\dot{V}O_2$ ), excessive utilization, or a combination of the two. In “cytotoxic” shock, tissue mitochondria are unable to utilize the  $O_2$  delivered.
- ✎ Hypovolemic shock is caused by acute blood loss of >30% of the circulating blood volume (class III/IV hemorrhage).
- ✎ Blood flow to organs is regulated by mechanisms that control systemic, regional, and local perfusion. Dysfunction can occur at any of these points.
- ✎ If  $\dot{V}O_2$  cannot be increased after injury, even if adequate  $\dot{D}O_2$  is assured, MODS may ensue and mortality is increased (12).
- ✎ The normal 70-kg patient consumes approximately 250 mL  $O_2$ /min and has a  $\dot{D}O_2 = 1000$  mL  $O_2$ /min. The  $\dot{V}O_2/\dot{D}O_2$  is known as the ER, which is normally about 25% (Fig. 1).
- ✎ The shock state has been described as evolving through stages. The first stage is typically called compensated shock.
- ✎ When compensation begins to fail, worsening circulatory changes and metabolic imbalances become manifest, and shock enters the second phase (uncompensated shock).
- ✎ Irreversible shock is said to occur when cellular damage is so extensive that even if hemodynamics are restored, the degree of cell injury/death that has occurred (or will occur due to apoptotic mechanisms) cannot be sufficiently repaired to sustain life.
- ✎ The state of “irreversible” shock can result from numerous causes, but is particularly devastating following hypovolemia and hypotension due to hemorrhage.
- ✎ Hypoperfusion and inadequate  $\dot{D}O_2$  to individual organ systems during shock can trigger a cascade of events that disrupt the function of these organs.
- ✎ Lung injury also results from circulating inflammatory mediators following reperfusion or blood product transfusion in hemorrhagic shock, and from cellular injury following burns or massive blunt trauma and bacterial toxins in septic shock.
- ✎ Because of compensatory mechanisms, there may already be as much as 30% to 40% blood volume loss by the time hemodynamic changes occur (Table 2).
- ✎ Major goals in resuscitation include controlling blood loss, repleting intravascular volume, and restoring adequate tissue  $\dot{D}O_2$ .
- ✎ Hypertonic fluids can provide rapid volume expansion, improved hemodynamics, lessen tissue edema, diminish inflammatory response, lower ICP, and decrease brain water compared with isotonic solutions.

- ✎ Blood products should be reserved for patients who are hemorrhaging briskly, and in more stable patients who are requiring transfusion due to dangerously low levels of red blood cells, platelets, or other factors (see Volume 2, Chapter 59).
- ✎ Avoidance of hypothermia (Volume 1, Chapter 40) is another primary consideration in the resuscitation of hypovolemic trauma patients.
- ✎ Pressors and inotropes should be used only as temporizing measures in the setting of isolated hypovolemic shock.
- ✎ Anaphylaxis is an IgE-mediated allergic reaction, and requires an initial exposure with sensitization to an antigen with synthesis of IgE.
- ✎ Obstructive shock is due to mechanical impediment to blood flow; that is, obstruction of venous return and/or arterial outflow from the heart.
- ✎ More recently, multidetector spiral CT angiography has emerged as the diagnostic imaging study of choice for pulmonary embolism (see Volume 2, Chapter 56).

## Myocardial Ischemia

Steven L. Orebaugh

Department of Anesthesiology, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania, U.S.A.

### EPIDEMIOLOGY OF CORONARY ARTERY DISEASE

Myocardial ischemia results from an abrupt decrease in the myocardial oxygen supply/demand relationship. This may result from rupture of pre-existing atherosclerotic plaque or an acute increase in demand in a patient with significant pre-existing coronary artery disease (CAD) (1). In the trauma setting, coronary vasospasm and coronary emboli may occur, along with direct trauma to the heart, resulting in ischemia in the absence of known pre-existing coronary disease (2). However hypoperfusion of myocardium supplied by coronary arteries with pre-existing lesions is the predominant ischemic mechanism. Additionally, coronary spasm, in response to a variety of stimuli, plays a variable role in the development of myocardial ischemic episodes when superimposed upon CAD (3).

An epidemic of cardiovascular diseases exists, with atherosclerosis as the chief among them (4). By far, the most common cause of overall mortality in the United States is CAD, which is responsible for one in five deaths (5). More than 1.1 million myocardial infarctions (MIs) occur annually in the United States, with a significant male predominance (as with trauma). Sudden cardiac death (SCD) is responsible for 250,000 premature deaths each year in the United States, and in over half of these patients, there was no pre-existing knowledge or symptoms of CAD (6).

Obstructive CAD is manifested in a variety of ways. It is useful to envision a continuum, based on the severity of signs and symptoms, which is influenced by the degree of coronary obstruction, the stability of atherosclerotic plaques, activation levels of the platelet and fibrin systems, coronary arterial spasm, and systemic and local inflammatory factors (7). Patients with CAD are often asymptomatic (8). When symptoms of the disease exist, they may manifest as stable angina (SA) pectoris, unstable angina (UA), nonST-segment elevation MI (NSTEMI), and transmural or ST-segment elevation MI (STEMI). In addition, CAD may present as SCD (1). Further complexity is added by the realization that myocardial ischemia is often clinically silent. Indeed, 17% of all MIs occur without symptoms, and another 17% are unrecognized due to atypical symptoms (8).

✎ **The presence of CAD significantly increases the risk of morbidity and mortality to any acutely injured patient.** ✎ The incidence of CAD in trauma patients ranges from 0.3% (9) to as high as 15% (10). Mortality rates in trauma patients with pre-existing CAD have been reported to be as high as 11.2% (10) and 18.4% (9) compared with a mortality of only 2.6% (10) and 3.2% (9) in corresponding cohorts without CAD. Given the high prevalence

of asymptomatic ischemic heart disease (6), many trauma patients with CAD at the time of injury may be undiagnosed.

Although several cases of direct traumatic coronary occlusion have been reported in trauma patients (11), the most common cause of myocardial ischemia in the trauma patient with CAD is hypoperfusion due to hemorrhagic shock. While young patients without CAD can tolerate a low flow state for brief periods, patients with critical coronary artery lesions will develop immediate myocardial ischemia, further exacerbating the shock state, and complicating the resuscitation.

In one retrospective study at a busy tertiary trauma center, only five cases of post-traumatic MI occurred over a 10-year period (12). Only one of these patients had chest pain, but all five developed heart failure. However, the expectation is that prospective studies would reveal more patients. Indeed, about 4% of trauma patients (and a large percentage of elderly) have pre-existing ischemic heart disease, which confers a higher mortality rate after trauma (13).

This chapter will review the considerations for CAD for the general population, and then discuss the specific issues related to the trauma patient. Many of the first-line treatments for acute coronary syndromes (ACS) in the nontrauma setting are relatively contraindicated following trauma (e.g., anticoagulation or antiplatelet drugs in setting of bleeding, nitrates in the setting of hypovolemia, or closed head injury, and beta blockers in the setting of hemorrhagic shock). Accordingly, many aspects of management for CAD in the trauma victim are complicated and different.

### PATHOPHYSIOLOGY OF MYOCARDIAL ISCHEMIA

#### Atherosclerosis of the Coronary Arteries

As the majority of cases of myocardial ischemia result from atherosclerosis of the coronary arteries, it is important to review the pathogenesis of this process. Focal changes of the vessel wall of middle-sized and large arteries lead to a softening of the intima and a hardening around it from a combination of lipid accumulation, smooth muscle cell proliferation, and immune cell activation (14). The epicardial coronary arteries, aorta, iliofemoral, and carotid arteries appear to be most susceptible to this process.

Atherogenesis begins with endothelial cell dysfunction at susceptible sites, including increased permeability to lipoproteins, accumulation of leukocytes, and other processes related to thrombosis, fibrosis, and neovascularization (15). "Fatty streaks," asymptomatic collections of lipid-laden macrophages or "foam cells," are the initial lesions of

atherosclerosis and can be seen in the fetuses of hypercholesterolemic women, as well as in normal adolescents (16). The grossly apparent streaks may regress if serum cholesterol is lowered, or progress to symptomatic atherosclerotic plaques. The activation of macrophages and T-cells is an important contributor to the progression of these lesions, perhaps allowing progression to full-fledged atherosclerotic plaques (17). **Atheromatous lesions progress in association with known risk factors for CAD, such as hypertension, and the influx of inflammatory cells.**

Risk factors for CAD, such as hypertension, diabetes, smoking, advanced age, and elevated cholesterol levels, are associated with endothelial dysfunction (17). Further, intimal thickening, resulting from mechanical influences on the vessel wall, tends to develop at areas frequently affected by atherosclerotic lesions. This focal adaptive thickening of the intima in association with endothelial dysfunction seems to predispose the development of atherosclerosis at these sites (18).

When the foam cells of a fatty streak begin to release lipid into the vessel wall, or when lipoproteins from the serum become trapped within the lesion, the streak begins to mature into an atherosclerotic plaque. Concomitant pathologic changes include proliferation of connective tissue, denuded areas of intima with platelet adhesion, and neovascularization at the base of the plaque (19). Additional inflammatory cells then migrate into the lesion, resulting in further progression (Table 1). An advanced plaque contains cellular debris, apoptic cells, connective tissue cells, and free cholesterol crystals. This is very rich in tissue factor (Fig. 1) (7).

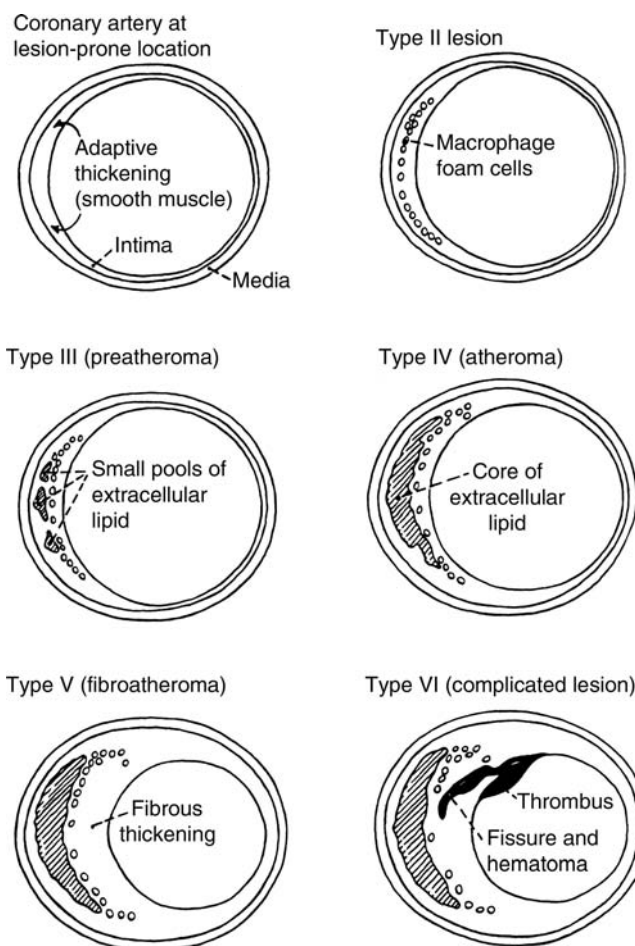

### Atherosclerotic Plaque Vulnerability to Rupture

Some atherosclerotic lesions are vulnerable to rupture or fissuring, which results in superimposed thrombosis of varying degrees. Thrombotic occlusion of the coronary lumen, whether subtotal or complete, is the basis for the majority of ACS (Fig. 2) (20,21). **Atheromatous plaque may be vulnerable to rupture, with resultant coronary artery thrombosis and occlusion, despite a relatively modest baseline impingement of the coronary lumen.** Plaques which are rich in lipid, especially those with greater degrees of inflammation and with thin fibrous "caps" are most susceptible to rupture (22). These are termed "vulnerable plaques." Surprisingly, the size of a plaque tells little about its vulnerability to rupture (23). Lesions which rupture and cause ACS show greater degrees of inflammation than other plaques (Fig. 3) (24). A

**Table 1** The Pathologic Characteristics of an Atheromatous Plaque

General characteristics	High vulnerability characteristics
Intimal thickening	↑ inflammation
Accumulation of lipid-laden macrophages (foam cells)	(e.g., ↑ CRP) Rich in lipid ↑ IL-18
Proliferation of connective tissue	Exuberant neo-vascularization
Neovascularization at base of lesion	Small "cap"
Fibrous "cap" on lumen surface of lesion	↑ greater degrees of inflammation

Abbreviations: CRP, C-reactive protein; IL-18, interleukin-18.

**Figure 1** Progression of atheromatous lesions in a coronary artery using the American Heart Association classification. Adaptive smooth muscle thickening constitutes a type I lesion; type II lesions require the infiltration of macrophage foam cells; type III lesions are characterized by small pools of extracellular lipid; type IV lesions contain a large core of coalesced lipid; fibrous thickening of the intima (so called fibroatheroma) characterizes the type V lesion; and type VI lesion involves intimal fissures with thrombus formation. *Source:* From Ref. 15.

role for infectious agents in atherosclerosis has been suggested but is not well elucidated (25).

Vulnerable, advanced plaques rupture with great frequency, and most of these episodes are asymptomatic. However, such lesions are subject to worsening inflammation and rapid progression (26). Plaque rupture may lead to formation of a small mural thrombus, which seals the lesion; or of a more substantial thrombus, which produces UA or MI. Both platelet adhesion and the deposition of fibrin are important components of the dynamic thrombosis, which complicates plaque rupture (27).

Rupture of a plaque may also be followed by hemorrhage into the atheroma, thereby encroaching on the lumen of the vessel. In addition, the rupture may also be followed by a coronary vasospasm. Such lesions may either cause chest pain, or other anginal equivalents, or may remain clinically silent. Obstruction of the lumen is often dynamic, with a fluctuating impediment to distal blood flow (20,21).

While unstable, ruptured plaques are usually evident on coronary angiography, the majority of atherosclerotic

**Figure 2** Coronary artery lesions showing areas of rupture and erosion. (B) A high-power view of the region outlined by the box in (A), showing macrophage infiltration of the thin fibrous cap (arrows). (C) Section proximal to rupture site (A) showing the propagated thrombus over a lesion resembling plaque erosion. (D) A high-power view of the region outlined by the box in (C) showing a smooth muscle cell—and proteoglycan-rich plaque. Without serial sectioning, the rupture site may not have been identified. This case exemplifies the histological diversity of some lesions that confound the diagnosis underlying the patient’s demise. *Abbreviations:* NC, necrotic core; Th, thrombus. *Source:* From Ref. 18.

plaques do not cause significant lumen narrowing and are thus not apparent during cardiac catheterization (28,29). Furthermore, regions of vessel wall affected by atheromas often undergo remodeling, which preserves the integrity of the vessel lumen.

☞ **Coronary angiography does not identify all high-risk lesions, because neither the size of the plaque nor the degree of stenosis correlates with its vulnerability to rupture (23).** ☞ Most MIs result from lesions that are not angiographically significant (7). Coronary calcification identified by electron beam computed tomography (CT) reflects the overall burden of atherosclerosis, although calcium-containing plaques may actually be more stable than lesions without calcium (30,31).

### The Ischemic Continuum

CAD may present as a continuum of clinical ischemic manifestations ranging from stable angina to STEMI (see box below).

**Box 1.** The Ischemic Continuum  
stable angina → UA → NSTEMI → STEMI

Atherosclerosis remains silent until the coronary lumen is reduced to the degree that blood flow is insufficient to meet the metabolic needs of the myocardium, typically when more than 70% of the cross-sectional area of the artery is obstructed. Such compromise classically produces a stable angina pattern, wherein the metabolic demand exceeds the

oxygen delivery only during exertion, producing chest discomfort or other symptoms. When stable angina occurs, reductions in metabolic demand result in restoration of the balance of oxygen supply and myocyte demand. Symptoms generally resolve at this point, and no myocardial damage occurs (32).

Patients with stable angina generally complain of exercise-induced (or emotionally induced) chest discomfort, but are symptom free at rest. Anginal “equivalents” include jaw or neck pain, shoulder or arm pain, and shortness of breath. Rest alone suffices to ameliorate the symptoms in these patients. The physiologic perturbations associated with major trauma (hypotension, tachycardia) as well as the supratentorial component (stress, pain, fear, and anxiety) can escalate a previously stable patient toward the right side of the ischemic continuum (Box 1), leading to myocardial ischemia or infarction.

More severe coronary obstruction gives rise to the ACS, including UA, NSTEMI, and STEMI (Table 2). ☞ **Instability and rupture of nonocclusive plaque leads to most episodes of ACS, because the subsequent exposure of reactive elements within the lesion leads to unpredictable degrees of thrombosis at the vascular luminal site (33).** ☞ Platelet adhesion occurs, following the luminal exposure of thrombin inducing constituents, and fibrin deposition is initiated. The extent of resultant thrombosis is related to local vessel wall abnormalities, rheologic characteristics of blood, and systemic factors, as originally described by Virchow (34). The thrombus which arises may occlude the coronary lumen embolize small particles downstream, or promote coronary vasospasm through the release of

**Figure 3** Range of plaque heterogeneity, determinants of rupture vulnerability (core size, cap thickness, inflammation, and repair), and the transformation from mature plaque to vulnerable plaque. Source: From Ref. 19.

vasoactive substances (35). Therapeutic maneuvers in ACS are leveled at these causes of compromised perfusion.

**Table 2** Pathophysiology of the Coronary Syndromes

Coronary syndrome	Pathophysiologic derangements
Stable angina pectoris during demand	Narrowing of coronary lumen, reduced blood supply, ischemia resolves with rest, no cellular injury
Unstable angina myocardial	Plaque disruption, dynamic coronary thrombosis, ischemia, limited cellular injury
NSTEMI myocardial ischemia	Plaque disruption, dynamic coronary thrombosis, greater degree of ischemia, some cell death
STEMI throughout the territory	Occlusive coronary thrombosis, ischemia
Death	Served by the affected coronary, transmural cell

Abbreviations: NSTEMI, nonST-segment elevation myocardial infarction; STEMI, ST-segment elevation myocardial infarction.

Autopsy evidence reveals that plaque rupture or fissuring occurs frequently in atherosclerotic lesions, but most of these undergo remodeling and heal without deleterious consequences to the patient (36,37). It appears that widespread activation of inflammatory biomolecules results in frequent plaque disruption in those with CAD. Only a small minority of these occurrences result in ACS (3). Certain inflammatory markers, such as C-reactive protein, may predict adverse outcome in such patients (38,39).

A wide range (in terms of size and thrombus content) of coronary lesions occurs in UA. Necropsy typically shows disrupted plaques with intraluminal thrombus, and some degree of preserved lumen patency. Most plaques which cause UA contain thrombus, implying disruption, while most other plaques in patients with stable angina do not contain any thrombus. In milder cases of UA, repeated episodes of vasospasm occurring at sites of lumen narrowing may be part of the underlying cause (7,40-42).

Intravascular ultrasound confirms that many "stable" coronary plaques are angiographically invisible due to arterial remodeling. Thus, angiography accurately demonstrates anatomic stenosis, but is an imperfect test for predicting the likelihood of future plaque rupture and consequent MI locations. Indeed, high grade (more than 50%) stenosis is responsible for less than one-third of MI (22). These lesions may progress to complete occlusion, but this tends to occur over years, and usually does not lead to acute MI due to the development of collateral coronary blood flow (43). The precise morphology of disrupted plaques leading to MI cannot currently be determined in vivo (7).

♣ **STEMI is caused by complete occlusion of a coronary artery, with simultaneous myocyte death in the territory supplied by that vessel (44). NSTEMI results from small areas of infarction of differing ages, probably caused by repeated episodes of transient occlusion, platelet emboli, or both (7,45).** ♣ In addition, it appears that SCD may be related to plaque rupture and thrombosis as well (33,46). Fifty percent to 70% of cases of CAD-related SCD are due to coronary thrombi (47).

**TRAUMA RELATED CAUSES OF MYOCARDIAL ISCHEMIA**

**Direct Mechanisms of Cardiac Injury**

**Myocardial Contusion**

Direct trauma to the heart may cause a variety of disturbances of cardiac structure and function, depending on whether the mechanism is blunt or penetrating (Table 3). ♣ **Myocardial ischemia is often clinically silent in the trauma patient.** ♣ Myocardial ischemia and infarction may be caused by cardiac trauma, blunt or penetrating, even in the absence of atherosclerosis of the coronary arteries. Such episodes are relatively infrequent, but require suspicion on the part of the examining physician. Numerous conditions in the trauma patient may mask myocardial injury or distract the examiner, including altered mental status (from head injury or intoxication), as well as coexisting painful fractures or soft-tissue injury.

Myocardial contusion is more common than coronary artery obstruction-related ischemia, after blunt chest trauma; and most of these cases arise from motor vehicle accidents (MVA). The mechanism of cardiac injury in this setting involves severe compressive forces delivered to the thorax.

**Table 3** Injuries Sustained Following Direct Cardiac Trauma (Blunt and Penetrating)

Blunt trauma	Penetrating trauma
Myocardial contusion	Myocardial laceration
Coronary dissection	Coronary laceration
Coronary thrombosis	Arteriovenous fistula
Coronary injury with delayed aneurysm formation	Coronary injury with aneurysm
Pericardial tamponade (may be delayed)	Pericardial tamponade (after acute presentation)
Posttraumatic pericarditis	Valvular or papillary muscle laceration
Valve or papillary muscle disruption	Foreign body retention embolism

Histopathologically, cardiac contusion is marked by hemorrhage into the myocardium, disruption of myofibrils, and followed by inflammatory cell infiltrates (48). Chest pain may be identical to that of myocardial ischemia, or may appear to be due to injury to the chest wall (49).

Myocardial contusion should be suspected in all patients with significant blunt chest trauma. No laboratory test has proven completely accurate in confirming the diagnosis. Cardiac enzyme determination [creatinine kinase (CK)] suffers from a lack of specificity, as it is frequently liberated by major trauma to skeletal muscle in multitrauma patients. The cardiac troponins are far more specific for injury to the myocardium (47,50,51). Nevertheless, the ability of these biomarkers to predict complications in the blunt chest trauma patient is poor (52). Electrocardiographic (ECG) abnormalities which may occur with myocardial contusion include tachycardia, nonspecific ST-segment and T-wave abnormalities, and supraventricular or ventricular tachydysrhythmias. None of these findings is very specific for contusion, as they occur with numerous other conditions (53). However, patients with normal troponins and a normal ECG are very unlikely to have significant myocardial contusion (52). Gated scintigraphy has also proven useful in the diagnosis of myocardial contusion (52).

Echocardiography, both transesophageal (TEE) and transthoracic (TTE), has proven to be a more useful immediate diagnostic tool in the patient with suspected myocardial contusion, and is especially useful in those with structural abnormalities resulting from trauma, such as papillary muscle injury (54). However, even when wall motion abnormalities appear on echocardiogram after blunt chest trauma, there is a low likelihood of complications that require intervention (48).

✎ **Most myocardial contusions require no specific therapy (other than monitoring), and these patients usually have an excellent prognosis.** ✎ Therapy for cardiac contusion is largely symptomatic and supportive. Only 2% to 4.5% of patients with myocardial contusion from blunt chest trauma require treatment of complications (55). Unlike ACS, there is no obstructing coronary lesion or thrombus at which to direct the therapy. Patients are generally monitored for early treatment of significant dysrhythmias, and if severe left ventricular dysfunction exists, concomitant coronary artery thrombosis or spasm should be ruled out, and inotropic agents may be useful (48). Patients with atrial or ventricular dysrhythmias should be monitored with continuous ECG for at least 24 hours following trauma.

Significant dysrhythmia, or hypotensive episodes, or both warrant an echocardiographic exam. Large contusions may result in prolonged or permanent left ventricular compromise, with the patient experiencing intermittent bouts of congestive heart failure (CHF). Patients who develop left ventricular aneurysms may benefit from surgical repair (56). However, the vast majority of patients with myocardial contusion do well and do not have long-term sequelae or ventricular dysfunction (57).

### Blunt Coronary Artery Injury

Coronary thrombosis secondary to blunt chest trauma is rare. Such cases appear to be due to intimal tears of the coronary arteries with dissection and subsequent thrombosis. These thrombi will result in MI unless either spontaneous thrombolysis or emergent invasive therapy intervenes to rapidly re-establish blood flow (Fig. 4) (58). ✎ **Blunt chest injury may produce injury to the right coronary artery (RCA) or left anterior descending (LAD) artery. These injuries often involve dissections resulting in MI, especially when the LAD coronary artery is injured.** ✎ Most case reports involve the LAD and RCAs, with the circumflex (CIRC) rarely becoming injured (58–60).

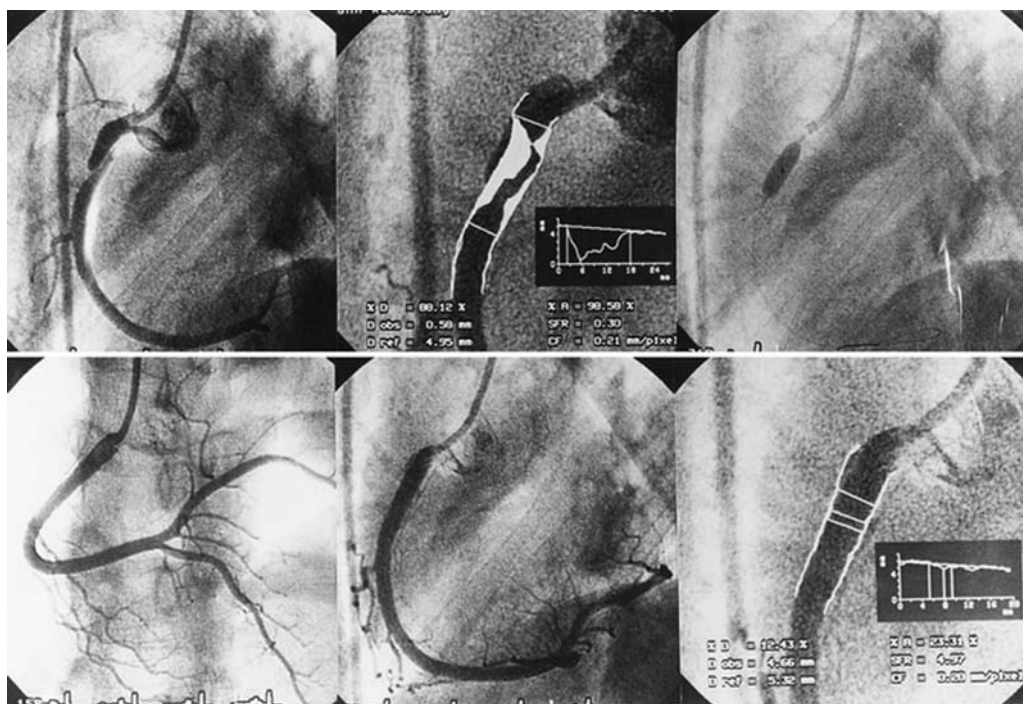

Electrocardiography, cardiac enzymes and troponins, and echocardiography may all prove useful in making the diagnosis of MI in blunt chest trauma. Each of these modalities provides greater specificity for the diagnosis of coronary artery injury than for the diagnosis of myocardial contusion. ST-segment elevation, reflecting a current of transmural injury, is common in this situation (58,59,61,62). Both creatine kinase MB isoenzyme (CKMB) and cardiac troponins will be elevated, reflecting infarcting myocardium, and the echocardiography will reflect wall motion abnormalities in the ischemic territory.

When coronary dissection with thrombotic occlusion is suspected, the patient should undergo coronary angiography if the clinical condition permits. Intracoronary thrombolysis has been described in the management of one such patient but severely injured patients may develop life-threatening hemorrhage from this intervention (60). Both percutaneous transluminal coronary angioplasty (PTCA) and coronary stenting have been successfully utilized in these patients to emergently re-establish coronary blood flow (58,59,62). Ventricular septal defect, coronary aneurysm, or ventricular aneurysm mandate surgical intervention (58).

### Penetrating Cardiac Trauma

Penetrating cardiac trauma commonly results from injury by sharp instruments or missiles. Mortality from these injuries is greater than 50% (63). As with myocardial contusion, the right side of the heart is injured more frequently than the left due to its orientation within the thorax (64). Coronary lacerations constitute only 5% of these injuries, and are usually sufficiently distal in the artery to minimize the degree of resultant myocardial injury (65).

Chest radiography, ECG, and echocardiography are utilized in the diagnosis of complications from penetrating chest trauma. When the patient has signs of life in the field or the emergency department, but becomes acutely unstable or experiences cardiac arrest, immediate resuscitative thoracotomy (Volume 1, Chapter 13) for presumed pericardial tamponade may be life saving (65). Surgical repair of any cardiac laceration is required after resuscitation.

**Figure 4** Angiogram showing a right coronary artery dissection (*upper left and middle*) following blunt chest trauma. After percutaneous transluminal coronary angioplasty and stenting (*upper right and lower*). The patient's ischemic symptoms improved after this procedure and was doing well after the one-year follow up. *Source:* From Ref. 58.

Another potential complication of penetrating chest trauma is arterial air embolism, which may produce myocardial ischemia or infarction. **Arterial air embolism, a complication of penetrating chest trauma, may be rapidly fatal and requires early suspicion and familiarity to diagnose the condition and effectively intervene.** This is typically the result of pulmonary laceration, with positive pressure ventilation favoring entrainment of air into open pulmonary veins (66). Subsequent embolization to the arterial tree and various arterial capillary beds follows, with resultant ischemia. Patients may present with typical manifestations of penetrating lung trauma, only to rapidly deteriorate when positive pressure ventilation is initiated (67). Management includes reducing airway pressures, ventilating with 100% oxygen, appropriate inotropic support, and immediate thoracotomy to clamp the hilum of the involved lung, thereby excluding the source of air embolization (68).

### Indirect Mechanisms of Cardiac Injury

The indirect stressors of hypotension and hypoperfusion probably trigger the majority of ischemic episodes occurring during the resuscitation phase of trauma patients with pre-existing CAD. However, many ischemic episodes occur two to three days or more following trauma and surgery (69,70). Inflammation also plays a seminal role in the progression and rupture vulnerability of atherosclerotic plaque. Multiple trauma leads to the release of inflammatory biomolecules and initiation of inflammatory cascades in animals and humans (71), but the relationship of these factors to plaque progression or instability after trauma is not well established.

The primary cause of death to trauma patients outside of the immediate period of injury is multiple organ system

failure. This appears to result from widespread inflammatory changes in the organ systems that are affected, more often out of proportion to the degree of insult (72). Complement activation, release of anaphylotoxins, as well as activation of both the coagulation and fibrinolytic systems often accompany major trauma. Each of these cascades can activate granulocytes. Adverse neutrophil-endothelium interaction occurs, leading to local microvascular dysfunction, dysregulation of blood flow, intravascular coagulation, and ischemic injury superimposed on toxic injury from oxidants and other products of activated neutrophils (73). A systemic inflammatory response syndrome (SIRS) often follows, which, when unregulated, causes further release of cytokines and prolonged activation of inflammatory cells, causing end-organ injury (also see Volume 2, Chapter 63) (72–77). Higher cytokine levels correlate with increased mortality rates in these patients (78,79).

Systemic inflammation is likewise deleterious in CAD. Various markers of inflammatory activation, such as C-reactive protein (CRP) and circulating leukocyte levels, have been linked to the progression of atherosclerotic plaques (80,81). Loss of smooth muscle cells in the fibrous caps of plaques has been suggested to result from cytokine production by activated leukocytes (82,83). This loss of smooth muscle cells predisposes a plaque to rupture. It is possible that circulating inflammatory molecules in trauma may adversely affect smooth muscle cells in pre-existing plaque, predisposing these patients to plaque rupture and increasing the likelihood of ACS.

**Systemic inflammation and adverse physical conditions (common accompaniments of major trauma) probably predispose the existing atheromatous plaques toward instability, followed by their rupture.** Shear forces may be exaggerated due to trauma, and labile vital signs in such patients can result in altered coronary

dynamics, leading to plaque fissuring or rupture. Adrenergic stimulation, a concomitant of multiple trauma, may play a role as well (80). Lastly, the determinants of clotting and clot stability can be dramatically altered by systemic trauma, with ill-defined effects on the process of coronary thrombus formation.

Major surgical procedures, much like multisystem trauma, can initiate a widespread inflammatory response, which, when unchecked, can have deleterious consequences. Incision, tissue dissection, vessel ligation, and cauterization may all result in cellular injury, release of tissue factor and cytokines, and initiation of the coagulation and fibrinolytic cascades (84,85). A SIRS may result, with progression to multiple organ system failure (73).

Both surgery and multiple trauma provide favorable conditions for the development of acute instability in atherosclerotic plaques. Each of these processes has been shown to release tissue factor and other inflammatory biomolecules, activate the thrombotic and fibrinolytic systems, and activate platelets and leukocytes, thus predisposing to small-vessel dysfunction and widespread tissue injury. Epidemiologic and pathophysiologic studies of myocardial ischemia and infarction in the trauma patient are scarce, but much work has been done to elucidate the nature and mechanisms of myocardial ischemia in surgical patients during the perioperative period.

As is the case with ACS outside of these settings, vulnerable atheromatous plaques put the patient at risk for plaque rupture, fissuring, or denudation with subsequent coronary thrombosis, followed by UA, MI, or spontaneous clot dissolution with re-establishment of coronary flow. A variety of historical factors and laboratory abnormalities have been established to qualify the likelihood of perioperative cardiac morbidity (Table 4). Those placing patients at high risk include recent MI with ongoing ischemia, active CHF, uncontrolled dysrhythmias, UA, or severe valvular disease (86). A large area of ischemic myocardium or ischemia in multiple different coronary territories on preoperative radionuclide perfusion studies or stress echocardiography also portends high risk (69). Intermediate degrees of risk are suggested by stable angina, diabetes mellitus, history of CHF, and more modest degrees of ischemia on perfusion/functional testing (69,86). Poor exercise capacity also helps

**Table 4** Major Risk Factors for Perioperative Cardiac Morbidity

Risk factors	Clinical examples
Historical	Recent MI with ongoing ischemic symptoms Active CHF Unstable angina Severe valve dysfunction
Surgical	Emergency surgery Major vascular (aortic) or peripheral vascular surgery Abdominal or thoracic surgery with large blood or fluid losses
Intraoperative	Prolonged tachycardia and/or hypotension ST-segment depression on ECG monitoring
Postoperative	ST-segment depression on ECG monitoring Prolonged tachycardia

*Abbreviations:* CHF, congestive heart failure; ECG, electrocardiogram; MI, myocardial infarction.

stratify risk of cardiac disease and the need for preoperative testing.

The invasiveness and immediacy of surgery are also important variables, with major vascular surgery carrying one of the highest risk profiles (70). Intraoperative factors are also closely tied to the risk of perioperative cardiac morbidity. Hypotension and tachycardia, particularly when they occur in tandem, are important contributors to myocardial ischemia and adverse cardiac sequelae (87). This may be related to increased myocardial oxygen demand, decreased oxygen delivery, shear stress on vulnerable plaques, or a combination of these.

Intraoperative ST-segment depression, and ischemic ECG changes in the immediate postoperative period are associated with postoperative MI (88). Segmental wall motion abnormalities evident on intraoperative TEE are more sensitive to ischemia than ST-segment analysis, but are not necessarily more predictive of outcomes (89). **Continuous electrocardiographic ST-segment evaluation provides the most practical means of monitoring for intraoperative myocardial ischemia.**

The postoperative period is just as important as the intraoperative period, perhaps more so, in the genesis of perioperative cardiac morbidity (PCM). Up to 90% of perioperative MIs occur in the first 72 hours postoperatively, with very few actually occurring in the operating suite (69,87). It is likely that systemic inflammatory mediators, liberated by surgical trauma, place patients at risk of plaque rupture and thrombosis throughout the perioperative period. **The risk of myocardial ischemia in the perioperative period is higher postoperatively than intraoperatively.**

## DIAGNOSIS OF MYOCARDIAL ISCHEMIA FOLLOWING TRAUMA

### Clinical Diagnosis

In stable angina pectoris, ischemia is typically manifested by chest pain, which may be dull, heavy, squeezing, or merely a sensation of pressure. Discomfort may be felt in the precordial or substernal region, or in the neck, jaw, arm, or shoulder. It is often difficult for the patient to precisely localize the pain (32). In the case of stable angina, symptoms occur with exertion or after exertion, and generally resolve within a few minutes of ceasing the activity.

In some patients, pain is not sensed, but anginal “equivalents” are experienced during ischemia. These include shortness of breath and vague chest heaviness (90). Ischemic episodes occur with no symptoms at all, in many patients, with ischemia detectable only by ambulatory ECG (91). The extreme variability among patients in symptoms experienced during myocardial ischemia makes the diagnosis challenging, and explains why significant numbers of patients are discharged inappropriately from emergency departments when experiencing MI (92).

Angina is considered unstable when (i) anginal symptoms occur at rest, or (ii) with increasing frequency, with levels of activity that were previously well tolerated, or (iii) becomes refractory to previously effective therapy (93). This intensifying symptomatology portends a poor prognosis. Like stable angina, many episodes of UA occur without producing symptoms or with atypical symptoms (91). **UA and NSTEMI are commonly indistinguishable on clinical grounds, manifesting as rest angina. They are, therefore, approached in a similar diagnostic and therapeutic fashion.** Unlike stable angina, in which atherosclerotic plaque produces limitations of blood flow in the

face of increased myocardial demand, UA and NSTEMI are caused by occlusive coronary thrombus at the site of a ruptured or denuded plaque. Arterial occlusion is probably intermittent, fluctuating with propagation and lysis of the clot, coronary vasospasm, mechanical disruption of the obstruction, and distal platelet emboli (94). In NSTEMI, symptoms are likely to prevail for a longer period of time before relief, implying a greater period of ischemia and cellular injury, detectable by chemical markers.

In STEMI, the signs and symptoms of classic MI are more likely to be manifest. These include unrelenting chest pain or pressure, dyspnea, and visceral symptoms such as diaphoresis and nausea (95). Hemodynamic instability, such as tachycardia and hypotension, are common, as are dysrhythmias. Chest pain in STEMI is frequently refractory to nitrate therapy, and often requires opioids or effective reperfusion to ameliorate its severity.

Despite the classic descriptors of anginal or ischemic pain, up to 90% of perioperative ischemic episodes are asymptomatic (70), and the majority of such events, after major trauma, appear to be clinically silent (12). **MI may manifest with ST-segment depression rather than elevation.** It will often be accompanied by ST-segment depression in the lead aVL (103). ST-segment elevations in V<sub>5</sub> or V<sub>6</sub> accompanying the pattern of inferior MI indicate posterolateral myocardial injury (104).

### Electrocardiographic Diagnosis

Historical and physical examination data are notoriously unreliable in diagnosing myocardial ischemia, following severe trauma or major surgery, making laboratory data (especially ECG and troponin values) essential. Electrocardiographic evidence of ischemia includes ST-segment depression, T-wave inversion, or both, in the territory of a particular coronary artery (96). In the operating room (OR), and potentially in the intensive care unit (ICU), continuous computer analysis of ST-segments improves the sensitivity of ECG for detecting ischemic episodes (88). For patients at high risk, ambulatory ECG can be utilized to document and quantify the number and duration of ischemic episodes (97). The number and duration of such episodes predicts the risk of PCM.

The diagnosis of MI by ECG criteria must be made rapidly for effective institution of therapy to commence. The changes on ECG reflect numerous processes in the myocardium so that coronary thrombi can be manifest in a number of different patterns, varying with artery length and size, location of the thrombus, degree of necrosis, collateral circulation, and cardiac orientation in the thorax (98). The time honored terms used to locate an MI include anterior, inferior, and lateral, corresponding to occlusion of the LAD, RCA, and CIRC arteries, respectively. Some authors maintain that the appropriate anatomic correlate of these occlusions should actually be anterior, lateral, and posterior (99).

ST-segment elevations permit the most rapid recognition of MI, though sensitivity of ECG for MI is only fair. **Classic ECG criteria for MI are only about 50% sensitive.** The standard criteria for diagnosis of acute STEMI is to have the ST-segment elevation greater than 1 mm in at least one lead (anterior or inferior), and ST-segment elevation greater than 2 mm in at least one anterior lead. This combination produces a sensitivity of 56% and specificity of 94% for MI (100). ST-segment depression in uninvolved areas of the myocardium as reflected on the ECG may reflect "reciprocal" forces. The position of the

ST-segment elevation in the precordial leads helps to identify the position of LAD occlusion as proximal or distal. Elevation in leads I and aVL predicts occlusion of the first diagonal branch of the LAD (98,101).

Inferior MI is classically manifested by ST-segment elevation in leads II, III, and aVF, 80% to 90% of which represent RCA occlusions. The other 10% to 20% represents CIRC occlusion, depending upon the patient's anatomy (102). **MI may manifest with ST-segment depression rather than elevation.** It will often be accompanied by ST-segment depression in the lead aVL (103). ST-segment elevations in V<sub>5</sub> or V<sub>6</sub> accompanying the pattern of inferior MI indicate posterolateral myocardial injury (104).

Unfortunately, the variable territory served by the CIRC and the placement of ECG leads renders occlusion of this artery difficult to diagnose. Only half of the occlusions are manifest as ST-segment elevation, most often in II, III, and aVF (105). When an inferior infarction pattern is accompanied by ST-segment depression in the precordial leads, posterior myocardial wall injury is likely (106–109), implicating the CIRC rather than the RCA as the infarct artery. To further elucidate injury to the posterior wall of the LV, leads V<sub>7</sub> through V<sub>9</sub> can be placed. These leads are placed in the same horizontal plane as V<sub>6</sub>, on the posterior thorax, and will show ST-segment elevation in posterior wall injury (102,105). They are much more sensitive and specific for posterior MI related to CIRC occlusion than the standard precordial leads (104).

Infarctions of the interventricular septum usually manifest as ST-segment elevation in leads V<sub>3</sub> and V<sub>4</sub> (110). Occlusion of the left main coronary produces a combination of ST-segment elevation in aVR and ST-segment depression inferiorly in lead II, with lateral depression in leads I and V<sub>4</sub>–V<sub>6</sub> (110). Infarction of the right ventricle often accompanies inferior MI and manifests on ECG as ST-segment elevation in V<sub>1</sub> and in the right precordial leads, especially V<sub>4R</sub> (111).

Many patients with acute MI do not have ST-segment elevations despite coronary occlusion. ST-segment depression is sometimes the only manifestation evident on the ECG. Depressions of 4 mm or more (except in aVR) are highly specific for acute MI, though not very sensitive (112). Diffuse precordial ST-segment depression, if maximal in leads V<sub>4</sub>–V<sub>6</sub>, suggests LAD occlusion. When this depression is maximal in V<sub>2</sub>–V<sub>3</sub>, CIRC involvement is more likely (113). When such depression is evident in the inferior leads and across the precordium, left main coronary or triple vessel disease is probably present (98).

An ECG monitor that can simultaneously display two channels is optimal for ischemia monitoring of high-risk patients in the OR and the ICU. Lead II is superior for monitoring the cardiac rhythm because of the clarity and size of the P wave. However, the precordial leads are the most sensitive for detecting significant myocardial ischemia. Indeed, London et al. (114) studied a large cohort of patients with known CAD undergoing noncardiac, mainly vascular surgery using continuous 12-lead ECG monitoring, and found that V<sub>5</sub> was most sensitive, detecting 75% of ischemic events. Simultaneously, monitoring both leads V<sub>4</sub> and V<sub>5</sub> increased sensitivity to 90%, whereas the standard II and V<sub>5</sub> array was only 80% sensitive (Fig. 5). However, lead II and concomitant V<sub>5</sub> monitoring is recommended, because lead II is most sensitive for P-wave evaluation and detects inferior wall ischemia (geographically separated from, and perfused by a different coronary artery than the V<sub>5</sub> area). The V<sub>5</sub> lead is usually placed over the left fifth intercostal

**Figure 5** Single-lead sensitivity for detection of myocardial ischemia during noncardiac surgery. *Abbreviation:* ECG, electrocardiogram. *Source:* From Ref. 120.

space just lateral to the mid-clavicular line. However, we frequently need to modify this location to accommodate surgical management in the OR and chest wall dressings following trauma in the ICU.

Conduction defects, such as bundle branch blocks, can make the diagnosis of MI more difficult, because repolarization abnormalities commonly accompany these disorders. However, the right bundle branch block (BBB) does not usually obscure the ECG evidence of MI (115). The left BBB presents more difficulty to the physician. Criteria have been proposed to distinguish new myocardial injury patterns in the left BBB (116), but the clinical utility of these criteria remains controversial (117). **Symptoms of acute myocardial ischemia, combined with new ECG manifestations of left bundle branch block, together are sufficient to diagnose acute MI.** Strong clinical evidence of myocardial ischemia

in association with a new left BBB is an indication for thrombolytic therapy or percutaneous coronary interventions (118).

A number of conditions may mimic acute MI or ischemia on ECG, and must be considered in the differential diagnosis. These include electrolyte abnormalities, acute pericarditis, acute pulmonary thromboembolism, thoracic aortic dissection, ventricular aneurysms, left ventricular hypertrophy and left BBB, hypothermia, and early repolarization patterns (98). Electronic permanent pacemakers may obscure the diagnosis of acute MI. ST-segment elevation of more than 0.5 mV in leads with negative QRS complexes have high specificity for acute MI, though these changes only occur in about half of the cases (119).

A significant proportion of patients with MI do not have the expected ECG changes described. **Ten percent of patients with acute MI have a normal ECG on presentation (92).** In one analysis of diagnostic modalities for acute cardiac ischemia, the sensitivity of prehospital ECG for acute myocardial ischemia was 76% (120). Thus, the diagnosis of acute myocardial ischemia or infarction may depend upon clinical suspicion and other laboratory data, as well as the ECG.

**Biochemical Testing**

Several biochemical tests are available to assist in the diagnosis of myocyte injury. These include creatine kinase (CK) and the MB fraction of CK, cardiac troponins I and T (cTnI and cTnT), and myoglobin (Table 5). These biomarkers have been primarily evaluated for the diagnosis of MI and not for myocardial ischemia. When infarction occurs, cellular proteins and enzymes are released into the bloodstream in time dependent fashion. This is less likely in the setting of ischemia without infarction.

CK is an enzyme found in myocytes, of which several subunits exist. The subunit most specific to cardiac

**Table 5** Biochemical Markers of Cardiac Injury

Marker	Hours til elevated	Peak elevation	Duration of elevation	Sensitivity, specificity, and comments
AST	8–12	1–2 days	3–6 days	Low sensitivity and specificity elevated with skeletal trauma and liver injury.
LDH	8–12	2–3 days	7–10 days	Low sensitivity and specificity elevated with skeletal trauma and liver injury.
CK	4–6	12–36 hrs	3–4 days	Low sensitivity and specificity elevated with skeletal trauma and liver injury.
CKMB	4–6	12–24 hrs	2–3 days	99% sensitive, 90–95% specific in absence of skeletal injury. Skeletal muscle has trace amounts of CKMB, thus limiting usefulness following trauma and surgery.
Myoglobin	2–3	6–12 hrs	24–48 hrs	Heme protein located in both skeletal and cardiac muscle. Nonspecific in setting of trauma or surgery. However, very sensitive, and an early marker.
HFABP	2–3	8–10	18–30	HFABP not widely available clinically yet, may emerge as useful measure of infarct size.
Troponins (T and I)	4–6	12–24 hrs	7–10 days	99–100% sensitive, 85–96% specific, increased specificity compared to others in the setting of trauma and surgery.

*Note:* Troponin T and I are isoforms of troponin.

*Abbreviations:* AST, aspartate transaminase; CK, creatine kinase; CKMB, creatine kinase MB isoenzyme; HFABP, heart fatty acid binding protein; LDH, lactate dehydrogenase.

myocytes is the MB subunit, though it appears in variable degrees in skeletal muscle as well. CK is reported in units of total enzyme activity, while CKMB is reported in units, or concentration, or as a percentage of total CK. Since CK and its MB subunit also appear in skeletal muscle, they may be elevated in circumstances which cause skeletal muscle injury, such as trauma, vigorous exercise, rhabdomyolysis, heat illness, and inflammatory conditions. These markers become detectable in serum four hours after myocyte injury, and peak levels occur at 12 to 24 hours (110,111), returning to normal at 24 to 36 hours. **In acute MI, serial determination for CKMB is more sensitive for the diagnosis than a single determination at presentation.** In a recent meta-analysis of studies conducted to evaluate the accuracy of CKMB in the diagnosis of acute MI, sensitivity of serial testing ranged from 68% to 90%, if samples were drawn at presentation and three or four hours later. However, sensitivity improved to nearly 100% in studies in which serial testing was performed at six hours or more after presentation (114). Specificities ranged from 90% to 96%, depending on whether the assay was drawn at presentation or serially thereafter.

Myoglobin is the best early indicator of myocardial ischemia in patients who have not sustained trauma or surgery. Indeed, it is detectable in serum at two to four hours after infarction, providing improved early sensitivity compared to CKMB (110). Sensitivity is improved for myoglobin as symptom duration increases, as with CKMB. The sensitivity of myoglobin for MI at presentation varies from 43% to 55% and specificity from 82% to 94% (114). When drawn serially, the sensitivity of myoglobin determinations improves to about 90%. However, myoglobin is also released from injured skeletal muscle myocytes. Accordingly, myoglobin is a useless marker of myocardial injury in the trauma or postsurgical patient.

Troponins are another type of protein released from cardiac myocytes during cellular injury. cTnI and cTnT are highly specific for myocardial injury, as they differ in significant ways from their skeletal muscle counterparts (121). Thus troponin assays are more specific for cardiac injury, and help to differentiate this condition from elevated CKMB due to skeletal muscle trauma (49–51). Troponin measurement is an essential feature of diagnosing MI or injury after surgical or accidental trauma (122).

Cardiac troponins appear in the serum four to six hours after myocyte injury. **Cardiac troponins are often released during myocardial ischemia, even without infarction.** The peak activity occurs at about 12 hours, but these markers remain elevated for around 3 to 10 days (123). Unlike CKMB or myoglobin, the cardiac troponins are also released during some episodes of UA, providing useful diagnostic and prognostic information that are not available from other biomarkers (3). In diagnosing acute MI, serial assays of cTnI and cTnT yielded a sensitivity of 90% to 100%, with a specificity that ranges from 85% to 96% (114). Because troponins are specific for the heart, they are, by far, the best measure of myocardial ischemia and infarction in trauma patients.

In summation, individual biomarkers drawn at the time of patient presentation for possible myocardial ischemia are not very sensitive, but their specificity is quite good, generally greater than 85%. When these markers are drawn serially over several hours after presentation, sensitivity is increased from less than 50% to over 80%. **Cardiac troponins are more useful than CKMB to diagnose MI in the multiple trauma patient, as they are more**

**specific for cardiac muscle injury.** In the future, markers of systemic inflammation, such as CRP and fibrinogen, may provide important diagnostic and prognostic information for those suffering from myocardial ischemia without infarction (124).

### Imaging Modalities and Stress Testing

The imperfect sensitivity of biochemical testing for acute MI is troublesome, but serial testing markedly improves this sensitivity. On the other hand, the sensitivity of biomarkers for acute myocardial ischemia without infarction, as in UA, is poor. In such circumstance noninvasive testing is frequently utilized to support (or exclude) the diagnosis. These testing modalities, which include rest and stress echocardiography, and radionuclide perfusion studies, are particularly valuable in patients with suspicious symptoms or findings who have normal biochemical testing and normal ECG, or nonspecific ECG abnormalities only (Table 6) (125).

Both TTE and TEE can be used to detect acute ischemia or prior infarction. In addition, Doppler color flow analysis can provide evidence of valvular dysfunction. Information about global cardiac function and abnormal anatomy or pathology can be obtained from these tests. Evidence of ischemia includes reduced contractility and segmental wall motion abnormalities. However, differentiation of prior infarction and current ischemic wall motion abnormalities is difficult. Resting echocardiography in the emergency department to evaluate low to moderate risk patients has shown sensitivity of 81% to 97% for cardiac ischemia (125,126). Exercise echocardiography or dobutamine stress echocardiography may improve upon the specificity of this test, which is reported to be between 43% and 83% for acute myocardial ischemia (127). TEE has proven to be extremely sensitive for intraoperative monitoring of ischemia (88).

Technetium-99m Sestamibi scanning utilizes radionuclide distribution to image myocardial blood flow, and is useful to demonstrate areas of reduced perfusion. This study has been shown to have high sensitivity for the diagnosis of ischemia in patients presenting with chest pain, ranging from 91% to 100%, with a range of specificity for MI between 49% and 84%. The sensitivity of this technique for acute myocardial ischemia, without infarction, is also quite good (126).

Exercise stress electrocardiography is less complex, less expensive, and less dependent upon operator expertise than the studies described previously. **Imaging modalities or stress testing may be utilized to improve the accuracy of the diagnosis of myocardial ischemia or**

**infarction in patients with equivocal or nonspecific ECG and biochemical testing.** ⚡ Reported sensitivities vary widely, from 29% to 90%, while specificity ranges from 50% to 99% (128,129).

### Detecting Intraoperative Myocardial Ischemia

Detection of intraoperative myocardial ischemia and ischemia in the ICU are more or less limited by logistical considerations. As noted earlier, TEE is highly sensitive in this regard. However, this technology is both very expensive and operator dependent. Computed ST-segment analysis of continuous ECG, utilizing two leads, has a high degree of sensitivity and reasonable specificity for detection of ischemia in the OR (88). Typically, leads II and V<sub>5</sub> are monitored (Fig. 5) (114). However, controversy exists as to which of the precordial leads is most sensitive (130). Ambulatory ECG is useful for detection of ischemia in the postoperative period, during which around 90% of episodes of myocardial ischemia are without symptoms (70).

In summary, the clinical diagnosis of myocardial ischemia and MI is unreliable. Electrocardiography is rapidly obtainable, inexpensive, noninvasive, and relatively accurate. However, some patients with MI have a normal ECG and others have a nonspecific tracing. NSTEMI is often indistinguishable from ischemia without infarction on ECG. For this reason, biochemical testing with CKMB isoenzymes, or cardiac troponins, or both markedly improves the diagnosis of MI. When the diagnosis remains uncertain, or when it is essential to exclude mechanical complications of infarction, imaging modalities such as echocardiography, gated scintigraphy, and radionuclide perfusion scanning are of value.

## THERAPY FOR MYOCARDIAL ISCHEMIA AND INFARCTION

The therapy for myocardial ischemia has substantially changed in the past decade. More emphasis is placed upon early re-establishment of coronary flow in the catheterization lab when such therapy is available, and medical therapy is more effective ever since the introduction of several new classes of drugs. It is convenient to discuss therapeutic interventions with respect to the ischemic continuum.

### Stable Angina Pectoris

SA pectoris may occur during exertion or stress, and therefore may occur in the perioperative period or after trauma. However, angina or evidence of ischemia in hospitalized patients will usually be considered UA, since the patients are generally at rest. The therapy of SA involves coronary vasodilation, preload reduction, reduction of myocardial oxygen demand, and prevention of platelet aggregation (Table 7) (131). ⚡ **Nitrates, calcium-channel blockers, and**

**beta-blockers, along with platelet inhibition, are the mainstays of medical management of stable angina.** ⚡

Nitroglycerine, whether sublingual or topical, is the time-honored method of providing selective coronary vasodilation, while at the same time reducing preload, wall tension, and therefore myocardial oxygen demand (132). Typically, sublingual nitroglycerine is utilized by the patient or physician for acute therapy of angina attacks, while more prolonged therapy is delivered via slow-release oral formulations or topical patches. The latter seem most efficacious when they are incorporated into a regimen, which includes a daily nitrate-free period (133).

Both calcium-channel blocking agents and beta-blocking drugs are utilized in SA to reduce myocardial oxygen demand. Calcium-channel blocking agents may also contribute to coronary vasodilation. Both these drug classes also have antihypertensive properties, thus reducing the afterload as well as contractility (131).

Aspirin is beneficial in SA, as it is in all of the ACS (134). By preventing platelet aggregation, which serves as the nidus for obstructing thrombosis, aspirin reduces the likelihood of MI and death in this population (135). Revascularization procedures, such as PTCA, coronary stenting, and coronary artery bypass grafting (CABG), are utilized selectively to reduce symptoms, improve quality of life, and increase life expectancy.

### Unstable Angina and Non-ST-Elevation Myocardial Infarction

In UA/NSTEMI, which are often indistinguishable at presentation, management is conducted with immediate attention to reducing ischemia, preventing further platelet aggregation, preventing fibrin deposition and, in some cases, re-establishing coronary patency by invasive means (Table 8) (124). Therapy of ischemia generally includes sublingual or intravenous nitroglycerine, although evidence for its efficacy is only fair. Supplemental oxygen is necessary if the patient is hypoxic, and morphine sulfate should be instituted if ischemic signs and symptoms are not relieved with nitrates (136). ⚡ **Antiplatelet and antithrombotic agents assume increasing importance in the therapy of UA and NSTEMI.** ⚡

Beta-receptor blockade is effective in ACS (136). Patients should receive a first dose intravenously if evidence of ischemia persists after the aforementioned interventions, and orally within 15 minutes thereafter (137). If beta-blockade cannot be tolerated due to adverse effects, a nondihydropyridine calcium-channel blocking agent should be used instead (136). For persistent hypertension despite beta-receptor blockade and nitrate administration, an angiotensin-converting enzyme (ACE) inhibitor should be initiated, especially in patients with CHF or diabetes.

Because of the central role of intracoronary thrombus in causing ACS, antiplatelet and anticoagulation therapies are essential components of the management strategy in this population. Aspirin is the primary antiplatelet agent used, and should be started immediately and continued indefinitely (136). Anticoagulation should be acutely instituted in these patients, with either intravenous unfractionated heparin or low-molecular-weight heparin (138). Several studies have established improved outcomes in ACS when enoxaparin, a low-molecular-weight heparin, was compared to unfractionated heparin (124). In addition, the American College of Cardiology recommends the addition of a glycoprotein IIb/IIIa receptor antagonist to the

Revascularization

**Table 8** Management of Myocardial Ischemia and Infarction

Goal	Drug or treatment	Comments
Ameliorate ischemia	Oxygen Nitrates (if not contraindicated by increased ICP) Morphine sulfate Beta-receptor blockade	Add ACE inhibitor within first 24 hrs for MI with ST-segment elevation
Prevent further platelet aggregation	Aspirin	In nontrauma setting may add glycoprotein IIb/IIIa inhibitor
Prevent further fibrin deposition	Intravenous unfractionated heparin, or Subcutaneous low-molecular-weight heparin	Anticoagulation with heparin contraindicated immediately following head injury, and in patients with trauma- or hemorrhage-related coagulopathy
Re-establish coronary patency	Percutaneous coronary intervention (especially if not a candidate for thrombolytics) Emergent coronary artery bypass grafting (when appropriate)	Thrombolysis (tissue plasminogen activator) in nontrauma patient Both PTCA and off-pump CABG have been successfully accomplished in selected trauma patients (see text for explanation)

*Abbreviations:* ACE, angiotensin converting enzyme; CABG, coronary artery bypass grafting; ICP, intracranial pressure; MI, myocardial infarction; PTCA, percutaneous transluminal coronary angioplasty.

aforesaid measures in patients who have continuing evidence of ischemia, hypotension or bradycardia, new bundle branch block, or markedly elevated biochemical markers of cardiac myocyte injury (124,136,138,139). These agents, which block platelet receptors permitting aggregation and progression of thrombus formation, are also indicated in patients in whom percutaneous coronary intervention (PCI) is to be conducted within the ensuing 24-hour period (138).

Opinions differ as to the necessity of early PCI, as opposed to a conservative strategy of medical management with deferred coronary arteriography, pending further clinical events or symptoms. ⚡ **Certain subsets of patients with UA/NSTEMI benefit from early percutaneous coronary intervention.** ⚡ Patients who appear to benefit from early PCI include those with high-risk profiles, such as recurrent rest angina, CHF, hemodynamic instability, sustained ventricular tachycardia, and prior CABG or PCI (136).

Indications for coronary revascularization in patients with ACS are similar to those for patients with chronic SA, depending upon coronary anatomy, life expectancy, ventricular function, functional capacity, severity of symptoms, and degree of myocardium at risk. The objective of such revascularization is to improve functional capacity, prevent progression of disease, relieve symptoms, and alter the prognosis. CABG is generally recommended for those with left main coronary disease, three vessel disease, and two vessel disease with significant LAD disease or with ischemia on noninvasive testing (135). Those with normal LV function and suitable multivessel CHD are generally treated with PCI.

### ST-Elevation Myocardial Infarction

Acute STEMI, also referred to as transmural or Q-wave MI, represents the most damaging of the ACS, with the greatest extent of cell death and the highest rate of early complications. However, prognosis of this entity has dramatically improved in the last two decades, with the introduction of effective thrombolytic drugs and establishment of the effi-

cacy of several other classes of medications, ushering in the modern era of active management of MI.

Historically important therapies, such as oxygen, nitrates, and morphine sulfate, have become ancillary interventions to the main focus of therapy, which is re-establishment of patency of the infarct-related artery (140). ⚡ **Re-establishing early patency of the infarct-related artery is key to limiting damage in STEMI.** ⚡ As in UA/NSTEMI, management of thrombosis is carried out with multiple classes of drugs, which act by distinctly different mechanisms. Antiplatelet agents, anticoagulants, and fibrinolytic agents all play an essential role in the therapy of STEMI (141). Numerous studies have shown that re-establishment of patency of the infarct-related vessel improves in-hospital and long-term survival (140).

Nearly three decades ago, randomized trials established that aspirin significantly reduced mortality in STEMI (142). Subsequent mega-trials investigated the efficacy of thrombolytic agents, demonstrating a reduction in mortality from approximately 15% to 7% (143). Tissue plasminogen activator (tPA) and its derivatives have become the favored agents for reperfusion in the United States, but controversy exists over whether or not these expensive agents are actually more efficacious or safer than streptokinase. Nevertheless, these large, randomized trials established that earlier intervention with thrombolytic agents in STEMI resulted in greater preservation of myocardium with reduced early and late adverse effects. Optimum benefit occurs when thrombolytics are administered within six hours of symptoms, although some benefit may be derived up to 12 hours later (140).

Criteria for thrombolysis include ST-segment elevation of greater than 1 mm in at least two contiguous limb leads or more than 2 mm in at least two contiguous precordial leads. The left BBB and permanent pacemakers may obscure this diagnosis, although diagnostic criteria have been proposed to detect acute MI, even under these circumstances (116).

Several adjunctive agents have proven beneficial in MI when used in conjunction with thrombolytics. Heparin is

administered to prevent coagulation, and intravenous unfractionated heparin is most commonly used in this setting (141). Aspirin is of established benefit, as noted earlier. Beta-receptor blockade is initiated early in the course of STEMI, if there are no contraindications, and continued thereafter, with a reduction in early and long-term mortality (144). ACE inhibitors, usually begun in the first 24 hours after presentation, also reduce postinfarction mortality, probably due to alterations of adverse neurohumoral influences on the myocardium, along with a favorable effect on ventricular remodeling (145). Nitroglycerine, useful for symptomatic improvement, has not been clearly shown to improve the outcome.

✎ **Percutaneous coronary intervention is evolving as the preferred therapy in STEMI, when available.** ✎ Up to two-thirds of patients with STEMI are not candidates for thrombolysis, due to contraindications to these agents, while PCI is almost always applicable, if available (146). Several randomized trials have been conducted which provide evidence that percutaneous coronary intervention is as efficacious as thrombolysis, or even more so, in the management of STEMI (147,148). Patients undergoing primary percutaneous coronary intervention appear to have improved infarct-related artery patency and a lower rate of intracranial hemorrhage compared to patients receiving thrombolytics (146). A meta-analysis of 10 studies, evaluating primary percutaneous coronary intervention compared to thrombolysis for STEMI, concluded that percutaneous coronary intervention confers a 34% reduction in mortality along with reduced nonfatal MI and hemorrhagic stroke rates (149).

Unfortunately, recurrent ischemia occurs before hospital discharge in around 10% to 15% of patients who receive angioplasty. Placement of coronary stents has been found to be safe and practical at the time of primary PCI in STEMI, with a reduction in the rate of restenosis. Glycoprotein IIb/IIIa inhibiting agents are efficacious in reducing restenosis in this setting as well, and are recommended as cotherapy for all patients receiving percutaneous coronary intervention (150). Percutaneous coronary intervention has been most effective for those older than 65 years of age, those with prior CABG, and for those patients with CHF or cardiogenic shock in association with STEMI (146).

### Myocardial Ischemia in the Multiple Trauma Patient

The treatment of MI in trauma is complicated by the likelihood of hemorrhagic complications in this population with many of the agents that are used to manage ACS. Thrombolysis is absolutely contraindicated in patients with major trauma, active bleeding, or surgery within the prior 10-day period, most of which apply to the hospitalized, injured patient (12). ✎ **Since thrombolysis is not feasible in the trauma patient, percutaneous coronary intervention is an important alternative for therapy of MI.** ✎ Even heparin may cause significant hemorrhage in the traumatized or postoperative patient, and its use must, therefore, be carefully balanced against the risk of complications. Management of ischemia and MI may well be confined to aspirin, nitrates [except in the setting of closed head injury with elevated intracranial pressure (ICP)], beta-blockers (may not be tolerated in acute shock state), and ACE inhibitors in this setting, along with the usual management of complications, such as CHF.

Some authors recommend early invasive monitoring for elderly trauma patients who have evidence of shock on presentation, or a high injury severity score, maintaining that this allows improved titration of oxygen delivery and

thus reduces organ injury and post-traumatic mortality (151,152). For patients with hemodynamic instability due to myocardial ischemia or infarction after major trauma, or who have persistent evidence of ischemia despite supportive therapy as outlined earlier, percutaneous coronary intervention is appropriate to re-establish coronary blood flow.

### Prophylaxis Against Myocardial Ischemia

Perioperative beta-blockade is associated with a significant reduction in ischemic episodes (153,154). One validated method entails postoperative titration of esmolol to a heart rate (HR) of 20% less than that which was determined preoperatively as the individual's ischemic threshold HR (153). The benefit of esmolol is its  $\beta_1$  selectivity, titratability, and short clinical duration. Most clinicians titrate beta-blockade to a HR of 60 beats per minute (153–155). As HR slows, myocardial oxygen demand decreases (less contractions per unit time) and supply increases (diastolic time increases, especially as HR falls below 70) because most of the coronary blood flow occurs during diastole, especially for the left ventricle. Indeed, diastolic time increases 15% when HR decreases from 70 to 50 beats per minute (156). With few contraindications (Table 9), beta-blockers are recommended for most high risk patients for prophylaxis against perioperative MI (PMI) undergoing major surgery (153,155). Poldermans reported a striking reduction in cardiac complications within 30 days postoperatively (3.4% vs. 34%) (153). In a placebo-controlled, double-blind study of 200 men with or at risk for CAD, Mangano (155) found a perioperative atenolol regimen that was associated with a reduction in two year mortality.

The ACC/AHA Perioperative Practice guidelines limits specific recommendations for beta-blockade use to patients with inducible ischemia (157). In this high-risk population, beta-blockers should be started days to weeks before surgery, and titrated to a resting HR from 50 to 60 beats/min preoperatively. No specific recommendations are made for lower-risk patients, or for intraoperative or postoperative therapy (157).

A recent review by London et al. (158) provides a thorough overview of the known and theoretical benefits and hazards of perioperative beta-blockade. They also recommend that the ACC/AHA guidelines be followed until the results from several recently launched, large-scale trials provide more substantial data. This paper, and the accompanying editorial by Kertai (159) triggered a flurry of correspondence regarding the relative merits of perioperative beta-blockade (160–162). The ongoing Perioperative Ischemic Evaluation (POISE) trial is currently enrolling patients in six countries, and will evaluate the effectiveness

**Table 9** Contraindications to Beta-Blockade

Absolute	Relative (strong)	Relative (weak)
Acute broncho-spasm following treatment	Strong Hx of bronchospastic disease SBP < 100 mmHg (after treatment with Neosynephrine)	Epidural or spinal anesthetic Fluid shifts anticipated
Third-degree heart block	Current exam or lab evidence of CHF	Hypovolemia Concurrent antihypertensives
Starting HR < 55 bpm		

*Abbreviations:* CHF, congestive heart failure; HR, heart rate; Hx, history; SBP, systolic blood pressure.

of perioperative beta-blockade in 10,000 moderate to high risk patients undergoing noncardiac surgery (160,161).

When beta-blockers are contraindicated (Table 9), calcium channel blockers or  $\alpha_2$  agonists (clonidine, or dexmedetomidine) may be better tolerated. Although nitroglycerin is effective in treating ischemia, it is not effective prophylactically. Nicardipine has been found to be more useful in reducing ischemia after coronary artery bypass (perhaps helping to decrease spasm) (163). Although dexmedetomidine caused a 20% reduction in blood pressure in both vascular surgery patients and healthy volunteers (treatable with phenylephrine), it was associated with fewer ST ischemic changes than placebo (164). The level of ischemia reduction and sedation appears to be similar to that found with clonidine, but future studies will delineate clinical situations for which each drug is indicated.

## PROGNOSIS

The prognosis for the patient with post-traumatic MI is less favorable than for patients who infarct outside of this setting. In one study, the mortality rate was 20% for patients with MI after trauma, as compared to an approximate 7% mortality rate for STEMI in the first 30 days after infarction (12). The elderly suffer higher rates of mortality after trauma than patients under 55 years of age, largely due to multisystem organ failure (MSOF) and sepsis (165). Ischemic heart disease, along with several other pre-existing conditions, significantly increases the post-traumatic mortality rate (13). Among 326 multitrauma patients older than 60 years, Tornetta (166) found that MI, along with acute respiratory distress syndrome (ARDS) and sepsis, was a major predictor of mortality. He reported 62% mortality in those sustaining MI in this retrospective investigation.

## EYE TO THE FUTURE

In the future, ongoing investigation into the underlying causes of atherosclerosis, including the role of systemic inflammatory influences and infectious agents, may permit more effective intervention in the early stages of this disorder. In particular, elucidation of inflammatory cascades in trauma and their role in influencing plaque vulnerability and ACS, will be of importance to the development of therapies which block this response to injury.

Research will continue into the epidemiology and therapy of MI in the setting of trauma and in the perioperative period, especially with regard to the safety of anticoagulation and antiplatelet agents, and the utility of percutaneous coronary therapy. As the nature of anticoagulant therapy is refined, more specific inhibitors of the particular steps in the coagulation cascade, such as factor Xa, may permit effective prevention of thrombosis, with less likelihood of systemic bleeding (34).

Recently, Le Manach et al. (167) have introduced a new approach to reduction of perioperative cardiac morbidity through the use of monitoring troponin I (cTnI). They studied 1152 consecutive patients undergoing abdominal infrarenal aortic surgery and measured cTnI release. One group did not have any abnormal elevations, and a second group had only mild increases of cTnI. However, two groups demonstrated increases of cTnI consistent with a

PMI. One of these "ischemic groups" demonstrated acute (<24 hours) increases of cTnI above threshold, and the other demonstrated prolonged low levels of cTnI release, followed by a delayed (>24 hours) increase of cTnI. The authors suggest that these two different ischemic patterns represent two distinct pathophysiologies: (i) acute coronary occlusion for early morbidity and (ii) prolonged myocardial ischemia for late events. They also suggest that early anti-ischemic treatment should occur in patients with elevated cTnI levels (prior to the development of irreversible necrosis).

The role of early percutaneous coronary intervention in trauma patients is currently under investigation. At the time of this writing, only seven cases have been reported describing the use of PCI to relieve acute CA occlusions, following blunt chest trauma (58,134,137,168–170), and only one case of concomitant PCI during repair of penetrating trauma (gunshot wound to the chest) (171). Temporary anticoagulation was used, with complete reversal at the end of the procedure to facilitate this last case. Furthermore, the development of specialized tools for off-pump coronary revascularization (e.g., shunts and coronary suturing devices) have already provided new techniques for the treatment of traumatic coronary artery lesions (172). These reports are illustrative of the multisystem approach required for successful treatment of these life-threatening injuries, and a great deal of work still needs to be done in this area.

Lastly, existing imaging technologies are being used in innovative ways to facilitate the diagnosis of myocardial and coronary artery injury in chest trauma. These include application of MRI (173) and intracoronary echocardiography (174).

## SUMMARY

Myocardial ischemia and infarction due to atherosclerosis are most likely to affect the geriatric trauma population, which is predisposed to poor outcomes due to this and a variety of other underlying diseases. Hypoperfusion of pre-existing coronary artery lesions is the dominant cause of ischemia in this population. Direct cardiac trauma with left ventricular dysfunction or infarction due to coronary artery thrombosis or laceration is less common but may affect any age group following chest trauma. Detection of myocardial ischemia in traumatized patients involves several subtle differences compared to the nontrauma population. Furthermore, the reliance on diagnostic laboratory testing is greater due to the inability of seriously injured patients to communicate their chest pain or distinguish it from that due to chest wall trauma. As one moves along the ischemic continuum from stable angina to STEMI, there is greater therapeutic emphasis on platelet inhibition, antithrombotic agents, and direct attempts to disrupt clot in the infarct related artery with fibrinolysis or PCI.

The management of suspected myocardial ischemia and infarction in trauma is complicated by the propensity of these patients to bleed with anticoagulation and the contraindication to thrombolytic administration in this population. Additionally, the use of nitroglycerine and other nitrates is relatively contraindicated in the setting of severe traumatic brain injury and elevated ICP. Anticoagulation must be carefully weighed against its hazards, as must use of antiplatelet agents. A greater reliance on percutaneous angioplasty and stent placement in this population in the setting of severe myocardial ischemia or MI should reduce

morbidity, though only case reports exist to support this therapeutic strategy.

## KEY POINTS

- ✎ The presence of CAD significantly increases the risk of morbidity and mortality to any acutely injured patient.
- ✎ Atheromatous lesions progress in association with known risk factors for CAD, such as hypertension and the influx of inflammatory cells.
- ✎ Atheromatous plaque may be vulnerable to rupture, with resultant coronary artery thrombosis and occlusion, despite a relatively modest baseline impingement of the coronary lumen.
- ✎ Coronary angiography does not identify all high-risk lesions, because neither the size of the plaque nor the degree of stenosis correlates with its vulnerability to rupture.
- ✎ Instability and rupture of nonocclusive plaque leads to most episodes of ACS, because the subsequent exposure of reactive elements within the lesion leads to unpredictable degrees of thrombosis at the vascular luminal site.
- ✎ STEMI is caused by complete occlusion of a coronary artery, with simultaneous myocyte death in the territory supplied by that vessel (44). NSTEMI results from small areas of infarction of differing ages, probably caused by repeated episodes of transient occlusion, platelet emboli, or both.
- ✎ Myocardial ischemia is often clinically silent in the trauma patient.
- ✎ Most myocardial contusions require no specific therapy (other than monitoring), and these patients usually have an excellent prognosis.
- ✎ Blunt chest injury may produce injury to the RCA or LAD. These injuries often involve dissections resulting in MI, especially when the LAD coronary artery is injured.
- ✎ Arterial air embolism, a complication of penetrating chest trauma, may be rapidly fatal and requires early suspicion and familiarity to diagnose the condition and effectively intervene.
- ✎ Systemic inflammation and adverse physical conditions (common accompaniments of major trauma), likely predispose existing atheromatous plaques to instability and rupture.
- ✎ Continuous electrocardiographic ST-segment evaluation provides the most practical means of monitoring for intraoperative myocardial ischemia.
- ✎ The risk of myocardial ischemia in the perioperative period is higher postoperatively than intraoperatively.
- ✎ UA and NSTEMI are commonly indistinguishable on clinical grounds, manifesting as rest angina. They are therefore approached in a similar diagnostic and therapeutic fashion.
- ✎ The diagnosis of myocardial ischemia is difficult to make on clinical grounds, especially in the trauma patient, who may have altered pain response for a variety of reasons, such as distracting injury, analgesic medications, or CNS injury.
- ✎ Classic ECG criteria for MI are only about 50% sensitive.
- ✎ MI may manifest with ST-segment depression rather than elevation.

- ✎ Symptoms of acute myocardial ischemia, combined with new ECG manifestations of left bundle branch block, together are sufficient to diagnose acute MI.
- ✎ Ten percent of patients with acute MI have a normal ECG on presentation.
- ✎ In acute MI, serial determination for CKMB is much more sensitive for the diagnosis than a single determination at presentation.
- ✎ Cardiac troponins are often released during myocardial ischemia, even without infarction.
- ✎ Cardiac troponins are more useful than CKMB to diagnose MI in the multiple trauma patient, as they are more specific for cardiac muscle injury.
- ✎ Imaging modalities or stress testing may be utilized to improve the accuracy of the diagnosis of myocardial ischemia or infarction in patients with equivocal or nonspecific ECG and biochemical testing.
- ✎ Nitrates, calcium-channel blockers and beta-blockers, along with platelet inhibition, are the mainstays of medical management of stable angina.
- ✎ Antiplatelet and antithrombotic agents assume increasing importance in the therapy of UA and NSTEMI.
- ✎ Certain subsets of patients with UA/NSTEMI benefit from early percutaneous coronary intervention.
- ✎ Re-establishing early patency of the infarct-related artery is the most important factor for limiting damage in STEMI.
- ✎ Percutaneous coronary intervention is evolving as the preferred therapy in STEMI, when available.
- ✎ Since thrombolysis is not feasible in the trauma patient, percutaneous coronary intervention is an important alter native for therapy of MI.

### INTRODUCTION

Dysrhythmias are commonly seen in the electrocardiogram (ECG) of patients suffering from trauma and critical illness. Some dysrhythmias result as exacerbations of underlying rhythm disorders. Most are due to the changes in the autonomic nervous system and electrolyte levels that often occur in the critically ill. Dysrhythmias in the trauma patient also result from ischemia, direct mechanical injury to the heart (e.g., myocardial contusion), or occur secondary to drugs or toxins. A review of normal electrophysiologic function will precede the discussion of the dysrhythmias most frequently encountered in trauma and critical illness.

### NORMAL SINUS RHYTHM

The conduction system of the heart comprises specialized cardiac myocytes. These myocytes spontaneously depolarize at their own intrinsic frequency. The normal sinus rhythm originates from sinus node cells located at the junction of the superior vena cava and right atrium (see Volume 2, Chapter 3, Fig. 13) and has spontaneous depolarization frequencies ranging from 60 to 100 beats per minute (bpm). The normal ECG reveals upright P waves in the inferior leads (I, II, and aVF) and lateral leads (I and aVL) and all of the V leads except for V1, where the P wave is biphasic. The P wave is normally inverted in aVR. Figure 1 shows a normal sinus rhythm in leads II and V5. The commonly measured intervals are shown in Figure 2. Alterations in these intervals will have both diagnostic and prognostic implications as described in this text.

The sinus node is richly innervated with both sympathetic and parasympathetic nerves. As a result, the heart rate is closely regulated by the autonomic nervous system. An increase in sympathetic tone, as often occurs in critically ill patients due to pain, fear, anxiety, hypovolemia, or withdrawal from opiates or alcohol, increases sinus rate. An increase in parasympathetic (vagal) tone or a decrease in sympathetic tone (as occurs with spinal shock) will decrease the sinus node-firing rate.

### BRADYCARDIA

Bradycardia is defined as a heart rate less than 60 bpm. However, bradycardia is not necessarily pathologic and needs to be interpreted in the light of the clinical setting.

A heart rate of 60 bpm or less may be appropriate for a patient at rest or sleeping. However, the same heart rate would be inappropriately low for a critically ill patient with fever and hypotension. Because the cardiac output is a product of heart rate and stroke volume, bradycardia leads to a decrease in cardiac output that can result in decreased tissue perfusion. Pathologic bradycardia, therefore, can be better defined as a heart rate that is too slow to meet the metabolic demand. The causes of pathologic bradycardia can be divided into two categories: sinus node dysfunction and heart block.

### Sinus Node Dysfunction

Failure of the sinus node to generate a cardiac impulse can result in sinus bradycardia, sinus pauses, or sinus arrest. Sinus node dysfunction can be due to either intrinsic structural abnormality of the sinus node or to extrinsic factors that affect the normally functioning sinus node. The most common cause of intrinsic sinus node dysfunction is idiopathic and is thought to be due to diffuse fibrosis of atrial tissue (including cardiac conduction fibers). Intrinsic sinus node dysfunction is most commonly seen in elderly patients and in patients with atrial tachydysrhythmias. Extrinsic factors that affect the sinus node are common (Table 1). Extrinsic factors that cause sinus node dysfunction do not cause structural changes in the sinus node and thus can be reversed once the offending factors are removed. The most common extrinsic causes of sinus node dysfunction include high vagal tone and sinus node-depressant drugs. High vagal tone can be seen in critically ill patients during endotracheal suctioning, in association with inferior wall myocardial infarction (MI) and with cervical spinal cord injury that results in unopposed vagal effect on the heart. Drugs such as beta-receptor blockers and calcium-channel blockers are common extrinsic drug-related causes of sinus node dysfunction. Nondrug-related extrinsic causes of sinus node dysfunction include hypothyroidism, increased intracranial pressure (ICP), and hypothermia. One of the important manifestations of sinus node dysfunction is tachycardia-bradycardia syndrome in which termination of an atrial tachydysrhythmia is followed by a sinus pause.

☞ **Bradycardia per se does not require specific treatment as long as it does not cause symptoms of hemodynamic compromise.** ☞ Symptoms related to sinus node dysfunction are often nonspecific and are difficult to identify. The first step in the treatment of sinus node dysfunction should be removal of extrinsic factors such as sinus

**Figure 1** Normal sinus rhythm obtained from an otherwise healthy 67-year-old male. The P waves are upright in leads II and V5. Heart rate: 76 bpm, PR interval: 148 msec, QRS duration: 76 msec, QT/QT<sub>c</sub>: 370/416 msec.

node-depressant drugs. Catecholaminergic drugs, such as isoproterenol and epinephrine, and vagolytic agents, such as atropine or glycopyrrolate, can acutely increase sinus rate and can be used if urgent intervention for bradycardia is needed. If bradycardia causes symptoms and is resistant to pharmacologic therapy, or if there is concern that the heart rate may decline further, a temporary transcutaneous pacemaker can be placed on the surface of the patient. Esophageal stethoscopes with pacing capabilities have also been used successfully. If one needs prolonged heart rate support, a transvenous temporary pacemaker, or a permanent pacemaker, is required.

### Abnormal Atrio-ventricular Conduction

Atrio-ventricular (AV) block occurs when there is a delay or failure of the atrial impulse to conduct to the ventricles. Abnormal AV conduction can occur at the level of the AV

**Figure 2** Commonly measured intervals on the electrocardiographic trace. The normal PR interval duration ranges between 0.12 and 0.2 seconds (120–200 msec). The QRS interval normally ranges from 0.05 to 0.12 seconds (50–120 msec). The normal QT interval varies with heart rate, age, and sex. In general, the QT interval should be less than half the preceding RR interval. However, when the heart rate is  $\leq 65$  bpm the normal heart rate corrected QT interval (QT<sub>c</sub>) is even lower. When the QT<sub>c</sub> becomes  $> 500$  msec there is increased risk of torsades de pointes and V-fib.

**Table 1** Extrinsic Causes of Sinus Node Dysfunction Resulting in Bradycardia

Drugs	Beta-receptor blockers Calcium-channel blockers Digitalis Antidysrhythmic drugs
High vagal tone	Inferior wall myocardial infarction Endotracheal suctioning Carotid massage
Increased ICP	Bradycardia associated with hypertension Mechanism of this “Cushing response” is not completely understood Traditionally, the hypertensive component is believed to result from brainstem ischemia Could result from activation of intracranial baroreceptors, or loss of supratentorial inhibition of brainstem vasomotor centers Bradycardia can be direct effect, or reflexic (of brainstem ischemia)
Hypothyroidism	Decreased inotropy and chronotropy
Apnea	Initially HR is increased due to increased sympathetic tone. Later, perhaps due to brainstem ischemia, bradycardia results
Hypothermia	Decreased sinus rate, and decreased PR interval, and decreased contractility ultimately. Osborn waves are seen just prior to V-fib (see Volume 1, Chapter 40, and Volume 2, Chapter 11)

*Abbreviations:* HR, heart rate; ICP, intracranial pressure; V-fib, ventricular fibrillation.

node or below in the bundle of His or beyond. Identification of the level of block is important because it determines the treatment strategy. Conduction block at the level of the AV node is usually due to abnormal vagal tone or to medications and does not usually require permanent intervention. However, an AV block below the level of the AV node represents damage to the conduction system and requires a permanent pacemaker.

AV block can be classified into first-degree AV block, second-degree AV block, high-degree AV block, and third-degree AV block or complete heart block. First-degree AV block is characterized by prolongation of the PR interval to more than 200 msec. In general, first-degree AV block does not cause any significant hemodynamic compromise and does not need intervention. Second-degree AV block can be classified into type I and type II. Type I, or Wenckebach AV block, is characterized by gradual prolongation of the PR interval, eventually leading to a P wave that does not conduct, resulting in the absence of a QRS complex (Fig. 3A). The level of block for type I second-degree AV block is in the AV node and is most commonly due to high vagal tone or to medications that produce block at the AV nodal level such as beta-blockers, nondihydropyridine calcium-channel blockers, and digoxin. One must inquire specifically about eye drops containing beta-blockers because they can have significant systemic absorption and can cause bradycardia and AV block. Type II AV block is characterized by a sudden drop in a QRS complex without gradual prolongation of the PR interval and represents more extensive disease in the conduction system (Fig. 3B). In general, type I second-degree AV block is associated

**Figure 3** (A) Type I second-degree AV block. There is a gradual prolongation of the PR interval prior to a nonconducted P wave. (B) Type II second-degree heart block. The PR interval is fixed prior to a nonconducted P wave. (C) Late coupled premature atrial contraction mimicking type II second-degree AV block. The fifth P wave is premature and has a P-wave morphology that is slightly different from other P waves. (D) Complete heart block with ventricular escape. (E) A-fib with complete heart block. The ventricular rate is slow and regular.

with narrow QRS complex escape beats, because these arise from the AV node. Type II AV block is associated with wide QRS complex escape beats, which arise from the ventricle. Late coupled premature atrial contractions (PACs) that do not result in ventricular contraction can be confused with second-degree AV block. Therefore, the P-wave morphologies prior to AV block need to be carefully scrutinized (Fig. 3C). Complete heart block or third-degree heart block is due to complete blockade of AV conduction. Complete heart block at the level of the AV node usually results in a junctional escape rhythm with narrow QRS complexes and a heart rate of approximately 50 bpm. Junctional rhythm is relatively stable and prolonged asystole is uncommon. Complete heart block occurring below the level of the AV node results in a slow ventricular escape rhythm with wide QRS complexes, typically at a rate less than 40 bpm (Fig. 3D). A ventricular escape rhythm is an unstable rhythm and may suddenly disappear, resulting in prolonged asystolic period. When there is a slow, regular ventricular rhythm in the setting of underlying atrial fibrillation (A-fib), complete heart block should be suspected (Fig. 3E).

Slow ventricular rates from heart block will result in a decreased left ventricular end diastolic volume (LVEDV) due to the lack of atrial contraction at end diastole. The subsequent decrease in cardiac output may be significant enough to result in inadequate tissue perfusion. Patients with heart block and moderate hypertension may maintain what appears to be an adequate blood pressure, but truly have occult inadequate tissue perfusion, which is evidenced by prerenal azotemia, hepatocellular injury, and congestive heart failure. In addition, complete heart block with a slow ventricular escape rate can be associated with bradycardia-dependent torsades de pointes. Therefore, patients with evidence of inadequate tissue perfusion should be promptly treated.

**⚡ Heart block at the level of the AV node usually does not require invasive therapy and only requires withdrawal of the offending agents, such as beta-blockers and calcium-channel blockers.** ⚡ Sometimes, infusion of a beta-agonist such as isoproterenol, or temporary pacing with either a transvenous or a transcutaneous pacemaker, can be used to support the heart rate until the medications are metabolized or excreted. A permanent pacemaker is almost never needed. However, heart block below the level of the AV node often causes more significant symptoms and requires a permanent pacemaker (Table 2).

**Table 2** Atrio-ventricular Blocks Categorized by Degree, and by Anatomic Location Relative to the AV Node, Along with Common Symptoms and Treatment

Degree of block	Level of block	Symptoms	Treatment
First-degree AV block (prolonged PR interval)	Proximal	No	None
	Distal	No	None
Second-degree AV block (intermittent block)	Proximal	No	None
		Yes	Removal of offending factors, temporary pacemaker
	Distal	No	Permanent pacemaker
		Yes	Permanent pacemaker
Third-degree AV block (no conduction of atrial impulses to the ventricles)	Proximal	No	None
		Yes	Temporary pacemaker
	Distal	No	Permanent pacemaker
		Yes	Permanent pacemaker

Abbreviation: AV, atrio-ventricular.

## TACHYDYSRHYTHMIAS

### Sinus Tachycardia

Sinus tachycardia is defined as a heart rate more than 100 bpm. The morphology of the P wave is similar to that in the baseline sinus rhythm, with positive P-wave deflections in leads I, II, III, aVF, and aVL. ⚡ **Sinus tachycardia usually has a gradual onset and termination.** ⚡ Sinus tachycardia in critical care settings is an appropriate physiologic response to stresses such as fever, hypovolemia, hypotension, pulmonary embolism, congestive heart failure, respiratory distress, and thyrotoxicosis. Drugs such as dobutamine, epinephrine, caffeine, and alcohol can also cause sinus tachycardia. In patients with unexplained sinus tachycardia, a vigilant search for its cause should be made. Pulmonary embolism, in particular, should be considered as a possible cause in a chronically ill patient in the critical care setting.

In general, sinus tachycardia does not require specific interventions to correct the heart rate itself, and treatment should be directed at addressing the underlying cause of the sinus tachycardia and removing any offending agents. However, beta-blockers such as esmolol and metoprolol, and calcium-channel blockers such as diltiazem and verapamil, can be used to slow the ventricular rate in patients in whom tachycardia might be harmful (e.g., myocardial ischemia, aortic stenosis, mitral stenosis, etc.). In the trauma intensive care unit (ICU) setting, sinus tachycardia often means the patient requires additional intravascular repletion, is hypoxemic or febrile, or suffering from pain and anxiety requiring opioid analgesics or other sedatives. Even when the problem is mainly anxiety or pain driven, adequacy of oxygenation, ventilation, fluid repletion, and systemic perfusion must be assured.

### Atrial Tachydysrhythmias

Atrial tachydysrhythmias include A-fib, atrial flutter, atrial tachycardia, and multifocal atrial tachycardia (MAT). Frequent symptoms associated with atrial tachydysrhythmias include a sensation of the heart racing, palpitations, dizziness, syncope, fatigue, shortness of breath, and chest pain. These symptoms are usually due to a rapid ventricular rate, which decreases cardiac output because of inadequate ventricular filling time.

A-fib is the most common sustained tachydysrhythmia and is frequently seen in critically ill and elderly patients. The cause of new-onset A-fib in ICU patients is not always obvious, although it is almost always related to elevated catecholamine levels associated with physiologic or pathophysiologic stress. Treatable causes of A-fib, such as thyrotoxicosis and pulmonary embolism, should always be sought.

The heart with A-fib is characterized by disorganized atrial depolarizations, with an irregularly irregular ventricular contraction rate. The fibrillating atria resembles a “bag of worms” when directly visualized or examined with transeophageal echocardiography (TEE). The ECG reveals baseline undulations without discernable P waves, and an irregularly irregular QRS with A-fib. The disorganized atrial depolarizations range between 300 and 500 depolarizations per minute and the ventricular rate in untreated patients varies from 100 to 180 bpm.

Atrial flutter is commonly seen in ICU patients, others with high catecholamine levels, and those with structural heart disease. Typically, the atrial rate is regular and ranges from 260 to 300 bpm, and the corresponding ventricular rate is 130–150 bpm due to a 2:1 AV block. Thus,

**Figure 4** Typical atrial flutter with sawtooth flutter waves in the inferior leads.

atrial flutter should be considered as the most likely rhythm when a patient develops an acute narrow complex tachycardia with a ventricular rate near 140 bpm. The ECG classically reveals a sawtooth pattern in the inferior leads and narrow positive flutter waves in leads II, III, and aVF (Fig. 4).

Ectopic atrial tachycardia (EAT) is most commonly due to an automatic focus and is usually seen in patients with chronic lung disease and digitalis toxicity. The automatic focus of atrial tachycardia is enhanced by catecholamines. Similar to sinus tachycardia, EAT typically has a gradual onset and termination. The ECG reveals an atrial rate of 120–250 bpm with a P-wave morphology that is different than that seen in sinus rhythm.

MAT is also commonly seen in patients with severe lung disease, especially in the setting of increased atrial stretch (i.e., volume overload) and in high catecholamine states. The atrial rate is, in general, 120–180 bpm. The ECG reveals multiple P-wave morphologies. Patients with MAT are usually elderly and often have prolonged ICU stays due to their pulmonary disease and comorbid conditions (see Volume 1, Chapter 37). Of the atrial tachydysrhythmias, MAT is one of the most difficult to treat, partly due to the triggering pathophysiology (long-standing pulmonary disease and atrial stretch).

Acute treatment of atrial tachydysrhythmias includes ventricular rate control, as well as acute conversion to and maintenance of sinus rhythm (Table 3). For ventricular rate control, agents that block AV nodal conduction, such as calcium-channel blockers, beta-blockers, or digoxin, can be used in hemodynamically stable patients. Repletion of potassium and magnesium is universally beneficial. Digoxin, once the foundation of therapy, is no longer recommended as the initial or stand-alone treatment when other (less toxic) AV node-blocking agents are available. In hemodynamically unstable patients, synchronized direct current (DC) cardioversion should be employed before rate-controlling drugs are administered.

⚡ **Acute conversion of atrial tachydysrhythmias to sinus rhythm can be accomplished either by synchronized DC cardioversion or by administration of antidysrhythmic agents.** ⚡ Hemodynamically unstable atrial tachydysrhythmias should be treated promptly with synchronized DC cardioversion. Atrial flutter requires less energy than A-fib to convert to sinus rhythm. Antidysrhythmic drugs can be used to convert atrial tachydysrhythmias and to maintain sinus rhythm in hemodynamically stable atrial tachydysrhythmias. Antidysrhythmic drugs will be discussed in more detail in a subsequent section.

Inadequate atrial contraction associated with A-fib and atrial flutter can result in thrombus formation in the atria, which may lead to systemic thromboembolism. The

**Table 3** Atrial Tachydysrhythmias: Diagnosis and Treatment

Atrial rhythm disorder	Heart rate (atrial/ventricular)	P waves	Treatment
Sinus tachycardia	100–180/100–180	Same as sinus rhythm	Treat underlying illness Beta-blocker, if symptomatic
Ectopic atrial tachycardia	120–250/variable	Different from sinus	Rate control with AV-blocking agents Rhythm control with antidysrhythmic drugs
Multifocal atrial tachycardia	100–140/100–140	Multiple P-wave morphologies	Rate control with AV-blocking agents Rhythm control with antidysrhythmic drugs
Atrial flutter	250–300/150 if untreated	Sawtooth in leads II, III, and aVF	Adenosine Rate control with AV-blocking agents
Atrial fibrillation	300–400/120–180 if untreated	No discernable P waves	Rhythm control with antidysrhythmic drugs Anticoagulation, if more than 48 hrs

*Note:* In most situations, normalizing  $[Mg^{2+}]$  and  $[K^+]$  and decreasing catecholamine levels will increase the ability to maintain normal sinus rhythms.

*Abbreviations:* AV, atrio-ventricular; VF, ventricular fibrillation.

risk of thromboembolism increases after A-fib or flutter is sustained for more than 48 hours. Therefore, cardioversion should be performed within 48 hours from the onset of A-fib or flutter to minimize the risk of embolization that can occur following cardioversion as the atria return to normal contraction. Beyond 48 hours, patients should receive a TEE to rule out mural thrombi, and be considered for anticoagulation prior to electric cardioversion.

### Atrio-ventricular Node-Mediated Dysrhythmias

The most common AV node-mediated tachycardias are the AV nodal re-entrant tachycardia (AVNRT) and the AV re-entry tachycardia (AVRT) shown schematically (Fig. 5). In patients with AVNRT, there are two inputs into the AV node, a slow pathway and a fast pathway. During the AVNRT, the electrical impulse propagates antegrade through the slow pathway and then retrograde through the fast pathway (Fig. 5A). The ECG reveals a narrow complex tachycardia with no discernable P wave, or retrograde conducted P waves that are visualized at the terminal portion of the QRS complexes (referred to as a pseudo r-prime). In AVRT tachycardias (Fig. 5B), the AV node is used for antegrade conduction and the accessory pathway is used for retrograde conduction; this larger circuit is sometimes referred to as macroreentrant. The P waves in AVRT will be retrograde conducted and seen between the QRS and the T wave (Fig. 5B).

✦ **Treatment of AV node-mediated tachycardias (AVNRT and AVRT) can be accomplished by administering drugs that increase the refractory period of the AV node. These drugs include calcium-channel blockers, beta-blockers, digoxin, and adenosine.** ✦ In patients without hypotension, vagal maneuvers (e.g., carotid massage) are often sufficient to terminate these dysrhythmias. However, in the setting of hypotension, the judicious administration of phenylephrine in 0.1 mg increments may terminate the dysrhythmia on its own or increase the pressure enough to allow the patient to tolerate the administration of a calcium-channel blocker or adenosine. A diagnostic test as well as therapeutic dysrhythmia conversion can be performed simultaneously by giving an intravenous bolus of 6–12 mg of adenosine. Because adenosine is rapidly degraded in the blood stream, it should be given through a large bore (preferably central) intravenous line followed by a bolus flush of intravenous fluids. Intravenous verapamil (2–10 mg) or diltiazem (10–20 mg) can also be used for acute

termination of AVNRT or AVRT. Because both of these calcium-channel blockers can cause some systemic vasodilation and hypotension, calcium chloride can be administered concomitantly in (250 mg) aliquots without inhibiting the calcium-channel blockade effect at the AV node. Digoxin is too slow acting, and should not be used emergently to control AVNRT or AVRT, but digoxin is typically added to further increase tone at the AV node. Maintenance and prevention can be accomplished with either intravenous or oral calcium-channel blockers or beta-blockers.

### Accessory-Pathway Mediated Tachycardia (Wolf-Parkinson-White Syndrome)

Wolf-Parkinson-White (WPW) syndrome is due to antegrade conduction down an accessory pathway linking the atrium and the ventricle. As a result, activation of ventricular depolarization is fused between the activation occurring through the normal AV nodal pathway and that occurring through the accessory pathway (a process referred to as pre-excitation). The resulting ECG trace reveals a characteristic “delta wave” type widening of the QRS, which is relegated to the basal portion of the ascending limb of the QRS complex. WPW affects about two to three out of 1000 people in the general population. Accessory-mediated tachycardias include orthodromic AVRT (retrograde conduction through the accessory pathway) and WPW atrial dysrhythmias (antegrade conduction down the accessory pathway) with a variable degree of pre-excitation and delta wave formation. Orthodromic AVRT uses the AV node–His bundle as the antegrade limb, and the accessory pathway for the retrograde limb during the tachycardia. Therefore, the ventricular activation pattern is normal and the QRS complex is narrow. Antidromic AVRT (e.g., WPW) uses the accessory pathway as the antegrade limb and the AV node–His bundle as the retrograde limb. When the ventricular activation is purely through the accessory pathway, the ECG reveals a wide complex tachycardia that can be difficult to differentiate from ventricular tachycardia (VT).

AVRT, like AVNRT, requires the AV node as the critical limb for re-entry. Therefore, agents that slow conduction in the AV node can terminate and prevent both of these dysrhythmias. Acutely, AVRT can be terminated with an intravenous bolus of either adenosine (6–12 mg) or a

**Figure 5** Schematic of AV node re-entry tachycardia (AVNRT) and AV re-entry tachycardia (AVRT). (A)  $V_1$  lead showing the typical electrocardiographic trace of AVNRT, along with a schematic of the re-entrant circuit. There is relatively slow anterograde conduction over the AV node with nearly simultaneous activity of the atrium and ventricle. This leads to P-wave activity within or at the end of the QRS complex. The arrow points to a pseudo r-prime in  $V_1$ , which represents P-wave activity during tachycardia. (B) In AVRT, the tachycardia circuit is macro re-entrant. Anterograde conduction occurs over the AV node–His Purkinje system to activate the ventricle. Retrograde conduction proceeds from the ventricle over the accessory pathway to activate the atrium. There is a requisite amount of time necessary from ventricular activation to atrial activation. This usually allows sufficient time for P-wave activity to be noted in the early ST segment (arrow in  $V_1$ ). *Abbreviations:* AVN, atrial-ventricular node; AP, accessory pathway; LBB, left bundle branch; RBB, right bundle branch. *Source:* From Ref. 77.

calcium-channel blocker such as diltiazem (10–20 mg) or verapamil (2–10 mg) (Table 4). Oral calcium-channel blockers or beta-blockers can be used on a regular dosing schedule to prevent recurrence.

Patients with WPW syndrome also commonly have atrial tachydysrhythmias such as A-fib requiring particular caution during termination. Because the accessory pathway can allow more rapid conduction than the AV node, the ventricular rate during atrial tachydysrhythmias is often quite rapid. Ventricular activation during atrial tachydysrhythmias is fused between activation through the

AV node–His bundle and the accessory pathway. Therefore, an ECG during A-fib in patients with WPW syndrome reveals a wide complex tachycardia that is irregularly irregular (Fig. 6).

♣ **Acute treatment of pre-excited A-fib should be targeted at slowing conduction in the accessory pathway rather than in the AV node. Pre-excited A-fib can be treated acutely with cardioversion (if patient is hemodynamically unstable) or adenosine, intravenous procainamide, ibutilide (1,2), or amiodarone (3).** ♣ One should avoid AV node-blocking agents (e.g., digoxin, calcium-channel blockers, or beta-blockers) in pre-excitation AVRT (WPW), because these may facilitate more rapid conduction through the accessory pathway and result in hemodynamic compromise. Chronic treatment of WPW syndrome includes radiofrequency ablation (RFA) or chronic administration of the above-mentioned antidysrhythmic drugs.

### Differential Diagnosis of Narrow Complex Tachycardias

Accurate diagnosis of a narrow complex tachycardia in the acute care setting is important, because the treatment options depend on accurate recognition and diagnosis of the tachycardia (Table 5). The first step is to determine whether the rhythm is regular or irregular. Irregular rhythms include A-fib, MAT, and sinus tachycardia with frequent PACs. Regular narrow complex rhythms include EAT, atrial flutter, AVNRT, or AVRT.

The ventricular rate is sometimes helpful. With a ventricular rate of 140–150 bpm, the most likely diagnosis is atrial flutter with 2:1 block. AVNRT or AVRT have ventricular rates of 160–240 bpm.

The onset and termination of the supraventricular tachycardia (SVT) are also helpful. Atrial tachycardia tends to have a warm-up period with a slight increase in heart rate as the tachycardia warms up. AVNRT and AVRT have relatively fixed heart rates.

When determining the type of SVT, one must evaluate the presence and morphology of the P waves. The best leads in which to look for P waves are leads II and  $V_1$ . Subtle changes in the ST-T waves may allow detection of P waves. With an EAT, P waves are usually seen at the terminal portion of the T waves or after the T waves. With an AVNRT, retrograde P waves are usually not visible, because they are buried within the QRS complex or are disguised as an R' in the  $V_1$  lead. With an AVRT, retrograde P waves can be seen in the ST segments.

Administration of adenosine can be used not only to acutely terminate the rhythm, but also as a diagnostic tool. A bolus injection of adenosine (6–18 mg) will result in termination of AV node-mediated re-entrant tachycardias including AVNRT and AVRT. A bolus injection of adenosine in atrial tachycardias, such as atrial flutter and EAT, will result in increased AV block and may allow visualization of P waves or flutter waves when the rhythm returns, helping to make an accurate diagnosis.

### Ventricular Tachydysrhythmias *Accelerated Idioventricular Rhythm*

An accelerated idioventricular rhythm (AIVR) is a dysrhythmia of ventricular origin that is slower than 120 bpm, and is most commonly seen in patients with recent myocardial injury. In general, it does not cause hemodynamic compromise and does not require treatment.

**Table 4** Atrio-ventricular Node and Accessory Pathway–Mediated Tachycardias: Diagnosis and Treatment

Rhythm disorder	Heart rate	P wave	Treatment
AVNRT	150–250	Retrograde P wave in the QRS or at the terminal portion of the QRS	AV-blocking agents Adenosine (A) Beta-blockers (A, C) Calcium-channel blockers (A, C) Digoxin (C)
AVRT	150–250	Retrograde P wave in ST segment	AV-blocking agents Adenosine (A) Beta-blockers (A, C) Calcium-channel blockers (A, C) Antidysrhythmics Class IA, IC, and III (C) RF ablation Cardioversion adenosine
Atrial fibrillation with WPW	150–300	Irregularly irregular wide complex QRS. No discernable P waves	Antidysrhythmics RF ablation Class IA (A, C), IC (C), and III (A, C)

*Abbreviations:* A, acute treatment; AV, atrio-ventricular; AVNRT, AV nodal re-entrant tachycardia; AVRT, AV re-entrant tachycardia (uses accessory pathway rather than the AV node); C, chronic treatment; RF, radiofrequency; WPW, Wolf-Parkinson-White syndrome.

**Figure 6** Pre-excited atrial fibrillation. There are slight irregularities in the RR interval (*arrows*).

### Nonsustained Ventricular Tachycardia

VT is commonly seen in critically ill patients. Nonsustained VT does not always cause symptoms, but does require prompt evaluation because it may proceed to sustained VT or ventricular fibrillation (V-fib). In evaluating patients with nonsustained VT, one needs to assess left ventricular (LV) function and search for underlying coronary artery disease, and determine if it is multifocal or unifocal.

Nonsustained VT in patients with preserved LV function and without myocardial ischemia has a good prognosis

and does not require further evaluation or treatment. In addition, nonsustained VT is seen frequently in patients with nonischemic dilated cardiomyopathy and usually does not require further evaluation or treatment. However, nonsustained VT in patients with ischemic cardiomyopathy and an LV ejection fraction (EF) less than 40% requires an electrophysiologic test to further assess the risk of sudden cardiac death (4,5).

⚡ **Of the nonsustained VTs, nonsustained polymorphic VTs with a rapid ventricular rate require special attention, because these unstable dysrhythmias are very likely to progress to V-fib.** ⚡ Nonsustained polymorphic VTs are most commonly associated with active myocardial ischemia or a prolonged QT interval. Recognition of nonsustained VT due to QT prolongation (Fig. 7) is particularly important, because administration of antidysrhythmic agents such as amiodarone would further prolong the QT interval, slow the heart rate, and increase the likelihood of causing a sustained polymorphic VT that could progress to V-fib.

**Table 5** Differentiation of Narrow Complex Tachycardias

Regular vs. irregular	Irregular	Atrial fibrillation, multifocal atrial tachycardia, sinus tachycardia with PACs
Rate	Regular 140 – 150 bpm 160–240 bpm	EAT, atrial flutter, AVNRT, AVRT Atrial flutter EAT, AVNRT, AVRT
Onset/termination	Sudden Gradual warm up	Atrial flutter, AVNRT, AVRT Sinus tachycardia, EAT
P waves	Not seen or at the terminal portion of QRS complex Seen on the ST segment Sawtooth pattern	AVNRT AVRT Atrial flutter
Response to adenosine	Increased AV block Termination	EAT, atrial flutter AVNRT, AVRT

*Abbreviations:* AV, atrio-ventricular; AVNRT, AV nodal re-entrant tachycardia; AVRT, AV re-entrant tachycardias; EAT, ectopic atrial tachycardia; PACs, premature atrial contractions.

**Figure 7** Nonsustained torsades de pointes in a patient taking sotalol. Note the prolonged QT interval and a large T wave from which nonsustained ventricular tachycardia starts.

Nonsustained polymorphic VT with QT prolongation should be treated promptly with intravenous magnesium, correction of underlying electrolyte disturbances, and withdrawal of offending drugs. Judicious doses of phenylephrine 0.05–0.1 mg bolus or phenylephrine infusion (25–75  $\mu$ g/min) may be required to maintain blood pressure in patients with this rhythm. If the nonsustained polymorphic VT continues despite the above measures, a transvenous temporary pacemaker can be placed to overdrive suppress the nonsustained VT.

### Sustained Ventricular Tachycardia

Sustained VT can be divided into monomorphic VT and polymorphic VT. The ECG reveals a wide complex tachycardia. Differentiation of VT from SVT with aberration will be discussed in a later section. Monomorphic VT is most commonly seen in patients with underlying heart disease including previous MI and cardiomyopathy (Fig. 8).

Sustained VT is occasionally seen in patients with a structurally normal heart. In patients with normal hearts, VT often arises from either the right ventricular (RV) outflow tract or the LV septum. Sustained VT originating in the RV outflow tract has tall upright R waves in the inferior leads (leads II, III, and aVF) and has a left bundle branch block (LBBB) pattern. Sustained VT originating in the LV septal area has a right bundle branch block (RBBB) pattern and normal or left axis deviation. The unique feature of these VTs in patients with normal hearts is that they behave more like SVTs and respond well either to calcium-channel blockers or to beta-blockers, sedatives, and analgesics. This is not surprising, given the typical trigger is a high catecholamine state (secondary to pain, fear, anxiety, or underresuscitation).

Sustained polymorphic VTs are divided into those with and without QT prolongation. Polymorphic VT with QT prolongation is called torsades de pointes, which is characterized by QRS complexes that alternately widen and narrow continuously as the electrophysiologic axis of the heart changes “twists around a point.” The underlying mechanism for QT prolongation is abnormal and prolonged repolarization of the ventricles. As a result, the T wave becomes abnormal and the QT duration becomes prolonged to an interval greater than the upper limit of the normal corrected QT duration (QT<sub>c</sub>) of 440 msec.

There are primary (or congenital) and acquired long QT syndromes. Primary long QT syndrome is a familial disorder. The acquired long QT syndrome is most commonly caused by

**Figure 8** Sustained monomorphic ventricular tachycardia. Note the retrograde P wave seen after every other QRS complex (arrows).

(i) drugs such as quinidine, procainamide, sotalol, amiodarone, tricyclic antidepressants, antihistamines, and quinolone antibiotics; and (ii) electrolyte disorders such as hypokalemia and especially hypomagnesemia. Other causes of QT prolongation are discussed below. Torsades de pointes due to acquired QT prolongation is more likely to occur in the setting of bradycardia (bradycardia-dependent) or it can follow long pauses (pause-dependent). Prolonged QT interval (and frequent PVCs due to the prolonged QT interval) should be promptly treated, so that polymorphic VT does not progress to V-fib, and the subsequent need for cardiac resuscitation can be prevented.

Acute treatment of sustained unifocal (monomorphic) VT depends on whether or not hemodynamic decompensation is associated. ⚡ **Hemodynamically unstable VT should be treated promptly with DC electrical cardioversion.** ⚡ Monomorphic VT can be treated using a synchronized low-energy shock. However, when the rate of VT is too rapid, synchronization may not work well, may delay treatment, may accelerate VT, or may convert VT to V-fib. When a nonsynchronized shock is given for rapid VT or fibrillation, the output should be high enough to depolarize enough myocardium to terminate VT. In general, the minimum output for a nonsynchronized shock should be 120 J with a biphasic defibrillator and 200 J with a monophasic defibrillator. If V-fib results, reshock with 300 J to convert to sinus rhythm, increasing to 360 J, if subsequent shocks are needed. Closed chest cardiopulmonary resuscitation (CPR) should always be started if cardioversion is not immediately available in the case of V-fib or hemodynamic unstable VT (without a pulse or pressure). Following termination of the VT, an antidysrhythmic agent such as amiodarone should be started to prevent recurrent VT while the causes of the VT are sought after. ⚡ **Hemodynamically stable VT can be treated with a pharmacologic agent. The first line of treatment is intravenous amiodarone or procainamide (6).** ⚡

Sustained polymorphic VT, in general, causes hemodynamic decompensation and requires prompt nonsynchronized DC cardioversion. Again, the output should be high enough to depolarize enough myocardium to terminate VT. Following termination of VT, the QT interval should be determined to rule out torsades de pointes. If the QT interval is not prolonged, an antidysrhythmic agent can be started. However, if the QT interval is prolonged, a magnesium infusion should be started, any underlying electrolyte disturbances should be corrected, and offending drugs should be withdrawn.

Similar to the atria in A-fib, the appearance of the entire heart during V-fib resembles a “bag of worms.” There is no significant ejection out of a ventricle during V-fib. Low-amplitude fibrillatory waves are seen on ECG. Accordingly, treatment of V-fib is immediate CPR until a defibrillator is available; then immediate cardioversion should proceed with 300 J escalating to 360 J.

### Differential Diagnosis of Wide Complex Tachycardias

The diagnosis of wide complex tachycardia is often difficult to make. However, accurate diagnosis of wide complex tachycardia is important for prompt and appropriate initial treatment and subsequent management. The differential diagnosis of wide complex tachycardias includes VT, SVT with aberration, SVT with underlying bundle branch block (BBB) or conduction delay, and SVT with ventricular depolarization through an accessory pathway. Several criteria have been developed to distinguish among wide

complex tachycardias. Factors to be considered include presenting symptoms, past medical history, and the ECG.

Presenting symptoms are not always reliable in deciding whether a wide complex tachycardia is VT or SVT with aberration. Although SVT tends to be more hemodynamically stable, sustained VT does not necessarily cause hemodynamic instability. One should not assume that if a patient is alert and hemodynamically stable, the wide complex tachycardia must be an SVT; the misdiagnosis of VT as SVT, and the treatment as such, may lead to catastrophic consequences.

Past medical history is important in differentiating VT from SVT with aberration (7). In patients with a history of previous heart disease, such as previous MI, heart failure, and congenital heart disease, a wide complex tachycardia is more likely to be VT than SVT and should be presumed to be VT unless one can be sure that it is an SVT with aberration.

☞ **The ECG is quite useful in distinguishing VT from SVT with aberration.** ☞

Ventricular rate is not a useful differentiation between VT and SVT because there is significant overlap between the two. However, AV dissociation, capture beats, and fusion beats are all associated with VT. Right superior axis, that is,  $-90^\circ$  to  $-180^\circ$ , is more likely to be VT than SVT. Additionally, the wider the QRS complex, the more likely the dysrhythmia is VT rather than SVT. A QRS duration longer than 140 msec with an RBBB morphology and a QRS duration more than 160 msec with an LBBB morphology, are more likely to be VT than SVT. Finally, QRS morphology is useful. In general, SVT with aberration leads to a more typical BBB pattern than VT, whether it is an RBBB or an LBBB pattern, whereas VT usually has a BBB pattern that is bizarre and atypical. The following features of the QRS morphology favor diagnosis of VT: (i) concordance of the precordial leads, that is, the QRS complex in the precordial leads are either all negative or all positive; (ii) presence of Q waves; and (iii) an RS interval longer than 100 msec. These criteria are useful in distinguishing VT from SVT with aberration. However, for most clinicians, distinguishing VT from SVT with aberration and remembering all the criteria is difficult. The more important determination is the patient's hemodynamic status. If the patient is stable, abundant time is available to measure RS intervals, and so on. If the patient is unstable, cardioversion is indicated. ☞ **The criteria for distinguishing VT from SVT include: (i) VT is more common than SVT with aberration, especially in patients with structural heart disease, (ii) SVT with aberration usually has a typical BBB pattern, (iii) when in doubt, treat wide complex tachycardias as VT, and (iv) obtain as much electrocardiographic documentation as possible including a 12-lead ECG and rhythm strips of the tachycardia's onset and termination.** ☞

## ANTIDYSRHYTHMIC DRUG SELECTION

Many dysrhythmias are triggered by reversible factors such as ischemia, stress, electrolyte imbalance, systemic illness, and drugs. Antidysrhythmic drugs themselves can cause as well as treat dysrhythmias. In a broad sense, the agents that are used to treat underlying illness can be considered to be antidysrhythmic agents. However, in this section, we will focus more on the drugs that are classically classified as antidysrhythmic due to their electrophysiologic effects on the heart (Table 6). Despite some shortcomings, the

Vaughn-Williams drug classification system is a useful way of classifying antidysrhythmic agents. Class I drugs affect sodium channels and thus depress the phase 0 (Fig. 9) of the action potential and slow conduction. This group of drugs is further subdivided into A, B, and C depending on their potency and their effect on repolarization. Subclass A has modest effects on the sodium channel, but prolongs repolarization. Subclass B has weak sodium channel-blocking action and has no effect on repolarization. Subclass C is the most potent sodium-channel blocker and has minimal or no effect on repolarization. Class II drugs are those that block beta-receptors. Class III antidysrhythmic drugs are those that prolong repolarization. Class IV drugs are those that block the calcium channel. All antidysrhythmic drugs have undesirable side effects, including the propensity to cause some dysrhythmias. For example, class IA and III drugs can prolong repolarization and cause polymorphic VT (torsades de pointes). Class IC drugs, especially in patients with underlying coronary artery disease, can cause sustained VT. Class II and IV drugs can cause heart block and bradycardia. Class I and III drugs can delay conduction in the His-Purkinje system, especially in patients with underlying conduction system disease, and may cause distal AV block with a very slow or no ventricular escape. Therefore, initiation of antidysrhythmic agents in patients with underlying LBBB or RBBB should be done cautiously.

Class IA drugs include quinidine, procainamide, and disopyramide. Because the class IA drugs affect the atria, AV node, and ventricles, class IA drugs work well for both atrial and ventricular dysrhythmias. It is particularly important to follow QT intervals in patients receiving class IA drugs due to their potential for causing QT prolongation resulting in torsades de pointes. Prolongation of the rate-corrected QT interval (QTc) is idiosyncratic and can occur with the first dose of class IA drugs. In general, drugs should be stopped if the QTc prolongs by 25% or beyond 550 msec.

Class IB drugs include lidocaine, mexiletine, and tocainamide. These drugs are useful in the treatment of ventricular dysrhythmias, but not in the treatment of atrial dysrhythmias. Class IB drugs have sodium channel-blocking effects with minimal QT interval prolongation.

Class IC agents include flecainide, moricizine, and propafenone. These drugs are also sodium-channel blockers but have minimal effects on repolarization. Class IC drugs are particularly useful in both converting and preventing the recurrence of atrial dysrhythmias. Although these drugs also work well for ventricular tachydysrhythmias, they are only employed when all other drugs and RFA are inadequate in patients with structural heart disease, particularly those with coronary artery disease (8). Intravenous forms of these drugs are not available in the United States.

Class III drugs prolong repolarization and affect the sinus node, AV node, atrial tissue, and ventricular tissue. They work well for atrial and ventricular dysrhythmias. Similar to class IA drugs, class III drugs also prolong the QT interval. The QTc interval should be carefully monitored and the drugs discontinued if the QTc interval is prolonged by 25% or beyond 550 msec.

Beta-blockers (class II) and calcium-channel blockers (class IV) drugs have their primary effect on the sinus node and AV node. These drugs are useful for ventricular rate control in atrial tachydysrhythmias, or to treat and prevent tachycardias involving the AV node. Like the class II and IV drugs, adenosine and digoxin affect the AV node, and are

**Table 6** Intravenous Antidysrhythmia Drugs of Use in Trauma and Critical Care Patients

IV drugs	Class	Route elimination	Half-life	Doses	Indication
Adenosine	Other	RBC and EC	< 10 sec	6–18 mg IV bolus followed by a bolus of flush	Termination of AV node-mediated tachycardia; diagnosis of SVT
Digoxin	Other	Renal	30–50 hrs	0.5 mg IV and then 0.25 mg × 2 over the next 4–8 hrs	Ventricular rate control in patients with LV dysfunction and CHF
Procainamide	IA	Both	6–8 hrs	500 – 1000 mg IV (max 50 mg/min) and then 1–4 mg/min Follow levels	Termination/prevention of atrial dysrhythmias
Lidocaine	IB	Hepatic	1–4 hrs	50–100 mg IV and then 1–4 mg/min	VT due to myocardial ischemia/infarct
Flecainide	IC	Hepatic, 75% Renal, 25%	7–24 hrs	50–100 mg PO BID	SVT (including A-fib/flutter ventricular rhythms only if refractory to other drugs and RFA)
Esmolol	II	RBC	9 min	0.5 mg/kg over 1 min and then 0.05–0.2 mg/kg/min	Termination and prevention of AVNRT and AVRT; ventricular rate control in atrial dysrhythmias
Propranolol	II	Hepatic	1–6 hrs	0.1–1.0 mg q3 min; maximum 10 mg	Termination and prevention of AVNRT and AVRT; ventricular rate control in atrial dysrhythmias
Amiodarone	III	Hepatic	3–15 wks	150 mg over 10 min followed by 1 mg/min for 6 hrs and then 0.5 mg/min 300 mg IV push followed by 1 mg/min for incessant VT/V-fib Maximum daily dose of 2 g	Atrial fibrillation; hemodynamically stable VTs Hemodynamically unstable VT and V-fib
Ibutilide	III	Mostly liver	6 hr	1 mg over 10 min and may repeat × 1 in 10 min	Acute termination of atrial dysrhythmias
Diltiazem	IV	Hepatic	3–5 hrs	10–20 mg IV	Termination and prevention of AVNRT and AVRT; ventricular rate control in atrial dysrhythmias
Verapamil	IV	Hepatic	3–7 hrs	5–10 mg IV	Termination and prevention of AVNRT and AVRT; ventricular rate control in atrial dysrhythmias

**Abbreviations:** AV, atrio-ventricular; AVNRT, AV nodal re-entrant tachycardia; AVRT, AV re-entrant tachycardia; CHF, congestive heart failure; EC, endothelial cells; IV, intravenous; LV, left ventricle; PO, per os; BID, twice a day; RBC, red blood cells; RFA, radiofrequency ablation; SVT, supraventricular tachycardia; V-fib, ventricular fibrillation; VTs, ventricular tachycardias.

**Figure 9** Ventricular muscle transmembrane potential (solid line) with superimposed ECG. Phase 4 is the resting membrane potential; phase 0 is the rapid depolarization phase (fast sodium channels open, making the inside of the cell less negative). Phase 1 is when the slower calcium channels open. During phase 2, the potassium channels open. During phase 3 (repolarization), the sodium is pumped back out, the potassium is pumped back inside the cell, and resting membrane potential is restored. Vaughn-Williams class IA and class IC drugs block the fast sodium channels and decrease phase 0. Class IA and class III drugs prolong repolarization reflected in a prolonged QT interval and increased risk of torsades de pointes.

used for ventricular rate control in atrial tachydysrhythmias, or to treat and prevent tachycardias involving the AV node.

## PACING AND NONPHARMACOLOGIC INTERVENTIONS

### Transcutaneous Pacing

♣ Transcutaneous pacing can be a useful adjunctive therapy in patients who require urgent heart rate support for symptomatic bradycardia. ♣ It can serve as a bridge to transvenous pacing, or be sufficient by itself for those patients whose risk of symptomatic bradycardia is too low to warrant a transvenous pacemaker. The major advantage of transcutaneous pacing is that it is noninvasive, and can be applied quickly by staff members who have no expertise in the insertion of transvenous pacemakers. However, transcutaneous pacing is less reliable and can cause significant discomfort in awake patients. As a result, long-term use is never indicated. During temporary use (in the operating room or ICU), patients should be anesthetized or at least sedated. When using transcutaneous pacing, it is imperative to ensure that each pacing output results in a ventricular capture. Watching only the ECG rhythm strip can be

misleading, because the high-energy output required for transcutaneous pacing may mask the QRS complex on the cardiac monitor. Therefore, a measure of stroke volume must be used to assess the ventricular response to each delivery of the electrical impulse. This is best done by following the arterial pulse in the invasive arterial line. In the absence of an arterial line, this is done by simply checking for a palpable pulse, or by assuring that each pulse-oximeter wave corresponds with a pacing output event.

### Temporary Transvenous Pacing

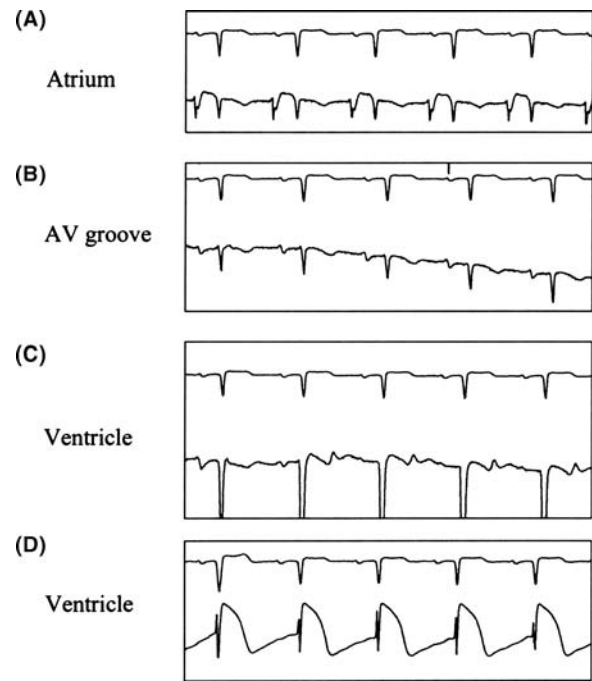

✎ **A transvenous pacemaker is needed in patients with symptomatic bradycardia, whether it is due to sinus node dysfunction or to AV block.** ✎ In general, a single-chamber ventricular pacemaker is adequate for the majority of patients.

There are two types of transvenous pacing catheters: a soft, balloon-tipped catheter, and a stiffer, nonballoon-tipped catheter. In general, a balloon-tipped catheter is preferable. However, during CPR in which there is inadequate cardiac output to direct the balloon into the RV, a stiffer catheter may be more successful. These stiffer catheters are best manipulated under fluoroscopic guidance.

Venous access can be obtained through the left subclavian, right internal jugular, or femoral veins. Placement of a transvenous catheter through the femoral vein requires fluoroscopic guidance.

Once venous access is obtained, a catheter can be placed in the RV using the guidance of intracardiac ECG. A precordial “V” lead is attached to the distal electrode of the catheter with the other four leads attached in standard position. As the catheter tip enters the right atrium, there is a sharp deflection corresponding to the surface P wave. As the catheter tip approaches the tricuspid valve, both the atrial and ventricular deflections can be seen. Once there is only a ventricular signal, the balloon is deflated and the catheter advanced until ST elevation is demonstrated on the monitor (Fig. 10). The distal electrode is attached to the negative pole and the proximal electrode to the positive pole (“proximal” for “positive”). The location of the catheter tip can be determined by the morphology of the paced QRS complex. An apical location of the catheter will give deep negative QRS complexes in leads II, III, and aVF, and a location in the outflow tract will give positive QRS complexes in the same leads.

Once the catheter is positioned, the pacing and sensing thresholds should be determined. The pacing threshold is the lowest amount of energy required to depolarize the ventricle. The pacing threshold is determined by setting the pacing frequency to a rate greater than the intrinsic pulse and then gradually decreasing the pacing output current until there is loss of ventricular capture. The usual ventricular pacing threshold is about 1 mA. The sensing threshold is the amplitude of depolarization or QRS complex detected by the pacemaker. The sensing threshold can be tested by setting the pacing frequency to a level below the intrinsic heart rate and then gradually decreasing the sensing setting on the pacemaker or increasing the millivolt setting. When the sensing is lost and the pacemaker starts pacing, the sensing setting is increased or the millivolt setting is decreased until every QRS complex is appropriately sensed. The maximum millivolt setting at which every QRS complex is sensed is the sensing threshold. One should try to obtain a ventricular sensing threshold of above 5 mV. The pacing and sensing threshold should be

**Figure 10** (A–C) Intracardiac electrograms recorded as the pacing wire is advanced from the right atrium, the atrio-ventricular (AV) groove, the right ventricle and then in contact with the ventricular wall. Note ST elevation when the pacing lead comes in contact with the ventricular wall (D).

checked daily to ensure proper functioning of the pacemaker.

Once the pacing and sensing thresholds have been determined, a temporary pacemaker can be programmed. In general, the ventricular output is set at 10–20 mA and the sensitivity at 1–2 mV.

### Cardioversion Therapy

Transthoracic DC cardioversion is an effective and rapid means to restore normal heart rhythms in patients with tachydysrhythmias. ✎ **When a tachyarrhythmia causes hemodynamic instability, urgent DC cardioversion is recommended.** ✎ The energy should be high enough to effectively terminate the tachyarrhythmia. The biphasic mode is more efficient at an equivalent energy dose. The mean energy for successful cardioversion of A-fib is 200 J with a monophasic waveform and 120 J with a biphasic waveform (9). For cardioversion of A-fib, electrode patches should be placed in an anterior and posterior location rather than anteriorly and apically. Conversion of atrial flutter usually requires less joules (and should be synchronized), whereas version of V-fib requires at least 300 J.

## TRAUMA CONDITIONS ASSOCIATED WITH DYSRHYTHMIAS

### Myocardial Contusion

#### Predisposing Mechanisms

Myocardial contusion refers to damage occurring to the myocardium from blunt trauma. The classic setting is a decelerational injury where an individual is moving forward, the chest strikes an immobile or slower object, and the heart is compressed within the thorax. Motor

vehicle accidents or falls from a significant height are common causes of decelerational injuries. However, any mechanical motion that generates stress on the heart or any direct transfer of energy to the heart can result in tissue damage and contusion (10).

It is estimated that anywhere from 16% to 76% of patients who suffer blunt trauma to the chest sustain a myocardial contusion. The huge variation in incidence is due to major differences in the method of defining contusion (11). Also see Volume 1, Chapter 25, and Volume 2, Chapters 19 and 25.

### Associated Injuries

A contusion caused by a deceleration injury is often accompanied by other injuries including aortic disruption, coronary or valvular disruption, pulmonary contusion and hemorrhage, and flail chest and tracheobronchial injuries. Patients who sustain more than one of these serious associated injuries often do not survive during transport to the hospital. If they do, the mortality with coexisting chest injuries is high, up to 67% in one series (12). Other less serious injuries, such as sternal fracture, are also associated with myocardial contusions, and when present should increase the awareness that a myocardial contusion may be present (13,14).

### Pathology

The pathology of contusion includes hemorrhage, edema and multiple foci of myocyte necrosis, and cellular fragmentation that can result in reduced blood flow and function. Contraction bands, seen in areas of necrosis, may result from ischemia-reperfusion and ionic abnormalities. The RV and septum are most commonly injured because of their location in the anterior portion of the thorax. Histologic lesions are similar to those observed after severe ischemic stress (15). The myocyte damage can result in a decreased contractile force and can affect the coronary vascular bed.

### The Diagnosis of Myocardial Contusion

It is known that mechanical injury to the heart can cause abnormalities of conduction, rhythm, and mechanical performance. Identifying the patients likely to have such complications, in order to monitor and treat them accordingly, is very difficult. Depending on diagnostic criteria, between 0% and 76% of patients with blunt chest trauma have a myocardial contusion (11). Because cardiac contusion may be complicated by lethal dysrhythmias, selecting the proper patients for monitoring is important (Table 7).

Contusion is, in essence, a pathological diagnosis, but because most cases of contusion are best diagnosed prior to reaching autopsy, clinical signs and symptoms are sought that would suggest injury. The various criteria for diagnosis include a predisposing mechanism of trauma, ECG abnormalities, cardiac enzyme elevation, and an abnormal echocardiogram.

### Electrocardiogram Abnormalities

Many studies have used any abnormality of ECG in the setting of a mechanical force to the chest as diagnostic of contusion. The most common findings are sinus tachycardia and extrasystoles. Frequent conduction abnormalities are RBBB, AV blocks, and A-fib. VT and V-fib are less commonly seen on ECG but are the most feared complications and are the impetus for monitoring patients with contusion. The anterior RV is more often affected by contusion than the more protected LV, so the classic leads do not always detect injury.

**Table 7** Diagnostic Criteria for Myocardial Contusion

Diagnostic criterion		Example
I	Predisposing mechanism	Blunt chest trauma
IIa	ECG dysrhythmias and other abnormalities	PACs, PVCs, sinus tachycardia, extrasystoles, right bundle branch block, atrial fibrillation, ventricular tachycardia, ventricular fibrillation
IIb	Elevated troponin	All other markers (CPK, MB) are nonspecific in the setting of trauma or major surgery
IIc	Abnormal echocardiogram (transthoracic or transthoracic)	Abnormal wall function (hypokinesis, dyskinesis, and akinesis) in the injured area (typically right ventricle)
IId	Contusion of heart directly visualized	Thoracotomy autopsy

*Note:* To make the diagnosis of myocardial contusion, there must be a category I criterion and at least one of the four category II criteria. The more category II criteria present, the higher the diagnostic accuracy.

*Abbreviations:* CPK, creatine phosphokinase; ECG, electrocardiogram; MB, the CPK isoform predominantly found in cardiac muscle; PACs, premature atrial contractions; PVCs, premature ventricular contractions.

Many patients with contusion may not have any ECG abnormalities on presentation, and concern has been raised that this criterion may eliminate too many patients who need observation. In one study, abnormal ECGs were present in 50% of patients with blunt trauma; the positive predictive value for needing some form of cardiac therapy was 28% with a 95% negative predictive value. In conjunction with troponin I, ECG had a 62% positive predictive value and 100% negative predictive value for blunt cardiac trauma victims requiring cardiac therapy (16). In another study, the presence of ECG abnormalities was 100% sensitive for those needing antidysrhythmic drugs or defibrillation (17). **Some authors suggest that a normal ECG three hours after minor cardiac trauma can exclude those who might develop cardiac complications (Table 7) (18).**

### Cardiac Enzymes

Creatine phosphokinase (CPK) isoenzymes: CPK and CPK-MB (the CPK isoform predominantly found in cardiac muscle) are frequently elevated in trauma patients, and thus, should not be used for diagnosing contusion. Even the MB isoform is released in patients with rhabdomyolysis; it accounts for 1% of CPK activity in skeletal muscle.

Troponin: Troponin T and I are released after both MI and contusion. Troponin I is exclusive to the myocardium and is superior to CPK-MB in diagnosing contusion. Troponin T may have some cross-reactivity with skeletal muscle, but depending on the assay, it too can be useful in detecting myocardial injury (11). Both troponins become positive four to eight hours after injury and peak 24 hours after injury. In animals, troponin I is a marker of anatomic and functional consequences of contusion and correlates well with extent of contusion (10,15,19). **Troponins are neither 100%**

specific nor sensitive; small injuries with undetectable troponin could lead to dysrhythmias; conversely hemorrhage and shock may lead to troponin release without contusion (10).

☞ In one study, troponin I had a positive predictive value of 48% and negative predictive value of 93% when detecting patients requiring cardiac therapy (16). Another study showed only a 23% sensitivity, a positive predictive value of 77% and negative predictive value of only 75% (11). However, differences in the definition of contusion account for much of the variability in studies of contusion.

If ECG and troponins suggest a MI, then angiography should be considered to detect coronary injuries, especially in young patients. As the population ages, the possibility of concurrent MI in the trauma victim will increase.

### Echocardiography

☞ TEE is preferable to transthoracic echocardiography in evaluating trauma patients except for viewing the pericardium (20). It is superior to helical computed tomography (CT) in detecting contusions (21). Unfortunately, the RV is more difficult than the LV to visualize, and the RV is more frequently involved in contusions. ☞ A study of 117 patients with blunt chest trauma showed that 42% had echocardiographic evidence of contusion: RV dysfunction in 32%, LV dysfunction in 15%, and both in 5%. A review of 50 records of patients who suffered sternal fracture and who had echocardiograms revealed that 22% of echocardiograms showed a pericardial effusion, which in no case was associated with other abnormal clinical findings. The authors concluded that a pericardial effusion on echo after trauma is not suggestive of contusion or other injuries (22).

### Complications of Contusion

☞ Myocardial contusion is associated with dysrhythmias and functional impairment, especially of the ventricle. ☞ It is also associated with an increased risk of hypotension, dysrhythmias, and arrest in the perioperative period (10). The incidence of complications is highest in the period immediately after injury. Most patients who survive admission to the hospital have a favorable prognosis (11).

### Dysrhythmias

Dysrhythmias are important complications because they are insidious, difficult to predict, and occur with increasing frequency when greater myocardial injury has occurred, as quantified by troponin levels (Fig. 11) (23). They can occur even after minor contusions and may be worsened by the metabolic and hemodynamic consequences of other injuries or heart failure. VT and V-fib are the most dangerous. Animal models show that the degree of arrhythmogenesis is related to the increasing kinetic energy of the blow. A blow leads to shortened and dispersed ventricular refractory periods with re-entrant VTs developing around an electrically silent area or a line of fixed conduction block. Almost all contusion-related dysrhythmias are re-entrant (Table 7) (24) (see section on treatment of "Ventricular Tachydysrhythmias").

Following myocardial contusion, A-fib has been noted in 2% to 15% of patients (11). In one series of 312 patients, A-fib was the most significant marker of outcome (25). It is usually treated with antidysrhythmics including cardiac glycosides, but direct cardioversion can be effective as well (26) (see section on treatment of "Atrial Tachydysrhythmias"). Intraoperative dysrhythmias were seen in 6% of patients who had had a myocardial contusion as well as intraopera-

**Figure 11** Increasing cardiac troponin I (cTnI) levels increased linearly with the risk of dysrhythmias following myocardial contusion. When the cTnI level was less than 1.0, the risk of no dysrhythmia was 7%. Source: From Ref. 23.

tive hypotension in 16% (27). ☞ Risk factors for perioperative mortality associated with contusion are old age, A-fib, and aortic rupture (14). ☞

### Functional Impairment

The RV is commonly involved in contusion, and echocardiography may show impairment of function. Although cardiogenic shock is rarely observed with myocardial contusion, the RV impairment can become significant in patients with pulmonary hypertension or acute respiratory distress syndrome (ARDS). In animal models, there is decreased ventricular compliance after myocardial contusion and shock and early decreases in LV maximal change in pressure over time (dp/dt max) (15).

### Therapy for Myocardial Contusion

There is no single therapy that prevents the complications of a myocardial contusion. The presence of RV dysfunction mandates careful preload, manipulation of mechanical ventilation to minimize airway pressures, and attention to other causes of increased RV afterload. Monitoring for dysrhythmias is important, and predisposition to malignant dysrhythmias must be considered when administering any treatment.

### Head Trauma and Myocardial Effects

Head trauma, subarachnoid hemorrhage, and other causes of increased ICP can lead to indirect lesions of the heart. It is postulated that increases in sympathetic activity with catecholamine release can lead to myocardial beta-receptor desensitization, coronary vasoconstriction, and myocyte damage (10,24). The elevated catecholamine state should be considered when treating any dysrhythmias (see section "Sinus Tachycardia"). In addition, the prolonged QT syndrome can occur in any head injury, which raises ICP.

### Thoracic Blast Injuries/Pulmonary Contusions

Blast injuries result from the direct effect of changes in atmospheric pressure. In addition, injuries can occur from objects accelerated by the blast or from the body itself being propelled by the blast energy. The role of myocardial contusions as a cause of dysrhythmias has been discussed above. Pulmonary

contusions are discussed in Volume 1, Chapter 25, and Volume 2, Chapter 25; however, the dysrhythmogenic blast effect is described here.

The high-energy release of an explosion leads to blast waves that can be propelled faster than the speed of sound. Primary injuries from the blast waves usually occur in gas-containing organs, including the chest. The pulmonary contusions that result are associated with bradycardia and hypotension unrelated to hemorrhage. Animal studies suggest that severe hypotension is not related to myocardial injury but to vagal nerve-mediated bradycardia and cardiogenic shock without compensatory vasoconstriction (28,29). Pulmonary C-fiber stimulation activates a vagal nerve reflex with bradycardia, peripheral vasodilation, and apnea, followed by rapid respirations. Bilateral vagotomy resolves these reflexes in an animal model (28,29). Treatment in patients is supportive, including administration of anticholinergic drugs (atropine and glycopyrrolate) and beta-agonists.

### Comotio Cordis

Comotio cordis is Latin for “cardiac concussion,” and refers to a blunt precordial chest impact that results in dysrhythmias and sudden death without evidence of heart injury at autopsy. Comotio cordis is separate from myocardial contusion because no actual heart damage occurs in the former, and the lethal dysrhythmias are thought to result from a purely electrical phenomenon. Comotio cordis commonly results from low-energy impacts, usually during sporting activities (e.g., baseball impact to anterior chest), where cardiac arrest likely results from ventricle fibrillation or from complete heart block (1). When the timing of a precordial impact occurs precisely within 1/100 of a second period before the peak of the T wave, these minor traumas will reliably result in ventricular fibrillation (30,31). Occasionally, impacts outside of this period result in unsustained polymorphic VT or transient complete heart block if delivered during the QRS complex (30,31).

## DRUG INTOXICATIONS AND ASSOCIATED DYSRHYTHMIAS

### Cocaine

Cocaine is a powerful sympathomimetic drug; popular for the energized, euphoric state it produces. The most common associated medical problem is chest pain. Cocaine use is also associated with cardiac ischemia and infarction, hypertension, dysrhythmias, sudden death, thrombosis, myocarditis, and cerebrovascular events (32–34).

### Cocaine-Induced Cardiovascular Toxicity: Overview

The cardiovascular complications of cocaine are ascribed to its inhibition of norepinephrine reuptake and stimulation of central sympathetic outflow, raising circulating catecholamines up to fivefold (35). The initial effect of cocaine on the cardiovascular system is vagotonic, followed by increased sympathetic stimulation (36). The blood pressure-raising effect of cocaine should normally be offset by a baroreceptor response lowering central sympathetic outflow—cocaine may offset this by directly increasing central sympathetic outflow to the heart leading to tachycardia and increased contractility. It is postulated that patients with conditions that impair baroreflex responses (such as heart failure, long-standing hypertension, or chronic cocaine abuse) may have exaggerated hypertensive responses to cocaine (37). An additional effect of cocaine is

its class I antidysrhythmic properties, which can impair cardiac conduction.

### Cocaine-Induced Ischemia

Cocaine-related ischemia can be caused by two mechanisms: (i) increased oxygen demand from an elevated heart rate and blood pressure; or (ii) decreased flow from vasospasm, coronary constriction, platelet aggregation, or thrombosis (33,38). Long-term use of cocaine is associated with premature atherosclerotic disease. Short- and long-term use are associated with an early coronary vasodilation that is followed by a transient decrease in coronary artery caliber, probably through alpha-adrenergic mechanisms. This constriction is most pronounced in diseased coronaries (33). Some of the vasospasm associated with cocaine may be due to endothelin-1 release that may sensitize the vasculature to vasoconstrictor stimuli (38). Cocaine use is also associated with intravascular thrombosis and platelet activation, predisposing to ischemia and infarction. Smoking exacerbates some of the effects of cocaine. The ECG in cocaine-induced chest pain may be difficult to interpret. J-point and ST-segment elevation due to early repolarization or LV hypertrophy can interfere with the diagnosis of ischemia.

### Cocaine-Induced Hypertension

Hypertension and hypertensive crises result from the direct effects of impaired norepinephrine uptake as well as from the enhanced sympathetic outflow. Conversely, hypotension can occur from a state of relative catechol depletion, from paradoxical suppression of the central nervous system (CNS), from ischemia, or from a direct toxic effect on the myocardium.

### Cocaine-Induced Dysrhythmias

Dysrhythmias associated with cocaine are diverse and are often associated with other cardiovascular disturbances such as hypertension, hypotension, or MI. It is reported that in 4% to 14% of patients with cocaine-induced MI, ventricular dysrhythmias will occur, with death in less than 2%.

There are many mechanisms whereby cocaine can facilitate dysrhythmias. It has sodium channel-blocking properties, its sympathomimetic effects lower the threshold for fibrillation, and it increases intracellular calcium that can result in afterdepolarizations and triggered dysrhythmias. However, the increased metabolic demands associated with the tachycardia and hypertension of an acute intoxication also predispose the myocardium to dysrhythmias. In the setting of abnormal myocardium, these can be particularly worrisome. Cocaine can produce ventricular dysrhythmias and fibrillation in the setting of ischemia. Long-term cocaine use leads to left ventricular hypertrophy (LVH) that predisposes to ventricular dysrhythmias.

There is evidence that differences in calcium channels may partly explain different sensitivities to cocaine-induced dysrhythmias including AV conduction block and sinus arrest (39). In studies of cocaine toxicity in animals, calcium-channel antagonists prevent malignant dysrhythmias and protect against MI.

### Treatment of Cocaine-Induced Ischemia and Dysrhythmias

☛ Benzodiazepines and nitroglycerin (NTG) are the first-line agents for patients with cocaine-induced ischemia (40).

☛ Benzodiazepines should be administered first as

they protect the brain against many of the ravages of acute cocaine intoxications and also decrease any CNS-mediated manifestations. Both NTG and verapamil reverse cocaine-induced hypertension and vasoconstriction. However, calcium-channel blockers may exacerbate the CNS toxicity of cocaine. Thus, all cocaine-toxic patients should receive benzodiazepine therapy. Furthermore, NTG and calcium-channel blockers should be given only after benzodiazepines have been used to stabilize the CNS (Table 8) (36). Phentolamine has also been shown to reverse cocaine-induced coronary constriction and is considered third-line therapy after benzodiazepine and NTG (32).

☞ **Because beta-blockers exacerbate this constriction, they should be avoided in patients with cocaine use.** ☞ Labetalol is likewise not indicated because the beta-antagonist effects outweigh the alpha-blocking effects. Sodium bicarbonate has been shown to reduce the cocaine-induced widening of the QRS complex and to reduce the incidence of associated VT. The use of benzodiazepines is considered first-line therapy, because they attenuate the cardiac and CNS toxicity of cocaine in animal studies (36). The use of aspirin is encouraged on a theoretical basis.

Lidocaine use in cocaine-induced dysrhythmias is controversial because, like cocaine, it is a sodium-channel blocker and could be pro-dysrhythmic in combination with cocaine. Limited studies suggest that lidocaine is probably safe several hours after cocaine use. Sodium bicarbonate is safe to use immediately following cocaine use and it reverses

cocaine-induced QRS prolongation (36). The proposed guidelines from the Toxicologic Oriented ACLS for treatment of cocaine-induced VT/V-fib are sodium bicarbonate and lidocaine and the avoidance of epinephrine and non-selective beta-blockers (40).

**Amphetamines**

Amphetamines, like cocaine, are sympathomimetic agents. Also like cocaine, the cardiovascular complications from amphetamines can include vasoconstriction, unpredictable blood pressure effects, dysrhythmias, and ischemia (35). The amphetamine class includes amphetamine, metamphetamine, and the popular drug, ecstasy. Ecstasy (3,4-methylenedioxymethamphetamine or “MDMA”) is a variant of metamphetamine but also has some of the properties of mescaline (41).

An abundance of evidence suggests that MDMA acts by increasing release of the monoamine neurotransmitters, noradrenaline, and to a lesser extent dopamine and by inhibiting the reuptake of serotonin (41). The increase in noradrenaline is responsible for the cardiac effects; the most common arrhythmia is sinus tachycardia, but sudden death has also been reported. MDMA has a plasma half-life of approximately eight hours with some active metabolites, so effects may be seen well after the original ingestion (see section on treatment of “Sinus Tachycardia”).

**Ma Huang and the Ephedra Alkaloids**

Ma huang, also known as ephedra, is one of the Chinese herbs belonging to the ephedra alkaloid class. It is a non-catecholamine sympathomimetic agent, which leads to release of endogenous catecholamines and directly stimulates alpha- and beta-receptors (41–43). Excess intake is associated with ischemia, hypertension, stroke, cardiomyopathy, and sudden death in the absence of structural heart disease (42). Dysrhythmias are similar to those induced by commercially available ephedrine and include VT (see section “Ventricular Tachydysrhythmias”).

**Alcohol**

Light to moderate intake of alcohol has been associated with improvements in cardiac risk. Moderate drinking appears to lower the risk of stroke, peripheral vascular disease, and perhaps type 2 diabetes (44). Heavier alcohol consumption (>3 drinks per day) increases the risk of hypertension, dysrhythmias, and hemorrhagic stroke. Chronic heavy alcohol use can be damaging to the heart and is associated with LV hypertrophy, mild systolic or diastolic dysfunction, and occasional biventricular dilatation, resembling a dilated cardiomyopathy (45). Early stages are often asymptomatic and associated with diastolic dysfunction; later symptomatic stages show systolic dysfunction as well (46). Dysrhythmias and other symptoms associated with alcoholic cardiomyopathy are similar to those of other dilated cardiomyopathies (46). ☞ **Acute effects of alcohol intoxication include paroxysmal A-fib, or “holiday heart,” which can be seen in healthy patients with structurally normal hearts (Table 3) (46–48).** ☞ In animals, acute alcohol can raise cardiac troponin-T levels, decrease systolic blood pressure, and increase heart rate (49). ☞ **Chronic heavy consumption causes an increase in catecholamine release and is associated with poor contractility, mitochondrial dysfunction, and ventricular dysrhythmias (49–51).** ☞

**Table 8** Pharmacotherapy for Cocaine-Induced Ischemia and Dysrhythmias

Priority	Drug	Rational/comments
First line	Benzodiazepines	Most patients with myocardial ischemia while toxic on cocaine have central nervous system effects that will only be controlled with benzodiazepines. Thus, midazolam should be administered first, followed by ativan.
	Nitroglycerin	Whenever myocardial ischemia is the predominant presenting symptom, nitroglycerin is indicated for direct coronary artery dilation.
Second line	Magnesium sulfate	Useful for the management of both atrial and ventricular tachydysrhythmias, including SVT and VT and torsades de pointes.
Third line	Consider sodium bicarbonate	Recommended in cases of severe acidosis (pH < 7.0, and/or rhabdomyolysis, or wide complex dysrhythmias). High-dose cocaine causes type I sodium channel blockade in the myocardium, which can be partially reversed with alkalinization.

Abbreviations: SVT, supraventricular tachycardia; VT, ventricular tachycardia.

## Tricyclic Antidepressant Toxicity

### Diagnosis

☞ Tricyclic antidepressants are a leading cause of morbidity and mortality due to drug intoxication in the United States. Initial ECG changes include widening of the QRS interval to  $>100$  msec, an R-wave amplitude of  $>3$  mm in aVR, and abnormalities in the terminal 40-msec QRS axis (T40-msec) (an axis between  $120^\circ$  and  $270^\circ$  rotation). These abnormalities on the presenting ECG are reported to predict seizures and dysrhythmias. ☞ In addition, it has been shown that the degree of QRS widening and T40-msec axis changes and the duration of their abnormality correlate with the likelihood of developing seizures and dysrhythmias. However, there is huge variability in the resolution of these changes and clinical improvement can occur despite persistence of ECG changes in some patients (51). Tricyclic antidepressants can behave like class IA antidysrhythmics and can prolong the QT interval as well (see section "Antidysrhythmic Drug Selection").

### Treatment

☞ Alkalinization is considered standard treatment for conduction delays or dysrhythmias associated with tricyclic toxicity. ☞ The goal is a systemic pH of 7.5 to 7.55; boluses are preferable to constant infusion (40). The beneficial effects of sodium bicarbonate are due to alkalosis and hypertonic sodium. Some have used hypertonic saline to treat tricyclic overdoses, but the experience with saline is not as extensive as with sodium bicarbonate (40). ☞ If dysrhythmias are resistant to sodium bicarbonate, then lidocaine is considered the drug of choice. ☞ Procainamide is contraindicated due to its class IA properties that are shared by the tricyclics (40). Whom to monitor and how long are difficult questions. Some authors recommend that patients with an abnormal QRS or T40-msec axis should be admitted and monitored for 24 hours with serial ECGs to determine worsening; patients who improve clinically and whose ECGs improve can be discharged from the ICU after that period (51).

## Theophylline Toxicity

Theophylline toxicity used to be very common; its incidence has somewhat decreased as beta-agonists, inhaled steroids, and other modalities have become pre-eminent in the treatment of asthma. ☞ Theophylline has a narrow therapeutic window and so overdose is not uncommon. The serious complications are hypotension, dysrhythmias, seizures, and death (52). Peak serum concentrations are helpful in predicting toxicity, but chronic users may be toxic at lower serum concentrations. ☞ In chronic users, age is a major predictor of toxicity (53).

## Dysrhythmias Associated with Theophylline Toxicity

Theophylline has direct effects on membrane depolarization; in addition, it antagonizes endogenous adenosine and has sympathomimetic effects (53). Dysrhythmias associated with theophylline toxicity are most commonly sinus tachycardia; other minor dysrhythmias include ventricular premature contractions, SVTs, and PACs. Major toxicity is associated with SVT, A-fib or flutter with rapid ventricular conduction, and VT.

## Treatment of Theophylline-Associated Dysrhythmias

☞ Treatment of dysrhythmias should be supportive and accompanied by treatment of the overdose: multiple doses of activated charcoal or hemoperfusion for those at highest risk, cardiorespiratory support, and correction of electrolyte abnormalities. ☞ Predictors of toxicity depend on whether the theophylline use is chronic or acute; chronic users are at greater risk of toxicity and the peak serum level is less predictive of toxicity in this group of patients (52). In acute theophylline intoxication, peak serum levels of  $>110$  mg/L predict a 50% chance of major toxicity. In chronic intoxication, serious side effects can occur at lower peak levels, and age is a better predictor of poor outcomes. Many will dialyze theophylline at lower levels:  $>60$  mg/L for chronic ingestion or  $>80$  mg/L with acute ingestion (54).

## Other Drugs of Abuse Associated with Dysrhythmias

Lighter fluid, glue, and other volatile hydrocarbons (e.g., toluene, gasoline, solvents, spray paint, and nail polish) are commonly abused by adolescents, and are commonly associated with cardiac dysrhythmias as well as neurotoxic effects. Cardiac dysrhythmias are the main cause of sudden death, and initial as well as prolonged use can lead to hypoxia, seizures, and fatal dysrhythmias (55). Sympathetic activation can lead to tachydysrhythmias and myocardial sensitization (35). Suppression of cardiac conduction or sinus node activity may also be seen (see subsections "Sinus Node Dysfunction" and "Abnormal Atrio-Ventricular Conduction").

Tetrahydrocannabinol (THC), the active ingredient in marijuana, can also cause dysrhythmias in susceptible individuals. Low doses of marijuana can increase sympathetic tone, whereas higher doses lead to bradycardia and hypotension from increased parasympathetic tone.

## Drugs and Conditions Associated with QT Prolongation and Torsades de Pointes

### Mechanisms Underlying Torsades de Pointes

Torsades de pointes is a polymorphic VT in which the axis of the QRS complex appears to twist around an isoelectric zero point. Torsades de pointes is triggered by early afterdepolarizations, and most commonly occurs in the setting of QT prolongation. Early afterdepolarizations are depolarizing potentials that develop because of failure of normal repolarization. They are referred to as "triggered" because they only occur in the presence of a preceding action potential. They are due to an imbalance in repolarizing currents due to reduced net outward current or enhanced net inward current. This can lead to oscillation of membrane potential, which can conduct to the ventricular myocardium and lead to tachydysrhythmias. Slowed outward potassium currents, enhanced inward calcium currents, or slowed inactivation of inward sodium currents can prolong the QT interval (56,57).

A number of clinical conditions are associated with QTc prolongation (Table 9). Foremost among these are acquired etiologies, including conditions that increase catecholamines, decrease potassium and magnesium (e.g., excessive diuretics), and drugs. Prolonged QT intervals are an important side effect of several antidysrhythmic drugs including class III and some class IA agents (Table 10).

A number of other drugs (Table 10) commonly used in critically ill patients have also been shown to prolong the QTc. There are variations in susceptibility to drug-induced

**Table 9** Clinical Conditions Associated with QT Prolongation and Torsades de Pointes

Condition type	Example
Acquired	Drugs (Table 10) causing QT prolongation Long pauses or bradycardia Short-long-short RR interval sequence Adrenergic stimulation Hypokalemia, hypomagnesemia, hypocalcemia Ischemia, hypoxia, stroke, subarachnoid hemorrhage, HIV, autonomic neuropathy
Hereditary syndrome	Sympathetic activation

torsades de pointes. Some patients have torsades de pointes without a markedly prolonged QT interval suggesting that other modulating factors must exist besides prolongation of the action potential. These modulating factors may include adrenergic stimulation, low heart rate, hypokalemia, ischemia, or hypoxia (57).

**Droperidol, Ondansetron, and Food and Drug Administration Black Box Warning**

On December 5, 2001, the Food and Drug Administration (FDA) issued a black box warning regarding the use of droperidol because of concerns that droperidol leads to QT prolongation and may increase the risk of torsades. However, many anesthesiologists immediately expressed concerns that the FDA had overreacted, given droperidol’s long track record of safety in the treatment of postoperative nausea and vomiting (PONV) (58). To further underscore this reality, Habib et al. (59) used the Freedom of Information Act to gain access to the 273 cases reported to the FDA between November 1, 1997, and January 2, 2002, upon which the FDA based their warning. Their survey of those 273 cases revealed that the vast majority had no direct connection between the administration of droperidol and QT prolongation or torsades (59).

Using a square-root model to simulate the expected prolongation of the QTc interval that would be produced by droperidol 0.625–1.25 mg IV, Paul White’s group found that small “antiemetic” doses of droperidol (1.25 mg) would be unlikely to produce clinically significant proarrhythmogenic effects in the perioperative period. Indeed, their calculations predicted QTc prolongation of up to only 18 ± 3 msec (60).

The degree of QTc prolongation and the risk of developing ventricular dysrhythmias following droperidol administration was recently studied by a Charbit et al. (61) in a PONV treatment study, and by White et al. (62) in a perioperative prophylaxis model. Charbit et al. compared QTc prolongation in patients receiving either 0.75 mg droperidol or 4 mg ondansetron for the treatment of PONV symptoms experienced in the postanesthesia care unit after surgery. The observed mean maximal prolongation in QTc were 17 ± 9 msec for droperidol and 20 ± 13 msec for ondansetron (Fig. 12) (61). These QTc prolongations were similar to those reported by White et al. (62) who demonstrated 15 ± 40, and 22 ± 41 msec for placebo, 0.625 mg droperidol, and 1.25 mg droperidol, respectively. White

**Table 10** Antidysrhythmia Drugs Strongly Associated with QT Prolongation and Torsades de Pointes

Classification	Drugs
Class IA Antidysrhythmics (torsades occurs at low-normal doses)	Quinidine Procainamide Disopyramide
Class III Antidysrhythmics (High doses are typically required to cause Torsades)	Sotalol Ibutilide Azimilide Dofetilide Amiodarone (rarely leads to torsades)
Antifungal	Itraconazole Ketoconazole
Antihistamine	Terfenadine Astemizole
Antioxidant–antiinflammatory	Probucol
Antiparasitic	Chloroquine Pentamidine
Antipsychotic/antidepressant	Haloperidol Tricyclic antidepressants
Antiviral	Amantadine Indinavir Ritonavir
Gastro propulsive	Cisapride
Immunosuppressant	Tacrolimus
Local anesthetic	Cocaine
Natural-occurring poison	Arsenic trioxide <sup>a</sup>
Neuroleptic-tranquilizer	Droperidol <sup>b</sup> Phenothiazines
Vasodilator and smooth muscle relaxant	Papaverine

<sup>a</sup>Encountered in contaminated ground water and as an industrial poisoning.  
<sup>b</sup>Droperidol received a black box warning by the Food and Drug Administration (FDA) which was most likely not warranted (see text for explanation).  
Source: From Ref. 44.

et al. (62) further demonstrated that the droperidol QT prolongations were not different from those achieved with saline placebo, and that other anesthetic drugs (including inhaled vapors) cause modest QT prolongation themselves. An accompanying editorial to the Charbit et al. and White et al. studies provides additional perspective about the general safety of droperidol, despite the clinically insignificant QT prolongation (63).

**Treatment of Torsades de Pointes**

♣ The mainstay of treatment for torsades de pointes is intravenous magnesium (2 g bolus over two to three minutes, then IV infusion at 2–4 mg/min with second 2 g bolus if necessary), potassium (if K is low), temporary cardiac pacing (at rates of 90–110 to prevent short-term recurrence), and correction of electrolyte imbalance. ♣ Rarely, an isoproterenol infusion to keep the heart rate at >90 is required. Isoproterenol should not be used in congenital forms of prolonged QT syndrome or in patients with ischemia, because beta-stimulation classically exacerbates hereditary long QT syndromes.

**Figure 12** Electrocardiogram (ECG) recordings in two representative subjects who received 0.75 mg droperidol (female, *left*) or 4 mg of ondansetron (male, *right*) to treat postoperative nausea and vomiting. Upper ECGs were obtained immediately before antiemetic administration, and the recordings performed after 2 and 10 minutes are shown below. The same chest lead is shown for each patient. Note the flattened T wave occurring after droperidol and changes in T-wave morphology after ondansetron. Recordings of ECGs conducted at a paper speed of 50 mm/sec and an amplitude of 20 mm/mV. *Source:* From Ref. 61.

## ELECTROLYTE IMBALANCE—ASSOCIATED DYSRHYTHMIAS

### Hypokalemia

Hypokalemia is a risk factor for dysrhythmias including conduction abnormalities and ventricular fibrillation. Potassium is the predominant intracellular cation and is important in the maintenance of the resting membrane potential. Disruption of the potassium gradient can lead to impaired cellular function and dysrhythmias. Hypokalemia increases the transmembrane potential, impairing conduction, enhancing automaticity, and leading to afterdepolarizations. The classic ECG changes of hypokalemia are a low-amplitude T wave associated with a “U” wave and are usually only seen at potassium levels <2.7 mmol/L (Table 11) (64).

In trauma patients, hypokalemia is usually due to catecholamines and the stress response, diuretics, or nasogastric drainage. Hypokalemia is exacerbated by sympathomimetic drugs.

Mild hypokalemia (3–3.5 mmol/L) is usually asymptomatic. More severe hypokalemia (2.5–3.0 mmol/L) may lead to symptoms of malaise, weakness, and constipation; symptoms correlate with the rapidity of the decrease in potassium (67). Severe hypokalemia is associated with rhabdomyolysis and renal magnesium wasting. Conduction abnormalities are unusual in patients without underlying heart disease, even with severe hypokalemia. At potassium levels below 2.5 mmol/L, ventricular extrasystoles may be seen, as well as paroxysmal atrial tachycardia, MAT, A-fib, or flutter (64,65). Severe hypokalemia can increase the likelihood of ventricular dysrhythmias including VT and V-fib (68).

In patients with ischemia, heart failure, or LVH, mild to moderate hypokalemia can lead to dysrhythmias. The prolonged repolarization associated with hypokalemia can lead to torsades de pointes in susceptible patients, especially in those with concurrent hypomagnesemia. In hypertensive

**Table 11** Potassium-Related Electrophysiologic Changes Predicted in the Electrocardiogram

Plasma potassium	ECG changes
Hyperkalemia	Decrease T-wave amplitude ST-segment depression Presence U wave Other findings (especially with low $Mg^{2+}$ ): Prolonged QT Extrasystoles VT, torsades de pointes, V-fib
Hypokalemia	Early changes: Peaked T waves (best seen in leads II, III, and V2–4) Later changes: P wave widens/flattens PR segment lengthens P waves disappear Terminal changes: QRS widens QRS merges with T wave: Sine wave pattern degrades to ventricular fibrillation

*Abbreviations:* ECG, electrocardiogram; V-fib, ventricular fibrillation; VT, ventricular tachycardia.

patients, potassium depletion associated with diuretic use has been correlated with the presence of ventricular dysrhythmias (69). In the absence of sodium restriction, hypokalemia can lead to increased systolic and diastolic blood pressure, presumably from urinary sodium retention. Hypokalemia may cause resistance to antidysrhythmic drugs (70).

☞ **The treatment of hypokalemia is potassium supplementation, intravenously if dysrhythmias are present. The rate of infusion should be no more than 20 mmol/hr and the ECG should be monitored.** ☞ Glucose-containing solutions should be avoided in the treatment of hypokalemia (71). Glucose can lower potassium levels in patients with initially normal potassium levels as well as in those with hypokalemia. This is presumably due to the stimulation of insulin, which drives potassium into cells and lowers serum potassium levels. Studies and case reports have shown decreases in serum potassium, the appearance of life-threatening cardiac dysrhythmias, and worsening muscle weakness during the infusion of potassium with glucose for the treatment of hypokalemia (Table 12). In addition to potassium, magnesium should be repleted because hypomagnesemia is often coexistent and can impair repletion of potassium.

### Hyperkalemia

In trauma patients, hyperkalemia may be due to renal failure or rhabdomyolysis (following burns, crush injuries, or compartment syndromes). Transient elevations in potassium may also be seen following the use of succinylcholine or as a result of acute acidosis.

Hyperkalemia reduces the transmembrane potential, which results in a shortened action potential, increased conduction, and lessened automaticity. In extreme cases, it can lead to very prolonged cardiac conduction manifesting as

**Table 12** Treatment of Abnormalities in Plasma Potassium Concentration

Treatment of hypokalemia	Treatment of hyperkalemia
Potassium: IV not >20 mm	Calcium IV
Monitor the ECG	Sodium bicarbonate IV
Proceed with extreme care if abnormal renal function	Insulin 10 units regular IV
Avoid glucose-containing solutions	Dextrose 50% ampule IV
Replete magnesium	$\beta$ -agonist Diuretic

Abbreviations: ECG, electrocardiogram; IV, intravenously.

peaked T waves on ECG followed by QRS prolongation appearing as sine wave activity (Table 11) (72). This must be treated emergently.

☞ **Acute treatment of hyperkalemia consists of membrane stabilization with calcium and transcellular shifting of potassium facilitated by insulin, glucose, bicarbonate, and beta-agonists.** ☞ Removal of potassium takes longer to accomplish and can be done with dialysis for severe cases, loop diuretics, fludrocortisone, or cation exchange resins (Table 12).

### Hypomagnesemia

Hypomagnesemia is a common condition associated with trauma and critical care. Hypomagnesemia is caused by decreased intestinal absorption or increased excretion through the kidneys. Renal excretion is enhanced by osmotic diuresis, as seen in hyperglycemia, or by drugs such as ethanol, aminoglycosides, or cisplatin (73). Hypomagnesemia leads to irritable membranes in both nervous and cardiac conduction tissues. Hypomagnesemia, like hypokalemia and hypocalcemia, can lead to prolongation of the action potential and triggered afterdepolarizations, which may lead to torsades de pointes.

☞ **Treatment of hypomagnesemia is repletion of magnesium. This may be done by a single 2-g bolus of magnesium over two to three minutes followed by an infusion of 2–4-mg/min in severe cases.** ☞ The usual total deficit is 1–2 mEq/kg of body weight; twice this amount must be administered to account for renal excretion of the repleted cation. This can be repleted more slowly by giving 49 mEq IV over three to six hours and repeating every 12 hours as necessary (73).

### Hypermagnesemia

Increased magnesium lowers the transmembrane potential, stabilizes the membrane, and lessens automaticity and afterdepolarizations. It can occasionally cause slowed AV conduction and ventricular conduction. In general, the arrhythmogenic risk of low magnesium is much greater than that of elevated magnesium levels, and hypermagnesemia is not usually associated with clinical dysrhythmias (72). At the neuromuscular junction, the action of magnesium is antagonized by calcium.

Treatment of pre-eclampsia with magnesium leads to marked maternal hypercalciuria, decreased serum calcium and ionized calcium, and an increase in parathyroid hormone in response. However, clinically significant hypocalcemia in either mother or fetus is unusual (74). ☞ **If hyper-**

**magnesemia is symptomatic and causing CNS depression, administration of calcium is appropriate.** ☞ Calcium can be given as 10 cc of 10% calcium gluconate diluted in 50–100cc of D5W and repeated, depending on calcium levels (73).

Further treatment, though rarely required, consists of renal excretion of magnesium, which can usually be accomplished with fluid administration and furosemide. Dialysis is necessary in symptomatic patients with renal failure.

### Hypocalcemia

Hypocalcemia, although less important in triggering dysrhythmias than hypokalemia and hypomagnesemia, is nevertheless a factor in prolonged action potential duration and triggered afterpotentials. The ionized calcium should be checked to determine if arrhythmogenic hypocalcemia is present; total calcium may be misleading if albumin levels are abnormal. Hypocalcemia can contribute to susceptibility to torsades de pointes. It can also mask digitalis toxicity. The ECG in hypocalcemia shows prolongation of the QTc interval.

Risk factors for hypocalcemia include renal failure, alkalosis, gastrointestinal bleeding, pancreatitis, and large volume transfusions of blood products due to the presence of the anticoagulant citrate-phosphate-dextrose (CPD) (73). Another important source of hypokalemia in critical care is renal replacement therapies, which commonly utilize citrate anticoagulant. Postoperative patients at risk for hypocalcemia include those following parathyroid adenoma resection (Volume 2, Chapter 61).

Symptoms of hypocalcemia include tetany, tingling, paresthesias, and in severe cases, seizures. ☞ **The treatment of hypocalcemia is IV repletion of calcium, which can be accomplished by either 10% calcium gluconate (93 mg of calcium per 10 cc) or 10% calcium chloride (272 mg of calcium per 10 cc) (73).** ☞ Both agents should be diluted to prevent venous irritation. In patients with possible digitalis toxicity, calcium should be given slowly with ECG monitoring, because it can enhance the effects of digitalis.

### Hypercalcemia

☞ **Excess extracellular calcium rarely leads to dysrhythmias.** ☞ Excess intracellular calcium, from catecholamines, ischemia, or digoxin, for example, may lead to dysrhythmias but these rhythms are not treated by lowering extracellular calcium. The ECG in hypercalcemia is characterized by prolongation of the PR interval, widened QRS, and shortening of the QT interval, followed by prolongation of the T wave (which may then normalize the QT interval) (74). The enhanced myocardial contractility associated with hypercalcemia can rarely result in midsystolic arrest.

Hypercalcemia is treated by saline hydration and loop diuretics to enhance renal excretion of calcium. Calcitonin and bisphosphonates can be used if saline hydration is inadequate. Octreotide does not lower plasma calcium; its use is only in prevention of stones.

### Hyponatremia and Hypernatremia

Hyponatremia and hypernatremia, while requiring correction due to CNS effects, are not associated with particular dysrhythmias. The diagnostic significance and treatment of these, and other, electrolyte disorders are discussed in Volume 2, Chapter 44.

## EYE TO THE FUTURE

Many of the recent advances in dysrhythmia management have occurred in the area of catheter-based ablation and device-based therapy. Catheter-guided RFA therapy has become the treatment of choice for various SVTs including accessory pathway-mediated tachycardia, AVNRT, EAT, and atrial flutter. More recently, there have been significant advances in our understanding of A-fib, and catheter-based ablation of A-fib is still time-consuming but increasingly successful. It appears that the posterior wall of the left atrium near the pulmonary veins is a key area in the initiation of A-fib. Catheter-based ablation targeted to this area appears very promising, with a high success rate and a low complication rate (75,76). If these early findings can be reproduced, catheter-based ablation of A-fib may become a more routine procedure.

Device-based therapy of dysrhythmias is another area of rapid development. It has been shown that automatic implantable cardiac defibrillators (AICDs) are more effective than antidysrhythmic drugs in treating VT and V-fib (4,5). Furthermore, indications for AICD implantation are expanding and an increasing number of patients are eligible for an AICD device. It has also become more common to see these devices in critically ill patients. Understanding and management of these devices by critical care providers will be important.

Most of the dysrhythmias seen in critical care settings such as paroxysmal SVT, A-fib, atrial flutter, and VT respond well to currently available antidysrhythmic therapies. However, the need still remains: (i) to deliver therapies that are more effective with fewer side effects and (ii) to identify patients who are more likely to develop dysrhythmias. Development of therapies with higher efficacy with few or no side effects is the goal of new therapeutic approaches. One of the major drawbacks of the currently available antidysrhythmic agents is their effect on other organs. Delivery of drugs to the target tissues by either local delivery or targeted delivery systems may lessen the systemic complications. One example of this approach is delivery of antidysrhythmic agents to the pericardial space to obtain high myocardial concentration without significant systemic concentration. In addition, there are drugs in development for atrial dysrhythmias that are specific to atrial tissue and thus avoid potential ventricular prodysrhythmias.

Another area of future advancement will be in targeting patients at high risk for dysrhythmias through genetic testing. For example, electrolyte disturbances such as hypokalemia and hypomagnesemia and the usage of QT-prolonging medications are common in the critical care setting. Unfortunately, QT prolongation and torsades de pointes are not uncommon in trauma and critical care. Although only a small fraction of trauma patients develop acute MI (Volume 2, Chapter 19), many develop dysrhythmias. Along with improved monitoring techniques, identification of these susceptible patients using noninvasive markers, or with genetic testing, may facilitate management of these patients and may become feasible in the near future.

## SUMMARY

Dysrhythmias are commonly associated with critical illness and trauma. Bradyarrhythmias should be treated only when symptomatic. At such time, placement of an external or transvenous pacemaker (depending on the availability

of devices and personnel) can be life-saving. Atrial and ventricular tachydysrhythmias can often be distinguished from each other by past medical history as well as by distinguishing features on the ECG. Treatment of hemodynamically stable atrial and ventricular dysrhythmias can be accomplished with medical therapy. Atrial and ventricular dysrhythmias in unstable patients must be treated promptly with electrical cardioversion or pacing.

Many mechanisms of trauma, such as decelerating injuries, blunt trauma to the chest, blast injuries, and head trauma can cause myocardial contusions complicated by dysrhythmias. Careful diagnosis and monitoring are essential to the care of these patients.

Overdoses of medications and other substances are commonly seen in emergency departments and associated with acute trauma, and can lead to critical illness and dysrhythmias. Treatment of these overdoses and dysrhythmias is tailored to the substance ingested; for example, tricyclic overdoses are treated with alkalization, and then lidocaine if dysrhythmias persist. Cocaine overdoses are treated with benzodiazepines as first-line therapy along with NTG; beta-blockers are avoided in this setting.

Other common causes of dysrhythmias in critical illness and trauma are related to electrolyte disturbances. Hypokalemia and hypomagnesemia are the most common and are treated with prompt IV replacement. Hyperkalemia can be life-threatening and should be treated emergently if ECG changes are detected. Because potassium is painful when administered to peripheral veins, it should be given via central line or via a peripherally inserted central catheter (PICC) line whenever possible.

## KEY POINTS

- ✎ Bradycardia per se does not require specific treatment as long as it does not cause symptoms of hemodynamic compromise.
- ✎ Heart block at the level of the AV node usually does not require invasive therapy and only requires withdrawal of the offending agents, such as beta-blockers and calcium-channel blockers.
- ✎ Sinus tachycardia usually has a gradual onset and termination.
- ✎ Acute conversion of atrial tachydysrhythmias to sinus rhythm can be accomplished either by synchronized DC cardioversion or by administration of antidysrhythmic agents.
- ✎ Treatment of AV node-mediated tachycardias (AVNRT and AVRT) can be accomplished by administering drugs that increase the refractory period of the AV node. These drugs include calcium-channel blockers, beta-blockers, digoxin, and adenosine.
- ✎ Acute treatment of pre-excited A-fib should be targeted at slowing conduction in the accessory pathway rather than in the AV node. Pre-excited A-fib can be treated acutely with cardioversion (if patient is hemodynamically unstable) or adenosine, intravenous procainamide, ibutilide (1,2), or amiodarone (3).
- ✎ Of the nonsustained VTs, nonsustained polymorphic VTs with a rapid ventricular rate require special attention, because these unstable dysrhythmias are very likely to progress to V-fib.
- ✎ Hemodynamically unstable VT should be treated promptly with DC electrical cardioversion.

- ✎ Hemodynamically stable VT can be treated with a pharmacologic agent. The first line of treatment is intravenous amiodarone or procainamide.
- ✎ The ECG is quite useful in distinguishing VT from SVT with aberration.
- ✎ The criteria for distinguishing VT from SVT include: (i) VT is more common than SVT with aberration, especially in patients with structural heart disease, (ii) SVT with aberration usually has a typical BBB pattern, (iii) when in doubt, treat wide complex tachycardias as VT, and (iv) obtain as much electrocardiographic documentation as possible including a 12-lead ECG and rhythm strips of the tachycardia's onset and termination.
- ✎ Transcutaneous pacing can be a useful adjunctive therapy in patients who require urgent heart rate support for symptomatic bradycardia.
- ✎ A transvenous pacemaker is needed in patients with symptomatic bradycardia, whether it is due to sinus node dysfunction or to AV block.
- ✎ When a tachyarrhythmia causes hemodynamic instability, urgent DC cardioversion is recommended.
- ✎ Some authors suggest that a normal ECG three hours after minor cardiac trauma can exclude those who might develop cardiac complications.
- ✎ Troponins are neither 100% specific nor sensitive; small injuries with undetectable troponin could lead to dysrhythmias; conversely hemorrhage and shock may lead to troponin release without contusion.
- ✎ TEE is preferable to transthoracic echocardiography in evaluating trauma patients except for viewing the pericardium. It is superior to helical computed tomography (CT) in detecting contusions. Unfortunately, the RV is more difficult than the LV to visualize, and the RV is more frequently involved in contusions.
- ✎ Myocardial contusion is associated with dysrhythmias and functional impairment, especially of the ventricle.
- ✎ Risk factors for perioperative mortality associated with contusion are old age, A-fib, and aortic rupture.
- ✎ Benzodiazepines and nitroglycerin (NTG) are the first-line agents for patients with cocaine-induced ischemia.
- ✎ Because beta-blockers exacerbate this constriction, they should be avoided in patients with cocaine use.
- ✎ Acute effects of alcohol intoxication include paroxysmal A-fib or "holiday heart," which can be seen in healthy patients with structurally normal hearts.
- ✎ Chronic heavy consumption causes an increase in catecholamine release and is associated with poor contractility, mitochondrial dysfunction, and ventricular dysrhythmias.
- ✎ Tricyclic antidepressants are a leading cause of morbidity and mortality due to drug poisoning in the United States. Initial ECG changes include widening of the QRS interval to  $>100$  msec, an R-wave amplitude of  $>3$  mm in aVR, and abnormalities in the terminal 40-msec QRS axis (T40-msec) (an axis between  $120^\circ$  and  $270^\circ$  rotation). These abnormalities on the presenting ECG are reported to predict seizures and dysrhythmias.
- ✎ Alkalinization is considered standard treatment for conduction delays or dysrhythmias associated with tricyclic toxicity.
- ✎ If dysrhythmias are resistant to sodium bicarbonate, then lidocaine is considered the drug of choice.
- ✎ Theophylline has a narrow therapeutic window and so overdose is not uncommon. The serious complications are hypotension, dysrhythmias, seizures, and death (54). Peak serum concentrations are helpful in predicting toxicity, but chronic users may be toxic at lower serum concentrations.
- ✎ Treatment of dysrhythmias should be supportive and accompanied by treatment of the overdose: multiple doses of activated charcoal or hemoperfusion for those at highest risk, cardiorespiratory support, and correction of electrolyte abnormalities.
- ✎ The mainstay of treatment for torsades de pointes is intravenous magnesium (2-g bolus over two to three minutes, then IV infusion at 2–4 mg/min with second 2-g bolus if necessary), potassium (if K is low), temporary cardiac pacing (at rates of 90–110 to prevent short-term recurrence), and correction of electrolyte imbalance.
- ✎ The treatment of hypokalemia is potassium supplementation, intravenously if dysrhythmias are present. The rate of infusion should be no more than 20 mmol/hr and the ECG should be monitored.
- ✎ Acute treatment of hyperkalemia consists of membrane stabilization with calcium and transcellular shifting of potassium facilitated by insulin, glucose, bicarbonate, and beta-agonists.
- ✎ Treatment of hypomagnesemia is repletion of magnesium. This may be done by a single 2-g bolus of magnesium over two to three minutes followed by an infusion of 2–4 mg/min in severe cases.
- ✎ If hypermagnesemia is symptomatic and causing CNS depression, administration of calcium is appropriate.
- ✎ The treatment of hypocalcemia is IV repletion of calcium, which can be accomplished by either 10% calcium gluconate (93 mg of calcium per 10 cc) or 10% calcium chloride (272 mg of calcium per 10 cc).
- ✎ Excess extracellular calcium rarely leads to dysrhythmias.

### INTRODUCTION

The use of transesophageal echocardiography (TEE) has expanded tremendously since its introduction into clinical use in the mid-1970s. TEE is used daily in the echocardiography laboratory, the operating rooms, and also the surgical intensive care unit (SICU). Its usefulness derives from its high capacity for both diagnosis and monitoring. Ultrasound studies are considered noninvasive procedures when performed from the thoracic surface (transthoracic tomographic views) and minimally invasive when performed from the esophagus (transesophageal tomographic views).

This chapter reviews the basic physical principles of ultrasound and echocardiography, echoanatomy, and a practical approach to performing an abbreviated trauma TEE examination when time is limited. Assessment of preload, afterload, contractility, and diastolic dysfunction will be reviewed. This is followed by a discussion of common valvular heart lesions and the general approach to the trauma patient. Clinically oriented discussions regarding the usefulness of TEE in the management of trauma patients in the operating room, SICU, and use of TEE as an emergency “rescue diagnostic tool” in the hemodynamically unstable patient are also provided.

A task force formed by the American Heart Association (AHA), the American College of Cardiology (ACC), and the American Society of Echocardiography (ASE) published guidelines in 1997 for clinical application of TEE (1) (Table 1). Class 1 indications are conditions for which there is scientific evidence and/or general agreement that the procedure is useful and effective. Class 2a indications are those of which there is conflicting evidence and/or divergence of opinion about usefulness, but the final assessment weighs in favor of its use. Class 2b indications are still useful but with less well established evidence or opinion. In SICU and trauma clinical scenarios, Class 1 indications for TEE include the evaluation of acute and life-threatening hemodynamic disturbances, evaluation of heart structure for possible endocarditis, guidance for placement of intracardiac devices, and drainage of pericardial effusion. Class 2a indications include the monitoring for myocardial ischemia, diagnosis of myocardial infarction, and evaluation

for a cardiac source of emboli (atheromatous disease, intracardiac thrombus/tumor, and intracardiac shunt). Finally, class 2b indications are related to diagnosis of post-traumatic cardiac lesions and acute aortic dissection.

### PHYSICS AND PRINCIPLES

#### Physics of Ultrasound

Sound waves are defined as mechanical vibrations that create rarefaction and compression of any medium through which they travel. The human ear can analyze sound waves with frequencies ranging from 20 Hz to 20 KHz. Ultrasound frequencies used for echocardiography are above this level, ranging between 1 and 20 MHz. Sound waves can be characterized by amplitude (dB), frequency (Hz), wavelength (mm), and velocity (m/sec). Increasing transducer frequency will give better resolution but less depth of penetration due to tissue absorption. For example, a 3.5 MHz TEE transducer (low frequency) will have decreased image resolution, but will be able to assess a structure far away from the probe [i.e., the apex of a large dilated left ventricle (LV) at a depth of 16–18 cm]. In contrast, a 7.5-MHz transducer (high frequency) will give excellent spatial resolution of a near structure, but depth of penetration will be diminished.

Ultrasound emitted by a transducer has a known frequency and a defined constant velocity within the medium through which it passes (1540 m/sec in soft tissue). This relationship between frequency, velocity, and wavelength is used to acquire appropriate data regarding cardiac structure and function. TEE utilizes two different technologies: structural imaging (A-Mode, M-mode, B-Mode, and 2D) and Doppler.

#### Structural Imaging: Two-Dimensional Echocardiography

The structural imaging process relies on the fact that a transducer will emit a signal at a known frequency, ranging from 2.5 to 7.5 MHz, and a known constant velocity, 1540 m/sec. After emission of the sound wave, the transducer becomes a receptor and waits for the signal to be reflected back by the structures along its pathway. Because the propagation velocity of the ultrasound is constant, the distance

**Table 1** Indications for Transesophageal Echocardiography in the Operating Room or Surgical Intensive Care Unit (ASA Practice Guidelines)

Indication	Examples
Class 1	Acute, persistent and life-threatening hemodynamic instability Unstable ICU patients with suspected valve disease or thromboembolic problems Patients with suspected aortic dissection/aneurysm/disruption who need immediate evaluation
Class 2	Monitoring for myocardial ischemia, myocardial infarction Patients with increased risk for hemodynamic disturbances in the perioperative setting Patients with intracardiac foreign bodies Intraoperative detection of air emboli in patients at risk Suspected cardiac trauma
Class 3	Intraoperative monitoring for emboli during orthopaedic procedures Intraoperative assessment of repair of thoracic aortic injury Perioperative evaluation of pleuro-pulmonary diseases Monitoring placement of central venous or pulmonary artery catheters

Note: Class 1, frequently useful in improving clinical outcome; class 2, perhaps useful with less clear influence on clinical outcome; class 3, controversial indication with unclear influence on clinical outcome

Abbreviations: ASA, American Society of Anesthesiologists; ICU, intensive care unit.

between the transducer and the reflected structure will be determined by the time it takes for the initial signal to emit and return to the transducer. The same signal will also have defined amplitude, which is related to the reflective characteristics of the structures met. The processing component of the echo machine can display this information in various ways. The earliest echo systems displayed the data by A-mode (amplitude vs. depth) on an oscilloscope screen. With increasingly powerful processing systems, the same data can be presented by M-mode (motion) where the different returned signals are presented on a gray-scale display over time on the horizontal axis. The temporal aspect of M-mode is useful for analyzing highly mobile structures, but is limited in its ability to provide information about the relationship between multiple structures. The M-mode gives data about only a thin cut of the cardiac structure (single scan line). The B-mode (brightness), also called two-dimension (2D) imaging, is the ultimate way to display the same data by dots on a screen monitor. The position of the dot on the screen is related to the calculated distance between the transducer and the structure represented. The brightness of the dot is related to the amplitude of the returning signal. With a high-capacity processing system, multiple scan lines can be analyzed quickly to produce a moving image with adequate temporal resolution. This is how 2D images of moving cardiac structures are produced in echocardiography. The reflection which occurs at the interface between two tissues and the intensity of the reflected signal will be related to the acoustic impedance between those tissues. Since ultrasound does not travel well through

air, it is essential to have an adequate medium between the transducer and the tissue, such as a water-soluble jelly. In order to obtain optimal 2D images, the angle between the transducer and the imaged structure should be as close to 90° as possible in order to minimize refraction and artifact formation (the angle of incidence of the transmitted ultrasound wave equals the angle of reflection).

### Doppler Echocardiography

The second physical principle used in cardiac ultrasound imaging is the "Doppler effect," defined as the apparent change in frequency observed when the source and observer are in motion relative to each other. For echocardiography, the Doppler shift is the difference between the initial known frequency and the backscattered signal returned from moving blood cells. ⚡ **From the Doppler shift, the velocity of the moving blood cells can be calculated.** ⚡ Ideally, the ultrasound beam should be parallel to blood flow with the scattered signal moving directly towards or away from the transducer. Keeping the crossing angle to less than 20° will limit error in blood flow velocity measurements.

The returning backscattered signal from the moving blood cells is composed of several different frequencies, which are analyzed by a fast Fourier transformation before being displayed using spectral analysis. Spectral analysis displays time on the horizontal axis and velocity on the longitudinal axis. The Doppler shifts indicating that the moving red cells are coming toward the transducer will appear above the baseline, whereas those traveling away from the transducer will appear below the baseline. Doppler echocardiography is commonly used to measure blood flow velocities in cardiac chambers, across valves, and in great vessels. These measured velocities are helpful for both diagnostic and monitoring applications. ⚡ **The modified Bernoulli equation can be used to transform velocities obtained by TEE into pressure units.** ⚡

$$P = 4v^2$$

where  $P$  = peak pressure gradient (mmHg) and  $v$  = peak velocity (m/sec) of flow across the valve. Data for this equation are usually obtained using continuous wave (CW) Doppler echo (described subsequently).

There are three types of Doppler echocardiography modalities: CW, pulsed wave (PW), and color Doppler. The use of CW Doppler necessitates two different crystals in the transducer. One is used for emitting ultrasound continuously and the other for receiving the returned signal. The CW Doppler will be able to measure all the velocities along a scanning line, but is unable to differentiate the exact location of the maximum velocity along that line (range ambiguity). The PW Doppler is different in that it uses one crystal that alternates between emitting and receiving. A sampling area for velocity measurement is determined by the echocardiographer, along a scanning line. The Doppler shift will correspond to the velocity measured at the sampling volume. The PWD signals must be sampled twice in order to get an accurate determination of the wavelength. This limits its ability to measure high velocities. The major limitation of PWD is that it can only measure a limited range of velocities without ambiguity in the speed or direction. Velocities outside the limits of the spectral display (the Nyquist limit) will "wrap around" and falsely appear as a reversal of flow (aliasing).

The color Doppler is a variation of PW Doppler. Simply explained, a larger sampling area for velocity

measurements is analyzed and presented as color-coded images superimposed on 2D images instead of a spectral display. ⚡ By convention, the velocities going away from the transducer are coded in shades of blue, whereas velocities coming toward the transducer are coded in shades of red (BART: Blue Away, Red Towards). ⚡ In clinical practice, color Doppler is used to get a semi-quantitative evaluation of velocities in cardiac chambers and valves. Precise quantification is done using either CW or PW Doppler. Color Doppler has the same intrinsic limit for maximum velocity measurement (Nyquist limit) as PW Doppler. When the measured velocities in the mapping area of color Doppler are above the Nyquist limit, they appear as an aliasing signal, depicted as a sudden reverse in color. For example, when evaluating normal mitral valve (MV) inflow during diastole using color Doppler, blue color would appear in the left atrium (LA) because blood flow is going away from the probe at low velocity. If red color suddenly appeared

during diastole near the valve, the velocities measured at that point are above the Nyquist limit of the color Doppler setting, suggestive of mitral stenosis.

In summary, echocardiography is done with ultrasound using two different modalities: 2D showing live motion images of the heart and great vessels in a gray scale, and Doppler echocardiography measuring blood velocity in cardiac chambers, valves, and orifices.

## TRANSESOPHAGEAL ECHOCARDIOGRAPHY ANATOMY Nomenclature

In 1999, the ASE and the Society of Cardiovascular Anesthesiologists (SCA) published a landmark paper with guidelines for performing a comprehensive perioperative multiplane TEE (2). This publication describes in detail the 20 cross-sectional views of a comprehensive TEE examination (Fig. 1). An experienced echocardiographer can perform

**Figure 1** The ASE/SCA 20-view exam. Transesophageal echocardiography cross-sections in a comprehensive examination. Twenty standard cross-sections and their abbreviated names are depicted by the line drawings. Probe manipulations required to produce each of the cross-sections are described in the text. *Abbreviations:* ME, mid-esophageal; ME LAX, mid-esophageal long-axis view; TG mid SAX, transgastric mid-short-axis view; TG basal SAX, transgastric basal short axis view; ME AV SAX, mid-esophageal aortic valve short-axis view; ME AV LAX, mid-esophageal aortic valve long-axis view; TG LAX, transgastric long-axis view; ME RV inflow-outflow, mid-esophageal right ventricle inflow-outflow; TG RV inflow, transgastric right ventricle inflow; ME asc aortic SAX, mid-esophageal ascending aortic short-axis view; ME asc aortic LAX, mid-esophageal ascending aortic long-axis view; desc aortic SAX, descending aorta short-axis view; desc aortic LAX, descending aorta long-axis view; UE aortic arch LAX, upper esophageal aortic long-axis view; UE aortic arch SAX, upper esophageal aortic short-axis view. *Source:* From Ref. 2.

**Figure 2** Terminology used for transesophageal echocardiography probe and transducer manipulations.

this exam in less than 10 minutes; however, for those less experienced, a complete exam can be time consuming and overwhelming. In this chapter, a concise and practical approach to the trauma patient will be presented, followed by a completion of the 20-view exam.

The modern multiplane TEE probe consists of a central flexible shaft with a controllable distal portion (last 10 cm). The transducer is embedded into the tip of the flexible shaft and mounted on an electric motor that permits rotation for multiplane imaging. With the patient supine and the TEE imaging structures in front of it, the terminology is always in reference to the heart. Superior is toward the head, inferior toward the feet, posterior toward the spine, anterior toward the sternum, and right and left being the patient's right and left sides, respectively. The probe itself can be advanced inferiorly, withdrawn superiorly, and rotated right and left (Fig. 2). The tip of the probe can be anteflexed or retroflexed with the large rotating knob. It can also be flexed left and right with the smaller knob. The internal transducer (multiplane) can be rotated forward (0–180° clockwise) or backward (180–0° counterclockwise) by another control on the handle. The depth of the scanning area and the multiplane angle should always be adjusted to have the screen show only the structures being evaluated. In general, cross sections of structures seen at multiplane angles below 45° are called short axis and those above 45° are called long axis.

### Abbreviated Trauma Transesophageal Echocardiography Examination

☞ The abbreviated trauma examination includes 12 of the 20 cross sections of the ASE/SCA comprehensive examination. ☞ The goal of this approach will be to identify

**Figure 3** Transgastric mid-short-axis (TG mid SAX) view. Abbreviations: LV, left ventricle; RV, right ventricle.

trauma-related injuries and evaluate the causes of hemodynamic instability. Additional views can be used for further evaluation if felt necessary by the echocardiographer.

The first view obtained is the transgastric mid-short axis (TG mid SAX) (Fig. 3). The authors would recommend starting with this view as one can rapidly diagnose many causes of hemodynamic instability. This view is obtained by advancing the probe past the esophagus and into the stomach, followed by anteflexion. The multiplane angle is generally best placed between 0° and 30°. Once the LV is seen in the center of the image, the probe is advanced or withdrawn slightly until both the anterolateral and posteromedial papillary muscles are shown equally. This will indicate that the probe is at the mid-level of the LV. Volume status, global and regional LV contractile function, right ventricular (RV) function, and evidence of pericardial effusion can all be evaluated with this highly versatile cross section.

The next view obtained is the mid-esophageal four-chamber view (ME 4 Chamber) (Fig. 4). From the TG mid-SAX view, the probe is withdrawn into the mid-esophagus with the multiplane angle at 0°. The tip of the probe often has to be slightly retroflexed in order to reduce apical foreshortening. This cross section shows the four chambers [right atrium (RA), RV, LA, and LV], as well as the MV and tricuspid valves (TV). The free wall of the RV is shown on the left, the septum is located in the middle, and the lateral wall of the LV appears on the right. With this view, chamber size and global contractile function can be examined. Regional wall motion of the septum and lateral wall of the LV at the basal, mid, and apical levels can be evaluated. The color Doppler can be used to evaluate the MV and TV for stenosis or regurgitation.

**Figure 4** Mid-esophageal four-chamber (ME 4 Chamber) view. Abbreviations: LV, left ventricle; RV, right ventricle; LA, left atrium; RA, right atrium.

**Figure 5** Mid-esophageal two-chamber (ME 2 Chamber) view. *Abbreviations:* LA, left atrium; LV, left ventricle.

Keeping the LV in the middle of the screen and rotating the multiplane forward to about  $90^\circ$  will give the mid-esophageal two-chamber view (ME 2 Chamber) (Fig. 5). The LA is seen at the top of the figure with the MV and LV below. The anterior LV wall on the right side of the figure and the inferior wall on the left side can be evaluated for regional contractile function. The LA appendage can also be visualized as a part of the LA covering the upper part of the anterior wall of the LV. Chamber size, LV contractile function, MV abnormalities, and thrombus in the LA appendage can be studied in this view. Color Doppler can be used to further study the MV, if necessary.

From the ME 2 Chamber view, the multiplane is then rotated to approximately  $130^\circ$  to obtain the mid-esophageal long-axis view (ME LAX) (Fig. 6). This view shows the antero-septal wall on the right side facing the posterior wall on the left, which can be evaluated for regional contractile function. The LV outflow tract (LVOT) and the aortic valve (AV) in long axis are above the antero-septal wall.

From the ME LAX view, rotating the multiplane back to  $0^\circ$  will give the ME 4 Chamber. Withdrawing the probe until the cusps of the AV are seen, and then turning the multiplane angle to approximately  $30^\circ$  will give the mid-esophageal AV short axis (ME AV SAX) (Fig. 7). The coaptation of the three aortic cusps (which resemble a Mercedes Benz sign) should be visualized in this view. The optimal depth is between 8 and 10 cm. The main focus of this cross section is to evaluate the AV structure and function. A nonquantitative estimation of LV stroke volume and cardiac output can be done, based on the extent of AV opening and the heart rate.

From the ME AV SAX view (approximately  $30^\circ$ ), rotating the multiplane angle to approximately  $115^\circ$  will give the

**Figure 6** Mid-esophageal long-axis (ME LAX) view. *Abbreviations:* Ao, aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

**Figure 7** Mid-esophageal aortic valve short-axis (ME AV SAX) view. *Abbreviations:* LA, left atrium; RA, right atrium; RVOT, right ventricular outflow tract.

mid-esophageal AV long-axis view (ME AV LAX) (Fig. 8). The AV is now seen in long axis in the middle with the LA shown above, the proximal ascending aorta on the right, and the LVOT below and to the left. The optimal multiplane angle is found when one visualizes the coaptation point between the right coronary cusp on the bottom of the figure and either the noncoronary or left coronary cusp in the middle of the aortic root. This view is optimal for color Doppler studies of the AV to look for aortic regurgitation (Nyquist limit above 50 cm/sec). This view is also useful for evaluation of AV structure and function as well as its relationship with the MV. A small part of the ascending aorta is also seen, along with the sino-tubular junction, the sinuses of Valsava, and the aortic annulus. An aortic dissection flap may be seen in the proximal ascending aorta if present.

The remaining views of the abbreviated trauma exam include important views of the aorta and pulmonary artery (PA). The descending aortic short-axis view (desc. aortic SAX) (Fig. 9) is obtained by placing the probe deep in the stomach and turning the probe to the left so that the ultrasound beam is pointing posterior. Depth is decreased to 6–8 cm. The probe can be withdrawn until the entire descending aorta has been visualized from its distal to proximal end. If the aorta is tortuous, the probe may be turned left or right to keep the image centered. At any level of the descending aorta, the multiplane angle can be rotated to  $90^\circ$  to image the aorta in long axis to obtain the descending aortic long-axis view (desc. aortic LAX) (Fig. 10). From the desc. aortic SAX view, the probe can be withdrawn into the upper esophagus until the aorta arches to the left side of the figure. This is the upper esophageal aortic arch long-axis view (UE aortic arch LAX) (Fig. 11). From this view, the

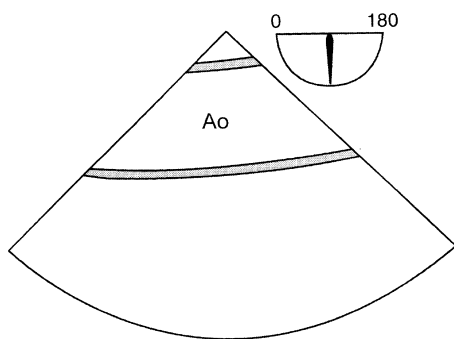

**Figure 8** Mid-esophageal aortic valve long-axis (ME AV LAX) view. *Abbreviations:* Ao, aorta; LA, left atrium; LV, left ventricle; LVOT, LV outflow tract.

**Figure 9** Descending aorta short-axis (desc aortic SAX) view. *Abbreviation:* Ao, aorta.

**Figure 10** Descending aorta long-axis (desc aortic LAX) view. *Abbreviation:* Ao, aorta.

**Figure 13** Mid-esophageal ascending aortic short-axis (ME asc aortic SAX) view. *Abbreviations:* Ao, aorta; RPA, right pulmonary artery; MPA, main pulmonary artery; SVC, superior vena cava.

**Figure 11** Upper esophageal aortic long-axis (UE aortic arch LAX) view. *Abbreviation:* Ao, aorta.

**Figure 14** Mid-esophageal ascending aortic long-axis (ME asc aortic LAX) view. *Abbreviations:* Ao, aorta; RPA, right pulmonary artery.

transducer is rotated 90° until the distal arch is seen in short axis [upper esophageal aortic arch short-axis view (UE aortic arch SAX)] (Fig. 12). In this view, the takeoff of the left subclavian artery can be seen in the upper right of the figure. These aortic views can be used to examine the proximal ascending aorta, the distal portion of the aortic arch, and the entire descending thoracic aorta for evidence of dissection, aneurysm, and atheromatous plaque. However, the distal ascending aorta and proximal arch cannot be examined because of the interposition of the air-filled trachea and left bronchus. The desc. aortic SAX view is also useful to visualize fluid in the pleural space. The last view of the abbreviated trauma exam is the mid-esophageal ascending aortic short-axis view (ME asc. aortic SAX) (Fig. 13). This view is obtained from the ME 4 Chamber view by rotating the multiplane to about 40° and withdrawing the probe, until a short-axis view of the proximal ascending aorta and a long-axis view

of the main and right PA are seen. The superior vena cava (SVC) is seen in its location between the right PA and the aorta. This view can be useful for Doppler studies across the PA and evaluation for a proximal pulmonary embolus (PE). The mid-esophageal ascending aortic long-axis view (ME asc. aortic LAX) (Fig. 14) provides additional information about the ascending aorta, and is obtained by rotating the multiplane 90° from the previous image. The authors believe that these 12 views are the most important and are sufficient for the initial brief evaluation of the acute trauma patient.

**Exam Completion**

In hemodynamically stable patients, as well as in previously unstable trauma patients, a complete examination should

**Figure 15** Deep transgastric long-axis (deep TG LAX) view. *Abbreviations:* LV, left ventricle; RV, right ventricle; LA, left atrium; Ao, aorta; LVOT, LV outflow tract.

**Figure 17** Transgastric long-axis (TG LAX) view. *Abbreviations:* Ao, aorta; LV, left ventricle; LVOT, LV outflow tract.

be performed as soon as time permits. To complete the ASE/SCA comprehensive 20-view exam, eight additional views are necessary. The deep transgastric view (deep TG LAX) (Fig. 15) is obtained by advancing the probe to approximately 45–50 cm, followed by anteflexion, left flexion, and a multiplane angle of  $0^\circ$ . The CW and PW Doppler can be used across the AV and the LVOT to evaluate for aortic stenosis and for calculating a left-sided cardiac output. The transgastric two chamber view (TG 2 chamber) (Fig. 16) is obtained by rotating the multiplane to about  $90^\circ$  from the TG mid-SAX view. Evaluation of wall motion of the anterior and inferior wall as well as the apex can be performed. The MV and subvalvular structures can also be seen. Rotating the multiplane angle forward to between  $90^\circ$  and  $120^\circ$  and turning the probe slightly to the right from the previous view will give the transgastric long-axis view (TG LAX) (Fig. 17). With this view, Doppler studies can be performed across the AV and LVOT. The transgastric RV inflow view (TG RV inflow) (Fig. 18) is obtained by turning the probe to the right from a TG mid-SAX view until the RV is in the center, then rotating the multiplane to about  $90^\circ$ . This view is useful for evaluating RV function and TV anatomy. The transgastric basal short-axis view (TG basal SAX) (Fig. 19) view is obtained by withdrawing the probe slightly from the TG mid-SAX view until the MV is seen. This view is useful for evaluating the MV as well as wall motion of all the basal segments of the LV. The ME mitral commissural view (ME mitral commissural) (Fig. 20) can be found by decreasing the multiplane angle to about  $60^\circ$  from the ME 2 Chamber view. This view is useful for further evaluation of MV anatomy. Portions of the posterior and anterior leaflets

**Figure 18** Transgastric right ventricle inflow (TG RV inflow) view. *Abbreviations:* RA, right atrium; RV, right ventricle.

can be closely studied. From the ME AV SAX view, the multiplane is rotated to  $80^\circ$  and turned to the left to obtain the mid-esophageal right ventricular inflow-outflow view (ME RV inflow-outflow) (Fig. 21) to show the TV and pulmonic valve. The RV inferior free wall is seen on the left, and the right ventricular outflow tract (RVOT) is seen on the right. This view is valuable in the assessment of RV function, tricuspid and pulmonary regurgitation. The last view, mid-esophageal bicaval view (ME bicaval) (Fig. 22) is obtained by turning the probe to the patient's right from the ME AV LAX view and rotating the multiplane to approximately  $110^\circ$ . Here, the RA is seen at the bottom with the LA above and the intra-atrial septum between. This view may be useful to look for a patent foramen ovale, evidence of pericardial tamponade, and assist with line placement.

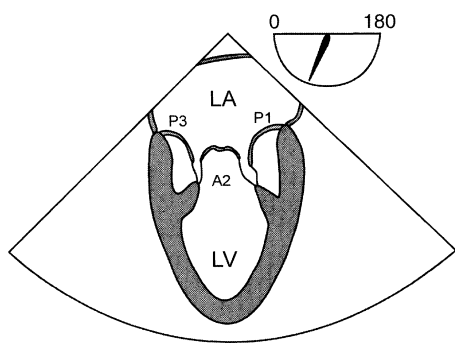

**Figure 16** Transgastric two-chamber (TG two chamber) view. *Abbreviations:* LA, left atrium; LV, left ventricle.

**ASSESSMENT OF PRELOAD, AFTERLOAD, AND MYOCARDIAL FUNCTION**

**Left Ventricular Preload Evaluation**

**Right Heart Filling Pressures vs. Transesophageal Echocardiography**

Heart muscle fibers need a particular baseline stretch (preload) to produce optimal fiber shortening. Consequently, the heart depends on an adequate end-diastolic volume to produce optimal stroke volume. Even with normal myocardial contractility the heart cannot produce normal stroke volume and cardiac output if end-diastolic volume, and thus muscle fiber baseline stretch are reduced. In clinical practice, myocardial preload is typically assessed indirectly, using pressure measurements in the RA [central venous

pressure (CVP) or pulmonary circulation—pulmonary artery capillary occlusion pressure (PACOP)].

There is a rather close correlation between PACOP or even CVP and LV end-diastolic volume (LVEDV) in most patients with normal LV function and normal pulmonary vascular resistance (PVR). Consequently, indirect assessment using pressure measurements may often be sufficient to guide volume therapy. However, in several subgroups of patients, indirect assessment of end-diastolic volume by pressure measurements becomes less reliable, because of poor correlation between PACOP and LV end-diastolic volume (3–6). Loss of correlation between pressure and volume measurements is typically found in patients in whom pressure measurements do not represent transmural filling pressure (e.g., high intrathoracic pressure, high PEEP), and in patients in whom higher filling pressures are needed to maintain end-diastolic volume because of an impaired ability of myocardial muscle fibers to relax (diastolic dysfunction) (4) (Table 2).

The improved ability of TEE in preload assessment was initially described for cardiac surgical patients (5–7), but is now also well documented and widely accepted for emergency patients or unstable patients in the SICU (8–11). Preload assessment is among the most common indications for a TEE examination in the SICU, and a TEE examination should always be added to filling pressure measurements if there is any doubt about adequacy of preload (9,11,12). However, echocardiographic preload assessment has a few limitations, particularly in patients with diastolic dysfunction and pre-existing cardiac disease (8). In these patients it is not possible to define a clear threshold for LV end diastolic area (EDA), below which there is no volume recruitable increase in LV function (8). In these instances, it is often helpful to repeatedly assess EDA, fractional area shortening and filling pressure during volume administration, and not to base the decision on a single TEE exam. It has also been suggested that adding PW Doppler data of transmitral (ventricular filling) and pulmonary venous blood flow (atrial filling) may further improve echocardiographic preload assessment. However, these parameters are markedly influenced by heart rate, rhythm, afterload, and other physiologic parameters that are poorly defined and constantly changing in SICU patients. Therefore, PW Doppler estimation of preload is of limited clinical usefulness.

**Practical Approach**

☞ Normally, the TG mid-SAX view is used to assess RV and LV myocardial preload. ☞ In the transgastric short-axis

**Table 2** Common Clinical Scenarios with Poor Correlation Between Pulmonary Artery Capillary Occlusion Pressure and Left Ventricular End-Diastolic Volume

Cause	Example
Elevated intrathoracic pressure	Ventilation with markedly increased I:E ratios Ventilation with high PEEP values
Elevated abdominal pressure	Retroperitoneal hematoma Abdominal compartment syndrome
Diastolic dysfunction	Sepsis High-dose catecholamine therapy Hypertrophic myocardium

*Abbreviation:* PEEP, positive end expiratory pressure.

**Table 3** Echocardiographic Findings Associated with Reduced Left Ventricular Preload (Hypovolemia)

End-systolic papillary muscle contact and loss of LV lumen (TG SAX view)
LV end-diastolic area $<5.5 \text{ cm}^2/\text{m}^2$ body surface area
Reduced LV end-diastolic area compared to baseline measurement
Increased fractional area shortening with decreased LV end-diastolic area

Abbreviations: LV, left ventricle; TG SAX, transgastric short-axis view.

view, the TEE beam can be easily directed to precisely traverse both papillary muscles, thereby producing a consistent and highly reproducible echocardiographic view. In contrast, it is often impossible to direct the TEE beam to exit through the apex of the heart in the four-chamber view, thereby typically underestimating end-diastolic volume. One can trace the area of the LV along the endocardial border at end diastole and see changes in EDA with volume loading. Echocardiographic indicators of reduced LV preload are listed in Table 3, the systolic papillary muscle attachment (kissing papillary muscle phenomenon) being the most obvious, consistent, and clinically useful. In the trauma and critical care setting, repeated evaluation of LV function and EDA before and after volume loading can add to the echocardiographic diagnosis of reduced LV preload (8,10).

### Left Ventricular Afterload Estimation

Using volume determinations and measurements of myocardial thickness, LV afterload can be assessed by calculating LV wall stress. In lesions where forward stroke volume does not equal total stroke volume [e.g., mitral insufficiency, ventricular septal defect (VSD)], LV wall stress may be a better way to assess LV afterload when compared to systemic vascular resistance (SVR), calculated from PA catheter data (13). Wall stress may be a better predictor of clinical outcome (e.g., myocardial ischemia) when compared to SVR (13). However, due to the complexity of the method and multiple confounding factors, LV wall stress has never gained widespread acceptance in clinical practice. Echocardiographic findings in a state with isolated low SVR show a vigorously contracting ventricle and a reduced end systolic area (ESA) similar to hypovolemia. However, the EDA is normal. In uncertain cases or when dealing with a mixed picture, information from a PA catheter can be useful.

### Global and Regional Left Ventricular Function Evaluation

TEE enables direct visualization of both global and regional LV function. Semi-quantitative assessment of global LV function is possible with basic knowledge in TEE, and in general is sufficient to solve most clinical problems. Detection and assessment of regional LV function is often subtle and should be done only by an experienced echocardiographer. The midpapillary region of the heart generates 80% of LV stroke volume and all three major branches of the coronary circulation (left anterior descending, circumflex, and right coronary) contribute to blood supply of this region (Fig. 23) (3,14). Consequently, the TG mid-SAX view (Fig. 3) is the imaging plane of choice to quickly assess LV function in the unstable patient or to continuously monitor LV function in the operating room.

**Figure 23** Coronary artery perfusion territories. Typical regions of myocardium perfused by each of the three major coronary arteries to the left ventricle. Other patterns exist because of normal anatomic variations or coronary disease with collateral flow. Mid-esophageal 4 Chamber (A), 2 Chamber (B), long-axis (C), and transgastric mid-short-axis views (D). Abbreviations: RCA, right coronary artery; LAD, left anterior descending (coronary artery); Cx, circumflex artery.

### Global Systolic Left Ventricular Function

☞ The evaluation of global LV function in the ICU and emergency patient is typically done semi-quantitatively, describing global LV function as hyperdynamic, normal, moderately impaired, or severely impaired. ☞ Semi-quantitative assessment of LV function has several advantages. It does not direct attention away from the important task of resuscitating the patient and allows complicated calculations to be done with the echo software. In addition, it does not give the impression of highly accurate values, which takes more time to perform. One must realize that semi-quantitative assessment relies on using a single diameter to assess three-dimensional LV ejection. Impaired LV function is often the consequence of coronary artery disease, which may be associated with significant regional wall motion abnormalities. The calculation of LV function using diameter or area measurements in a single plane in the presence of regional wall motion abnormalities may therefore be less accurate. Fractional area change (FAC) is the proportional area change during systole, and provides a rapid and reliable index of global LV systolic function. The TG mid-SAX view (Fig. 3) is used, and areas are

derived by freezing and tracing the endocardial borders during systole (ESA) and diastole (EDA). The papillary muscles should be excluded from the trace.

$$\text{FAC} = \text{EDA} - \text{ESA} / \text{EDA} \times 100$$

The normal range of FAC is from 36% to 64%. In the presence of wall motion abnormalities, FAC overestimates the true ejection fraction (EF). Using two orthogonal echocardiographic views, ME 4 Chamber (Fig. 4) and ME 2 Chamber (Fig. 5), EF can be calculated using the modified Simpson's formula. This method is the most accurate in the presence of regional wall motion abnormalities.

Although sufficient for clinical practice, all parameters of global LV function mentioned earlier are preload and afterload dependent and therefore have their limitations in describing myocardial contractility. Echocardiographic parameters, such as length of pre-ejection period, end-systolic pressure-volume relationship, circumferential fiber shortening rate, and end-systolic stress/end-systolic area relationship, have all been evaluated in clinical or experimental studies as less pre- and afterload-dependent indices to describe myocardial contractility.

Cardiac output measurements can be done with TEE using 2D echocardiographic measurements alone or more commonly, adding transmitral or aortic Doppler flow velocity data. Difficulties in obtaining a proper Doppler signal (angle) and a number of assumptions when calculating the orifice of flow (errors in diameter measurements are squared) cause significant variability and miscalculations. In addition, repeated cardiac output determinations are necessary in most SICU patients, making PA catheter the preferred option to determine cardiac output. Computer software has become commercially available for continuous echocardiographic LV function monitoring. It automatically detects end-diastolic and end-systolic LV endocardial borders and does a beat-by-beat calculation of fractional area shortening. This technique has many pitfalls and problems and is rarely used in clinical practice.

### **Echocardiographic Evaluation of Diastolic Function**

Diastolic dysfunction has become increasingly more recognized as an important reason for cardiac dysfunction and morbidity in SICU patients, in particular in those with septic syndrome or high-dose inotropic support. The causes of diastolic dysfunction include abnormal reuptake of calcium, myocardial ischemia, hypertension, aortic stenosis, and hypertrophic cardiomyopathy. Several echocardiographic parameters to characterize and assess diastolic dysfunction are available, based on Doppler flow measurements of transmitral and pulmonary venous blood flow. The 2D echocardiographic findings associated with LV diastolic dysfunction include increased myocardial thickness, reduced end-diastolic volume despite high filling pressures, and a typical interrupted biphasic pattern of diastolic filling (instead of the smooth continuous pattern of normal diastolic filling). Doppler echocardiography is used to characterize diastolic dysfunction more in detail (4). The PW Doppler signal at the tips of the atrioventricular valves (ventricular inflow) is typically biphasic with a larger E-wave (early ventricular filling) and a smaller A-wave (atrial systole) with the normal E to A ratio being 2:1 (Fig. 24). In patients with diastolic dysfunction, the contribution of atrial contraction to diastolic filling becomes more important, and the ratio between E- and A-wave is

**Figure 24** Pulse wave Doppler flow characteristics at the tips of mitral valve leaflets (left ventricular inflow), mid-esophageal 4 Chamber view. Normal biphasic pattern of the signal with a larger E-wave (diastolic ventricular filling), and a smaller A-wave (atrial contraction).

altered (maximum velocity, velocity time integral, acceleration and deceleration, duration of E/A-wave). To reduce the confounding influence of LA pressure and compliance on LV filling, PW Doppler signals at the tips of the atrioventricular valves are often combined with the PW Doppler flow profiles in the left upper pulmonary vein (atrial inflow). Mitral annular Doppler tissue imaging and color M-mode transmitral propagation velocity are relatively preload-insensitive measures of LV diastolic dysfunction. However, it should be noted that the sensitivity and specificity of Doppler echo findings used to characterize diastolic dysfunction in the unstable SICU patient is limited, and they should be interpreted very cautiously.

### **Regional Left Ventricular Function**

Monitoring of regional LV function to detect intraoperative myocardial ischemia was one of the first indications for the perioperative use of TEE by anesthesiologists. Standard ECG and PA catheter monitoring detect less than 50% of all intraoperative ischemic events (3,15). Considering the therapeutic and prognostic significance of myocardial ischemia in the increasing number of older perioperative and post-traumatic patients, a sensitive tool to detect myocardial ischemia is undoubtedly of significant clinical importance.

Regional wall motion is characterized by a systolic inward motion (endocardial movement) and systolic wall thickening (Fig. 25). Regional wall motion may be classified as normal, hypokinetic, akinetic, or dyskinetic. Endocardial movement is easier to assess when compared to myocardial thickening (Table 4). Assessment of myocardial thickening is significantly improved with M-mode echocardiography, in particular with the less experienced investigator. A reduction in myocardial blood flow of about 20% will create hypokinesis, and the segment will become akinetic with a reduction in blood flow of more than 90% (16). For a rapid initial assessment of regional wall motion in emergency situations, the TG mid-SAX view is chosen (Fig. 26). All three major branches of the coronary circulation are represented in this echocardiographic plane. The mid-esophageal views (ME 4 Chamber, ME 2 Chamber, and ME LA) supplement the TG mid-SAX view (especially when difficult to obtain), providing a more thorough evaluation

**Figure 25** Impaired (*left*) and normal (*right*) regional left ventricular wall motion, transgastric short-axis view, M-Mode. *Note:* Normal pattern of contractility with systolic thickening and inward motion. Akinetic myocardial segment with loss of systolic thickening and inward motion (of the posterior wall).

of the basal, mid and apical levels of the LV (Fig. 26). For a comprehensive echocardiographic evaluation of regional LV function, the 16-segment model endorsed by the ASE is recommended (14).

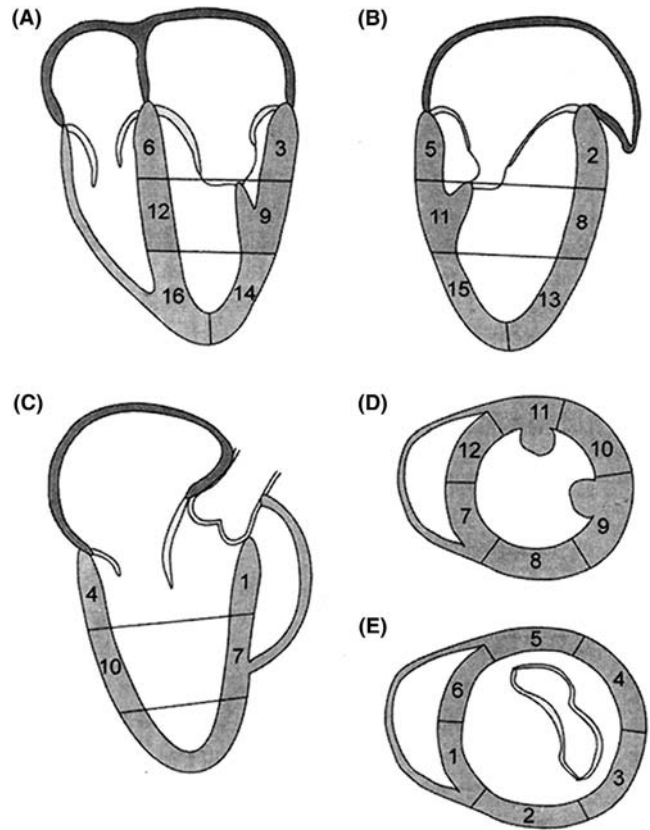

✎ The single most important cause of regional wall motion abnormality is myocardial ischemia. ✎ Other causes of wall motion abnormalities include myocardial hematoma, myocardial contusion, intraventricular conduction abnormalities (left anterior hemiblock or pacemaker stimulation), myocardial stunning, intracoronary air, hypovolemia, and mitral stenosis. Loss of active thickening of the myocardium is an earlier (seconds) and more sensitive sign of interrupted myocardial blood flow compared to ST-T segment alterations (minutes) or increases in PACOP (low sensitivity and specificity) (3,11). However, TEE assessment of regional wall motion abnormalities has some limitations, in particular with the less experienced investigator. Oblique echocardiographic views can mimic (foreshortening) or miss (pseudo thickening) even significant, extensive regional wall motion abnormalities.

**Right Ventricular Function**

Compared to evaluation of global LV function, echocardiographic assessment of global and regional RV function is complicated by the nongeometric, asymmetric, crescent shape of this chamber, making quantitative measurements less reliable. Thus, RV size and function is best assessed in a qualitative manner (17). Standard views in which to evaluate RV size and function are IG mid-SAX, ME 4

**Table 4** Contraction Patterns of Normal and Altered Regional Left Ventricular Function

Contractility	Radial shortening	Thickening
Normal	More than 30%	>30%
Hypokinetic	10–30%	10–30%
Akinetic	None	None
Dyskinetic	Systolic radial widening	Systolic thinning

**Figure 26** Sixteen-segment model of the left ventricle. (A) Four-Chamber view shows the three septal and three lateral segments. (B) Two-Chamber view shows the three anterior and three inferior segments. (C) Long-axis view shows the two anteroseptal and two posterior or inferolateral segments. (D) Mid-short-axis view shows all six segments at the midlevel. (E) Basal short-axis view shows all six segments at basal level. Basal segments—1, basal anteroseptal; 2, basal anterior; 3, basal lateral; 4, basal posterior (inferolateral); 5, basal inferior; and 6, basal septal. Mid-segments—7, mid-anterseptal; 8, mid-anterior; 9, mid-lateral; 10, mid-posterior (inferolateral); 11, mid-inferior; and 12, mid-septal. Apical segments—13, apical anterior; 14, apical lateral; 15, apical inferior; and 16, apical septal.

Chamber, TG RV inflow, and the ME RV inflow–outflow views (Table 5).

The RV consists of an RV free wall and a septal wall, which it shares with the LV. The RV free wall can be divided into basal, mid, and apical segments corresponding to the adjacent LV segments in the ME 4 Chamber view. Normal RV thickness is less than half of the LV and measures <5 mm at end diastole. Right ventricular hypertrophy (RVH) is present when RV wall thickness exceeds 6 mm. In patients with RVH, a prominent trabeculae pattern is often seen, especially at the apex.

In the ME 4 Chamber view, normal RV appearance is triangular compared to the elliptical LV, and its length extends for only about two-thirds the length of the LV. The apex in this view is formed by only the LV, and the end diastolic cross-sectional area of the RV is less than 60% of the LV area. When RV area exceeds LV area, severe RV enlargement is present. As the RV dilates, its shape changes from triangular to round. When the cardiac apex is formed by the RV rather than the LV, the RV is dilated. Because of the

**Table 5** Echocardiographic Parameters that Describe Right Ventricular Function

Parameter	Normal	Pathological
RV shape	Semilunar	Round, dilated
RV size	<2/3 LV size	<LV size, moderate enlargement >LV size, severe enlargement
RV free wall thickness	<6 mm	<10 mm, moderate hypertrophy >10 mm, severe hypertrophy
RV free wall motion	Normal	Hypokinetic, moderate dysfunction Akinetic, severe dysfunction
Septal motion	Contraction with LV	Paradoxical contraction with RV Diastolic leftward shift

Abbreviations: LV, left ventricle; RV, right ventricle.

complex geometry and contraction pattern of the RV, regional wall motion can be difficult to assess. In general, akinesia or dyskinesia of the RV free wall needs to be present for wall motion abnormality to be definitively diagnosed.

Normally, the ventricular septum functions as part of the LV and maintains a convex curvature toward the RV throughout the cardiac cycle. As the RV dilates or hypertrophies, the septum flattens. When RV mass exceeds LV mass, paradoxical septal motion appears (inward movement toward LV in diastole). With RV volume overload (atrial septal defect, tricuspid regurgitation, and pulmonic regurgitation) septal distortion is maximal at end diastole, corresponding with timing of peak diastolic overfilling of the RV. During systole, the end-diastolic septal flattening reverses, and there is paradoxical systolic septal motion toward the RV cavity. In RV pressure overload, maximal septal distortion is at end systole and early diastole, corresponding to the time of peak systolic afterload of the RV.

## ASSESSMENT OF VALVULAR FUNCTION

Quantitative detailed assessment of valvular dysfunction necessitates advanced knowledge in echocardiography, valvular anatomy, and cardiology. It should be done only after a comprehensive echocardiographic examination, including multiple 2D planes and various PW and CW Doppler calculations. There are a number of possible pitfalls when assessing the hemodynamic significance of a valvular lesion, and only specially trained cardiologists and cardiovascular anesthesiologists should do advanced echocardiographic evaluation of valvular lesions. However, an abbreviated 2D and semi-quantitative color Doppler examination of the valves must be done in the case of hemodynamically unstable or septic patients. This preliminary qualitative echocardiographic valve assessment can be done with a basic level of education in echocardiography, and allows one to exclude significant valvular pathology and reliably detect common valvular lesions relevant for the trauma or critically ill patient in the SICU: vegetations in patients with endocarditis, acute valvular regurgitation after trauma, myocardial infarction, septic valve destruction, and acute aortic insufficiency (AI) in patients with type A aortic dissection.

### Mitral Valve Evaluation

The MV can be easily examined with TEE. The MV structures include the annulus, leaflets, chordae tendinae,

papillary muscles, myocardium, and the fibrous skeleton of the heart. The MV annulus is described as a saddle-shaped, three-dimensional ellipsoid with a high, more basal short axis (seen in the ME LAX view), and a lower, more apical long axis (seen in the ME commissural view). The MV is bileaflet with an anterior and posterior cusp (Fig. 27). The larger anterior cusp covers approximately two-thirds of the area of the mitral annulus and one-third of the circumference. The smaller posterior cusp covers approximately one-third of the area of the mitral annulus and about two-thirds of the circumference. The valve leaflets join at the anterolateral and posteromedial commissures. The posterior leaflet is divided into three scallops (P1, P2, and P3; Carpentier classification) with corresponding adjacent anterior valve segments (A1, A2, and A3).

The anterolateral and posteromedial papillary muscles attach to the MV via the chordae tendinae with both muscles

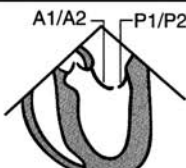

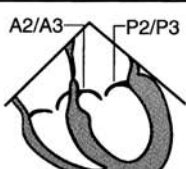

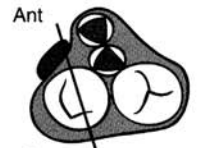

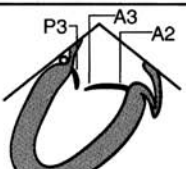

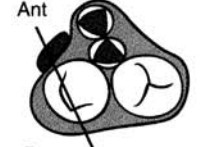

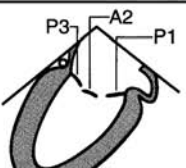

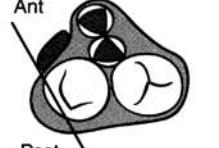

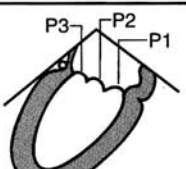

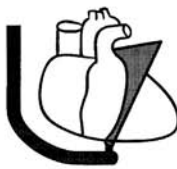

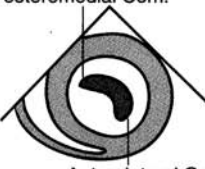

**Figure 27** Mitral valve anatomy: transgastric basal short-axis view. The valvular tissue can be divided into two commissural regions: anterolateral and posteromedial. There are two leaflet areas: anterior and posterior. Clefs along the free margin of the posterior leaflet identify the individual scallops as P1, P2, and P3. The anterior leaflet has less clearly defined segments, designated A1, A2, and A3.

attaching to both valve leaflets. TEE examination consists of four mid-esophageal views (ME 4 chamber, ME commissural, ME 2 Chamber, and ME LAX) and two transgastric views (TG basal SAX and TG 2 Chamber). Using the mid-esophageal views one can closely look at all segments of the MV (Fig. 27). The systematic evaluation of the MV is depicted in Figure 28.

✎ **Color flow Doppler serves as an important screening tool in the mid-esophageal views to detect evidence of mitral regurgitation (MR).** ✎ Secondary effects of MR include dilation of the LA or LV. If MR is detected, a more thorough evaluation can be done with transmitral and

pulmonary venous PW Doppler studies. The causes of MR can be divided into abnormalities of the valve leaflets, mitral annulus, chordae tendinae, and papillary muscles.

Mitral stenosis is now a rare finding, as the occurrence of rheumatic heart disease has decreased with the use of antibiotics. Features of mitral stenosis seen on TEE exam include restricted movement of the valve leaflets, commissural fusion, and calcification of the valvular and subvalvular structures. Left atrial dilatation with a normal or more typically small empty LV may also be seen. Additional valuable information can be obtained by using CW Doppler studies.

<p><b>5-Chamber</b> Allows localization of pathology to the anterior or posterior leaflet. Specific scallops difficult to identify based only on this view, but generally shows anterior elements of the valve.</p>		
<p><b>4-Chamber</b> Allows localization of pathology to the anterior or posterior leaflet. Specific scallops difficult to identify based only on this view, but generally shows posterior elements of the valve.</p>		
<p><b>2-Chamber Anterior</b> Shows a long anterior leaflet (A2/A3) and a short segment of the posterior leaflet (P3). Note that the part of the anterior leaflet that coapts with the P3 scallop is the A3 segment.</p>		
<p><b>2-Chamber Mid</b> Three scallops and two coaptation points are seen: P3, P1, and a variable amount of A2, which disappears during diastole.</p>		
<p><b>2-Chamber Posterior</b> No coaptation point seen. The plane cuts through the posterior leaflet only. Usually demonstrates mostly P2, with some P1 and P3.</p>		
<p><b>Short Axis</b> This view is most useful with color Doppler to localize the site of regurgitation. However it rarely demonstrates the nature of the pathology.</p>		<p>Posteromedial Com.  Anterolateral Com.</p>

**Figure 28** Systematic examination of the mitral valve. In this examination, the mitral valve is viewed in multiple cross-sections to delineate leaflet anatomy. The “5-Chamber” cross-section is accomplished by withdrawing the probe slightly from the standard 4-Chamber cross-section, until the left ventricular outflow track is in view. The center column shows the planes of the different cross-sections as viewed from directly above the base of the heart. The 2-Chamber “anterior,” “mid,” and “posterior” cross-sections are variations of the standard 2-Chamber cross-section and are accomplished by turning the probe from the patient’s right to left. P1, P2, and P3 refer to the three scallops of the posterior mitral leaflet, and A1, A2, and A3 refer to the juxtaposed segments of the anterior mitral leaflet. The right column shows the leaflet segments seen in the corresponding cross-section. *Source:* From Ref. 49.

### Aortic Valve Evaluation

High-resolution images of the AV can easily be obtained with TEE because of its close proximity to the esophagus. The AV consists of three cusps (right, left, and noncoronary) with three outpouchings called the sinuses of Valsalva. Normal AV area ranges from 2–4 cm<sup>2</sup>. TEE examination includes the ME aortic short axis, ME LAX, TGLAX, and deep TGLAX views.

The most frequent cause of aortic stenosis is calcific degeneration associated with aging. Other causes include rheumatic disease, congenital bicuspid or unicuspid valve, subaortic and supravalvular stenosis. In the ME AV SAX view, findings may include fusion of the commissures, calcification, and restricted valve movement. Planimetry can be used to estimate valve area, but in the presence of calcifications. Doppler studies across the valve in the deep transgastric view give a better estimate of valve area. In the ME AV LAX view restricted valve movement, calcifications- and doming of the valve leaflets may also be seen.

AI can be caused by problems of the aortic cusps or by problems with the ascending aorta. Valvular problems include endocarditis, traumatic injury, rheumatic and myxomatous changes, and congenital abnormalities. Conditions affecting the ascending aorta include aortic dissection (from blunt trauma or hypertension), chronic hypertension, Marfan's syndrome, cystic medial necrosis, and aneurysm. The 2D echocardiography using the aortic views can be used to look for structural abnormalities of the AV, such as vegetations, abscess formation, failure of aortic cusps to coapt properly, thickening of aortic cusps, dilatation of the aortic annulus, and presence of a bicuspid valve. Dilatation of the LV occurs from chronic volume overload, and may also be noted. Color Doppler using the ME AV SAX view can help localize the site of regurgitation. Color Doppler of the AV long-axis view can be used to screen for and quantify AI. Using the ratio of jet width to LVOT has been used to quantify the severity of AI (<0.25: 1+, 0.25–0.46: 2+, 0.47–0.64: 3+, and >0.64: 4+).

### Endocarditis

Suspected infective endocarditis is a common indication for a TEE examination in medical ICU patients (18–20). TEE is superior to transthoracic echocardiography (TTE) for the diagnosis of smaller vegetations and/or complications of endocarditis (Fig. 29). This TEE examination frequently leads to significant changes in the patient's clinical management (18–24). **The classic echocardiographic features of infective endocarditis are vegetations: shaggy, irregular, highly mobile echo-dense structures located on the low-pressure side of a valve leaflet.** On occasion, the

**Figure 29** Infective endocarditis with highly mobile vegetation (arrow) on the anterior mitral valve leaflet. Abbreviation: LV, left ventricle.

vegetation will appear to be attached to an intracardiac foreign body, such as a central venous catheter or a pacemaker lead. The length of the vegetation (>15 mm) and the mobility (highly mobile, small basis) seem to predict probability of embolism. Consequently, besides complications (leaflet perforation, abscesses, valve destruction, and fistulas), length and mobility of the vegetation should be considered when discussing a possible surgical intervention. Diagnostic sensitivity and specificity of TEE for infective endocarditis is high (>90%) (1,3,15,22). However, pre-existing valve pathology (myxomatous degeneration, annular calcifications) can make the diagnosis less reliable. Only repeated examinations documenting progression or regression of the echo densities establish a definite diagnosis. Acute endocarditis remains a clinical diagnosis and requires positive blood cultures. The 2D examination should also focus on leaflet thickening or calcifications, reduced systolic valve opening with doming of leaflets (in mitral stenosis typically combined with LA enlargement and spontaneous echo contrast), structural lesions causing acute valvular regurgitation (aortic cusps prolapse into LVOT, MV leaflet prolapse into LA, leaflet perforation, ruptured chordae tendinae or papillary muscle), and mitral or tricuspid annular dilatation.

Color Doppler interrogation in multiple cross sections allows a good semi-quantitative assessment of the hemodynamic significance of a regurgitant lesion using length,

**Table 6** Color Doppler Classification of the Severity of Mitral and Aortic Valve Regurgitation

Severity	Mitral regurgitation extension of regurgitant jet in LA	Aortic regurgitation extension regurgitant jet in LVOT
Trivial, grade 1	Mitral annulus area only	25% LVOT diameter
Mild, grade 2	1/3 LA height	25–45% LVOT diameter
Moderate, grade 3 <sup>a</sup>	2/3 LA height	45–60% LVOT diameter
Severe, grade 4 <sup>a</sup>	Roof of LA or pulmonary veins	60% LVOT diameter

<sup>a</sup>Any mitral regurgitant jet with a width more than 5.5 mm at the origin (vena contracta) and any aortic regurgitant jet exceeding the tip of the anterior mitral valve leaflet should be considered hemodynamically significant. Note that an equivalent classification of regurgitant jets in the right atrium may be used to stage tricuspid regurgitation.

Abbreviations: LA, left atrium; LVOT, left ventricle outflow tract.

**Figure 30** Mitral valve regurgitation, grade IV, mid-esophageal 4-Chamber view, color Doppler. Eccentric jet, along the posterior MV leaflet reaching the roof of the LA. Abbreviations: LV, left ventricle; LA, left atrium; AMVL, anterior mitral valve leaflet.

diameter, and area of the regurgitant jet (Table 6; Fig. 30). Previously unknown stenotic lesions are a rather uncommon echocardiographic finding in ICU patients evaluated with TEE and should always be assessed by a cardiologist, as should any suspected pathology in patients with valve prosthesis.

## ACUTE TRAUMA EVALUATION

TEE is an important tool for the evaluation of the heart, great vessels, and surrounding tissues in the trauma patient. It is useful following both penetrating and blunt chest traumatic injuries. The following section will first discuss the clinical usefulness of TEE in trauma patients, followed by a description of the main differential diagnosis of lesions found in that population. Limitations and safety issues of TEE in trauma patients will also be discussed.

A retrospective study published by Mollod and Felner (25) in patients with either penetrating or blunt chest trauma, showed that 15 of 16 patients had significant abnormal findings, resulting in new surgical or medical management of the lesions. In a landmark prospective study on the systematic use of TEE on patients with multiples injuries, Catoire et al. (26) studied 70 patients: group 1 (patients in whom the initial clinical evaluation supported the need for further evaluation), and group 2 (patients without symptoms of thoracic or mediastinal injury). Use of the TEE yielded new diagnoses in 70% of trauma patients in group 1, but only in 33% of those in group 2. They concluded that TEE is of utmost importance in patients with multiple injuries, with or without clinical evidence of thoracic or mediastinal injuries. Another prospective study with 34 consecutive blunt chest traumas revealed that 65% of the patients had clinically relevant TEE findings, ranging from myocardial contusions to valvular ruptures (27). Karalis et al. (28) compared TTE with TEE in a prospective study of 105 patients with severe blunt chest traumas. TEE appeared to be more sensitive than TTE, especially for aortic lesions.

However, compared to newer multidetector CT scans, TEE is supplementary (see Volume 1, Chapter 25). TEE misses significant injuries in the arch and in branch

vessels, which are seen on newer multidetector CT scans, and lacks the ability to provide comprehensive information about other thoracic structures. On the basis of available literature, TEE is an adjunct diagnostic modality evaluation of the multiply injured patient. Its greatest asset is in the realm of continuous intraoperative monitoring of myocardial function, filling states, and assessment of hemodynamic instability. ⚡ **The use of TEE in the acute trauma patient is only indicated in patients without esophageal injury, and after intubation of the trachea has been achieved.** ⚡

## Practical Approach

Most of the information necessary for an accurate assessment of the heart and surrounding vascular structures on a trauma patient can be obtained with the abbreviated TEE examination described earlier (section “Abbreviated Trauma Transesophageal Echocardiography”). In addition, the proximal ascending aorta, distal arch, and the descending aorta views must be evaluated for a complete assessment. PW and color Doppler can be used to characterize aortic flow and velocity. In aortic dissection, the presence or absence of flow in one lumen is very helpful to identify the true and false lumen. Laminar versus the turbulent characteristic of the flow pattern can be used for a better understanding of the anatomy of the lesion. It is crucial to begin the examination with a differential diagnosis in mind. Common traumatic injuries include myocardial contusion, pericardial effusion with or without tamponade physiology, valvular rupture, traumatic shunts and fistulas, thrombus, aortic trauma, and hypovolemia. Aortic dissection, myocardial contusion, and surgically correctable lesions will be discussed elsewhere in more detail.

## Pericardial Diseases: Effusion, Hematoma, and Tamponade

⚡ **Echocardiography is the diagnostic tool of choice to detect and evaluate pericardial effusion and tamponade (29).** ⚡ Pericardial tamponade is an important diagnostic consideration in patients presenting with tachycardia, low cardiac output, and high filling pressures. Theoretically, pericardial tamponade can be differentiated from myocardial failure by pulsus paradoxus. However, in clinical practice, echocardiography leads to the diagnosis. Pericardial effusion and hematoma are characteristically echo-free spaces between the epicardium and the pericardium, and are detectable and diagnosed with sensitivity and a specificity of almost 100% (Fig. 31). Quantification has been tried, but in clinical practice semi-quantitative description of the amount of pericardial effusion is more common. Pericardial thrombus from coagulated blood is difficult to detect, as the echo density is almost the same as that in myocardium (Fig. 32). Coagulated blood in the pericardium is often found in atypical locations and restricted to a small area (Fig. 33). Therefore, diagnosis of shock secondary to pericardial tamponade by thrombus may be very tricky and should be done only by an experienced echocardiographer. Whether pericardial effusion is of any hemodynamic relevance can be judged by certain echocardiographic findings (Table 7), but if there is any doubt, decision for emergency pericardiocentesis should be based predominately on hemodynamics. The most important echocardiographic indicator of hemodynamic significance is the systolic inward shift of the RA (Fig. 34). The most specific finding is diastolic collapse of the RV wall. Diastolic collapse of the RV indicates that the pericardial pressure exceeds the intramural pressure and is

**Figure 31** Pericardial effusion. (Left) A transgastric mid-short-axis view demonstrating pericardial effusion (PE) surrounding heart. (Right) A mid-esophageal four-chamber view demonstrating fluid PE within the pericardial sac impinging upon the right atrium and ventricle. Abbreviations: RA, right atrium; RV, right ventricle; LV, left ventricle; PE, pericardial effusion.

consequently a rather late indicator of tamponade in case of RV pressure overload (e.g., pulmonary hypertension). The amount of effusion present is also a poor indicator of the hemodynamic relevance. Small amounts of blood (60–80 mL) accumulating within minutes may cause shock, whereas large amounts of effusion accumulating over weeks may be well tolerated.

### Aortic Trauma

Approximately 80% of patients who sustain traumatic aortic injury (TAI) die at the accident site (30). For the remaining 20% that reach the hospital alive, an expeditious and precise evaluation of their injuries is conducted as described in Volume 1, Chapters 8 and 14. Computed tomography (CT) technology has become the dominant imaging modality for providing definitive diagnosis of blunt TAI (see Volume 1, Chapter 25). Aortography is used where new-generation

CT is not available, and in the further evaluation of aortic branch vessel injuries that are ambiguously visualized on thoracic CT. TEE also can be used in the early diagnosis of aortic injuries (aortic wall hematoma, intimal flap, and disruption), and is useful in the setting of critically ill trauma victims because it can be performed in the operating room, SICU, or the trauma resuscitation unit. However, the TEE is mainly adjunctive to multidetector CT angiography in terms of initial evaluation.

In order to understand the images seen with TEE during the aorta evaluation, a brief review of the aortic anatomy and history is useful. The aorta is formed by three main layers of tissue, from the inside lumen to the outside. There is the intima, a regular, smooth and thin layer of endothelial cells; the media, which is a thicker muscular layer; and the adventitia, a stronger and more fibrotic layer of tissue. Current TEE probes provide sufficient spatial resolution to differentiate between the intima, media

**Figure 32** Pericardial thrombus—mid-esophageal bicaval (ME bicaval) view. Arrow denotes pericardial thrombus. There is increased echodensity of the thrombus compared to blood. Abbreviations: LA, left atrium; RA, right atrium.

**Table 7** Echocardiographic Signs of Pericardial Tamponade

Moderate to large pericardial effusion
RV collapse during diastole
RA collapse during systole
LA collapse during systole
LV collapse during diastole
Decreased LV filling with inspiration and decreased transmitral E-wave velocity with inspiration <sup>a</sup>
Increased RA and RV filling with inspiration and increased tricuspid E-wave velocity with inspiration <sup>a</sup>

<sup>a</sup>Assumes spontaneously breathing patient.

Abbreviations: LV, left ventricle; RV, right ventricle; RA, right atrium; LA, left atrium.

**Figure 34** Systolic inward shift of right atrium (RA)—ME 4 Chamber view showing tamponade with inward indentation of the RA. Abbreviations: LA, left atrium; RA, right atrium; RV, right ventricle.

and adventitia, based on their thickness and differing echogenicities. Accordingly, a variety of traumatic aortic injuries have been described, depending on reference consulted (30,31). Traumatic aortic injuries include intimal tears, either localized or with extension creating a traumatic aortic dissection, aortic ruptures, and intramural and mural hematomas. In more than 90% of the cases, the initial tear occurs at the aortic isthmus, defined as the aortic segment between the left subclavian and the first intercostal arteries.

Abrupt decelerations have a maximal impact at this location because the aorta is relatively immobile (attached by the ligamentum arteriosum) compared to the more freely mobile arch. Lesions can also be found in the arch vessels and in the descending thoracic aorta at the level of the diaphragm.

Although aortography had long been considered the gold standard for aortic evaluation, this modality presents significant limitations in its ability to diagnose intimal lesions without dissection and intramural hematoma. CT angiography using high-resolution multidetector devices is now emerging as the gold standard. The sensitivity and specificity of both TEE and spiral CT angiography are clearly above 95%, when compared to surgical or post-mortem diagnosis (32). In 1993, Nienaber et al. (33) compared TEE, CT scan, and MRI for their diagnostic ability for aortic dissection on 110 patients. The sensitivity and specificity of MRI proved to be slightly superior to TEE and CT scan. However, MRI accessibility for the unstable patient is somewhat limited, and that represents a significant problem for the trauma population. Panco et al. showed that TEE was not only very accurate in the establishment of the appropriate diagnosis, but provided other crucial information, such as presence and localization of intraluminal thrombus, function of the AV, possible retrograde coronary dissections with LV contractile dysfunction, and hemodynamically significant pericardial effusions. TEE has also been proven to be highly valuable for follow-up evaluation of the initial pathology (34).

#### Intimal Tears

Localized intimal tears appear as small (1–2 mm), thin, mobile, echo-dense intraluminal appendages of the aortic walls. The media and adventitia are intact, and no turbulent intra-aortic flow is visualized when color Doppler mapping studies are done over the aortic wall. The aortic contour is also preserved. Vignon et al. (31) showed in their 1995 study that the conservative management of localized tears was appropriate, and that no surgical intervention was needed. At the other end of the spectrum, it is possible that an intimal tear can be large enough to create an entry point for the blood stream and create a separation between the intima and the media. This will result in the creation of an intraluminal intimal flap (Fig. 35). These lesions are called traumatic aortic dissections. The intimal flap is usually thin ( $2.2 \pm 0.7$  mm), highly mobile, and travels parallel to the isthmus wall. The short-axis view of the aortic lumen will usually present two lumens of different sizes. The difference between the true and the false lumen is

**Figure 35** Aortic tear. Both images are descending aortic short-axis views (left). The descending aorta is visualized and the intimal flap (\*) is shown (right). The aortic dissection with intimal flap (\*), as well as the accompanying hematothorax (\*\*) are shown.

made by evaluating the systolic flow expansion of the true lumen. Interestingly, the true lumen is very often the smaller one. Finally, the aortic contour is usually symmetrically enlarged (31). The management of traumatic aortic dissection is usually medical, if limited to the descending aorta and if no organ perfusion appears to be compromised. This is supported by the natural history of these lesions: the false lumen will most likely thrombose and a clot can be seen on follow-up studies.

### **Aortic Ruptures**

Aortic ruptures, also called traumatic aortic disruptions, occur when the lesions involve the entire intimal and medial layers, with the adventitia usually intact. Appropriately, these lesions are also called subadventitial ruptures. An aortic rupture will present with a thick, relatively immobile medial flap ( $4.2 \pm 0.8$  mm) traveling perpendicular to the aortic isthmus and traversing the entire aortic lumen (31). Two lumens can be seen in the short-axis views, but they are usually about the same size and have even flows, with Doppler evaluation. The aortic contour will also appear irregularly enlarged. Because those patients may die suddenly secondary to a rupture of the adventitial layer, they should be managed surgically as soon as possible. TEE can help the trauma physician distinguish between an intimal tear with dissection and an aortic rupture. This difference is of crucial importance, because of their different management strategies.

### **Intramural Hematoma**

Aortic trauma can also result in rupture of the vasa vasorum, resulting in an intramural hematoma. TEE examination shows no intimal flap and an intact intima. The aortic wall appears to have a crescent or circular increased wall thickness. Intramural hematoma involving the ascending aorta typically measure  $7 \pm 2$  mm, whereas descending aorta hematoma measure  $15 \pm 6$  mm. The intima is still smooth with no apparent rupture. The wall hematoma may also contain a hypoechoic area, representing small pockets of blood inside the wall. There is no communication between the thickened wall and the vessel lumen when evaluated by Doppler echocardiography. The natural history of intramural hematoma is such that 60% of patients will progress to rupture or dissection within a one-year follow-up. Nienaber et al. (35) clearly demonstrated that intramural hematoma are part of the spectrum of aortic dissection with flap and should clinically be managed the same way.

### **Myocardial Contusion**

Myocardial contusion is characterized by direct myocardial injury or cell death of a variable portion (width and thickness) of the heart muscle. Clinically, this diagnosis can be made by ECG changes, cardiac enzyme elevation, nuclear studies, or echocardiographic evaluation (see also Volume 1, Chapter 25).

The classic echocardiographic myocardial contusion will be defined by the presence of new segmental wall motion abnormalities, often associated with a reduced global contractile function and an anterior pericardial effusion. Because most of the myocardial trauma is related to the rapid deceleration and contact between the heart and the sternum, the most anterior myocardial structures (RV free wall and anterior wall of the LV) are more commonly involved. The ME RV inflow–outflow view, the ME 4 Chamber view, and the ME 2 Chamber views are most useful

for evaluation of the relevant structures. In addition, the TG mid-SAX view can help identify anterior pericardial effusions. New wall motion abnormalities are present in areas where there is enough myocardium to be damaged and will usually appear to be more echogenic compared to other segments. This precision is important because the patient may have significant baseline wall motion abnormalities.

One important point related to the early diagnosis of myocardial contusion is to identify the diagnostic modality that will be more powerful in predicting serious complications. In a large meta-analysis including more than 4000 patients of both retrospective and prospective studies, Maenza et al. (36) showed that ECG abnormalities and high rise in CPK-MB enzymes were the best ways to identify patients who will develop complications related to myocardial contusion. Only a few recent TEE studies were included in this meta-analysis. A more recent study published in 2001 by Wiener et al. (37) compared the usefulness of TEE to the CPK-MB, in 50 patients. Even though the study was limited, TEE was shown to be a better diagnostic tool compared to the use of cardiac enzymes alone, for the diagnosis of more serious myocardial contusions, including those with significant pericardial effusions and severe wall motion abnormalities.

### **Surgically Correctable Lesions**

Significant chest trauma, either blunt or penetrating, can cause structural damage to the heart. Most frequently involved are one or both atrioventricular valves. The TV and MV can have either a valve laceration or rupture of a supporting structure (chordae tendinae, papillary muscle), resulting in hemodynamically significant regurgitant lesions (38–41). Traumatic fistulas between the sinuses of Valsalva and the main PA or the aorta have also been described (25). Penetrating trauma can cause pericardial lesions and potentially myocardial tear with pseudoaneurysm formation or VSD. In all these cases, TEE permits prompt diagnosis and aggressive intervention leading to successful surgical repair of complex cardiac traumatic lesions. The abbreviated TEE examination described earlier can help the clinician to establish or rule out the presence of those diagnoses, even during the early evaluation period.

### **Other Diagnoses**

Wall thrombus secondary to severe hypokinetic or akinetic wall segments can develop quickly after trauma and represent a serious threat for either pulmonary or systemic emboli (38). The thrombi are usually adjacent to the less contractile myocardial segments and will appear as an echo-dense (brighter) signal with an apparent increase in wall thickness protruding inside the chamber cavity. Mobile thrombus may indicate impending embolization.

### **Limitations of TEE for Trauma Evaluation**

Like any other diagnostic modality, TEE has limitations that must be considered when evaluating the trauma patient. Of great initial importance is the recognition that TEE is contraindicated in the setting of known or likely esophageal injury (31). The next important consideration is that the trauma patient is at high risk for pulmonary aspiration. Thus, TEE should only be employed in those patients who are already tracheally intubated (i.e., the airway is protected).

The acoustic shadow created by the trachea and left bronchus make it difficult, if not impossible, to visualize the distal part of the ascending aorta and proximal arch.

Fortunately, isolated lesions of these areas are extremely rare, and when injuries are present, they typically extend beyond this “blind spot,” becoming accessible for evaluation by TEE. Another potential pitfall is the misdiagnosis of artifacts for real lesions. For example, reverberation artifact from a PA catheter or side lobes artifact from atherosclerotic plaque can be mistaken for aortic dissection, particularly in the proximal ascending aorta. It must be kept in mind that a real pathologic finding will be seen consistently in multiple imaging planes and not only in one specific view. One must also keep in mind that TEE is not the perfect tool to evaluate the LV apex. TTE can complete the initial TEE examination if nothing convincing is seen with TEE.

## ECHOCARDIOGRAPHY IN THE SURGICAL INTENSIVE CARE UNIT

Studies conclusively demonstrating that diagnostic information yielded by a TEE exam can reduce morbidity or mortality in particular clinical scenarios are completely missing (3). Training and availability of TEE vary markedly between institutions, and often TEE is not used only because the equipment or an experienced echocardiographer is not available. Consequently, indications for a TEE examination in the SICU vary tremendously among institutions. An increasing number of retrospective studies have demonstrated increasing benefit of TEE on patient management in the ICU. About 20% to 40% of all TEE examinations in the ICU yield new unexpected information with therapeutic consequences (Table 8) regardless of whether surgical, general, or medical ICUs are studied (18–24). The most common cardiocirculatory problems evaluated with TEE were hemodynamic instability, monitoring of LV filling, monitoring of global RV or LV function, suspected valvular lesions, and endocarditis in septic patients (Table 1).

### TEE vs. Transthoracic Echocardiography

Although the focused abdominal sonography for trauma (FAST) is now a standard portion of the initial evaluation of the trauma patient as described in Volume 1, Chapters 8, 16, and 27, the surface or TTE can also be used in selected patients in the ICU. The diagnostic sensitivity and specificity of TTE is often limited in surgical, post-traumatic, or ventilated patients. Inability to adequately position the patient, positive-pressure ventilation, hematoma, subcutaneous emphysema, wounds, surgical incisions, chest tubes, and dressings all limit the possible windows for a comprehensive

transthoracic examination and often result in poor imaging quality (20). In about 25% to 50% of all ICU patients investigated with both TTE and TEE, only TEE revealed important diagnostic information. This new information changed the diagnosis or treatment prescribed by TTE in 15% of patients (19,22). Furthermore, TEE was more specific and sensitive when compared to TTE in certain clinical scenarios involving suspected endocarditis and evaluation of valvular dysfunction (Table 9). Therefore, TEE is often preferred to TTE for post-traumatic or postsurgical patients in the ICU requiring evaluation of cardiothoracic structures.

### TEE vs. Pulmonary Artery Catheter

The PA catheter has served as the gold standard for the advanced hemodynamic monitoring of unstable critically ill patients over the last several decades. No prospective clinical study has evaluated if or when semi-invasive monitoring with TEE should replace PA catheterization. In clinical practice, TEE has replaced PA catheterization in some institutions. In a significant number of patients, TEE yields important additional diagnostic information and a complete evaluation of an unstable patient is probably optimized if the PA catheter data and TEE are used together (5,7,9,11). Both techniques have their particular advantages and limitations (Table 10); hence, these modalities should be considered to be complementary. TEE yields anatomic information that cannot be obtained with a PA catheter (valvular dysfunction, septal rupture, pericardial tamponade, and end-diastolic LV dimension) and provides a fast answer to most questions that a clinician may have concerning a hemodynamically unstable patient. The major advantage of a PA catheter is the easy and reliable determination of cardiac output, stroke volume, filling pressures, and mixed venous oxygen saturation. TEE allows estimation of systolic PA pressure in the presence of tricuspid regurgitation; however, a detailed characterization of pulmonary vascular pathology (e.g., pulmonary arterial resistance) is only possible with PA catheter. Stroke volume calculations are possible with TEE, but can be quite cumbersome in clinical practice.

### Contraindications and Complications of TEE for Critical Care

☞ There are few contraindications for a TEE examination, most of them related to a pre-existing oropharyngeal or esophageal pathology. ☞ Some of these contraindications (i.e., esophageal varices, penetrating

**Table 8** Impact of New Diagnostic Information from Transesophageal Echocardiography

Evaluation of left atrial pathology (e.g., left atrial appendage thrombus)
Search for cardiac source of emboli

chest trauma without prior esophagoscopy) may be considered relative in the case of life threatening hemodynamic instability (Table 11).

Most experts consider TEE a safe technique with a low complication rate, which has been well documented for sedated and nonintubated cardiac patients (Table 12). Frequency and type of complication may be different in anesthetized, intubated patients in the ICU; however, data are almost completely missing. Theoretically, pressure or thermal lesions may occur during prolonged probe insertion. Therefore, the probe should be left in the esophagus only for a few hours. Transient bacteremia is another theoretical consideration, which is considered trivial by most experts. Prophylactic antibiotics are not generally used. In smaller children, esophageal probes may cause airway compromise. Mortality associated with TEE has been solely secondary to esophageal perforation in patients with unidentified pre-existing esophageal pathologies.

## RESCUE TRANSESOPHAGEAL ECHOCARDIOGRAPHY FOR THE HEMODYNAMICALLY UNSTABLE PATIENT

Sudden, unexpected hemodynamic instability is the most common indication for a TEE examination in the ICU (18–22). ⚡ **TEE examinations in patients with acute hemodynamic disturbances result in a major therapeutic impact (surgical or medical) in over 50% of patients examined (10,19,21).** ⚡ According to the ASA practice guidelines, (3)

acute and persistent life-threatening hemodynamic instability is a class 1 indication for a perioperative TEE investigation in noncardiac surgical patients. Although there are only few clinical studies prospectively or independently evaluating the diagnostic efficiency of TEE in patients with hemodynamic instability, those who regularly use the TEE to diagnose unstable patients in the SICU are well aware of the benefits. TEE is a minimally invasive bedside test and can avoid potentially dangerous transport of unstable patients within the hospital (e.g., to the radiology department for CT scan or angiography). Compared to the invasive evaluation of right heart catheterization, diagnostic information is typically available more rapidly with TEE. In addition, TEE yields information about anatomical lesions and blood flow abnormalities that cannot be obtained with alternative diagnostic tests in clinical practice (e.g., traumatic MV insufficiency, post infarct VSD).

## Practical Approach

In patients with acute hemodynamic instability, there are five echocardiographic parameters that should be evaluated as rapidly as possible: (i) preload of the RV and LV, (ii) global and regional myocardial function, (iii) acute valvular dysfunction, and (iv) cardiac, and (v) extracardiac anatomical or structural lesions that may be responsible for shock. The time necessary to evaluate these parameters may vary, but the establishment of a diagnosis is possible within a few minutes. A basic, abbreviated trauma TEE exam (see section “Abbreviated Trauma Transesophageal Echocardiography”) rather than a comprehensive echocardiographic evaluation is often most appropriate, especially when cardiopulmonary arrest is imminent. Abnormal LV preload and myocardial dysfunction are important diagnostic possibilities (Table 13). Common anatomical or structural lesions amenable to immediate echocardiographic diagnosis in patients with sudden, unexpected hemodynamic instability include (i) pericardial effusion hematoma, (ii) valvular dysfunction, (iii) myocardial infarction with or without ventricular septal rupture/free wall rupture, (iv) aortic rupture, aortic dissection, (v) LVOT obstruction, SAM phenomenon, and (vi) pulmonary embolism direct embolus visualization not always possible (Table 14). Diagnostic sensitivity and specificity for these anatomical and structural lesions vary to some degree but are in general high enough to establish diagnosis and initiate emergency therapeutic interventions.

**Table 10** Advantages and Limitations of Using Transeophageal Echocardiography vs. a Pulmonary Artery Catheter in Critically Ill Patients

Parameter	TEE	PA catheter
Left and right ventricular End-diastolic volume (preload)	Direct +++	Indirect ++
Cardiac output	+(+)	+++
Pulmonary circulation	+(+)	+++
Anatomical information	+++	None
Abnormal blood flow, shunts	+++	+
Pericardial tamponade	+++	Indirect signs
Valvular dysfunction	+++	Indirect signs
Observer dependency	Significant	Moderate
Complications	<0.1%	1–5%

Note: +++, optimal information, diagnostic and monitoring method of choice; ++, often adequate information, significant limitations in particular patients; +, limited clinical usefulness.

Abbreviations: PA, Pulmonary artery; TEE, transesophageal echocardiography.

**Table 11** Contraindications to a Transesophageal Echocardiography Examination in Acutely Injured Patients

Trauma to the oropharynx or esophagus
Unprotected airway
Recent esophageal or gastric surgery
Tumor of the esophagus or esophageal stenosis
Pathology of the oropharynx (Zenker diverticulum)
Unstable cervical spine injury <sup>a</sup>
Penetrating chest/neck trauma before esophagoscopy <sup>a</sup>
Esophageal varices more than grade II <sup>a</sup>
History of unclear dysphagia <sup>a</sup>

<sup>a</sup>May be used if patient is in acute life-threatening condition and diagnostic information from TEE is considered essential for patient management.

**Table 12** Transesophageal Echocardiography Examination: Incidence of Complications

Complications	Incidence (%)
Hypoxia	~0.5
Hypo-, hypertension	~0.5
Dysphagia, bleeding	~0.5
Dysrhythmias	~0.2
Laryngospasm	~0.1
Esophageal perforation	0.02
Death	0.01

In the rare cases where TEE is not diagnostic, it still provides valuable information about the exclusion of the most frequent clinical entities causing hemodynamic compromise.

## Echocardiographic Features of Common Acute Problems

### Hypovolemia

The advantages of TEE include not only a rapid and minimally invasive diagnostic approach, but also an increased sensitivity in the detection of reduced LV preload in emergency situations. (5,9,11,19). To assess RV and LV preload, the TG mid-SAX view is the imaging plane of choice. There are typical 2D echocardiographic findings indicating hypovolemia (Table 3), the systolic papillary muscle attachment (kissing papillary muscles) being the most obvious, consistent and useful in clinical practice (Fig. 36A,B). The clinical usefulness of 2D echo is sometimes limited by the significant variations in the LV end-diastolic area representing

normovolemia. Both systolic papillary muscle attachment (e.g., in patients with LV hypertrophy) and a LV end-diastolic area more than 5.5 cm<sup>2</sup>/m<sup>2</sup> body surface area (e.g., patients with pre-existing dilated cardiomyopathy) may represent normal LV preload in particular patients.

### Myocardial Ischemia, Infarction, and Left Ventricular Failure

TEE enables a direct visualization of both global and regional LV and RV function. Semi-quantitative assessment of myocardial function is sufficient in emergency situations and allows a rational diagnostic approach (Figs. 37 and 38). ⚡ **A particular advantage of echocardiography in the unstable patient is its ability to promptly diagnose structural complications.** ⚡ Structural abnormalities seen by TEE in patients with acute myocardial infarction include aneurysm, papillary muscle rupture with MV insufficiency, ventricular septal rupture, pericardial effusion, and LV free wall rupture.

### Tamponade

Myocardial tamponade can occur acutely following penetrating trauma to the heart, or chronically following blunt trauma. Tamponade can also occur postoperatively following surgery on the heart where the pericardium is open but clot and blood are contained in the anterior or posterior mediastinum resulting in tamponade physiology (Table 7).

### Pulmonary Embolism

The echocardiographic diagnosis of PE (Fig. 39) is based on the signs of RV pressure overload (hypokinetic, dilated RV with leftward shift of the interventricular septum) and in more than half of the patients by the direct visualization of embolic material (Fig. 39) in the RA or central pulmonary circulation (Table 14). TEE is more sensitive in cases with significant pulmonary hypertension, where at least 30% of the pulmonary vessels are obstructed by embolic material. However, TEE is more specific (i.e., if seen less on diagnostic), but not as sensitive as spiral CT (i.e., may have significant distal emboli not seen at all with TEE).

Echocardiographic signs of RV pressure overload are detected in 80% to 90% of patients with PE and hemodynamic instability (42,43). In patients with acute cor pulmonale based on clinical findings or TTE, TEE can identify pulmonary emboli with high sensitivity and specificity (42–46). Therefore, in many institutions TEE is considered the diagnostic tool of choice for unstable patients with suspected PE, as it not only allows diagnosis with high sensitivity, but also allows exclusion of diseases mimicking PE, such as myocardial infarction, aortic dissection, or

**Table 13** Common Echocardiographic Findings and Underlying Cardiac Pathologies in Patients with Unexpected Prolonged Hemodynamic Instability and Abnormal Preload or Myocardial Contractility

Clinical condition	TEE findings
Reduced LV preload (hypovolemia)	Systolic papillary muscle contact and reduced RV EDA Consider pulmonary hypertension if RV EDA increased!
Reduced global myocardial function (left or biventricular contractile failure)	Increased RV and LV EDA Moderate to severely reduced FAC (consider myocardial ischemia or myocardial infarction when regional wall motion abnormalities are present!)
Regional myocardial dysfunction (myocardial infarction)	Regional wall motion abnormalities with normal/increased LV EDA and moderate to severely reduced FAC

Abbreviations: EDA, end diastolic area; FAC, fractional area of contraction; LV, left ventricle; RV, right ventricle; TEE, transesophageal echocardiography.

**Table 14** Echocardiographic Findings in Patients with Pulmonary Embolism

Finding	Frequency
Dilated, hypokinetic right ventricle <sup>a</sup>	85%
Leftward shift of ventricular septum	70%
Dilated pulmonary artery <sup>b</sup>	70%
Signs of right ventricular failure	≤50%

<sup>a</sup>Typically combined with hyperdynamic left ventricle with end-systolic papillary muscle contact.

<sup>b</sup>Compared to aortic diameter in basal short-axis view.

<sup>c</sup>In case of severe pulmonary embolism with significant hemodynamic compromise.

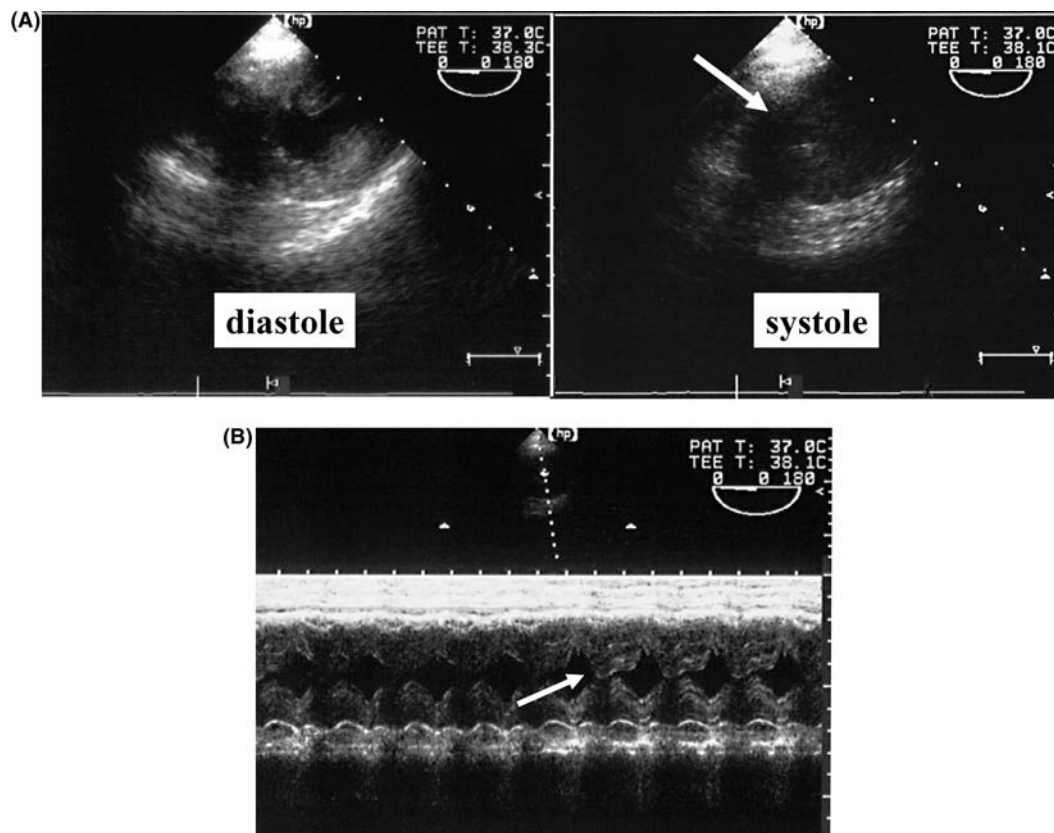

Source: From Ref. 25.

pericardial tamponade. Echocardiography is not as useful for patients with suspected PE and stable hemodynamics; rather, a spiral CT scan is superior. It should be noted that detection of embolic material in the central pulmonary circulation by TEE is limited by inability to image the left main PA. Therefore, TEE can never be used to definitely exclude the uncommon scenario of central PE limited to the left PA. Without direct embolus visualization, echocardiographic

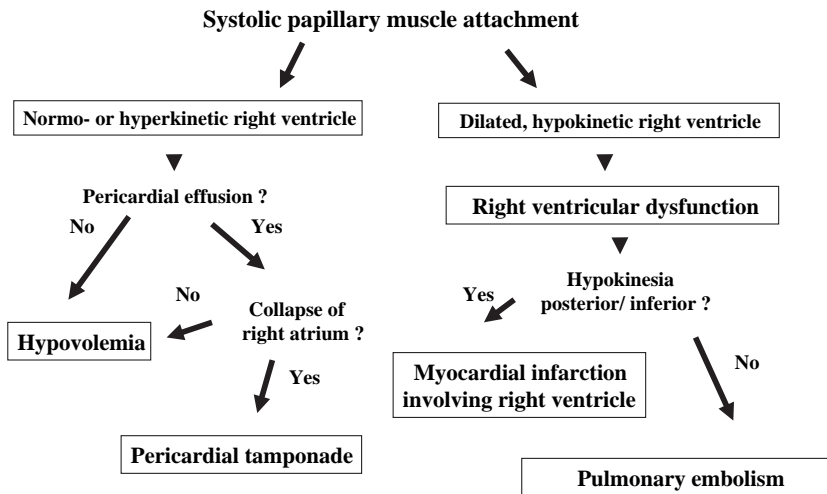

signs of PE may be mimicked by RV infarction and RV pressure overload secondary to respiratory insufficiency.

### Aortic Dissection

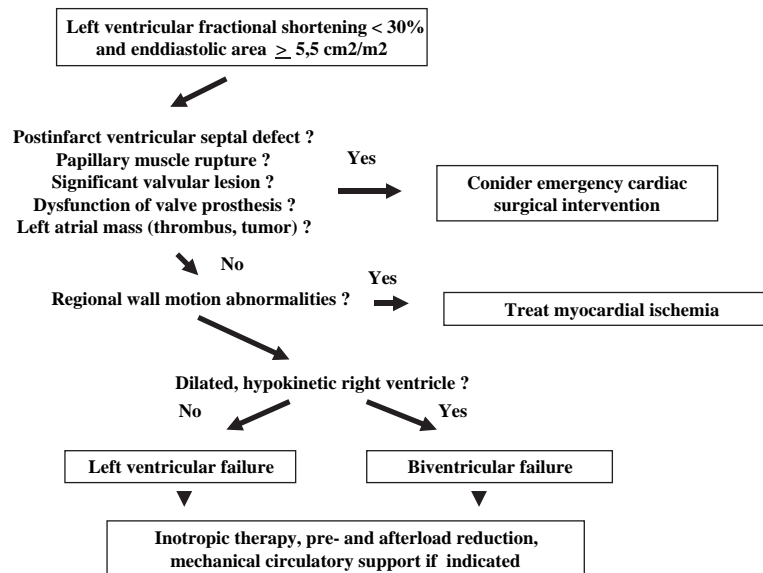

Aortic dissection (Fig. 39) is another possible reason for acute hemodynamic instability, where TEE has significant diagnostic abilities not only in the emergent but also in the elective evaluation of the patient. Diagnostic sensitivity and specificity ranges from 88% to 100% and 77% to 100%, respectively (3,47,48). Diagnostic sensitivity and specificity of TEE was initially comparable to CT scan or angiography (48). However, with the newer multidetector CT scans, TEE plays a secondary and supplemental role (see also Volume 1, Chapter 25). ⚡ **Although TEE has a definite role in the diagnosis of aortic dissection, an important diagnostic pitfall occurs when the dissection is restricted to the proximal part of the ascending aorta (extraordinarily rare).** ⚡ Many institutions use the simplified Stanford classification to grade aortic dissection, as it allows one to differentiate two distinct risk groups with a different therapeutic approach (Table 15) (Fig. 40). The echocardiographic characteristics of aortic dissection include a true (extension with systole) and a false lumen, divided by an intimal flap (highly mobile echo-dense structure in the aortic lumen). In most cases, TEE can clearly define the extent of the dissection (type A or B), the intimal tear (Doppler) and diagnose possible complications, such as pericardial effusion/tamponade, pleural effusion, coronary artery involvement (type A) and AV insufficiency (type A).

## EYE TO THE FUTURE

The field of echocardiography has evolved quickly in the last decade. The introduction of multiplane TEE probes has dramatically changed our perspective on the heart structures. More changes will come in the next decade. Echocardiography is a very dynamic area of medicine with a substantial amount of research conducted every year. Myocardial echo contrast and 3D echocardiography are probably the two most exciting technologies of the future.

Echo contrast agents have been used for research purposes for about 10 years and are now commonly used for clinical applications. These intravenous agents contain microbubbles (4–8  $\mu$  in diameter) that possess a high reflective capacity. When present in the cardiac chambers, it raises the impedance between the blood and the tissue and improves the quality of the signal returned to the ultrasound system. The clinical result is an improvement in the echocardiographic viewed endocardial borders, which allows for

**Table 15** Stanford Classification of Aortic Dissection

	Stanford type A	Stanford type B
Aortic segments involved	Involves ascending aorta	Restricted to descending aorta
Frequency	More common	Less common
Mortality without surgery	More than 90%	About 40%
Therapeutic approach	Surgical intervention	More conservative <sup>a</sup>

<sup>a</sup>Surgical intervention in selected cases and in case of complications (ischemic, bleeding).

**Figure 40** Stanford classification of aortic dissections based upon the presence or absence of involvement of the ascending aorta. The primary intimal tear in type A dissections can be in the ascending aorta (1), arch (2), or descending aorta (3). The intimal tear is usually distal to the left subclavian artery in a type B dissection. *Source:* From Ref. 50.

improved evaluation of global and segmental contractile function of the heart. Some agents are composed of bubbles small enough to enter the myocardial microcirculation. With adequate circulation, the myocardium should appear to be very echo-dense (brighter) because of the presence of the contrast agent. If significant coronary stenosis is present, the contrast agent should not be able to reach the myocardium and no echo-dense signal would come from that specific area. Clinically, it could help the clinician to identify noninvasively the myocardial perfusion and be able to distinguish coronary artery disease from stunned or contused myocardium related to trauma.

With the spectacular evolution of computer processing systems, it is becoming increasingly possible to analyze huge amounts of information in a very short period of time. This represents the basic requirement for 3D echocardiography. As stated in the introduction, one of the main challenges of echocardiography is to use several 2D planes to recreate a 3D composite of the heart structure. By letting computers integrate this information and display it in a 3D representation, echocardiography in the next generation will be much more intuitive and easier to analyze.

## SUMMARY

TEE will likely play an increasing role in the evaluation of the trauma patient. The main indications for TEE, in the context of this chapter, are assessment of the hemodynamically unstable patient, evaluation of valvular

pathologies, diagnosis of blunt cardiac injury and myocardial ischemia, and assessment of traumatic aortic lesions.

Echocardiography is supported by two different applications: 2D imaging and Doppler echo. The 2D echo presents a real-time image of the heart, based on the time it takes for the ultrasound to travel back and forth between the transducer and the imaged structure. Doppler echo measures the velocity of blood flow in the chambers or across the valves. Color Doppler represents an easy way to display the measured velocities superimposed on the 2D image. Using the modified Bernoulli equation, measured velocities can be transformed to pressure units, and echo becomes a non-invasive tool to estimate intracardiac pressures.

The abbreviated trauma TEE examination consists of 12 imaging planes aimed at diagnosing causes of hemodynamic instability and traumatic lesions. With experience, the abbreviated TEE exam can be done in less than five minutes and can provide an excellent assessment of heart and great vessel structures and function.

TEE adds important diagnostic information to the hemodynamic evaluation of the patient in the operating room and in the ICU. It enables direct visualization of both global and regional ventricular function. In addition, it improves preload assessment, especially in patients in whom the right heart filling pressures do not correlate well with LV end diastolic volume.

A TEE examination should include a 2D as well as semi-quantitative color Doppler evaluation of valve function to detect endocarditis and traumatic or septic valve destruction.

Although indications for a TEE examination vary markedly between institutions, studies consistently demonstrate that 20% to 40% of all TEE exams in the ICU yield new, important diagnostic information. A complete hemodynamic evaluation of the unstable patient is greatly facilitated by the immediate availability of TEE.

According to the ASA, TEE evaluation of patients with acute, persistent, and life-threatening hemodynamic instability will improve clinical outcome. TEE has proven to be invaluable in diagnosing and treating pericardial tamponade and other causes of acute myocardial dysfunction.

## KEY POINTS

- ✍ From the Doppler shift, the velocity of the moving blood cells can be calculated.
- ✍ The modified Bernoulli equation can be used to transform velocities obtained by TEE into pressure units.
- ✍ By convention, the velocities going away from the transducer are coded in shades of blue, whereas velocities coming toward the transducer are coded in shades of red (BART: Blue Away, Red Towards).
- ✍ The abbreviated trauma examination includes 12 of the 20 cross sections of the ASE/SCA comprehensive examination.

- 9 Normally, the TG mid-SAX view is used to assess RV and LV myocardial preload.
- 9 Evaluation of global LV function in the ICU and emergency patient is typically done semi-quantitatively, describing global LV function as hyperdynamic, normal, moderately impaired, or severely impaired.
- 9 Regional wall motion may be classified as normal, hypokinetic, akinetic, or dyskinetic.
- 9 The single most important cause of regional wall motion abnormality is myocardial ischemia.
- 9 Color flow Doppler serves as an important screening tool in the mid-esophageal views to detect evidence of MR.
- 9 The classic echocardiographic features of infective endocarditis are vegetations: shaggy, irregular, highly mobile echo-dense structures located on the low-pressure side of a valve leaflet.
- 9 The use of TEE in the acute trauma patient is only indicated in patients without esophageal injury, and after intubation of the trachea has been achieved.
- 9 Echocardiography is the diagnostic tool of choice to detect and evaluate pericardial effusion and tamponade (29).
- 9 Localized intimal tears appear as small (1–2 mm), thin, mobile, echo-dense intraluminal appendages of the aortic walls.
- 9 There are few contraindications for a TEE examination, most of them related to a pre-existing oropharyngeal or esophageal pathology.
- 9 TEE examinations in patients with acute hemodynamic disturbances result in a major therapeutic impact (surgical or medical) in over 50% of patients examined (9,19,21).
- 9 A particular advantage of echocardiography in the unstable patient is its ability to promptly diagnose structural complications.
- 9 Although TEE has a definite role in diagnosis of aortic dissection, an important diagnostic pitfall occurs when the dissection is restricted to the proximal part of the ascending aorta (extraordinarily rare).

### INTRODUCTION

Mechanical cardiopulmonary assist devices have been infrequently employed following trauma, mainly due to concerns of anticoagulation and exacerbation of bleeding from injuries. In addition, solitary injury to the heart requiring use of only an intra-aortic balloon pump (IABP), right ventricular assist device (RVAD), or left ventricular assist device (LVAD) is also rare. More common in trauma is the need for combined therapy with extracorporeal life support (ECLS) due to bilateral pulmonary contusions and concomitant right and/or left ventricular failure (1). Although still rarely used in support of the acute trauma patient, a few case reports from specialized centers have demonstrated successful results using these support modalities (discussed below).

More commonly, cardiac surgical patients often require short durations of IABP use or RVAD/LVAD support, whereas ischemic injury recovers following infarction and/or surgery. Finally, a large number of critically ill patients who are admitted to surgical intensive care units (SICUs) with end-stage cardiomyopathies require long-term cardiopulmonary support as a bridge to heart transplantation, a bridge to recovery, or as final “destination therapy.” All of these devices are undergoing dramatic advances and are increasingly employed in SICU patients.

This chapter reviews the state-of-the art mechanical cardiopulmonary assist devices that can be of use in SICU patients following cardiac surgery, trauma, or chronic heart disease. Although many trauma and critically ill patients will not be candidates for these therapies, this field of medicine is rapidly evolving. Accordingly, all clinically active intensivists must be aware of the available technologies, because the indications for these devices continue to broaden.

The chapter begins with a review of standard IABP indications and use, followed by an introduction to a new implantable IABP device. Next, the basics of RVADs, LVADs, and biventricular assist devices (BiVADs) are provided, focusing on short-term use (i.e., bridge to recovery of native myocardial tissue). The current status of long-term ventricular assist devices (VADs) are presented as a bridge to

transplantation, as well as a permanent solution (i.e., destination therapy). The common complications associated with VADs are reviewed, and the pulsatility considerations in VAD design are also discussed.

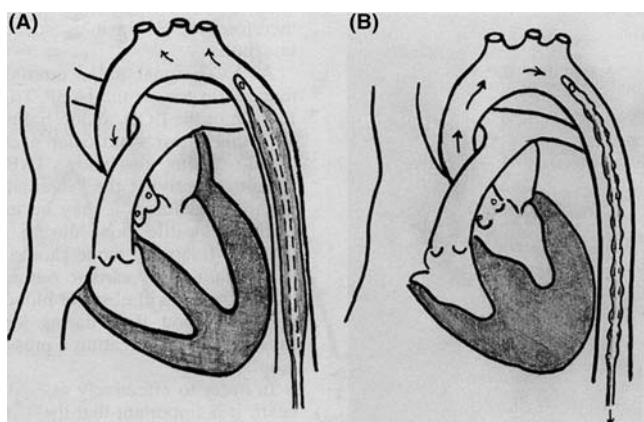

Next, the role of ECLS, including veno-arterial support with extracorporeal membrane oxygenation (ECMO), for trauma and critically ill patients and pump failure is summarized. The use of veno-veno circuits (where only oxygenation is impaired and pump function is adequate) is contrasted with the veno-arterial ECMO systems (which are required if pump function is also impaired). The “Eye to the Future” section reviews the recent innovations in miniaturization of these devices.

### INTRA-AORTIC BALLOON PUMP

**✎ The IABP is a percutaneously inserted device, which provides intra-aortic counterpulsation. ✎** Thus, it does not truly pump blood systemically, but rather augments diastolic pressure (and coronary arterial blood flow) and decreases the afterload of the left ventricle (LV) immediately prior to systole [improving LV ejection fraction (EF)]. In contrast to the VADs and the total artificial heart (TAH), the IABP requires a pumping heart to work (the pump may be failing, but must have some baseline function). In situations where the LV function is nonexistent or so diminished that meaningful ejection is absent, IABP is often insufficient, and an evaluation for VAD may be required.

#### Insertion Principles

Initially, IABP devices were inserted via a femoral artery (FA) cut down (2). However, since 1979, percutaneous placement of the IABP has been achieved via the FA, using a modified Seldinger technique (3). The IABP device is approximately 70 cm long and the balloon is positioned in the descending aorta, just distal to the left subclavian artery takeoff (Fig. 1). Positioning can be verified in the operating room (OR) or SICU using transesophageal echocardiography (TEE), or via chest radiography.

**Figure 1** Intra-aortic balloon counterpulsation increases cardiac output and coronary and cerebral perfusion, and decreases ventricular workload by inflating (A) and deflating (B) during cardiac diastole (aortic valve closure) to displace blood to peripheral vessels.

### Inflation/Deflation Physiology

The IABP balloon is rapidly inflated and deflated by a pneumatic system that shuttles helium through an electronically controlled solenoid valve between the IABP console and the balloon (4). The inflation–deflation sequence is timed to the cardiac cycle by sensing the “R” of the electrocardiogram (ECG) rhythm or the diastolic notch (or other features) of the arterial pressure waveform. The IABP inflates during diastole (Figs. 1A and 2) and deflates just prior to systole (Figs. 1B and 2).

The inflation period provides diastolic augmentation, which can significantly increase intra-aortic diastolic blood pressure. This diastolic inflation increases the retrograde flow from the aorta into the coronary arteries and the great vessels and, to a much lesser degree, helps speed along the blood distal to the balloon down the descending aorta.

Deflation occurs immediately prior to systolic ejection, thus causing a vacuum-like effect in the aorta, decreasing the afterload of the LV, and enhancing LV EF. Deflation occurs during the PR interval of the ECG waveform, and the exact

**Figure 2** Arterial pressure waveform in the unassisted (left) and intra-aortic balloon pump (IABP) assisted condition (right). The balloon inflates during diastole following a trigger signal from the T-wave of the electrocardiogram or the diastolic notch on the A-line trace. This diastolic inflation increases the flow into the coronary arteries and the great vessels, and to a much lesser degree, helps speed along the blood distal to the balloon. Deflation causes afterload reduction.

**Table 1** Intra-aortic Balloon Pump Inflation/Deflation Errors

Error	Physiologic effects
Early inflation (inflation prior to dicotic notch)	Potential premature closure of aortic valve Potential increase in LVEDV and LVEDP or PCWP Increased left ventricular wal stress or afterload Aortic regurgitation Increased MVO <sub>2</sub> demand
Late inflation (inflation after the dicotic notch)	Suboptimal diastolic augmentation Suboptimal coronary artery perfusion
Early deflation (deflation prior to end diastole)	Suboptimal coronary perfusion Potential for retrograde coronary and carotid blood flow Angina may occur as a result of retrograde coronary blood flow Suboptimal afterload reduction Increased MVO <sub>2</sub> demand
Late deflation (deflation after end diastole)	Afterload reduction is essentially absent Increased MVO <sub>2</sub> consumption, due to the left ventricle ejecting against a greater resistance and a prolonged isovolumetric contraction phase IABP may impede left ventricular ejection and increase the afterload.

*Abbreviations:* IABP, intra-aortic balloon pump; LVEDP, left ventricular end diastolic pressure; LVEDV, left ventricular end diastolic volume; MVO<sub>2</sub>, myocardial oxygen consumption; PCWP, pulmonary artery capillary wedge pressure.

timing can be easily adjusted using controls on the IABP console.

Timing of inflation and deflation is critical, as errors (Table 1) can increase myocardial oxygen consumption (MVO<sub>2</sub>), and decrease coronary artery perfusion. If inflation is too early or deflation too late, ventricular afterload is actually increased. If inflation is too late or deflation too early, then the diastolic augmentation is less robust. Initial settings generally require some adjustment by the bedside clinician while viewing the nonaugmented versus augmented arterial blood pressure (BP) waveforms that are generated with manipulations of the inflation and deflation times. Anticoagulation with heparin is utilized to maintain an activated clotting time (ACT) between 180 and 200 seconds.

### Indications and Contraindications

The IABP should be considered for use in patients who have LV dysfunction, but still have some ejection, and in whom short-term recovery is expected (Table 2). In those with coronary artery disease, or a hypertrophic LV myocardium (as occurs with aortic stenosis or long-term hypertension), the diastolic augmentation may be the most important component supplied by the IABP. Whereas those in congestive heart failure from a weak and dilated cardiomyopathy, may benefit most from the afterload reduction properties provided by the IABP. In both cases, the expectation is that the IABP will help improve the perfusion and function of

**Table 2** Indications and Contraindications for Intra-aortic Balloon Pump*Indications for IABP*

Cardiogenic shock  
 Acute cardiac instability following PTCA misadventure  
 Unstable angina  
 Preheart transplant/post failed transplant  
 Myocardial contusion following blunt abdominal trauma  
 Inability to wean from CPB  
 Acute mechanical deterioration (VSD, MR)

*Contraindications of IABP*

Aortic valve insufficiency  
 Acute aortic trauma  
 Severe aorto-iliac atherosclerotic disease  
 Irreversible myocardial disease in a nontransplant candidate

*Abbreviations:* CPB, cardiopulmonary bypass; IABP, intra-aortic balloon pump; MR, mitral regurgitation; PTCA, percutaneous transluminal coronary artery angioplasty; VSD, ventricular septal defect.

the LV and that, over time, intrinsic function is expected to recover.

Absolute contraindications of IABP are relatively few; mainly aortic insufficiency and/or recent aortic injury (Table 2). Relative contraindications include severe atherosclerotic aorto-iliac disease, an irreversible LV failure in a patient who is not a candidate for an implantable device or transplant.

As patients recover from LV failure, the IABP can be weaned off, initially transitioning from 1:1 to 1:2, then 1:3, and 1:4 or less, and finally off IABP augmentation. If the LV dysfunction worsens while on IABP, considerations for placement of a VAD may need to be contemplated.

### Long-Term Implantable Intra-aortic Balloon Pump (Kantrowitz CardioVad™)

Recently, an implantable IABP has been introduced, the “Kantrowitz CardioVad” (LVAD Technology, Detroit, Michigan, U.S.A.) (Fig. 3). This electrically powered, pneumatically driven device functions in a manner similar to a standard IABP, but is permanently anastomosed in a side-to-side fashion to an oval-shaped window in the descending thoracic aorta. A textured polyurethane surface subsequently develops a nonthrombogenic psuedointima, which maintains contact with the blood. Inflation and deflation of the device are triggered automatically from the electrical activity of the heart.

Like the IABP, the CardioVad provides diastolic augmentation of coronary perfusion pressures and systolic unloading of the failing ventricle, but this device retracts from the aortic lumen during systolic deflation. The result is that cardiac output ( $\dot{Q}$ ) can reportedly be increased by around 40% with the CardioVad (depending on the after-load) (5), in comparison to the 20% to 25% augmentation of forward  $\dot{Q}$  achievable with the conventional IABP (6,7). In addition, as there is an ostensibly nonthrombogenic surface in contact with the blood, anticoagulation is not required, and the device can be turned on and off at will by the patient without increasing the risk for thromboembolic events. Thus, this new device is characterized as “non-obligatory.”

The initial clinical experience with the CardioVad in nontransplant-eligible patients with end-stage cardiac failure (5), demonstrated that it can be implanted with

**Figure 3** The Kantrowitz CardioVad™. As described in the text, the device is surgically anastomosed in a side-to-side fashion to an oval window cut from the proximal descending aorta. Because the balloon retracts fully during deflation, an increased forward augmentation of stroke volume is realized, compared to the conventional IABP. System control and pneumatic power are delivered to the device through a unique “percutaneous” cable. The modular design of this mechanism makes it more like a phone jack than a percutaneous cable. The internal aspect of the “jack” is coated with the recipient’s fibroblasts to potentially decrease the incidence of infection at the site. *Source:* Courtesy of LVAD Technology, Inc.

very low perioperative morbidity and mortality, and the degree of support obtained was sufficient to reverse heart failure, improve end-organ dysfunction, and remove inotrope dependency. By 30 days, investigators observed significant increases in cardiac index, and significant decreases in right atrium (RA) pressures, pulmonary artery capillary wedge pressure, blood urea nitrogen (BUN), and creatinine. No significant differences were found in platelet counts.

Recent modifications to the CardioVad™ have decreased device length and improved forward stroke volume to 60 mL (Dr. Valluvan Jeevanandam, personal communication). A feasibility trial is now in progress, testing the CardioVad in patients with compensated heart failure, who are on intermittent or continuous inotropic therapy. Pilot and pivotal trials are planned.

### VENTRICULAR ASSIST DEVICES

Several Food and Drug Administration (FDA)-approved VADs are available to support the circulation in patients with ventricular failure refractory to maximal pharmacologic interventions and/or IABPs. Circulatory support with these devices is generally accomplished by placing cannulas in the heart and great vessels, so as to divert blood from the failing side of the heart to a pump, which then returns the diverted blood to the arterial circulation immediately downstream of the failing ventricle.

**Figure 4** The Thoratec<sup>®</sup> Ventricular Assist Device and cannulation approaches for univentricular left heart support (A) and biventricular support (B and C). Although the Thoratec device is depicted, this figure illustrates commonly used cannulation strategies for all currently available ventricular assist devices. As described in the text, cannulas are placed in the heart and great vessels to divert blood returning to the failing side of the heart to the pump. The blood collected in the ventricular assist device blood chamber is then ejected into the arterial circulation, immediately downstream of the failing ventricle. *Abbreviations:* AO, aorta; Apex, left ventricular apex; IAG, cannula inserted via the interatrial groove and directed towards the LA roof; LA, left atrial appendage; LVAD, left ventricular assist device; PA, pulmonary artery; RA, right atrium; RVAD, right ventricular assist device. *Source:* Courtesy of Thoratec Corporation.

These devices are becoming increasingly used in patients with bleeding risks (e.g., trauma patients), due to the heparin-bonded circuits that obviate the need for full systemic heparinization and the consequent bleeding complications.

As depicted in Figure 4, for LV support, blood is continuously drained as it returns to the left side of the heart from the left atrium (LA) or the LV, and is then pumped into the ascending aorta. For RV support, venous return to the right side of the heart is continuously drained from the RA or RV, and pumped into the main pulmonary artery (PA). The diverted blood not only provides the stroke volume, which will be pumped forward as the output from the supported side of the heart, but by unloading (decompressing) the failing ventricle, wall tension is markedly decreased. This dramatically reduces myocardial oxygen demand in the failing ventricle, which potentially facilitates myocardial recovery.

### Short-Term Ventricular Assist Device Support Overview

Acute ventricular failure can result from a variety of insults, including ischemia (e.g., acute myocardial infarction (AMI) or stunned myocardium during cardiotomy), acute and/or chronic pressure and volume overloads (e.g., severe acute valvular dysfunction), and inflammatory processes (e.g., acute viral myocarditis).

In the trauma setting, myocardial contusion and ventricular failure generally affect the RV to a greater extent than the LV. This is because the RV is directly underneath the anterior thorax and is more often contused following blunt trauma to the anterior chest. However, heretofore RVADs have rarely been employed following acute

trauma. Rather, in cases of severe chest trauma, combined pulmonary contusions and concomitant heart failure can call for the use of ECMO to support both the injured heart and lungs (discussed subsequently).

In cases where acute LV dysfunction is the primary problem, regardless of the etiology, counterpulsation therapy with an IABP (Fig. 1) can often provide sufficient short-term LV “assistance” to allow hemodynamic stabilization, preventing cardiogenic shock. (Note use of the IABP is contraindicated in cases of acute aortic injury or aortic regurgitation).

☛ **When maximal pharmacologic interventions and an IABP fail to restore hemodynamic stability, extracorporeal support may be required to re-establish and maintain systemic perfusion, and to prevent the catastrophic sequelae of cardiogenic shock.** ☛ Currently approved VADs include:

- The Abiomed BVS5000<sup>®</sup> (Abiomed, Danvers, Massachusetts, U.S.A.; Fig. 5)
- The AB5000 ventricle<sup>®</sup> (Abiomed, Danvers, Massachusetts, U.S.A.; Fig. 6)
- The Thoratec<sup>®</sup> VAS (Thoratec Laboratories, Pleasanton, California, U.S.A.; Fig. 7)
- Standard centrifugal pumps (several manufacturers; Fig. 8) (8)

All of the devices listed above are paracorporeal (the pump heads reside outside the body), and can provide left (LVAD), right (RVAD), or biventricular (BiVAD) support. With the exception of centrifugal pumps (which provide continuous flow), these devices provide pneumatically driven pulsatile outflow. Anticoagulation during short-term

**Figure 5** The Abiomed BVS5000<sup>®</sup>. Since FDA approval as a bridge-to-recovery in 1992, the BVS5000 has been used to support more than 6000 patients, in over 500 U.S. centers. The device is available in more than 85% of adult cardiac transplant centers and more than 85% of all cardiac surgery teaching institutions. (A) The BVS5000 blood pump. (B) The BVS5000 system controller and pole-mounted blood pumps. The typical configuration for biventricular support with the BVS5000. Pumps are kept mounted on a pole at the bedside. The height of the pumps can be adjusted to optimize gravity-drainage filling and pneumatically accomplished ejection. *Source:* From Ref. 9; courtesy of ABIOMED.

**Figure 6** The AB5000<sup>®</sup> ventricle. The pump head, pictured here, is connected to the heart and great vessels by cannulas tunneled through the skin of the upper abdomen (Fig. 1). The drive-line emerging from the left of the device alternately provides vacuum to assist filling and compressed air to accomplish ejection. According to the Abiomed worldwide voluntary registry, since FDA approval in October 2003, the AB5000 ventricle has been used to support more than 88 patients, in more than 35 U.S. centers. The longest duration of support was 149 days, with an average duration of support of 15 days; 22% of those supported were transitioned from BVS5000 pumps. *Source:* From Ref. 10; courtesy of ABIOMED.

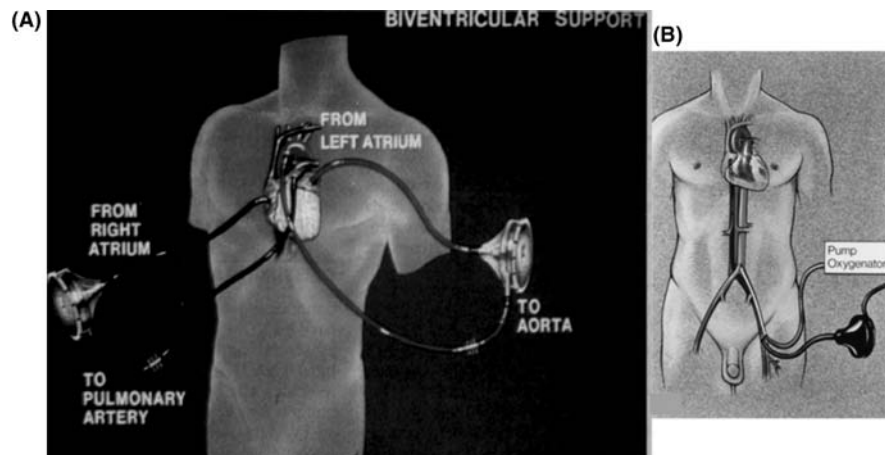

support is generally maintained with heparin to a minimum ACT of 180 to 200 seconds. It should also be noted that none of these devices by themselves can provide oxygenation or removal of waste from the blood. They simply act as pumps to maintain effective output from the failing side of the

**Figure 7** The Thoratec<sup>®</sup> VAS. Although it was originally introduced in 1976, and FDA-approved as a bridge to transplantation in 1994, the Thoratec VAS was not FDA-approved for postcardiotomy support until 1998. Since then, Thoratec reports the use of its device to bridge more than 806 patients to recovery. The maximum reported duration of support was 340 days, with a mean duration of 19 days. As depicted, the inflow and outflow cannulas are connected to the heart and great vessels by cannulas tunneled through the skin of the upper abdomen. The drive-line (lower right of the device) alternately provides vacuum to assist filling and compressed air to accomplish ejection. *Source:* From Ref. 8; courtesy of Thoratec Corporation.

heart (Fig. 8A). However, oxygenators can be inserted between the pump heads and the systemic arterial cannula site, in situations requiring ECMO support (e.g., Fig. 8B).

Myocardial recovery may be rapid or slow. If short-term support cannot be weaned, consideration for chronic circulatory support devices must be made. The rates of successful weaning from short-term circulatory support have improved over the last decade, from the previously dismal past. Abiomed, for example, recently reported that experienced centers, with well-defined protocols for patient selection and timing of intervention, are achieving

**Figure 8** Potential cannulation strategies for circulatory support with centrifugal pumps. (A) Cannulations of the heart and great vessels (Fig. 1). The large controllers that power the pump heads are not shown. (B) Percutaneous femoral cannulations.

ventricle survival approaching 50% in the postcardiotomy cardiogenic shock population using the BVS5000 and AB5000 VADS (9,10). When used to support the circulation following an AMI, the survival of patients is reported to be 42% with the AB5000 ventricle (mean number of days supported = 25.4) and 27% with the BVS5000 (mean number of days supported = 5.2) (11).

✎ **The importance of prompt intervention to restore adequate systemic perfusion, and careful patient selection for prolonged treatment cannot be understated, if expectations are for successful bridge to recovery with a VAD.** ✎ Clearly, any patient who is unlikely to survive, regardless of the re-establishment of effective systemic perfusion, should not even be considered for VAD support. When the myocardial injury is deemed to be of the variety that is likely to recover and the clinical assessment is otherwise favorable, VAD support may be considered. However, one cannot wait until there is profound cardiogenic shock, with significant injury to the lungs, kidneys, liver, brain, and splanchnic beds, to initiate mechanical circulatory assistance, because experience has shown that the patient is unlikely to survive (12). Factors influencing outcome with the Abiomed BVS5000 device are shown in Table 3. It is likely, however, that such principles apply to virtually every bridge-to-recovery support device. A variety of important considerations and relative contraindications to mechanical circulatory assistance that must be duly considered, prior to implantation of a VAD are provided in Table 4.

✎ **If the myocardium does not recover after a period of short-term support, then a decision must be made as to whether the patient is an acceptable transplant candidate.** ✎ If so, their support may be maintained until a donor heart becomes available (device permitting), or their VAD may be switched to a device capable of providing long-term support, as a bridge to transplantation. If the patient is not transplant eligible, he must either be evaluated for permanent implantation of an approved VAD as “destination therapy” (discussed below), or the difficult decision must be made to terminate support.

**Table 3** Factors Influencing Outcomes with the Abiomed BVS5000®

Good outcomes occur when
Support is commenced to correct marginal hemodynamics within 30–45 min of attempted pharmacologic treatment (with or without an IABP)
The time between the first attempt to wean from CPB and BVS implant is <6 hr
The BVS implant occurs as part of the initial operation
Due consideration is given to whether the patient requires uni- or biventricular support; and
Hemostasis is assured before leaving the operating room
Poor outcomes occur when
Signs of other end-organ failure are present
The patient is >75 yr old; and
The patient is brought back to the operating room for implantation after a period of time

*Abbreviations:* BVS, ABIOMED BVS5000 left ventricle assist device; CPB, cardiopulmonary bypass; IABP, intra-aortic balloon pump.

**Table 4** Considerations Before Initiation of Rescue Mechanical Circulatory Assistance with a Ventricular Assist Device

Patient is not a transplant candidate (though VAD use may allow improvements in clinical status that may improve transplant eligibility)
Presence of prosthetic valves (increased risk of thromboembolic complications)
Significant aortic regurgitation (decreased effective forward flow from an LVAD and failure of LV decompression that will encourage myocardial recovery. Aortic valve must be repaired or replaced before engaging LVAD support)
Congenital heart disease (certain forms may preclude conventional VAD support. Ironically, extracorporeal membrane oxygenation may be the only hope for some patients with CHD)
Patent foramen ovale (must be recognized and closed before engaging VAD support with currently available LVADs)
Prior cardiac surgery (reoperative sternotomy may predispose to significant perioperative bleeding. Femoral cannulations can potentially be used to ensure rapid restoration of adequate systemic perfusion, whereas careful mediastinal dissection proceeds)
Small body surface area (outflow from the many currently available devices may be too high for patients with BSA < 1.5 m <sup>2</sup> . Possibly can use the Thoratec® VAS for small adults or centrifugal pumps for pediatric patients)
Presence of advanced systemic disease (comorbidities, such as severe COPD, malignancy, end-stage renal or hepatic disease, overwhelming sepsis, progressive neurological disorder, etc., may make meaningful recovery unlikely)

*Note:* This is a nonexhaustive list of anatomical issues and other patient factors that either make urgent ventricular assist device placement or use difficult, make the patient more likely to have major complications, or make meaningful recovery unlikely. Some of the issues on this list are easily resolved as long as they are recognized, but must be considered nonetheless.

*Abbreviations:* CHD, congenital heart disease; COPD, chronic obstructive pulmonary disease; LV, left ventricle, LVAD, left ventricular assist device.

### Recent Innovations in Short-Term Ventricular Assist Device Support

Approximately 7% to 10% of patients with AMI develop cardiogenic shock, and this remains the leading cause of mortality in this population (13–15). As discussed above (Table 3), a key determinant of the overall success of bridge-to-recovery is the rapidity with which the failing ventricle can be decompressed, and resumption of adequate systemic perfusion assured. One of the recognized limitations of the currently available devices, which can serve as a bridge-to-recovery following an AMI, is that they must be implanted in a cardiac OR, often utilizing cardiopulmonary bypass (CPB). Even assuming the immediate availability of the OR, the device, and the necessary surgical, anesthesia, perfusion, and nursing personnel, delays are inevitable. A likely factor contributing to the low success rates of previous bridge-to-recovery studies was a delay in treatment due to the need to coordinate these various resources prior to transport and VAD implantation. During this interval, the failing ventricle is likely to be pressure and volume overloaded, while the renal, splanchnic, and peripheral tissue beds are underperfused.

The ability to deploy a rescue device rapidly, at the first diagnosis of acute ventricular insufficiency in the emergency department, the cardiac catheterization laboratory, or the SICU, without the need for sternotomy and CPB would potentially have great impact on not only immediate, but ultimate patient survival. In addition, some complications of CPB, such as perioperative bleeding and the sequelae of the systemic inflammatory response, would be minimized. Once immediate survival is assured, such a device can conceivably be changed later, to another capable of providing a longer term of support. It was considerations such as these that drove the development of several new and innovative short-term assist devices.

### The TandemHeart® pVAD™

Extracorporeal centrifugal pumps have long been used to provide mechanical circulatory assistance via both intrathoracic (Fig. 8A) and percutaneous femoral (Fig. 8B) cannulation strategies (16). Although standard intrathoracic cannulations require sternotomy in the OR, percutaneous femoral arterial and venous cannulations can be performed in many locations outside the OR setting. The downside of femoral venous cannulation, however, is that ventricular decompression is usually inadequate to substantially reduce  $\dot{M}\dot{V}O_2$ .

The TandemHeart pVAD (percutaneous ventricular assist device; Cardiac Assist, Inc., Pittsburgh, Pennsylvania, U.S.A.; Fig. 9) utilizes a full-sized centrifugal pump and an innovative cannulation strategy that does result in significant decompression of the failing LV. In addition, a percutaneous, Seldinger-type, cannula deployment system enables rapid cannula placement to assure rapid resumption of systemic perfusion.

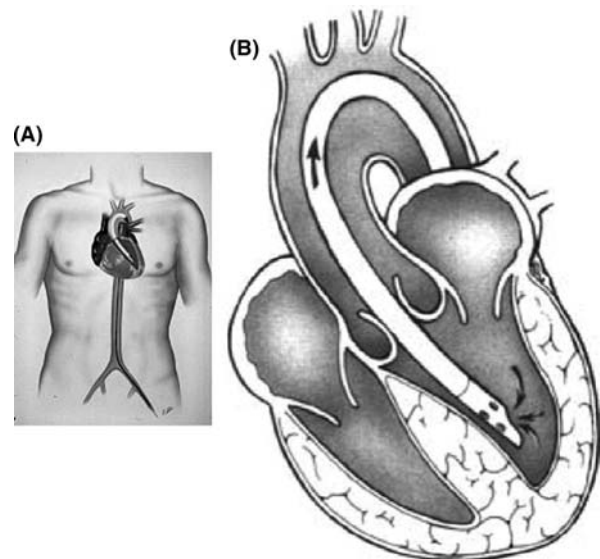

**Figure 9** The TandemHeart® pVAD™. (A) As described in the text, the femoral artery and vein are percutaneously cannulated. The venous cannula is advanced across the interatrial septum into the left atrium. Outflow from the device is directed into the femoral artery. (B) A close-up of the centrifugal mechanism. *Source:* Courtesy of Cardiac Assist, Inc.

With this device, a 21 French venous inflow cannula is percutaneously advanced retrograde from the femoral vein, through the RA, and across the interatrial septum into the LA (Fig. 9). Continuous, nonpulsatile outflow from the centrifugal device (strapped to the patient's leg) is directed into the FA. LA to FA flows of 2.5–5 L/min can be generated by pump speeds in the range of 4500–7500 RPM, to encourage resolution of cardiogenic shock. Heparinization to an ACT of 180–200 seconds is used during support.

Reportedly, the TandemHeart has been implanted in more than 100 patients as a bridge-to-recovery, following acute MI-induced cardiogenic shock. A review by Thiele et al. (17), reports the results of TandemHeart use in 18 consecutive patients with cardiogenic shock following AMI. Fifty-six percent of the patients in their series survived, and were successfully weaned from support. The TandemHeart has also been successfully employed as a bridge-to-recovery following cardiectomy with failure to wean from CPB (18), and as a margin of safety in high-risk patients undergoing percutaneous coronary interventions with stenting (19–21). Although a theoretical downside to cannulation of the FA for device outflow is retrograde arterial perfusion through the potentially diseased aorta of a patient with atherosclerosis, cerebral embolism has not been reported as a significant problem. The TandemHeart already holds a CE mark (Conformité Européene) in Europe. FDA approval of this device in the United States is pending.

### Hemopump®

Miniaturized continuous flow devices that employ a longitudinal “Archimedes Screw”-like impeller have also been used in the past as a “bridge-to-immediate survival.” In the late 1980s and early 1990s, the Hemopump (Nimbus Medical, Inc., Rancho Cordova, California, U.S.A.; Fig. 10) was implanted in patients in cardiogenic shock, in

**Figure 10** The Hemopump®. (A) As described in the text, the Hemopump was inserted via surgical cut-down into the femoral artery, and advanced retrograde up the aorta and across the aortic valve into the left ventricle (LV). Blood was impelled from the LV to the ascending aorta. (B) A close-up of the Hemopump. The arrows indicate the direction of blood flow.

**Figure 11** The Impella®. (A) Biventricular support with the Impella. The left ventricle (LV) is supported here by surgical placement of the microaxial catheter into the LV retrograde from the ascending aorta. The right ventricle is supported here by surgical cannulation of the right atrium, with the output directed into the main pulmonary artery. (B) A cutaway view reveals the impeller design of the Impella device. *Source:* Courtesy of ABIOMED.

FDA-approved clinical trials. This axial flow device was surgically introduced into the FA and advanced retrograde under fluoroscopic guidance, up the aorta and across the aortic valve into the LV. A high-speed impeller inside the device casing drew blood from the LV, and propelled it into the ascending aorta at a maximum of approximately 3.5–4 L/min. Reportedly, decompression of the failing LV was adequate to decrease myocardial oxygen demand (22), and the observed improvements of cardiac output, mixed venous oxygen saturation, pulmonary capillary wedge pressure, and splanchnic blood flows were found to be superior to that with IABP counterpulsation therapy (23–25). However, actual clinical results were modest at best with this device [survival around 32% at 30 days (26)], and failure of device insertion occurred in nearly 25% of patients (27). The high cost of conducting clinical trials eventually forced the abandonment of the Hemopump, but it did serve to show that an intraventricular axial flow device could be successfully employed to provide mechanical circulatory support.

### Impella®

The Impella Pump System (Abiomed Inc., Danvers, Massachusetts, U.S.A.) (28) is a new, catheter-based, axial flow device that can be used to support the left, right, or both ventricles (Fig. 11). Depending on the location and status of the patient, the device can be deployed surgically or percutaneously. The Impella system may also be of use in high-risk patients undergoing off-pump coronary artery bypass grafting (CABG) surgery or difficult percutaneous coronary interventions. A mechanical or severely calcified aortic valve contraindicates the use of the Impella for LV support. Significant aortic insufficiency may also represent a relative contraindication.

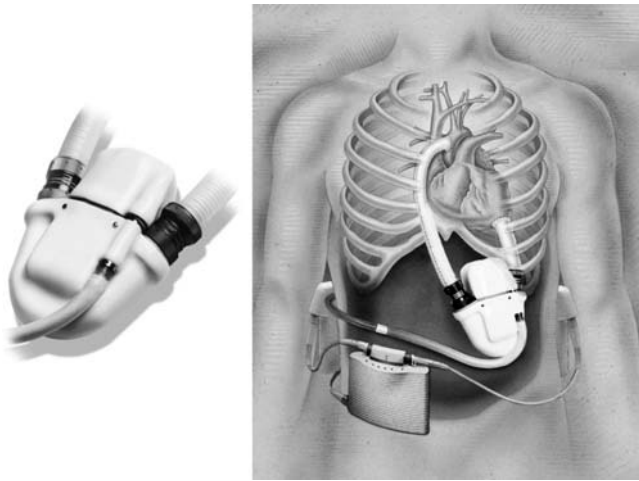

A recent review of an initial clinical experience with the Impella in patients with cardiogenic shock reports significantly increased cardiac outputs, decreased pulmonary capillary wedge pressures, and decreased lactate levels by six hours of support (29). Sixty-eight percent of the patients were successfully weaned from support, though only 38% survived. Among the observed complications were clinically significant hemolysis in 38% of the patients and one instance of pump displacement. The Impella system was recently acquired by Abiomed, and clinical trials intended to establish its efficacy as a bridge-to-recovery are ongoing.

### Long-Term Ventricular Assist Device Support Bridge-to-Transplantation

Critically ill patients with chronic, progressive ventricular failure due to cardiomyopathy can often be temporized with medications, and occasionally with biventricular pacing. But for those who progress to end-stage ventricular failure, the HeartMate® LVAD (Thoratec Corporation, Woburn, Massachusetts, U.S.A.; Fig. 12) and the Novacor® LVAD (WorldHeart Corporation, Ottawa, Canada; Fig. 13) are the devices most often used as a bridge-to-transplantation in the United States. The original pneumatically powered HeartMate device was FDA-approved in 1994, and the Novacor in 1998. Both are used as LVADs only, draining blood from the LV apex to a large pump head implanted in the preperitoneal space of the abdomen, and returning blood to the ascending aorta (Figs. 4, 12, and 13). Both devices produce pulsatile flow by mechanical compression of a blood chamber, and both devices require a

**Figure 12** The HeartMate® XVE LVAD. Blood is drained from the left ventricle apex to the pump and ejected into the ascending aorta. The pump head is completely implanted in the preperitoneal space of the abdomen. The current model requires that a cable from the device be tunneled through the abdominal wall to connect to the external system controller and power supply. *Source:* Courtesy of Thoratec Corporation.

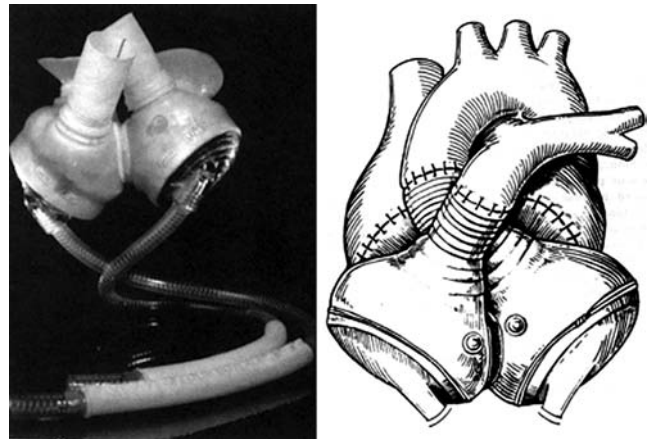

**Figure 13** The Novacor<sup>®</sup> LVAD. Blood is drained from the left ventricle apex to the pump and ejected into the ascending aorta. percutaneous cable to connect the implanted device to an external power source and system controller.

Since FDA approval in 1995, patients with biventricular failure are most often bridged to transplantation with the Thoratec VAD (Fig. 7). Available statistics from their respective manufacturers indicate that more than 1300 patients have been implanted with the Novacor, more than 4100 with the HeartMate, and more than 1700 with the Thoratec worldwide. Recently reported rates of successful

**Figure 14** The implantable ventricular assist device (IVAD). Titanium clad pump IVAD. *Source:* Courtesy of Thoratec Corporation.

**Figure 15** The CardioWest<sup>™</sup> TAH. As described in the text, the failed native heart is removed and the CardioWest TAH is implanted orthotopically, anastomosed to cuffs of native atria and the great vessels. *Source:* Courtesy of SynCardia Systems.

bridging-to-transplantation with these devices are in the range of 51–78% (30–33).

Thoratec has recently introduced a titanium-clad implantable version of their Thoratec pump: the IVAD<sup>®</sup> (implantable ventricular assist device; Thoratec Corporation, Woburn, Massachusetts, U.S.A.; Fig. 14). Currently, the IVAD is the only FDA-approved implantable device that can provide biventricular assistance. According to the manufacturer, as of September 2003, 30 patients with advanced heart failure have been supported with the IVAD as a bridge-to-transplantation or for postcardiotomy ventricular failure, in Europe and the United States. Sixty-eight percent were successfully treated through transplantation or ventricular recovery, with many of these patients discharged to their homes through the use of the TLC-II Portable VAD Driver. At the time of this writing, no published reports of IVAD use in patients have appeared in the peer-reviewed, indexed literature.

The CardioWest<sup>™</sup> TAH (Total Artificial Heart; SynCardia Systems, Tucson, Arizona, U.S.A.; Fig. 15) is also currently available, in select centers in the United States, Canada, and France, as a bridge-to-transplantation for patients with biventricular failure. This device is a pneumatically powered biventricular pump that is implanted orthotopically (the native heart is removed and replaced by this device). Since 1993, approximately 225 of these devices have been implanted clinically (34). The reported rate of successful bridge-to-transplantation with this device is in the order of 79% (35). When compared to devices like the HeartMate and the Novacor, a major potential disadvantage of the CardioWest device as a bridge-to-transplantation is a lack of portability, significantly limiting potential for physical rehabilitation and outpatient use, though a smaller and more portable driver is reportedly in development. Another potential disadvantage to a device of this type is that the native heart must be excised, significantly limiting therapeutic options if device failure occurs or infection develops.

#### **Permanent Support (Destination Therapy)**

♣ Only one out of every 2273 patients with end-stage heart failure is likely to receive a heart transplant. ♣

**Figure 16** The number of adult cardiac transplants performed in the United States, 1998–2004. *Source:* From Ref. 39.

Permanent replacement of the failing heart has always been the major driving force behind research and development in the field of mechanical circulatory assistance. Of the estimated 5,000,000 patients currently living with heart failure in the United States (36), it is estimated that only between 40,000 (37) and 100,000 (38) could potentially meet transplant criteria. Furthermore, transplantation may not be a feasible option for the vast majority of heart failure patients, because there are only around 2200 donor organs available annually in the United States (Fig. 16) (39). In addition, many heart failure patients are ineligible to receive a transplant because of advanced age and comorbidities.

The REMATCH trial (Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart failure, completed June 2001) demonstrated that the use of an LVAD (the HeartMate VE) was not only an effective tool to treat patients with advanced heart failure, but resulted in more than twice the survival rate and an improved quality of life, in comparison to optimal medical management (40–42). This was especially the case if the patient was less than 60 years old (Table 5). Thus, for the vast majority of patients with end-stage cardiac disease, it would appear that intentionally permanent implantation of a mechanical assist device may be the best option available, if they are to survive. Based on the results of REMATCH, the FDA approved the HeartMate in November 2002 for transplant-ineligible patients as “destination therapy”; in essence, permanent implantation of a VAD is their “final destination.” By November 2002, improvements to the HeartMate device resulted in the HeartMate XVE, and it is this device that has been implanted for destination therapy patients.

**Table 5** Summarized Results of the REMATCH Trial

	HeartMate®	Medical therapy
1 yr survival (age <60)	52% (74%)	25% (33%)
2 yr survival	23%	8%
Median survival	408 days	150 days

*Note:* REMATCH stands for Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart failure. *Source:* From Ref. 42.

**Figure 17** Patient accrual for destination therapy with the HeartMate® XVE by month and year. *Source:* From Ref. 41.

According to the manufacturer, as of May 2005, 260 patients have been implanted with the HeartMate XVE as Destination therapy. The statistics presented in Figure 17 (41) indicate that patient accrual for destination therapy started out slowly, but has steadily increased with time, reflecting a growing acceptance of this management strategy by cardiologists and patients with end-stage heart failure.

Thus far, destination therapy with the HeartMate XVE has been associated with fewer observed adverse events and a better survival rate than reported in the REMATCH trial (42). The authors’ conclusion was that improved outcomes likely reflect improvements in the HeartMate XVE device (compared to the HeartMate VE used in REMATCH), and increased experience with patient management.

The INTrEPID trial (Investigation of NonTransplant-Eligible Patients who are Inotrope Dependent) was recently conducted to establish the ability of the Novacor LVAS to provide destination therapy, but the FDA failed to approve the Novacor for this indication based on the INTrEPID data. The RELIANT trial (Randomized Evaluation of the Novacor LVAS In A NonTransplant Population) currently randomizes patients to receive either the Novacor LVAS or the HeartMate XVE LVAS as a bridge to transplantation. The purpose of this trial is to demonstrate that use of the Novacor LVAS is superior to optimal medical therapy, by demonstrating equivalence to HeartMate XVE LVAS, which has already been approved for destination therapy.

### Complications Associated with Ventricular Assist Device Support

Despite the impressive rates of successful short- and long-term support with VADs, infection, thromboembolic complications, and mechanical problems remain major issues to be overcome.

**Table 6** Summarized Rates of Infectious Complications from a Large Series of Long-Term Support at a Single Center in Germany

	Novacor®	HeartMate®	Thoratec®
Driveline infection	26%	18%	2%
Pocket infection	11%	24%	NA
Systemic sepsis	24%	11%	26%

*Abbreviation:* NA, not applicable. *Source:* From Ref. 30.

### Infection

Infections associated with currently available devices tend to be more common with long-term devices, and often occur along the percutaneous components and in the device pocket. Although infections within the devices themselves are rare, sepsis is not uncommon. A recent large series, reviewing bridge-to-transplantation with the HeartMate in the United States, reported that 45% of patients developed “infection,” with 72% of the observed infections at the exit site of the percutaneous driveline (32). Table 6 summarizes the rates of infectious complications from a recent large series of long-term support in Germany (30). Thus, the presence of percutaneous components appears to be an important predisposing factor to infectious complications.

### Thromboses

For short-term devices, heparin therapy is usually utilized to maintain an ACT of 180 to 200 seconds. If the ACT is allowed to drift lower for a significant time, thrombosis can form in the rotor heads and/or circuits, requiring replacement. Thromboembolic complications remain a major problem with all of these devices. A recent review of 228 patients on long-term support with the Thoratec, Novacor, and HeartMate as a bridge to transplantation reported cerebral embolism in 24%, 39%, and 16%, respectively, despite adherence to recommended anticoagulation protocols (30). The HeartMate has a blood chamber composed of sintered titanium microspheres, to encourage the ingrowth of a neointima. Once the neointima is developed, formal anticoagulation with warfarin is generally considered to be unnecessary, though some centers maintain their patients on antiplatelet therapy during support. By comparison, the Novacor has a blood chamber made of smooth polyurethane which is thrombogenic, and mandates anticoagulation with warfarin. The international normalized ratio (INR) is generally maintained at 2.5 to 3.5 times normal, during support with a Novacor. Anticoagulation during long-term Thoratec support is with warfarin (INR 2.5–3 times normal), though antiplatelet agents are often prescribed as well.

### Mechanical Problems and Device Durability

Short-term support devices rarely have problems of durability, however, the long-term devices do have a finite life span. On July 26, 2005, WorldHeart (the manufacturer of the Novacor LVAS) proudly announced that a Novacor recipient from the INTrEPID trial has entered his fifth year of support. However, despite such encouraging results, it is not currently known for how long available “long-term” devices like the HeartMate and the Novacor can function. Destination therapy ideally refers to at least 10 to 15 years of support, and experience has shown that the Novacor and the HeartMate have a limited lifespan. Although they may be able to sustain a patient for a few years, these devices were intended as temporary bridges-to-transplantation; they were neither designed nor engineered with permanent use in mind.

Based on anecdotal and published worldwide in vivo experience to date, a reasonable estimate of the average lifespan of a single Novacor device is in the order of three and a half to four years, and that of a single HeartMate VE device is around two years (though the HeartMate XVE that is currently available may have an increased longevity). Results of in vitro testing of these devices (43–45) by their respective manufacturers reveals that the “reliability” of the HeartMate VE at two months and one year is reportedly 93.5% and

84.7%. In contrast, that of the Novacor is greater than 99.9% at both of these timepoints. Additionally, the reported “reliability” of the Novacor at two years and three years is 98.3% and 85.9%, respectively. Unfortunately, information about the reliability of the HeartMate at these later timepoints is not available.

In addition to issues of overall longevity, a recent large series of LVAD support for bridge-to-transplantation reported that 9% of patients supported by a HeartMate experienced mechanical problems with their device (compared to no mechanical problems observed with the Novacor) (30). Although only 1% of HeartMate-supported patients in a large multicenter series in the United States experienced “mechanical failure,” there were 435 “confirmed device malfunctions” of one sort or another in the 280 supported patients, and 9% of the supported patients needed to use “backup components” because of “cable or controller malfunction” or “pump stoppage” (32).

### Importance of Pulsatility in Ventricular Assist Device Design

Pulsatility has always been considered a desirable characteristic of VAD design, due to the ability of pulsatile flow to maintain “normal” physiology. However, creating 5–6 L/min of pulsatile flow creates several physical engineering conundrums: (i) The blood chamber must be of sufficient size to allow a physiologically meaningful stroke volume. Because there is an upper limit to the possible number of pump strokes per minute, a fairly large device is required, which tends to exclude small adults and pediatric patients. (ii) To facilitate the requisite pumping action, artificial unidirectional valves are required to prevent retrograde flow during pump systole. The presence of these valves (as well as the potentially thrombogenic blood contacting surfaces and the potential for periods of stasis during the pulsatile pump cycle) mandates anticoagulation. (iii) Although the pump heads of the Novacor and the HeartMate are implantable, they currently require connection to an external controller and power source. The presence of percutaneous lines, connecting the external components to the implanted pump, greatly increases the potential for infection. High rates of infection, with requisite antibiotic treatment, and repeated trips to the OR for incision and drainage of driveline abscesses certainly impair a patient’s quality of life, and makes systems with percutaneous components less attractive as a long-term, permanent management strategy for heart failure. (iv) Durable, reliable pumping action requires some fairly complex engineering, which (by definition) is always going to be less than maximally efficient (and unquestionably more intrinsically expensive) than some simpler device. Current diaphragm type pumps like the Novacor and HeartMate require pusher plates, with struts, springs, bearings, and servo-mechanisms. All these moving parts are subject to wear and tear, and ultimate mechanical failure (usually, it’s the bearings that wear out first).

Biomechanical engineers have designed a variety of continuous flow devices, with an eye toward providing solutions to the above mentioned problems. (i) From a mechanical standpoint, continuous flow devices are simple, consume less power, and are generally more durable because there is essentially only one moving part (the impeller). (ii) Since the flow is continuous, artificial unidirectional valves are not required and stasis is minimized, decreasing the need for formal anticoagulation. (iii) There is a potential for less hemolysis with the newly designed continuous flow devices, than with pulsatile flow (46). (iv) These

devices can be miniaturized and produce a wide range of flow rates, making them suitable for adult or pediatric use.

However, the physiologic consequences of long-term, continuous, nonpulsatile flow continue to raise concern. **✎ Pulsatile flow has long been felt to be superior to continuous flow, in terms of its ability to maintain normal homeostasis and physiology.** ✎ It has been demonstrated that nonpulsatile flow initially causes: (i) stagnation in capillary beds, leading to tissue edema and increased arteriovenous shunting, resulting in decreased oxygen extraction and impaired lactate clearance (47); (ii) redistribution of intrarenal and intrahepatic blood flow, resulting in renal and hepatic insufficiency (48,49); (iii) impairment of carotid baroreceptor function, resulting in increased mean arterial pressure (MAP) and systemic vascular resistance (50); (iv) adverse alterations of catecholamines, prostaglandins, and cytokine levels (49); (v) electrolyte imbalance, fluid overload, and anemia (51,52).

**✎ More recent studies conducted over the last decade have demonstrated that humans and animals can adapt to nonpulsatile flow, so long as that flow is maintained at somewhat supranormal levels (46).** ✎ If one maintains at least 20% or 30% higher flows than generally utilized for pulsatile support, the abnormal physiology tends to correct itself. Although pulsatile flow does appear to better maintain physiologic homeostasis and allows more efficient oxygen metabolism at lower flow rates (especially in elderly patients with noncompliant blood vessels), many of the differences appear to be attenuated as the rate of nonpulsatile flow increases on a mL/kg/min basis, with no demonstrable differences as nonpulsatile flow rates approach 100 mL/kg/min (7 L/min for a 70-kg person) (39). As a conventional point of reference, the typical flow rates employed during the routine conduct of nonpulsatile CPB are in the range of 50–60 mL/kg/min. This information, along with technological advances over the last two decades in the areas of miniaturization technology, computer chips, and biocompatible materials, have allowed for the design and development of the axial flow VADs and miniaturized, implantable centrifugal pumps, now in human clinical trials.

A final major desirable feature of the VAD of the future is total implantability; there should be no percutaneous components (cables, conduits, or wires) to encourage infection. With the development of the so-called “TET coil” (TET stands for transcutaneous energy transmission), one can deliver power and programming across the skin without skin puncture. One no longer needs cables, wires, or conduits crossing the skin. Basically, two sophisticated induction coils are aligned (one external, one internal), and energy is transduced across the skin. In addition to energy to power the device, programming information and functional interrogation can be relayed via the TET coils.

## EXTRACORPOREAL MEMBRANE OXYGENATION AND CO<sub>2</sub> REMOVAL

The use of ECLS in trauma and critical care is a relatively recent event. Indeed, ECMO was first employed in a trauma patient in 1972, when conventional therapeutic modalities were exhausted in a patient with respiratory failure. One of the major reasons why ECMO has not been widely used for respiratory failure in trauma patients is the common contraindication to systemic heparinization that

results in the presence of concomitant injuries to brain, liver, and other organs. Another reason for the initial reluctance to use ECMO in trauma and critical care resulted from the initial prospective controlled trial, using ECMO in patients with severe acute respiratory distress syndrome (ARDS) by Zapol et al. (53), which demonstrated extremely high mortalities in both the ECMO (91%) and control (91%) groups. This experience resulted in minimal utilization of ECMO, even in severe, refractory cases. However, many criticized this study, because the ECMO was started very late in the course, and because lung protection ventilation strategies were not employed.

In 1979, Gattinoni et al. (54) provided far better results in patients who were started on veno-venous extracorporeal oxygenation and CO<sub>2</sub> removal (ECCO<sub>2</sub>R) early in the progression of their disease. Because this strategy utilized a veno-venous system to manage severe respiratory failure, no arterial pressure support was provided to the patients. This technique involved the extrathoracic cannulation of both the internal jugular (IJ) vein and the femoral vein, using cutdown. Blood was drained from the common femoral vein (both proximally and distally) and the distal IJ vein, and then was returned to the proximal IJ vein (54). This cannulation system was later improved to a percutaneous system (55).

Later, Alan Morris (56) performed a prospective, controlled, computer-randomized study, comparing standard ventilation therapy (using pressure control) to ECCO<sub>2</sub>R, and did not demonstrate any survival benefit from the ECCO<sub>2</sub>R.

Despite the results from these early prospective studies, there are more recent retrospective, uncontrolled, prospective, and anecdotal reports of the successful use of ECMO in severe, refractory ARDS, including those with trauma. Lewandowski et al. (57), in a prospective, noncontrolled trial, demonstrated a 55% survival in patients treated with ECMO utilizing a clinical algorithm. Kolla et al. (58), retrospectively reviewed 100 patients that were treated with ECMO between 1990 and 1996, and found a 54% survival rate in ARDS patients with severe hypoxia.

**✎ Michaels et al. (59) retrospectively reviewed the results of ECMO in trauma patients, and found 50% mortality and documented a 59% nonlethal bleeding complication rate.** ✎ Most publications in trauma patients have consisted of case reports involving combined RV failure, LV hypokinesis, and respiratory failure (60,61). Despite significant additional trauma including splenic and liver injuries (61), and even a ruptured thoracic aorta (62), ECLS has been successfully employed without significant bleeding complications, and with excellent clinical results (50–62).

The current ECLS technique recommended for isolated respiratory failure is veno-veno cannulation, using a percutaneously placed arterial CPB cannula (Bio-Medicus; Eden Prairie, Minnesota, U.S.A.) placed in the right IJ vein (advanced to the mid-RA) and either femoral vein (advanced to the common iliac vein), as per the technique used by Prannikoff et al. (63). Using the percutaneously placed bio-medicus cannulas, Prannikoff et al., were able to achieve flows ranging between 22.4 and 127.8 mL/kg/min, with cannulas ranging from 19–23 F (Table 7). In these patients, a jugulo-femoral bypass direction is used preferentially over a femoro-jugular bypass, because the right IJ access to the RA allows for use of a short, low-resistance cannula, and drainage is better. In patients with respiratory failure along with concomitant pump failure, a form of mechanical cardiopulmonary support is also required, and an

**Table 7** Characteristics of Bio-Medicus Cannulas

Cannula size	Length, cm	M-number	Expected flow at 100 cm H <sub>2</sub> O gradient, L/min
17 F	25	3.05	2.4
	50	3.4	1.8
19 F	25	2.8	3.8
	50	3.15	2.3
21 F	25	2.6	5.0
	50	2.9	3.5
23 F	25	2.4	6.5
	50	2.65	4.8
25 F	50	2.55	5.5
27 F	50	2.4	6.5
29 F	50	2.3	7.0

Note: The “M-number” is an experimentally derived resistive factor that describes this pressure/flow relationship, and it allows for the estimation of flow for any specific cannula, given a defined pressure change across the circuit.

oxygenator that returns blood to the arterial circulation (i.e., ECMO) is optimal.

In trauma patients, femoral vein to common FA cannulation has been successfully used (61), as has the RA to ascending aorta cannulation technique (60). Those with the most experience in trauma patients all emphasize the importance of aggressive resuscitation and early employment of ECLS technology (1,59,63,64). However, these patients should be systematically evaluated for appropriateness of utilizing all forms of extracorporeal support.

## EYE TO THE FUTURE

Rotary continuous flow pumps represent the next generation of VAD technology, and can employ an axial or centrifugal design. Although axial flow devices can be smaller and often consume less power, they typically require much higher rotational speeds to generate clinically relevant blood flow, compared to centrifugal devices, which (despite miniaturization) tend to be larger, heavier, and are sensitive to changes in afterload. A potential advantage of centrifugal devices, however, is that they can generate higher pressures at lower flow rates, due to a typically larger forward displacement volume.

As all of the new devices described below are still in human clinical trials at the time of this writing, details of patient outcomes and information about specific complications with the various devices are limited to a handful of publications in the indexed literature. Moreover, the majority of available publications report results of relatively early clinical experiences with the new devices, some of which have been modified/improved as a result of information obtained in the course of their trials. Thus, one must bear in mind that a given device may eventually prove better suited to certain indications and clinical situations than another, and that the ultimate success (or failure) of a given device will only be revealed with the passage of time, and increased experience with that device. It should also be noted that many more devices have been designed and tested than are discussed below. Those

**Figure 18** The MicroMed DeBakey VAD<sup>®</sup>. Top left: As described in the text, the DeBakey VAD is used as a left ventricular assist device, drawing blood from the left ventricle apex and returning it to the ascending aorta. A percutaneous cable providing power and system control exits the skin at the right lower abdomen. Top right: As a size comparison, the device and impeller can be seen with a standard AA battery. Bottom: A cutaway view of the device. Source: Courtesy of Micromed Technologies, Inc.

presented here are key devices, about which there is information published in peer-reviewed, indexed literature.

## The Axial Flow Pumps

### MicroMed DeBakey VAD<sup>®</sup>

In the mid-1980s, a fortuitous collaboration between Drs. DeBakey and Noon (65), and engineers from the NASA Johnson Space Center in Houston, resulted in the development of one of the first axial-flow LVADs. This device eventually became the LVAD we know today as the MicroMed DeBakey VAD (MicroMed Technologies, Houston, Texas, U.S.A.; Fig. 18), now in human clinical trials. As depicted in Figure 18, the 75 mm long × 25 mm in diameter device is used as an LVAD, positioned between the left ventricular apex and the ascending aorta; 10,000 rpm will produce 5–6 L/min flow at a pressure of 100 mmHg, and consumes less than 10 W of power.

According to the manufacturer, more than 330 patients have already been implanted with the DeBakey VAD at 14 centers, in seven countries. European and U.S. clinical trials of the device as a bridge to transplantation began in November 1998 and June 2000, respectively. A CE mark in Europe was awarded in May 2001. Also in 2001, the device was modified with the addition of a Carmeda<sup>®</sup> heparin coating of the blood-contacting surfaces (which has subsequently been removed). A further miniaturized version of the DeBakey VAD (the DeBakey VAD Child heart pump) received FDA Humanitarian Device Exemption (HDE) approval in March 2004, and successfully served as a bridge to transplantation in a 14 year old with congenital heart disease, from September to November 2004.

Though the device is still the subject of human clinical trials, a few investigators have published the details of their early experiences with the DeBakey VAD (66–68). Despite overall survival of 50% or more in these trials, reported impressions of the device have varied (based apparently on complications encountered).

**Figure 19** Jarvik 2000 Flowmaker<sup>®</sup>. This axial flow pump was formerly known as the Jarvik 2000 LVAS. *Left:* the size of the device can be seen compared to a surgeon's hand. *Right:* The Flowmaker is implanted in the left ventricle apex with outflow directed into the descending thoracic aorta. The cable providing power and system control can be seen emerging from the device, and heading craniad to emerge from the skin at the base of the skull (see text for details). *Source:* Courtesy of Texas Heart Institute, 2000.

The DELTA<sup>™</sup> trial (Destination Evaluation of Long Term Assist) currently randomizes transplant-ineligible patients with end-stage failure to receive either the DeBakey VAD or the HeartMate XVE LVAS as destination therapy. Up to 360 patients, at 30 clinical sites, will be enrolled in a 2:1 randomization scheme (DeBakey VAD:-HeartMate), under the supervision of the International Center for Health Outcomes and Innovation Research (InCHOIR). The first DELTA patient was implanted with a DeBakey VAD at California Pacific Medical Center in November 2004.

#### **The Flowmaker<sup>®</sup> (the Device Formerly Known as the Jarvik 2000 LVAD)**

The Flowmaker (Jarvik Heart, Inc., New York, New York, U.S.A.; Fig. 19) is an electrically powered, miniaturized axial flow pump, now in human clinical trials in the United States and Europe. The entire device weighs 85 grams and measures 2.5 cm in diameter × 5.5 cm long. It has typically been described by the media as "the size of a C-cell battery." All blood-contacting surfaces are composed of smooth titanium. A number of surgical approaches have been used to implant the device, including midline sternotomy, left thoracotomy, and subcostal incision. As depicted in Figure 19, the device is implanted in the left ventricular apex, and outflow from the device can be directed into the descending thoracic aorta or ascending aorta, depending on the surgical approach. Anticoagulation is recommended when the outflow is to the descending aorta, to prevent stasis and potential thrombosis in the aortic root. The current version of the Flowmaker uses a percutaneous cable to provide power and system control (though a totally implantable configuration with a TET coil is under development). The cable exits the skin of the abdomen with devices implanted as a bridge to transplantation, but when the device is implanted for permanent use (destination therapy), the cable is tunneled craniad (through the pleura and across the neck), to exit the skin at the base of the skull just behind the left mastoid process. Apparently, the vascularity of the skin in this area permits a very low incidence of infection in this site.

When physiologic conditions are optimal, impeller rotation at 8000–12000 rpm can produce flows on the order 6–7 L/min (69) to assist native ventricular ejection. Increasing pump speed has been demonstrated to have direct effects on hemodynamic indices, in direct relation to the level of ventricular unloading. Increasing impeller rotation from 8000 to 12,000 rpm results in linear increases in MAP and cardiac index, and linear decreases in pulmonary capillary wedge pressure and the amount of time the aortic valve stays open in systole. Impeller speeds greater than 12,000 rpm reportedly produce complete unloading of the LV, with a resultant pulse pressure less than 20 mmHg (70).

As mentioned above, the various new devices will undoubtedly declare themselves as best suited to specific clinical scenarios and certain patient populations, once experience has demonstrated their individual strengths and weaknesses. This already appears to be the case with the Flowmaker. According to a recent publication by Dr. Frazier (71), the main goal of this device is to "partially reduce the LV size and end-diastolic pressure," as this may allow reverse remodeling of the failing LV. Thus, patients likely to benefit most from the Flowmaker are those who require "true left ventricular assistance," and not "total capture of the LV output." Further, that the use of the Flowmaker "may be justified in severely impaired class III and IV (but not preterminal) patients."

Human clinical trials of this device as a bridge-to-transplantation in the United States, began at the Texas Heart Institute (THI) in April 2000. In 2002, the FDA gave permission for patients to be discharged to home with an implanted Flowmaker. A recent review (71) reports that, as of 2004, 35 patients have received the device as a bridge-to-transplantation, in four U.S. clinical centers (29 were implanted at the THI). Three were discharged home to await their new heart. Eighteen patients were successfully bridged to transplantation, and 12 died during support. The average duration of support was 67 days. One patient had his Flowmaker explanted and exchanged for an approved pulsatile device, and four patients remained supported.

European clinical trials began shortly after the U.S. trials, and are evaluating the Flowmaker for both destination therapy and as a bridge to transplantation. As of 2004, 17 patients had been implanted (14 permanent implants and three bridges) in five clinical centers. Ten patients have reportedly been discharged home in the European trials (71). There have, thus far, been no reported device failures nor episodes of significant hemolysis. One European patient has reportedly been supported by the Flowmaker for longer than four and a half years (72).

RV failure is known to occur in up to 30% of LVAD supported patients (73,74), due to alterations in RV geometry resulting in increased RV compliance and decreased RV contractility, in the presence of increased RV preload (75). Feasibility studies using the Flowmaker for biventricular support (in calves) yielded favorable results (76). Although the LVAD was implanted in the LV, the RVAD was implanted in the RA (through the same left thoracotomy incision). Further study is required to assess the efficacy of biventricular support with the Flowmaker in humans with biventricular heart failure.

#### **HeartMate II<sup>®</sup>**

The HeartMate II LVAS (Thoratec Corporation, Pleasanton, California, U.S.A.; Fig. 20) is an axial flow pump that

**Figure 20** The HeartMate II<sup>®</sup>. The HeartMate II is implanted in a configuration similar to that shown for the DeBakey VAD (video clip 1) and many other axial flow devices now in clinical trials. Blood is drawn from the left ventricle apex to the device and impelled into the ascending aorta. *Source:* Courtesy of Thoratec Corporation.

evolved from the original Hemopump. At 7 cm long, it occupies approximately one-eighth the volume of the pulsatile HeartMate<sup>®</sup> I, but can generate the same output. Using the battery analogy mentioned earlier, this device is about the size of a D-cell battery. Impeller speeds range from 6000–15,000 rpm with a 10 L/min maximum output. A microprocessor-controlled algorithm adjusts pump speed to meet the changing flow demands of the body. Like the pulsatile HeartMate I, some of the blood-contacting surfaces are lined with sintered titanium microspheres to encourage neoendothelialization. The impeller is made of smooth titanium. Inflow and outflow cannulations of the left ventricular apex and the ascending aorta are similar to that of the HeartMate (and most of the other devices). Although a totally implanted configuration with a TET coil is under development, the current system requires a percutaneous drive-line that exits the skin of the right lower abdomen.

The first human implant was performed at the Sheba Medical Center in Israel, in July 2001 (77), but the specific results have not been made publicly available. It is known, however, that the initial European clinical trial was terminated early, due to thrombus formation at the inlet and outlet of the device. Since that time, the device has been redesigned (the positions of textured surfaces have been altered), and is now being implanted in a U.S. clinical trial. The redesigned HeartMate<sup>®</sup> II was recently implanted in an 18-year-old male with severe heart failure (idiopathic cardiomyopathy) and multisystem organ dysfunction, as a bridge-to-transplantation (78). For this patient, 8600 rpm produces approximately 4.4 L/min of flow, during which he still has native ventricular ejection (echocardiographically demonstrated by aortic valve opening). During exercise, his pump speed adjusts up to 9000 rpm (approximately 5.3 L/min of flow). There has been no significant hemolysis observed, and he has been supported for longer than six months with a New York Heart Association (NYHA) class I status (maintained on warfarin anticoagulation).

### **The Berlin Heart INCOR<sup>®</sup> and the MagneVad<sup>®</sup>—Magnetically Levitated, Bearingless Axial Flow Pumps**

All the axial flow pumps discussed above utilize bearings at the two ends of their impeller. Thrombus formation at the sites of these bearings has been a problem with several of

**Figure 21** The Berlin Heart INCOR<sup>®</sup>. Like the majority of the new axial flow VADs, the INCOR draws blood from the left ventricle apex and returns it to the ascending aorta. However, unlike all the other devices, the impeller is magnetically levitated. Without bearings, the durability of the device is likely to be very long, and the potential for thrombosis is markedly diminished. *Source:* Courtesy of Berlin Heart.

the new axial flow devices (67,68). As discussed above, the HeartMate II had to be redesigned after thrombus formation was detected at the inlet and outlet stators, in the initial human implantation experience. The Berlin Heart INCOR<sup>®</sup> (Berlin Heart AG, Berlin, Germany; Fig. 21) and the MagneVad (Gold Medical Technologies, Inc, Valhalla, New York, U.S.A.; Fig. 22) are innovative axial flow devices, with non-contacting magnetic bearings. Theoretically, this should eliminate the potential for thrombus formation at the points of impeller-bearing contact. Additionally, without points of contact, the durability of such a device is likely to be very long, because there are no contacting moving parts to wear out.

**Figure 22** The MagneVad<sup>®</sup>. Like the Berlin Heart INCOR, the MagneVad is a bearingless, magnetically levitated axial flow device, now under development in the United States. *Source:* Courtesy of Gold Medical Technologies, Inc.

**Figure 23** The VentrAssist™ LVAS. *Source:* Courtesy of Ventracor, Ltd.

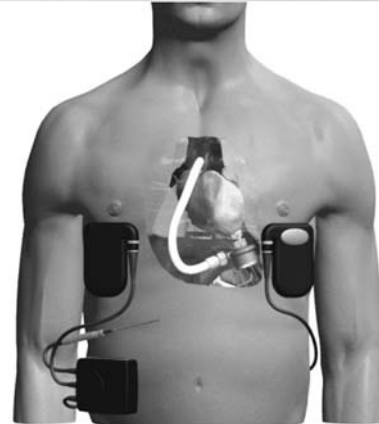

The INCOR is a very successful axial flow device that has been implanted in more than 200 patients in Europe since June 2002. According to the manufacturer, 12,000 rpm produces 7 L/min of flow against a pressure of 150 mmHg, and consumes 8.5 W of power. The efficiency of the magnetically levitated rotor is reportedly greater than 90%. The INCOR received a European CE mark in 2003. According to press releases from Berlin Heart, as of July 2005, the longest duration of support is more than 1000 days. The average duration of support has been 167 days, with 24 patients supported for more than one year, and four for longer than two years. Twenty-five patients have been successfully discharged to home during support. As discussed above, the advantage of magnetic levitation of the impeller (without bearings) is a minimization of thrombotic risk. Presentations by Berlin Heart at the 2003 ASAIO conference in Washington, DC, indicated that thrombus formation had not been observed in patients (79). The Magnevad is still under development in animal trials, and has not yet been implanted in humans.

### Centrifugal Continuous Flow Pumps

#### **VentrAssist™**

The VentrAssist LVAS (Ventracor Ltd., Sydney, Australia; Fig. 23) is a hydrodynamically suspended, electromagnetically driven, miniaturized centrifugal blood pump that provides continuous flow of up to 10 L/min at 3000 rpm (80). It weighs just 298 grams (10 oz) and measures 60 mm (2.5 inches) in diameter, making it suitable for both children and adults. This new device was primarily designed for destination therapy, but has been successfully used as a bridge-to-transplantation, and has also shown promise as a bridge-to-recovery.

According to the manufacturer, the VentrAssist has now been implanted in more than 30 patients in Australia, New Zealand, and Europe as part of a CE mark trial. Although press releases have been extremely positive and it is known that several VentrAssist patients have been successfully discharged to home, no specific information about the device recipients, complications, or durations of support, has been published as of the time of this writing. The first implant in the United States was performed on July 18, 2005, at the University of Maryland Medical Center in Baltimore, as part of a feasibility study intended to establish an application for FDA approval. This U.S. feasibility trial will enroll 10 patients, in up to five hospitals across the country, and is managed by the InCHOIR.

**Figure 24** The CorAide™ Pump. *Top:* The device. The percutaneous cable which delivers power and system control can be seen emerging from the bottom, and the outflow cannula can be seen emerging from the side of the device. *Bottom:* The configuration of the implanted CorAide is demonstrated. *Source:* Courtesy of Arrow International.

#### **CorAide™**

The CorAide LVAS (Arrow International, Inc, Reading, Pennsylvania, U.S.A.; Fig. 24) is a magnetically and hydrodynamically suspended miniaturized centrifugal blood pump that provides continuous flow of 2–8 L/min. Weighing just 293 grams with a forward displacement of 84 mL, flows of 3–5 L/min have been achieved with this device, at pump speeds around 2700 rpm, consuming just 4 watts of power (81). This new device was developed by Arrow International and the Cleveland Clinic Foundation, and, according to the manufacturer, can serve as a potential bridge-to-recovery, a bridge-to-transplantation, or can provide long-term cardiac support.

The CorAide is currently in a European clinical trial to assess its safety and performance. According to the manufacturer, the first implant took place in Germany in May 2003, in a 65-year-old male, as a bridge-to-transplantation. Though the implantation was reportedly uneventful, high levels of hemolysis were noted by postoperative day 3. The CorAide was explanted and replaced by a different support device to bridge the patient to transplantation. As a result, the clinical trial was temporarily put on hold. There have now been five patients implanted with the CorAide, since the trial was resumed in February 2005, and “all patients are recovering as expected” (Carl Botterbusch, personal communication). No specific information about these patients is available in the peer-reviewed, indexed literature at the time of this writing.

**Figure 25** The Terumo Duraheart<sup>®</sup>. *Source:* Courtesy of Terumo Heart, Inc.

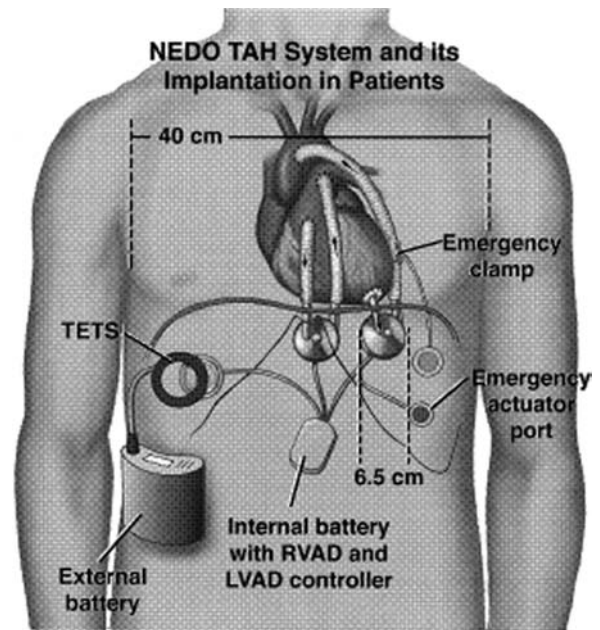

### **Duraheart<sup>®</sup>**

The Terumo Duraheart (Terumo Cardiovascular Systems Corporation, Ann Arbor, Michigan, U.S.A.; Fig. 25) is an implantable centrifugal device with a magnetically levitated impeller, but its inner surfaces are heparin bonded, eliminating the need for anticoagulation during support. Compared to the VentrAssist and the CorAide, the Duraheart is larger (72 mm diameter, 45 mm height), heavier (540 g), and has a significantly bigger forward displacement volume (180 mL). A pump speed of 2600 rpm can produce flows of 10 L/min (82).

A European clinical trial of the Duraheart began in January 2004. According to a very recently published review, as of August 2004, 10 patients have been implanted. Reportedly, three patients “met the primary endpoint” of the trial (evaluating the safety and performance of the Duraheart), four were able to be discharged, and one underwent transplantation after 138 days of support. The outcome of the remaining patients is unknown, but it is reported that “there were no cerebrovascular accidents, deaths, or infections,” and that the longest support duration was 170 days (82).

### **The NEDO Projects**

From 1995 to 2004, the NEDO projects (New Energy and Industrial Technology Development Organization) encompassed a number of mechanical circulatory support devices (MCS) in development at Japanese universities, hospitals, national research institutes, and private companies. The Terumo Duraheart described above was one such project. Another of the NEDO projects focused on a pivot-bearing-supported centrifugal flow pump that could be used for uni- or biventricular support, and could be configured in different ways, depending on the needs of the patient. Currently called the Miwatec/Baylor<sup>®</sup> biventricular MCS (Miwatec Co., Ltd., Hokkaido, Japan; Fig. 26), this multipurpose miniaturized centrifugal device produces 5 L/min of flow at rotational pump speeds under 2000 rpm, and

**Figure 26** The Miwatec/Baylor<sup>®</sup> Device. As discussed in the text, this miniaturized centrifugal pump is intended to be multi-purpose, and can be configured to suit the needs of the individual patient. Specifically, the miniaturized centrifugal devices can be paracorporeal (like a Thoratec) for short-term assistance (bridge to recovery), implanted in the preperitoneal space for long-term assistance (bridge to transplantation), or permanent (destination therapy). *Abbreviations:* LVAD, left ventricular assist device; RVAD, right ventricular assist device; TET, transcutaneous energy transmission. *Source:* From Ref. 82.

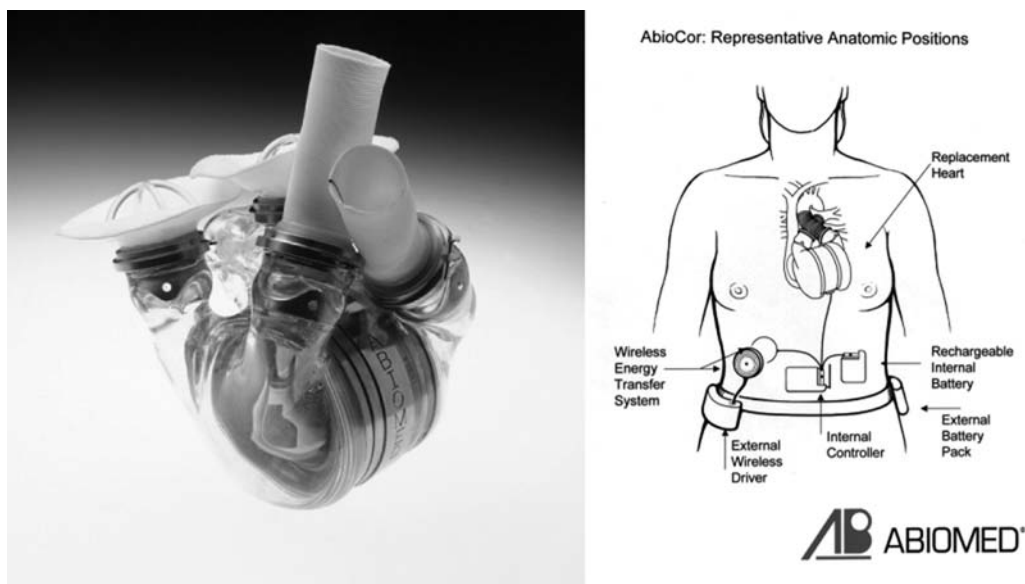

consumes around 7 watts of power (82). Reportedly, clinical trials are planned for the United States and Europe in the near future.

### **The HeartMate III<sup>®</sup>**

The HeartMate III (Thoratec Corporation, Woburn, Massachusetts, U.S.A.; Fig. 27) is a miniaturized centrifugal flow device with a magnetically levitated impeller. The device occupies approximately one-third the volume of the HeartMate I, but reportedly can produce flows of 7 L/min at a pressure of 135 mmHg, at just under 5000 rpm. The device

**Figure 27** The HeartMate III<sup>®</sup>. The HeartMate III is implanted in a manner similar to most of the other new continuous flow devices, drawing blood from the left ventricle apex and returning it to the ascending aorta.

**Figure 28** The AbioCor™ Implantable Replacement Heart. *Left:* The device as it appeared at the beginning of the feasibility study. Note the struts on the atrial inflow appendages. These struts were removed from subsequent implantations during the feasibility study, once they were identified as a likely location of thrombus formation. *Right:* The appearance of an implanted AbioCor with components labeled.

will use a totally implanted configuration, with power transfer and system control via a TET coil. Sophisticated control algorithms will allow device responsiveness to physiologic demand, and alternating rotational speeds will allow for some pulsatility. This device is not yet in human clinical trials. A recent feasibility study using the HeartMate III for biventricular support (in sheep) yielded favorable results (72). Further study is required to assess the efficacy of biventricular support with the HeartMate III, in humans with biventricular heart failure.

**New Innovations in Total Artificial Heart Technology**

The AbioCor™ Implantable Replacement Heart (Abiomed, Danvers, Massachusetts, U.S.A.; Fig. 28) represents a major advance in artificial heart technology, because it is electrically powered and truly, totally implantable. Unlike the pneumatically driven TAHs of the past (83–85) and the CardioWest device available today, the AbioCor is motor driven, so a percutaneous source of compressed air is not required. Additionally, TET is used to supply the motor-driven hydraulic pumping of the artificial ventricles with power and system control.

As depicted in Figure 28, the failed, native heart is removed, and this device is implanted orthotopically, directly anastomosed to cuffs of native atrial tissue and the great vessels. The AbioCor weighs around two pounds, and consists of two ventricular pumps, each with SV 60 mL. Instead of compressed air, ejection from the artificial ventricles is hydraulically effected by a high-efficiency centrifugal pump, which operates unidirectionally, whereas a cylindrical rotary valve alternates the direction of hydraulic fluid flow between right and left pumping chambers. A microprocessor controller allows device output to be responsive to physiologic demand. Overall, the AbioCor can reportedly produce pulsatile flows in the range of 4–8 L/min. Because the device produces pulsatile flow, there are four artificial trileaflet valves to prevent retrograde flow

during pump systole, mandating formal anticoagulation with Coumadin.

A clinical feasibility study for the AbioCor was approved in January 2001, for up to 15 patients. The purpose of this study was to assess the safety and probable benefit of the AbioCor, as a potential therapy for those patients with biventricular failure whose therapeutic options had otherwise been exhausted, and had a high probability of dying within 30 days. Fourteen patients were implanted with the AbioCor, at six clinical centers. Although all 14 have now expired, device performance was truly impressive, with one patient supported for more than a year. Figure 29 shows the length of AbioCor support of the initial 14 implantees. Of the 14 patients enrolled in the feasibility study, two died in the OR, 10 did not leave the hospital (except for day passes for four patients), one was discharged to a nearby hotel, and one was discharged home (86).

As might be expected in any study population with significant comorbidities, complications were frequently

**Figure 29** Length of support of the initial 14 implantees with the AbioCor™ Implantable Replacement Heart. *Source:* From Ref. 86.

encountered. Details of the AbioCor experience with the first seven human implants was recently published (87). Thromboembolic complications were a big problem initially, but the ostensible source of the thrombi was identified fairly early as the struts on the atrial inflow appendages (Fig. 28), and these were removed prior to subsequent implants. Other encountered complications were not so unusual for any cardiac surgical population requiring mechanical circulatory assistance, and included perioperative bleeding, respiratory failure, transient renal and/or hepatic insufficiency, and multisystem organ failure. One patient reportedly died of a severe aprotinin reaction in the OR. Interestingly, one of the two patients who were ultimately discharged to home, survived multiple episodes of aspiration requiring tracheostomy and an episode of neuroleptic malignant syndrome.

Results from the initial implants were submitted to the FDA in September 2004, for marketing approval under a HDE. Under the HDE application, up to 4000 patients a year who are not eligible for a heart transplant would have the potential to be eligible for an AbioCor. On June 23, 2005, the FDA ultimately denied the application, citing concerns about patient inclusion criteria and device labeling, potential benefit versus risk of the device, anticoagulation protocols, and quality-of-life versus quantity-of-life issues. The complete transcript of the FDA Medical Devices Advisory Committee Circulatory System Devices Panel Meeting can be viewed online (88).

Abiomed has acquired the rights to the Penn State TAH, and have now introduced the AbioCor II (Fig. 30). This device incorporates the best technologies of both the AbioCor and the Penn State heart. The AbioCor II is 35% smaller than the original AbioCor (potentially implantable in more of the adult population), and has been designed with the goal of five-year reliability. This device is currently being evaluated in preclinical animal studies. Abiomed reportedly intends to submit for an Investigational Device Exemption in 2006, in order to begin clinical trials, with a goal of seeking premarket approval by 2008.

**Figure 30** The AbioCor™ II. The AbioCor II combines the best technologies of the AbioCor I and the Penn State total artificial heart, in an implantable replacement heart that is 35% smaller than the AbioCor I.

## SUMMARY

Cardiopulmonary mechanical assist devices represent powerful assets in our armamentarium against acute and chronic cardiopulmonary failure. In the case of pure cardiac failure, LV support is most commonly required, and the initial short-term assistance is generally provided with an IABP. An LVAD is required when combined inotropic and IABP utilization results in inadequate  $\dot{Q}$  and perfusion pressures. The most common cause of RV failure is LV failure. However, occasionally a temporary RVAD is employed for acute RV dysfunction, following ischemia related to coronary artery disease or following a heart transplantation. When biventricular dysfunction is present, a BiVAD is employed.

Whether used as a bridge-to-recovery, a bridge-to-transplantation, or as permanent “destination therapy,” outcomes have been increasingly encouraging as experience has grown, and the various components comprising these devices continue to be improved.

In the case of respiratory failure not responding to conventional mechanical ventilator therapy, utilization of ECLS devices have resulted in improved outcomes. For those without pump failure, veno-venous (ECCO<sub>2</sub>R) technologies are adequate. Whereas, when both cardiac and respiratory failure are present together, a veno-arterial (ECMO) type of ECLS is required. Due to the recent improvements in membrane technologies, and because of heparin bonding to ECLS circuits, systemic heparinization is no longer required. Rather, ACTs in the 180 to 200 seconds range are adequate to prevent thromboembolic complications. Thus, these devices are suitable for acute trauma patients, providing brain injuries are absent or of a nonhemorrhagic type.

Miniaturization and newer pump technologies are being studied as the next generation of VAD. Innovative new devices promise increased device longevity, with fewer complications and an improved quality of life for patients who would otherwise succumb to heart failure.

## KEY POINTS

- ✎ The IABP is a percutaneously inserted device, which provides intra-aortic counterpulsation.
- ✎ When maximal pharmacologic interventions and an IABP fail to restore hemodynamic stability, extracorporeal support may be required to re-establish and maintain systemic perfusion, and to prevent the catastrophic sequelae of cardiogenic shock.
- ✎ The importance of prompt intervention to restore adequate systemic perfusion, and careful patient selection for prolonged treatment cannot be understated, if expectations are for successful bridge to recovery with a VAD.
- ✎ If the myocardium does not recover after a period of short-term support, then a decision must be made as to whether the patient is an acceptable transplant candidate.
- ✎ Only one out of every 2273 patients with end-stage heart failure is likely to receive a heart transplant.
- ✎ Despite the impressive rates of successful short- and long-term support with VADs, infection, thromboembolic complications, and mechanical problems remain major issues to be overcome.
- ✎ Pulsatile flow has long been felt to be superior to continuous flow, in terms of its ability to maintain normal homeostasis and physiology.

- ✦ More recent studies conducted over the last decade have demonstrated that humans and animals can adapt to nonpulsatile flow, so long as that flow is maintained at somewhat supranormal levels (46).
- ✦ Michaels et al. (59), retrospectively reviewed the results of ECMO in trauma patients, and found 50% mortality and documented a 59% nonlethal bleeding complication rate.
- ✦ Rotary continuous flow pumps represent the next generation of VAD technology, and can employ an axial or centrifugal design.

### INTRODUCTION

Respiratory failure is one of the most common reasons for admission to the intensive care unit (ICU) following trauma or critical illness, and remains a leading cause of morbidity and mortality. This chapter reviews the pathophysiology of acute respiratory failure (ARF), and provides a practical approach to diagnosis and therapeutic management. This review is complementary to the material covered in Volume 2, Chapter 24, which surveys the acute respiratory distress syndrome (ARDS).

Apart from the application of life-support measures during management of ARF, the initial emphasis involves an intense search for the primary etiology of respiratory failure. The important principles of early and accurate diagnosis are emphasized throughout this text. Early diagnosis (in the first hours or days of disease) increases the likelihood that appropriate specific therapy will be applied, and decreases the likelihood that the patient will progress from ARF to full-blown ARDS.

Pulmonary embolus (PE) is an important and common source of ARF following trauma and critical illness. Because the problem of deep venous thrombosis (DVT) and consequent PE is so pervasive in patients suffering from trauma, burns, and critical illness, an entire chapter has been dedicated to the subject (Volume 2, Chapter 56). Accordingly, PE is only briefly reviewed here.

This chapter does provide an important survey of infectious causes of pneumonia, because almost all ICU patients with ARF will either begin with an infectious etiology, or become secondarily infected. In addition to reviewing the organisms commonly associated with respiratory infections, practical strategies to minimize nosocomial infections are provided. This chapter is also complementary to Volume 2, Chapter 48, which reviews ventilator-associated pneumonia (VAP), and focuses more closely on the organisms that cause VAP. Therefore, this chapter surveys all of the clinically relevant organisms causing respiratory failure.

Finally, this chapter provides only an abbreviated summary of management principles for patients with ARF, because Volume 2, Chapters 24 to 29 in this volume cover these topics in exquisite detail.

### DEFINITIONS AND EPIDEMIOLOGY

#### Consensus Definitions

The presence of persistent hypoxemia (with or without hypercapnia) is clearly evidence of respiratory system failure. However, a universally accepted definition of ARF does not yet exist. In contrast, definitions for acute lung injury (ALI) and ARDS have been agreed upon by the American-European Consensus Conference, and are summarized in Table 1 (1). Additionally, the American College of Chest Physician (ACCP)/Society of Critical Care Medicine (SCCM) consensus statement on sepsis syndrome defines respiratory failure as a respiratory rate  $>20$  breaths/min or  $\text{PaCO}_2 <32$  mm Hg, or the need for mechanical ventilation to treat an acute respiratory process (2). The ACCP/SCCM definition of respiratory failure does not specifically account for hypercapnic respiratory failure. Because the most important consideration in assessing the need for mechanical ventilatory support is the overall clinical condition of the patient, any complete definition of ARF should include criteria for ALI, along with a measure of overall patient status.

Respiratory failure can be classified as oxygenation failure (hypoxemic), ventilation failure (hypercapnic), or both (combined). Differentiation between these conditions can be made on the basis of the arterial blood gas (Table 2).

**Arterial blood gas (ABG) analysis is the single most important laboratory test for defining the severity of ARF. In addition to quantifying the severity, ABG analysis assists in differentiating the cause of ARF, and is useful in decision making regarding intubation and mechanical ventilation.**

Age should be considered when quantifying the degree of hypoxemia appropriate for patients, when breathing room air. A physiologic increase in the alveolar to arterial (A-a) oxygen gradient occurs during aging, with a gradient as high as 30 mmHg at age 80 (3). This gradient will be exacerbated when higher inspired oxygen concentrations are used, as there is a normal increase in A-a gradient of 5–7 mmHg with every 10% increase in inspired oxygen concentration (4).

If the patient has not improved with the administration of supplemental oxygen, or if the work of breathing (WOB) is excessive, or the patient's debilitated state does not allow him to perform the required WOB, the patient should be

**Table 1** American–European Consensus Conference Definitions of Acute Lung Injury and Acute Respiratory Distress Syndrome

	Acute respiratory distress syndrome
Acute lung injury	
Acute onset of respiratory failure	Acute onset of respiratory failure
Bilateral infiltrates on chest radiograph	Bilateral infiltrates on chest radiograph
No evidence of left atrial hypertension (PAOP <sup>a</sup> < 18 mmHg)	No evidence of left atrial hypertension (PAOP < 18 mmHg)
PaO <sub>2</sub> /FiO <sub>2</sub> < 300 mmHg	PaO <sub>2</sub> /FiO <sub>2</sub> < 200 mmHg

<sup>a</sup>Although classically, pulmonary artery occlusion pressure (PAOP) should be <18 to make the diagnosis of noncardiogenic pulmonary edema, occasionally noncardiogenic etiologies will occur with PAOP ≥ 18. *Abbreviations:* PaO<sub>2</sub>/FiO<sub>2</sub>, ratio of partial pressure of oxygen in arterial blood to the fraction of inhaled oxygen; PAOP, pulmonary artery occlusion pressure. *Source:* From Ref. 1.

transported to the ICU for more aggressive interventions and closer monitoring. Most importantly, the clinician needs to vigorously pursue the inciting cause of respiratory failure, rather than merely provide supportive care in the form of endotracheal intubation and mechanical ventilation. Importantly, the clues to the etiology are usually most apparent during the initial hours of respiratory failure, and may become lost after 24 to 48 hours of ventilatory support. Furthermore, recent clinical trials suggest that early intervention in the form of antibiotics and fluid resuscitation may decrease mortality from respiratory failure, so identifying the precipitating cause will suggest the most effective therapy (5,6).

### Epidemiology

In a recent European study, the incidence of ARF was 78 patients per 100,000/yr, with an overall 90-day mortality of 41% (7). In addition, the lung is often the primary source for sepsis syndrome in patients presenting with ARF (8). The common need for mechanical ventilation, and the

costs and complications associated with this intervention, make this patient population responsible for a significant component of health care expenditures.

ARF is the leading cause of admission to the ICU in most settings. Using the definition of a PaO<sub>2</sub>/FiO<sub>2</sub> 200 and the need for mechanical ventilatory support, Vincent (9) estimated that 34% of all ICU admissions were for ARF that progressed to ARDS, and that those patients had a mortality of 34% versus a mortality of 16% for patients admitted for other diagnoses. Arroliga et al. (10), identified the incidence of ARDS at 15 cases/100,000/yr in Ohio. As ARDS is only a subset of all patients with ARF, the overall incidence of ARF would be expected to be much higher. Clearly, ARF, along with sepsis syndrome, are leading causes of both ICU admission and morbidity and mortality. Volume 2, Chapter 24 discusses the pathophysiology and progression from ALI to ARDS that results, when any one of a multitude of disorders becomes severe enough to disrupt the alveolar epithelial capillary barrier.

## PATHOPHYSIOLOGY OF ACUTE RESPIRATORY FAILURE

### Acute Hypoxemic Respiratory Failure: Gas Exchange Dysfunction

Hypoxemia is defined as inadequate blood oxygenation, and should be conceptually differentiated from hypoxia, which indicates deficient oxygen concentration anywhere (inside or outside the body), but typically means low PO<sub>2</sub> in the tissues. Acute hypoxemic respiratory failure is present when the partial pressure of oxygen in arterial blood (PaO<sub>2</sub>) is less than 60 mmHg, in the setting of low or normal arterial partial pressure of carbon dioxide (PaCO<sub>2</sub>). The presence of tissue hypoxia leads to anaerobic cellular metabolism, and if the tissue PO<sub>2</sub> remains too low for too long, cell death will occur. Hypoxemia in ARF can result from a number of conditions, listed in Table 3. Each of these pathologic processes leading to hypoxemia will be considered separately. However, the critically ill patient with respiratory failure often presents with a combination of these processes coexisting. Additionally, others begin after the initial event, and all conditions may contribute to the degree of hypoxemia experienced by the patient.

**Table 2** Classification of Respiratory Failure by Arterial Blood Gas Analysis

Classification	Acute hypoxemic	Hypercapnic (ventilatory failure)	Combined (periop, posttrauma)
P <sub>(A-a)</sub> O <sub>2</sub>	↑	→	↑
PaO <sub>2</sub>	↓	↓ <sup>a</sup>	↓
PaCO <sub>2</sub>	Initially ↓ Later, may ↑	↑	Initially maybe ↑, →, or ↓ Later ↓
Examples	Pulmonary edema pneumonia	CNS depression Neuromuscular weakness Airflow obstruction	Postchest trauma or post-op with pain and atelectasis
Comments	Any condition causing mixed venous blood to traverse nonventilated lung units results in right-to-left transpulmonary shunt. When severe, acute hypoxemic respiratory failure results	In ventilatory failure, gas exchange abnormalities result from decreased alveolar ventilation, resulting in hypercapnea and proportional hypoxia	Combined respiratory failure is common following trauma and postop. Lower lung volume due to splinting from pain leads to atelectasis, smoking history, fluid resuscitation, and leaky capillaries (burns, SIRS, sepsis, etc.) all contribute further

<sup>a</sup>PaO<sub>2</sub> often becomes normal with ↑ FIO<sub>2</sub> in pure hypoventilatory (hypercapnic) respiratory failure.

*Abbreviations:* ↓, decreased; ↑, increased; →, normal; CNS, central nervous system; PaCO<sub>2</sub>, partial pressure of carbon dioxide in the arterial blood; PaO<sub>2</sub>, partial pressure of oxygen in the arterial blood; P<sub>(A-a)</sub>O<sub>2</sub>, alveolar-to-arterial oxygen gradient; SIRS, systemic inflammatory response syndrome.

**Table 3** Five Pathophysiologic Processes that Cause Acute Hypoxemic (Low PaO<sub>2</sub>) Respiratory Failure

Process	P(A-a)O <sub>2</sub>	Response to 100% O <sub>2</sub>	PaCO <sub>2</sub>	Clinical examples
Low PIO <sub>2</sub>	Normal	↑↑ PaO <sub>2</sub>	Normal	Elevation (e.g., Denver, Mexico City) low FIO <sub>2</sub> (e.g., plumbing or tank hook-up error)
Hypoventilation	Normal	↑↑ PaO <sub>2</sub>	↑↑	Opiate overdose Myasthenia Gravis Guillian-Barre syndrome
$\dot{V}_A/\dot{Q}$ mismatch	↑↑	↑↑ PaO <sub>2</sub>	Normal	Segmental atelectasis (low $\dot{V}_A/\dot{Q}$ ) or sub segmental pulmonary emboli (high $\dot{V}_A/\dot{Q}$ )
Shunt ( $\dot{Q}_s/\dot{Q}_t$ )	↑↑	No improvement	Normal	Noncardiogenic pulmonary edema (2° aspiration, sepsis, SIRS, etc.)
Diffusion limit	↑↑	↑↑ PaO <sub>2</sub>	Normal	Pulmonary edema and associated interstitial edema

Note: PIO<sub>2</sub> = FIO<sub>2</sub> (P<sub>B</sub> - P<sub>H<sub>2</sub>O</sub>).

Abbreviations: ↑↑, increased; FIO<sub>2</sub>, fractional concentration of inspired oxygen; P<sub>B</sub>, barometric pressure; P<sub>H<sub>2</sub>O</sub>, partial pressure of water; PaCO<sub>2</sub>, partial pressure of carbon dioxide in the arterial blood; PaO<sub>2</sub>, partial pressure of oxygen in the arterial blood; P(A-a)O<sub>2</sub>, alveolar-to-arterial oxygen gradient; SIRS, systemic inflammatory response syndrome (see Volume 2, Chapter 63);  $\dot{V}_A/\dot{Q}$ , alveolar ventilation to perfusion ratio.

### Oxygen Consumption and Delivery

In order to fully evaluate the adequacy of tissue oxygenation, the concepts of oxygen delivery (DO<sub>2</sub>) and oxygen consumption ( $\dot{V}O_2$ ) will be briefly reviewed. The factors contributing to the value of DO<sub>2</sub> are oxygen content (CaO<sub>2</sub>) and cardiac output (Q), as shown in Equation 1:

$$\dot{D}O_2 = CaO_2 \times \dot{Q} \quad (1)$$

where CaO<sub>2</sub> is the arterial oxygen content (expressed in mL O<sub>2</sub>/dL blood) and Q the cardiac output (expressed as L blood/min). The CaO<sub>2</sub> can be calculated by simultaneously measuring an ABG and hemoglobin (Hb) concentration in a patient, as shown in Equation 2.

$$CaO_2 = [Hb] \times 1.34 \times Sat_{arterial} + 0.003 \times PaO_2 \quad (2)$$

Using Equation 2, a patient with an Hb = 15, and 100% saturation of arterial Hb with O<sub>2</sub> has a calculated CaO<sub>2</sub> = 20 mL O<sub>2</sub>/dL blood = 200 mL O<sub>2</sub>/L blood. Some O<sub>2</sub> is also dissolved in plasma (0.003 × PaO<sub>2</sub>), the amount of which is generally negligible. However, in low O<sub>2</sub> saturation conditions, where patients are supported with high FiO<sub>2</sub>, and especially at higher barometric pressures (i.e., at sea level or in a hyperbaric chamber), the dissolved O<sub>2</sub> component can become more significant.

The Q is most often measured using the thermodilution method, via a pulmonary artery (PA) catheter. The normal resting Q for a 70-kg patient is approximately 5 L blood/min. Thus, the normal DO<sub>2</sub> for a 70-kg patient is 1000 mL O<sub>2</sub>/min (5 L blood/min × 200 mL O<sub>2</sub>/L blood).

The  $\dot{V}O_2$  can be determined for various vascular beds or organs. However, if not otherwise stated, the  $\dot{V}O_2$  represents the total amount of O<sub>2</sub> consumed by all tissues in the body and is expressed as mL/O<sub>2</sub>/min.

The  $\dot{V}O_2$  can be determined clinically in two ways, either by indirect calorimetry, where actual oxygen uptake is measured (subtraction of expired from inspired volume of oxygen), or by use of the Fick mass balance equation (Equation 3):

$$\dot{V}O_2 = \dot{Q} \times (CaO_2 - CvO_2) \quad (3)$$

where CaO<sub>2</sub> is calculated using Equation 2 and using the saturation of the arterial blood (obtained from the ABG),

and the CvO<sub>2</sub> is also calculated by using Equation 2, but uses the venous O<sub>2</sub> saturation taken from the mixed venous blood gas (obtained with a PA catheter). The Fick method does not take into account oxygen consumed by the lungs. Normally, lung tissue oxygen extraction is negligible. However, in the setting of ALI, pulmonary oxygen consumption may be significantly increased. Thus, the Fick method may be prone to inaccuracy compared to indirect calorimetry, in the setting of ALI (11). The normal value for  $\dot{V}O_2$  is about 250 mL/min for a 70-kg patient, or about 3 to 4 mL/kg/min. The  $\dot{V}O_2$  varies in concert with the metabolic needs of the body, and may be increased by fever or the systemic inflammatory response syndrome (SIRS), as described in Volume 2, Chapter 63.

### Ventilation-Perfusion Abnormalities

Ventilation and perfusion ( $\dot{V}/\dot{Q}$ ) are normally well matched (see Volume 2, Chapter 2). However, when hypoxic pulmonary vasoconstriction (HPV) is blunted, underventilated areas of the lung are overperfused, resulting in hypoxemia. Conversely, when certain areas of the lung are underperfused (as occurs in pulmonary embolism), areas of high  $\dot{V}/\dot{Q}$  (and alveolar dead space) result. The oxygen content of these high  $\dot{V}/\dot{Q}$  regions is elevated, and the CO<sub>2</sub> content is lower than normal. Following a PE, blood will also be forced to increase flow to nonobstructed low  $\dot{V}/\dot{Q}$  regions. Because the very low oxygen content of the now overperfused (low  $\dot{V}/\dot{Q}$ ) lung units cannot be sufficiently compensated by the higher oxygen content of the underperfused (high  $\dot{V}/\dot{Q}$ ) lung units, the aggregate mixing of the blood results in hypoxemia. Furthermore, pulmonary emboli release factors into the pulmonary circulation that increase the right-to-left transpulmonary shunt (discussed subsequently), further impairing oxygenation.

A number of factors influence alveolar dead space, including age, posture, and body size (12). Significant abnormalities in alveolar dead space result from a number of pathologic conditions occurring in trauma and critical care. The processes that increase the alveolar dead space include all conditions that increase ventilation beyond the concomitant pulmonary perfusion, as occurs when excessive tidal volume or positive end expiratory pressure (PEEP) is employed; as well as when impaired cardiac output occurs,

due to hypovolemia (common in trauma), pump failure (myocardial ischemia, tamponade), and so on. Alveolar dead space is also increased by pulmonary embolism (Volume 2, Chapter 56). Additionally, situations that impair HPV (e.g., inhaled anesthetics and other pulmonary vasodilators) will increase alveolar dead space. The anatomic dead space is defined as the volume of gas in the conducting airways. The alveolar dead space and anatomic dead space combined yields the physiologic dead space. The physiologic dead space can be measured by determining the dead space to tidal volume ratio using the Bohr equation (Equation 4):

$$V_D/V_T = \frac{P_a \text{CO}_2 - P_{ET}\text{CO}_2}{P_a\text{CO}_2} \quad (4)$$

where  $V_D/V_T$  represents the dead space to tidal volume ratio,  $P_a\text{CO}_2$  is the partial pressure of carbon dioxide in arterial blood, and  $P_{ET}\text{CO}_2$  is the partial pressure of carbon dioxide in a mixed-expired gas sample.

The most common clinical scenarios leading to ventilation-perfusion mismatching include blood loss following trauma or during surgery, and in the nonoperative setting, exacerbations of chronic obstructive pulmonary disease (COPD), pneumonia, and atelectasis. Many drugs will blunt the ability of the pulmonary circulation to respond appropriately to hypoxia by vasoconstriction. These drugs are commonly used in the ICU, and include nitrates, inotropes, inhaled anesthetics, and calcium-channel blockers (13).

☞ **Many of the drugs used in the ICU have vasodilator properties and can worsen oxygenation by blunting HPV and exacerbating  $\dot{V}/\dot{Q}$  mismatching.** ☞

### Right-to-Left Transpulmonary Shunt

Right-to-left transpulmonary shunting, sometimes referred to as venous admixture, refers to alveoli that are perfused but not ventilated, resulting in the effluent of nonoxygenated blood from these lung units, and ultimate mixing of oxygenated and nonoxygenated blood, decreasing the  $P_{aO_2}$ . The normal healthy person has less than 5% transpulmonary shunt. This normal shunted blood results from two sources: (i) the anatomic shunt of blood that empties directly to the left atrium or left ventricle (LV); and (ii) a very small amount of normal, transpulmonary shunting (blood that flows through the lungs in the normal pathways, past alveolar units that are not exposed to gas exchange). The anatomic shunts that are present in all normal patients include the thebesian veins and the bronchial circulation, both of which empty their deoxygenated blood directly into the left side of the heart. Intracardiac shunts are pathologic, and not considered part of the normal right-to-left transpulmonary shunt. When pathologic intracardiac shunts are present, they can contribute large quantities of deoxygenated blood to the left side of the heart, resulting in profound hypoxemia. The foramen ovale is physiologically closed in most normal adults; however, it remains probe patent in as many as 30% of adult patients. The probe-patent foramen ovale may open in the setting of elevated right atrial pressures, as can occur in secondary RV failure (i.e., due to pulmonary artery hypertension—as occurs in numerous disease states such as advanced ARDS). Other pathologic anatomic shunts include pleural-based arteriovenous shunts seen in patients with hepatic cirrhosis—so-called hepato-pulmonary syndrome—reviewed below (also see Volume 2, Chapters 36 and 37). ☞ **The most common causes of right-to-left transpulmonary shunting in ICU patients are direct pulmonary pathologic entities, such as pneumonia, atelectasis, and noncardiogenic pulmonary edema.** ☞ Each of these entities causes blood flow to bypass gas-exchanging portions of the lung.

The degree of shunt can be calculated using the shunt equation (Equation 5):

$$\frac{\dot{Q}_s}{\dot{Q}_t} = \frac{C_{cO_2} - C_{aO_2}}{C_{cO_2} - C_{vO_2}} \quad (5)$$

where  $\dot{Q}_s/\dot{Q}_t$  is the shunt blood flow expressed as a fraction of total blood flow,  $C_{cO_2}$  the calculated alveolar capillary blood content,  $C_{aO_2}$  the measured oxygen content of arterial blood, and  $C_{vO_2}$  the measured oxygen content of mixed venous blood. Although some intensivists will calculate the  $\dot{Q}_s/\dot{Q}_t$  using the above shunt equation, a clinically useful estimate can be made using the shortcut suggested by Pierson (14). Providing the patient is on an  $F_{IO_2}$  of 1.0, and the  $P_{aO_2}$  is 150 mmHg or more, there is approximately 5% shunt for every 100 mmHg the  $P_{aO_2}$  is below 700 (14).

The degree of right-to-left transpulmonary shunt is also reflected in the  $P_{aO_2}/F_{IO_2}$  (or “P/F”) ratio (normally approximately 500) (15,16). Using the alveolar air equation (Equation 6), one can calculate the expected  $P_{A}O_2$  and, as first proposed by Bendixen, calculate the alveolar-to-arterial  $PO_2$  difference [ $P(A-a)O_2$ ] (17). In the absence of any significant right-to-left transpulmonary shunt, the  $P_{aO_2}$  (measured with an ABG) will be essentially the same as the  $P_{A}O_2$ , calculated from the alveolar air equation (Equation 6).

$$P_{A}O_2 = [(P_B - P_{H_2O}) \cdot F_{IO_2}] - \left[ \frac{P_a\text{CO}_2}{RQ} \right] \quad (6)$$

The alveolar air equation predicts that the  $P_{A}O_2$  will be decreased when there is: (i) a decrease in either the barometric pressure, or the  $F_{IO_2}$ , or (ii) an increase in the  $P_a\text{CO}_2$ . The  $P_{aO_2}/F_{IO_2}$  ratio can be used to roughly, and quickly, determine the degree of right-left transpulmonary shunt. When the  $P_{aO_2}/F_{IO_2}$  is  $<300$ , the threshold for ALI is achieved, whereas a  $P_{aO_2}/F_{IO_2} <200$  meets the criteria for ARDS (Table 1).

Although shunt units will not be affected by the administration of 100% oxygen, hypoxemia from  $\dot{Q}_s/\dot{Q}_t$  mismatching will be improved. In clinical practice, patients often have a combination of both shunt and  $\dot{V}/\dot{Q}$  mismatch. Thus, oxygen should always be administered to the hypoxic patient regardless of the putative mechanism.

### Diffusion Impairment

Impairment of oxygen diffusion into alveolar capillaries may occur with infiltration of the alveolar airspaces. This occurs most commonly with pulmonary edema, either cardiogenic or noncardiogenic. The increased diffusion distance for oxygen may result in incomplete oxygenation of venous blood, especially when diffusion impairment exists in combination with high  $\dot{Q}$  and/or anemia. It is unclear what the clinical significance of diffusion impairment is, as other mechanisms, such as ventilation-perfusion mismatching and right-to-left transpulmonary shunting, are likely more significant causes of hypoxemia.

### Decreased Mixed Venous Oxygen Content

Decreased  $C_{VO_2}$  rarely exists as an isolated entity, but commonly occurs in concert with other causes of hypoxemia such as anemia, low cardiac output, and increased systemic oxygen consumption (i.e., fever). If venous blood is not fully oxygenated during passage through the lungs, then unsaturated blood enters the arterial circulation. Treatment of low mixed venous oxygen content is based upon the etiology.

In the setting of anemia (Volume 2, Chapter 54), treatment consists of transfusion, and in the setting of low  $Q$ , inotropes are used, whereas in the case of fever, antipyretic therapy may be indicated. Sedatives may be administered to critically ill patients to decrease the  $\dot{V}O_2$ . Paralytic agents by themselves should not be employed for this purpose. Considerable controversy exists regarding the precise goals of  $\dot{D}O_2$  in critically ill patients (see Volume 2, Chapter 17).

### Alveolar Hypoventilation

The alveolar air equation (Equation 6) predicts a decrease in  $P_{A}O_2$  if there is an increase in  $P_{a}CO_2$  (as occurs with hypoventilation). So, even if alveolar uptake of  $O_2$  is normal and  $\dot{D}O_2$  is normal, the patient may ultimately become hypoxic, because the increase in partial pressure of  $CO_2$  in the alveoli leaves less space for  $O_2$ .

The  $CO_2$  concentration in the alveoli increases during alveolar hypoventilation. Accordingly, the alveolar partial pressure of oxygen and other gases must fall. In the absence of supplemental oxygenation, hypoxemia will occur. The most common clinical scenario for alveolar hypoventilation is decreased respiratory drive from opiate administration, although patients with neuromuscular or central nervous system (CNS) disorders can develop the same complication. In trauma patients, drugs, CNS disorders, and mechanical ventilatory problems (e.g., pneumothorax) can all occur simultaneously.

The oxygenation defect seen with alveolar hypoventilation may be overcome by increasing the  $F_{I}O_2$ , thereby increasing the diffusion gradient for oxygen into the alveolar capillaries. The most common clinical entities associated with acute hypoxemic respiratory failure are listed in Table 4.

### Acute Hypercapnic Respiratory Failure: Ventilatory Dysfunction

Failure of the ventilatory system results in hypercapnea and respiratory acidosis, and in the absence of supplemental oxygen, hypoxemia. Ventilatory failure can result from CNS injury or dysfunction, with consequent alterations in respiratory drive, as well as from respiratory musculature weakness as in patients with Guillin-Barré syndrome, or due to increased WOB, as occurs in severe bronchospasm or decreased  $C_L$  or increased  $V_D$  (e.g., PE), or patients with COPD. A review of the medical history, physical examination, chest radiograph (CXR), and blood gas analysis can usually identify the etiology of the ventilatory failure. In the case of neuromuscular disease, electromyography (EMG) testing or consultation by a neurologist may be required to differentiate between neuronal, muscular, or neuromuscular junction (NMJ) dysfunction. Acute hypercapnic respiratory failure can be identified when the ABG reveals a  $P_{a}CO_2$  greater than 50 mmHg. Each of these systems will be examined independently.

### Carbon Dioxide Production and Clearance

Carbon dioxide is produced as an end product of cellular metabolism, with a normal steady-state production of approximately 200 mL/min in a 70-kg patient. If alveolar ventilation is inadequate to eliminate the total  $CO_2$  produced, then hypercapnea and respiratory acidosis will ensue. Therefore, in the steady state,  $\dot{V}CO_2$  can be defined as the product of alveolar ventilation and arterial  $P_{a}CO_2$ ,

as shown in Equation 7.

$$P_{A}CO_2 \approx P_{a}CO_2 = \frac{\dot{V}CO_2}{\dot{V}_A} \quad (7)$$

The alveolar  $PCO_2$  ( $P_{A}CO_2$ ) varies during the ventilatory cycle.  $P_{A}CO_2$  falls at the commencement of inhalation, and rises during exhalation. The end tidal  $P_{A}CO_2$  is nearly equal to the  $P_{a}CO_2$ , whereas the exhaled  $PCO_2$  (measures  $P_{ET}CO_2$ ) is slightly lower; the greater the alveolar dead space, the greater the difference between the  $P_{ET}CO_2$  and the  $P_{a}CO_2$ .

An increase in  $P_{a}CO_2$  must be due to either an increase in production or a decrease in elimination, with decreased elimination due to either a decreased minute ventilation or increased dead space ventilation (or both). Increased  $CO_2$  production may result from fever or overfeeding, both of which should be corrected in patients with severe ARF. Diagnosis of increased  $CO_2$  production can be made with indirect calorimetry. Adjustment of enteral or parenteral nutrition, or treatment of fever, can be further monitored with indirect calorimetry to follow the expected decrease  $CO_2$  production.

### Ventilatory Mechanics

A number of factors will contribute to abnormalities in ventilatory mechanics, including decreased lung or chest wall  $C_L$ , increased intra-abdominal pressure, and neuromuscular dysfunction. Pure ventilatory failure will manifest itself by hypercapnea. Having an intubated patient perform a spontaneous breathing trial provides information regarding the patient's ability to do their WOB. However, a high RSBI (i.e.,  $RR/Vt > 100$ ) does not specify whether the WOB is too high, or if the patient is too weak. Accordingly, the evaluation of mechanical failure seeks pulmonary mechanic data that isolate the variables of interest. The maximum inspiratory pressure ( $P_{IMAX}$ ) is another weaning parameter (pulmonary mechanic) that reflects the patient's strength. The  $P_{IMAX}$  is obtained by occluding the endotracheal tube (ETT) with a negative pressure measuring device (see Volume 2, Chapter 28). The  $P_{IMAX}$  may vary with age and gender, but normal healthy individuals can usually generate negative pressures less negative than  $-80$  to  $-100$  cmH<sub>2</sub>O (18). Having a patient perform a vital capacity (VC) breath will also identify mechanical abnormalities related to respiratory muscle weakness, but this measurement is also dependent upon the lung and chest wall compliance. In mechanically ventilated patients, measurement of peak inspiratory pressure, plateau pressure, and dynamic hyperinflation or intrinsic positive end-expiratory pressure (PEEP) further characterize the mechanical abnormalities associated with ARF.

### Work of Breathing

In normal circumstances, the WOB is very small, representing less than 2% of the basal metabolic rate. Under pathologic conditions, however, when respiratory system compliance decreases and/or airway resistance increases, the WOB can be substantial, utilizing a larger portion of the oxygen delivery. In patients with ARF, minute ventilation demands are high because of increased dead-space fraction (e.g., PE), or cause airflow obstruction (e.g., kinked ETT or copious secretions). With further increases in airflow obstruction, the WOB is markedly elevated because of active expiratory

**Table 4** Pathophysiology and Diagnostic Clues Associated with Common Clinical Conditions Causing Acute Respiratory Failure

Clinical condition	Physiologic abnormality	Diagnostic clues
Acute bacterial pneumonia	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ , ( $\downarrow$ 'd $\text{PaO}_2$ ), fever ( $\uparrow$ 'd $\dot{V}\text{CO}_2$ ), $\downarrow$ 'd $C_L$ , and $\uparrow$ 'd $R_{AW}$ all cause $\uparrow$ WOB	Fever, WBC (left shift), infiltrate on CXR, purulent sputum
Viral and atypical ( <i>Mycoplasma</i> , <i>Legionella</i> ) pneumonias	S/A	WBC not very elevated, more monocytes, diffuse alveolar pattern on CXR, sputum normal
Fungal pneumonia	S/A	Immunosuppressed patient, cavitory lesions on CXR
Asthma	Broncho constriction and mucus plugging of airways, $\uparrow$ 'd $\dot{V}/\dot{Q}$ , $\uparrow$ 'd $R_{AW}$ all cause $\uparrow$ WOB	Wheezing, $\uparrow$ 'd expiratory phase, CXR: flat diaphragms, and $\uparrow$ 'd A-P diameter; use of accessory muscles
COPD	S/A, plus bronchitis and or emphysema: ( $\downarrow$ 'd DLCO)	S/A, often $\uparrow$ 'd serum $[\text{HCO}_3^-]$ due to chronic hypercarbia
Upper airway obstruction	$\uparrow$ 'd $R_{AW}$ , $\uparrow$ 'd $\text{PaCO}_2$	Stridor (heard in neck), snoring
Aspiration	Epithelial injury: R $\rightarrow$ L shunting, ( $\downarrow$ 'd $\text{PaO}_2$ ), $\uparrow$ 'd lung $\text{H}_2\text{O}$ : $\downarrow$ 'd $C_L$ , bronchial injury: $\uparrow$ 'd $R_{AW}$ : $\uparrow$ WOB	CXR infiltrate classically in superior segments of lower lobes (especially right side)
Pulmonary embolism	$\uparrow$ 'd $V_D/V_T$ , $\uparrow$ 'd $\dot{V}_E$ , $\uparrow$ 'd $\dot{V}/\dot{Q}$ , $\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$	Hx DVT, Hx trauma, abrupt $\uparrow$ 'd dyspnea after position change
Myocardial failure	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (cardiogenic pulmonary edema)	$\downarrow$ 'd $\dot{Q}$ , $\uparrow$ 'd atrial pressures, ECG changes
Neuromuscular disorders	$\downarrow$ 'd $\dot{V}_E$ —due to $\downarrow$ 'd NMJ function	$\downarrow$ 'd twitch and $\downarrow$ 'd muscle strength Tensilon improves (if myasthenia G)
Chest wall trauma	$\downarrow$ 'd $\dot{V}_E$ —due to pain induced splinting	Rib fractures, $\downarrow$ 'd $V_T$ , $\downarrow$ 'd MIF
Pulmonary contusion	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	Lung contusion on CXR or CT
Hemo-pneumothorax	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (lung collapse 2° blood or air)	Hemo-pneumothorax on CXR/CT
Fluid overload	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (hydrostatic pulmonary edema)	$\uparrow$ $\uparrow$ Fluid resuscitation, $\uparrow$ 'd atrial pressures, $\downarrow$ 'd Albumin $\dot{u}$
Fat embolism	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	Hx proximal long bone Fx
Near-drowning	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	Trauma involving water
Burns	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	$\uparrow$ BSA Burn, or inhaled smoke
Head injury	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (neurogenic pulmonary edema)	Especially with SAH
Renal failure	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (hydrostatic and noncardiogenic pulmonary edema), $\downarrow$ 'd $C_L$ , $\uparrow$ WOB	left atrial pressures, $\downarrow$ 'd albumin, $\pm$ LV dysfunction
Pancreatitis	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	$\uparrow$ amylase, $\uparrow$ lipase, $\uparrow$ inflammation
Liver failure	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	$\uparrow$ LFTs, $\downarrow$ 'd albumin, edema, $\pm$ porto- pulmonary syndrome
Sepsis/SIRS	$\uparrow$ 'd $\dot{Q}_S/\dot{Q}_T$ (noncardiogenic pulmonary edema)	$\uparrow$ inflammation (multiple etiologies)

**Abbreviations:**  $\uparrow$ , increase;  $\downarrow$ , decrease; BSA, body surface area; BUN, blood urea nitrogen,  $C_L$ , compliance;  $\text{CO}_2$ ,  $\text{CO}_2$  production; Cr, creatinine; CT, computed tomography; CXR, chest radiograph; DLCO, diffusion capacity; DVT, deep venous thrombosis; ECG, electrocardiogram; Fx, fracture; Hx, history of; LV, left ventricle; MIF, maximum inspiratory force; NMJ, neuromuscular junction;  $\text{PaCO}_2$ , partial pressure of  $\text{CO}_2$  in arterial blood;  $\text{PaO}_2$ , partial pressure of oxygen in arterial blood;  $\dot{Q}$ , cardiac output;  $\dot{Q}_S/\dot{Q}_T$ , shunt flow/cardiac output (in this context same as right-to-left transpulmonary shunt);  $R_{AW}$ , airway resistance; S/A, same as above; SAH, subarachnoid hemorrhage;  $\dot{V}_E$ , minute ventilation;  $V_T$ , tidal volume;  $\dot{V}/\dot{Q}$ , ventilation/perfusion ratio;  $V_D/V_T$ , dead space to tidal volume ratio; WBC, white blood cell count; WOB, work of breathing.

efforts. This increased demand will often lead to ventilatory failure, as respiratory and accessory muscles fatigue. The WOB can be measured with esophageal manometry, and the workload partitioned between the patient and the mechanical ventilator. The precise WOB threshold that should be done by the patient is not well understood. A more detailed discussion of ventilatory mechanics and the WOB, in terms of normal pulmonary physiology and weaning parameters are found in Volume 2, Chapters 2 and 28, respectively.

### Neural Control of Breathing

Respiratory drive originates in the medulla and triggers inspiratory efforts. In rare cases, patients may have primary alveolar hypoventilation, usually secondary to other disease processes. The most common associated illnesses are obesity, with obesity hypoventilation syndrome, and chronic poliomyelitis. Far more common is respiratory depression secondary to the use of opiates or benzodiazepines. Patients in the ICU are particularly prone to disorders of the NMJ,

so-called “critical illness polyneuropathy” (Volume 2, Chapter 6). This is a syndrome that may be present 50% to 70% of the time in mechanically ventilated patients with sepsis (19). Critical illness polyneuropathy is characterized by polyneuropathy-induced muscular weakness and difficulty weaning from mechanical ventilation. Diagnosis may be made by EMG. Other myopathies may result from steroid use (20), and in particular, from the combination of steroids and neuromuscular blocking drugs in acute asthmatics (21). Patients proving difficult to wean from mechanical ventilation should be evaluated for myopathy or other neurologic dysfunction.

## CLINICAL PRESENTATION OF ACUTE RESPIRATORY FAILURE

### Diagnostic Approach to Acute Respiratory Failure

The importance of determining the etiology of ARF cannot be overstated. Often, the clues regarding the etiology are fleeting, and may only be available at the bedside immediately prior to intubation. These clues (Table 4) must be actively sought out, gathered, and chronicled by the physician called to intubate the patient, prior to transfer to the ICU. Examples of clues that should be sought, and will be missed if not reported by the intubating physician, include the presence of: (i) vomit in a patient’s oropharynx passing below cords, involving the trachea and bronchi; (ii) ST segment depression during the ARF event, which resolves following intubation and mechanical ventilation; (iii) pulmonary edema fluid prior to intubation and the administration of PEEP; 4) stridor; etc. Accordingly, the diagnostic approach to ARF starts with a focused medical history, and physical examination at the bedside.

### History

Because of critical illness, a patient’s complete medical history cannot always be fully obtained. Clinical clues to the history of present illness (relevant to ARF) are invaluable, as mentioned above. Regarding the past medical history, it is useful to ascertain whether the patient has any underlying lung pathology such as COPD or asthma, whether the patient has a history of tobacco use, or whether s/he has had any recurrent problems such as congestive heart failure (CHF), pneumonia, or bronchitis. Knowledge of underlying pulmonary or cardiac conditions may influence the clinician’s decision to move directly to endotracheal intubation, or to temporize with noninvasive positive pressure ventilation (NIPPV). A patient who was doing well prior to moving or getting out of bed, who abruptly develops respiratory failure, shows no signs of aspiration, and has clear lungs provides a good history and physical for an acute PE. Historical factors may also influence the choice of induction agents for endotracheal intubation, and may further guide the selection of a particular mode of mechanical ventilatory support, impact the level of PEEP, tidal volume setting, or initial setting of I:E ratio. Finally, knowledge of pulmonary function testing and baseline oxygenation and ventilation (via ABG evaluation) can help establish acceptable weaning parameters when respiratory status begins to improve.

### Physical Examination

Physical examination of the patient with respiratory failure begins with chest observation of respiratory rate and pattern (including use of accessory muscles or paradoxical breathing), auscultation of breath sounds and any evidence of stridor, and blood pressure measurement. Although this

valuable diagnostic information is being obtained, it is essential that the “ABCs” of resuscitation are being employed, by assuring a patent airway, and treating with supplemental oxygen. Examination may reveal surgical scars, indicating prior surgery, such as a thoracotomy or prior tracheotomy. Barrel-chested patients, for instance, are more likely to have COPD. The presence of subcutaneous emphysema is highly suggestive of pneumomediastinum, and tracheal deviation may indicate tension pneumothorax.

Auscultation of breath sounds may reveal a variety of diffuse or specific findings, which may help to diagnose an underlying condition or the cause of ARF. Close observation of the patient’s respiratory pattern can provide valuable information: Is the chest moving paradoxically? Does the patient appear to be breathing with diaphragmatic, or more with accessory, musculature? Is there equal excursion of both sides of the chest? Is there dullness (effusion, atelectasis, pneumonia), or hyperresonance (pneumothorax, blebs) in any areas of the lungs? Heart rate and blood pressure measurement are essential.

A patient with an acute exacerbation of COPD or reactive airway disease may have low systolic blood pressure, resulting from dynamic hyperinflation, increased intrathoracic pressure and consequent decreased venous return to right atrium, increased afterload of the right ventricle (RV) and consequent decreased LV filling and stroke volume. Patients may be diaphoretic or confused, and patients with hypercapnea may exhibit somnolence, seizures, or myoclonic jerks.

### Arterial Blood Gas Analysis

Initial assessment of a patient with ARF is facilitated by obtaining focused laboratory data; especially pulse oximetry, CXR, ECG, and ABG. Only with an ABG can quantitative determinations about the severity of the ARF be made. These determinations include calculation of shunt fraction ( $\dot{Q}_s/\dot{Q}_t$ ),  $P_{aO_2}/F_{iO_2}$ , and alveolar dead space ventilation. Analysis of the ABG and serum electrolyte panel can provide additional clues that may facilitate the diagnosis and management of these patients. Elevated  $PaCO_2$  in the presence of a high serum bicarbonate level suggests chronic  $CO_2$  retention. The Henderson-Hasselbach equation may be used to estimate the patient’s baseline degree of  $CO_2$  retention. The  $PaO_2$  will be essential in assessing those patients who are receiving supplemental oxygen, and for whom the institution of NIPPV or endotracheal intubation may be imminent. Furthermore, the  $PaO_2$  may serve to provide the only accurate measure of oxygenation for those patients whose decreased peripheral perfusion limits the use of pulse oximetry.

### Oximetry and Capnometry

In patients with ARF, the decision to proceed to endotracheal intubation may be made on the basis of physical examination and oximetry, particularly if the patient is in distress and there is no time to obtain an arterial blood gas. Most patients require oxygen saturation greater than 90%, particularly in the setting of critical illness. Oximetry provides a rapid, reliable assessment of oxygenation in critically ill patients, and is the standard of care for continuous monitoring in both the ICU and operating room (OR). However, oximetry is prone to errors; for example, carbon monoxide poisoning may show falsely high oxygen saturation, whereas patients with methemoglobinemia will present with a pulse oximeter saturation of 85%, regardless of the true oxygen saturation as determined

by co-oximetry (see Volume 2, Chapter 8). The reason for these errors with pulse oximetry is that only the two species oxy-Hb and Hb are measured by these devices. Accordingly, the initial blood gas assessment of the patient with ARF should include co-oximetry, which will characterize the various hemoglobin species present (including oxy-Hb, Hb, met-Hb, and carboxy-Hb).

☞ **Many commonly used drugs can cause methemoglobinemia, which will worsen hypoxemia and acidosis. These drugs include dapsone, local anesthetics (benzocaine and prilocaine), commonly used nitrates (nitroprusside, nitroglycerin), and sulfonamides. Diagnosis may be made with co-oximetry that measures various hemoglobin species. Treatment is with methylene blue.** ☞

Capnometry allows measurement of end-tidal CO<sub>2</sub> (PetCO<sub>2</sub>). In normal subjects, the PetCO<sub>2</sub> is usually 3–5 mmHg less than the arterial PCO<sub>2</sub>. Patients with COPD, and those with respiratory failure, have an increased dead space fraction, and the PetCO<sub>2</sub>-PaCO<sub>2</sub> gradient will be much larger. However, capnometry is extremely useful in a number of settings; for continuous respiratory monitoring, and importantly, for documenting intratracheal placement of the ETT during intubation. Capnometry also allows detection of expiratory flow obstruction, as the expiratory curve will fail to reach a plateau, suggesting delayed release from alveoli with long exhalation time constants.

### Radiographic Evaluation

Chest radiography is an essential component in the diagnostic work up of ARF; it can substantially narrow the differential and sharpen the focus in developing a treatment plan. A clinical diagnosis of pneumonia, for example, is supported by the presence of an infiltrative process on the radiograph. Chest radiography will also help to diagnose underlying pathology that may be linked directly or indirectly to the ARF, such as an enlarged cardiac silhouette or the presence of apical scarring in a patient with a history of mycobacterial disease. The presence of an increased anterior-posterior diameter, flattened diaphragms, and hyperinflation are common findings associated with COPD. The presence of pulmonary interstitial emphysema can alert the clinician to a potential imminent pneumothorax. Pulmonary interstitial emphysema can appear as perivascular halos, pneumatoceles, intraseptal air collections, and linear streaks of air radiating from the hila, parenchymal cysts, and subpleural air collections. However, most pneumothoraces are not diagnosed until an apicolateral visceral pleural line is detected. Reliance on this presentation will result in the underdiagnosis of pneumothorax in critically ill patients. Subpulmonic pneumothorax can be detected by visualizing a “deep sulcus” sign, as well as by hyperlucency of the superior abdominal area. Anteromedial pneumothorax may be diagnosed by the presence of a mediastinal border outlined by pleural air or by a linear air density along that border. Many patients with ARF are unable to be positioned upright, thereby making the detection of pneumothorax more difficult with chest radiography. Tracheal deviation with contralateral displacement of the heart and mediastinal structures, as well as ipsilateral lung collapse, may provide essential clues of a potentially life-threatening tension pneumothorax.

Differentiation of cardiogenic versus noncardiogenic pulmonary edema can be difficult. The presence of Kerley-B lines represent interstitial edema, and their presence, along with evidence of vascular cephalization, suggests the presence of cardiogenic pulmonary edema. However, even

experienced clinicians may be unable to determine the cause of edema in the supine ICU patient (22). Likewise, the severity of pulmonary infiltration does not always correlate with the severity of respiratory failure.

An entirely normal appearing CXR (other than slight decreased pulmonary arterial markings), in a patient with acute onset respiratory failure, is suggestive of an acute PE. Chest radiography will not always provide the clinician with specific clues that will lead to a clear diagnosis, but it can rule out many of the common etiologies of ARF, allowing the clinician to narrow the likely list of causes.

### Sputum Evaluation

Sputum evaluation is an essential component of the diagnosis of both community-acquired and nosocomial pneumonias. Both culture and Gram stain can provide important diagnostic therapeutic information. The Gram stain can be more reliable than sputum culture for diagnosing pneumonia, whereas the culture helps define antimicrobial resistance. Indeed, if an organism is cultured from sputum, but not shown as a predominant species in the Gram stain, it often represents colonization of the tracheo-bronchial tree. The Gram stain is an excellent tool for determining the focus of early antibiotic therapy. The sensitivity and specificity of sputum culture depends on criteria used for a definition of positivity and negativity. There is a very hazy evidence base defining the efficacy of sputum culturing, and is often most useful in the identification of unusual infectious causes of respiratory failure, and in identifying antibiotic resistance of certain organisms. It should be kept in mind that even in the setting of bacterial pneumonia, sputum culture is positive less than 50% of the time (23).

### Clinical Entities Associated with Acute Respiratory Failure Airway and Airflow Disorders

Airflow disorders are frequently life-threatening, with the most common processes being asthma and exacerbations of COPD (Table 4). Both disease entities are common, with more than 17 million individuals having asthma in the United States (24). Physical examination may demonstrate expiratory wheezing, which may decrease in intensity as the patient fatigues. Other physical examination findings associated with both asthma and COPD include a prolonged expiratory phase and accessory muscle use. ARF with airflow limitation is usually hypercapneic, so ABG sampling is essential. The use of oximetry may be misleading, as these patients usually oxygenate well, even with impending ARF.

#### Asthma

Asthma is an inflammatory process characterized by both bronchoconstriction and mucus plugging of small airways. A number of precipitating factors may trigger an asthma exacerbation, including upper respiratory infections, pneumonia, inhaled irritants, and allergens (25,26). ☞ **Patients with acute asthma exacerbations are normally hypertensive because of catechol release. Those that are normotensive or hypotensive and tachycardic may have elevated intrathoracic pressure impeding venous return, and are at increased risk for cardiopulmonary arrest during endotracheal intubation.** ☞ Although an asthma attack is usually easy to identify on physical examination, measurement of fraction of exhaled volume in the first second (FEV<sub>1</sub>) and forced vital capacity (FVC) can be used to track the severity of illness.

Patients develop ARF from asthma exacerbations when expiratory flow obstruction progresses to the point where accessory muscles fail, resulting in hypercapnea and acidosis. Wheezing may be inspiratory and/or expiratory. Other physical examination findings can include pulsus paradoxus. A rising PaCO<sub>2</sub> in the setting of maximal noninvasive therapy is a worrisome sign, and is suggestive that the patient may require intubation and mechanical ventilation. Particularly worrisome is the presence of hypotension, which suggests high intrathoracic pressure and decreased venous return; these patients are at particularly high risk for hypotension and/or cardiac arrest during endotracheal intubation and with positive pressure ventilation (27,28). Mechanical ventilation management includes a prolonged exhalation phase, slow respiratory rate, low tidal volume, and intravascular bolus of fluid, while waiting for medical therapy (e.g., inhaled  $\beta$ -agonists, etc.) to work.

Radiographic findings in asthma may be unimpressive, but a CXR should be obtained to rule out pneumothorax, to identify a pneumonic process, and to evaluate the degree of pulmonary hyperinflation or diaphragmatic flattening. Laboratory testing should be done, as intensive bronchodilator therapy may result in life-threatening hypokalemia. Creatine phosphokinase levels may be elevated from respiratory muscle fatigue (29). Arterial blood gases should be obtained to assess the severity of acidosis and hypoxemia, and to help decide the need for intubation and/or ICU admission. Acidosis is often multifactorial, with a major respiratory component and a variable metabolic contribution (depending upon the systemic perfusion) (30).

Initial therapy begins with inhaled  $\beta$ -agonists, and consideration given to the addition of inhaled anticholinergic therapy with ipratropium bromide (31). However, in pure asthma, ipratropium bromide provides minimal additional benefit beyond that caused by the inhaled  $\beta$ -agonist. Additionally, because asthma is an inflammatory disorder, early, aggressive treatment with corticosteroids is essential. The recommended dosing is intravenous methylprednisolone, 120–180 mg/day, divided in three or four doses, for at least 48 hours (25). Theophylline, a phosphodiesterase inhibitor, is preferable to placebo, but has more toxicity than  $\beta$ -agonist and steroid therapy, and does not provide additional benefit to those drugs once they have been instituted (32).

### Acute COPD Exacerbations

Patients with COPD often develop respiratory failure, as a result of exacerbation of their chronic bronchitis and/or emphysema. It can be particularly difficult to define ARF in this patient population, as the severity of their baseline pulmonary function is highly variable. Many patients are on chronic oxygen therapy, and others have varying degrees of carbon dioxide retention. COPD is a common disease, affecting as many as 16 million Americans (33). Clinical presentation usually includes dyspnea, cough, and sputum production. Wheezing may be variably present, and accessory muscle use is common. Patients may have a history of upper respiratory infection, and sputum should be obtained for Gram stain and culture. The precipitating factors for COPD exacerbation include infection, medication noncompliance, and environmental exposures (34). Admission labs revealing an elevated [HCO<sub>3</sub><sup>-</sup>] may provide clues that the patient is a chronic CO<sub>2</sub> retainer (Table 4).

Like asthmatics, patients with COPD are also faced with impaired expiratory flow of gases. However, these patients may also experience these limitations at baseline.

It is useful to follow these patients with periodic evaluations of their PaCO<sub>2</sub>, FEV<sub>1</sub>, and FEV<sub>1</sub>/FVC. If a significant component of emphysema is present, diffusing capacity (DLCO) should be measured in order to assess diffusing capacity. The COPD patient not only exhales against a markedly elevated resistance, but also breathes with a higher residual volume, making the WOB more difficult to accomplish, with increased reliance on accessory muscles. Dynamic hyperinflation results in increased intrinsic PEEP, which further limits alveolar ventilation. Areas of hyperinflation impair blood flow and give rise to an increasing dead space fraction, making the elimination of a given quantity of carbon dioxide dependent on a larger minute ventilation. Although exacerbations are characterized primarily by hypercapnea, hypoxemia is often present in those breathing room air, because of alveolar hypoventilation and poor ventilation/perfusion matching (35). With exacerbations, the patient can no longer maintain the required WOB, and endotracheal intubation with mechanical ventilatory support may become necessary.

Management of COPD exacerbations starts with supplemental oxygen. Many of the clinical signs and symptoms may be treated with oxygen alone, as ventilation/perfusion matching and pulmonary hypertension will both respond favorably (36). Oxygen therapy should not be withheld because of concern about blunting the hypoxic drive to breathe, rather it should be titrated to keep oxygen saturation at least 90% (37,38). As with acute asthmatics, corticosteroid therapy is essential, and should be supplemented with inhaled  $\beta$ -agonists. However, these patients (in contrast to younger asthmatics) will further benefit from inhaled ipratropium bromide (Atrovent<sup>®</sup>) therapy. Ipratropium bromide is an anticholinergic drug, which does not cause tachycardia. Ipratropium bromide is administered as an inhaler, by itself, or along with albuterol as combination therapy (Combi-vent<sup>®</sup>). Severely bronchospastic patients should receive 125 mg methylprednisolone intravenously, every six hours, for three days, followed by an oral prednisone taper (39). Inhaled corticosteroids are useful for chronic therapy, but may not be efficacious without intravenous methylprednisolone for acute exacerbations.

### COPD and Upper Airway Obstruction

Upper airway obstruction may result in ARF, either directly through interference with oxygenation and ventilation, or indirectly by causing negative pressure pulmonary edema. Patients usually present with stridor, and careful auscultation may help identify the anatomic site of obstruction: inspiratory stridor is generally associated with an extrathoracic obstruction, whereas expiratory stridor is associated with intrathoracic obstruction (Table 4). High-pitched stridor is usually glottic in origin. There are numerous causes of airway obstruction, including trauma, infection, tumor, angioedema, foreign body aspiration, and vocal cord dysfunction.

✎ **Inspiratory stridor is usually due to an extrathoracic obstruction (supraglottic or periglottic) and expiratory stridor is usually due to an intrathoracic process.** ✎ Physical examination can help determine the cause of stridor.

After initial resuscitation, radiographic evaluation is essential, and may be done with chest and lateral neck radiography, but may require computerized tomography or magnetic resonance imaging (40). Arterial blood gases should be obtained to assess the severity of hypercapnea and oxygenation deficit. Patients with trauma-induced neck injuries and stridor should go directly to the OR for airway evaluation and management. ✎ **The key principles**

of airway management for stridor are: (i) maintain spontaneous ventilation, (ii) avoid blind intubation techniques (may convert partial obstruction into complete obstruction), (iii) awake fiberoptic intubation is often the best diagnostic tool and method of airway intubation, and (iv) equipment and personnel capable of performing a surgical airway must be present until the airway is secured.  $\curvearrowright$  All patients presenting with airway obstruction should be admitted to the ICU for observation, if surgical intervention is not planned. A carefully designed plan for emergent airway access needs to be in place, with appropriate equipment and personnel immediately available.

### Aspiration of Gastric Contents

Aspiration pneumonia occurs when gastric contents enter the lung. Injury can result from three major factors: (i) epithelial burn from the low pH of gastric juice, (ii) obstruction from particulate matter, and (iii) infection from oropharyngeal bacteria. The aspiration injury that occurs also predisposes the lung to secondary infection. Patients at risk for aspiration pneumonia include those with diminished pharyngeal reflexes, and those with a decreased level of consciousness. Critically ill patients are at risk because of the presence of gastroparesis, resulting in high gastric volume. Early enteral nutrition, when tolerated (defined as residuals < 400 cc), does not increase the risk of this complication.

Diagnosis may be difficult, as CXR may initially appear grossly normal. Diagnostic testing is controversial, as transtracheal aspiration may primarily identify colonizing flora, rather than organisms causing pneumonia. Sputum culture or blood culture will identify organisms in only a small percentage of patients, whereas protected brush specimens also have low sensitivity (41). CXR may eventually show infiltrate in the superior segment of the right lower lobe (Table 4). However, diffuse bilateral infiltrates may develop as the lung injury progresses. Care is primarily supportive, with empiric antibiotic therapy used only in immunocompromised patients, or in those having rapid deterioration. Focused therapy can be started when specific organisms are identified by bronchoalveolar lavage (BAL) Gram stain, or a predominant organism is cultured from BAL, sputum, or blood.

### Thromboembolism

Venous thromboembolism is a ubiquitous and difficult problem in all trauma and critically ill patients, and is covered in greater detail in Volume 2, Chapter 56. Prophylaxis is essential, but still imperfect. The most worrisome complication is PE. The occurrence of PE in a spontaneously ventilating patient is usually associated with significant tachypnea and moderate hypoxemia, associated with an acute increase in alveolar dead space and shunting without a concomitant new lung infiltration (Table 4). Patients who are weak and debilitated may not be able to do the requisite increased WOB to overcome the increased alveolar dead space, and may become hypercapnic. Similarly, patients entirely dependent upon the mechanical ventilator for breathing will have an acute decrease in  $P_{ET}CO_2$ , and a consequent increase in  $PaCO_2$  due to the increased alveolar dead space following PE (providing the minute ventilation is maintained stable). Hypoxia also occurs in all of these scenarios; partly due to the redistribution of pulmonary blood flow to low V/Q and shunt regions, and partly due to the vasogenic factors released from the embolus increasing alveolar capillary leak (e.g., histamine, bradykinin, etc). This hypoxemia can be

further exacerbated in the settling of alveolar hypoventilation, in the absence of supplemental oxygen therapy.

All trauma and ICU patients require thromboprophylaxis, guidelines for which have recently been published by the American College of Chest Physicians (Volume 2, Chapter 56) (42). The source of emboli are multiple and generally involve the lower extremities and pelvic veins, but also include the upper extremity venous system, particularly in patients with central venous catheterization. Diagnosis of pulmonary embolism relies on a high index of suspicion, and is confirmed with objective testing including spiral computed tomography or angiography. Respiratory failure from thromboembolism is usually hypoxemic, with ventilation-perfusion mismatching and increased alveolar dead space as a result of vascular obstruction.

Immediate treatment with heparinization (unless contraindicated) will prevent further clot formation, and although it has no intrinsic fibrinolytic effect, will provide clot dissolution results at the end of one week, similar to that provided by thrombolytic therapy, with far less side effects. When heparin is contraindicated, high-risk patients should receive inferior vena caval filters (Volume 2, Chapter 56).

### Collagen-Vascular Pulmonary (Autoimmune) Disease

Patients may develop ARF from parenchymal abnormalities, due to aspiration (discussed earlier), infectious pneumonias (discussed subsequently), neoplasm (not reviewed here), and collagen-vascular disease-related conditions described in this section. Patients with pulmonary fibrosis are particularly susceptible to these conditions. It is increasingly recognized that collagen vascular diseases result from autoimmune disorders (see Volume 2, Chapter 52).

These patients most commonly present with dyspnea and cough. Chest radiography may be normal, or may demonstrate reticular densities. These abnormalities may make it difficult to document a pulmonary infection. Indeed, infection may be the precipitating factor for ARF in patients with underlying pulmonary fibrosis. Many of these patients are on chronic steroid therapy, and may require stress-dose supplementation if they develop ARF.

Goodpasture's syndrome and Wegner's glomerulonephritis are common causes of patients presenting with alveolar hemorrhage (43). These are both pulmonary-renal autoimmune syndromes associated with substantial morbidity and mortality. The pathophysiology includes antibodies against basement membrane proteins in the lung and kidney, resulting in both respiratory and renal failure. Patients will require immunosuppressive therapy, usually with both corticosteroids and an antiproliferative agent like cyclophosphamide (44). Hemodialysis is commonly required, and may be combined with plasma exchange. Presentation of ARF secondary to systemic lupus erythematosus (SLE) may be similar to that seen in Goodpasture's, but alveolar hemorrhage is less common (45). As in Goodpasture's disease, infection should be vigorously pursued and treated in patients with SLE.

### Cardiovascular Failure

Effective management of ARF requires knowledge of the underlying processes. Unraveling these processes can be complicated, as when trying to differentiate between cardiogenic and noncardiogenic pulmonary edema (Table 4). Both, ventricular systolic and diastolic dysfunction can give rise to ARF, as can valvular abnormalities such as severe mitral valve insufficiency (46). Clinical differentiation can be

made on the basis of history and physical examination, but most patients will require echocardiography or PA catheterization to make a definitive diagnosis. Supplemental oxygen therapy should be implemented initially before any other intervention. Not only will this help with hypoxemia, it may directly treat ischemic cardiac dysfunction that is giving rise to the ARF. If pulmonary edema fluid can be obtained, then measurement of the edema fluid protein/plasma protein ratio can identify an exudative (sepsis or ALI) versus transudative (left atrial hypertension or CHF) cause for the pulmonary edema (47). Diastolic dysfunction, whether in combination with myocardial ischemia or secondary to systemic hypertension, may also cause ARF secondary to pulmonary edema.

Noninvasive positive pressure ventilation should only be considered if the underlying process causing the respiratory failure has resolved, and if there is no evidence of active cardiac ischemia. In patients with ongoing ischemia, endotracheal intubation and mechanical ventilation should be used. Many of the patients who present with ARF in this setting respond well to pharmacologic therapy, such as diuretics and afterload reducing agents. Although several studies have shown a benefit with NIPPV in the setting of ARF, few have indicated a clear benefit when the etiology of the ARF is clearly cardiac. The use of NIPPV may be comforting for the patient with pulmonary edema secondary to CHF, and may help to unload the LV while improving oxygenation. But the clinician should consider endotracheal intubation if there is no improvement after several hours of pharmacologic interventions, if there is any evidence of cardiac ischemia, or if the patient's WOB becomes too great (see Volume 2, Chapter 27).

### Neuromuscular Disorders

Although there are multiple neurologic disease processes that cause ARF, several occur much more commonly in the ICU setting. The end result for most of these processes, such as myasthenia gravis or the Guillain-Barré syndrome, is respiratory muscle weakness (48).

Myasthenia gravis is a disorder of the NMJ, which can present as ARF. The disease is caused by circulating antibodies that target the junctional acetylcholine receptors. The result can be marked inhibition of muscle contraction. Although the extraocular muscles, eyelid levators, and other head and neck musculature are most typically affected, respiratory muscles can fatigue, whereas sensation and reflexes are normal. Weakness and fatigability of the diaphragm and chest wall musculature is most commonly invoked as the etiology of ARF, but bulbar symptoms can be responsible as well. The  $P_{IMAX}$  and VC can both be utilized to assess respiratory muscle strength (48). Given the fluctuating weakness and fatigability characterized by this disease, it can be difficult to interpret the  $P_{IMAX}$  and VC.

Once the diagnosis of myasthenia gravis is suggested, confirmation should be sought with a "Tension test." Edrophonium hydrochloride (Tensilon<sup>®</sup>) is a rapid-onset, short-acting cholinesterase inhibitor (Table 4). Myasthenic weakness typically resolves dramatically within one minute of intravenous administration, and improved strength (including  $P_{IMAX}$  and VC) will persist for at least 10 minutes after the administration of 5–10 mg. Cholinergic side effects (gastrointestinal hyperactivity, bradycardia, cardiac dysrhythmias, diaphoresis, etc.) can occur. Accordingly, patients should be monitored with ECG, and intubation and resuscitation equipment must be

available. Once the diagnosis of myasthenia gravis is made, a neurological consultation should be obtained, and the patient may be started on pyridostigmine, a longer-acting oral anticholinesterase. Definitive therapy may include plasmapheresis, corticosteroids, and a thymectomy. Failure to inspire with normal tidal volume breaths leads to increased areas of atelectasis and  $\dot{V}/\dot{Q}$  mismatch, which then results in hypoxemia. If tidal volume breaths are excessively low, then hypercapnea ensues, and the patient will become distressed. In the minority of patients, myasthenic exacerbations will require mechanical ventilatory support. Given that the time course of the exacerbation is uncertain, most patients require intubation. This intervention also provides airway protection for more generalized weakness that may involve upper airway muscles. Intubation, if required, is best accomplished without the use of neuromuscular blocker drugs. These severe exacerbations that require mechanical ventilatory support are most commonly caused by infection. The administration of neuromuscular blockers in the surgical setting, cholinergic crisis, and poor compliance with medications represent other situations that further inhibit NMJ function.

Other diseases of the NMJ that can result in ARF are the Eaton-Lambert syndrome and botulism. Both of these entities are rarely seen, compared to myasthenia gravis. As opposed to myasthenia, which usually presents in females in the third decade of life, the Eaton-Lambert syndrome is more commonly seen in elderly men with small cell bronchogenic carcinoma (49). Botulism occurs when the neurotoxin produced by the anaerobic, gram-positive, sporulating bacterium, *Clostridium botulinum*, binds irreversibly to the presynaptic terminal, resulting in inhibition of acetylcholine release. Because the bulbar musculature is affected first, most patients present with diplopia and dysphagia. Most patients' symptoms will progress to descending weakness or frank paralysis of the skeletal musculature that can cause profound respiratory failure. As with myasthenia, patients will often require urgent endotracheal intubation, both for the ability to provide adequate positive pressure ventilation, as well as to provide airway protection in the setting of bulbar muscle weakness. Again, following the MIF and VC will be helpful for the clinician in assessing the progression of disease.

The Guillain-Barré syndrome is a disease of the peripheral neurons, and results from a nonspecific infectious etiology. The disease, which is also referred to as acute post-infectious polyneuropathy, is commonly encountered in the critical care setting. The pathophysiology of the disease involves demyelination of the peripheral and autonomic nervous systems, which is believed to be caused by a hypersensitivity reaction within several weeks of an upper respiratory tract or gastrointestinal tract infection. The disease is characterized by progressive weakness that is most commonly symmetric. Despite the fact that not all patients with the Guillain-Barré develop ARF, patients should be monitored closely. Should there be evidence of declining respiratory (VC) or bulbar muscle strength (poor handling of secretions or a weak cough or gag), patients should be admitted to the ICU for closer monitoring.

## Trauma-Related Etiologies of Acute Respiratory Failure

### Chest Trauma

#### Chest Wall Injury

Patients presenting with chest trauma may have multiple etiologies of ARF (also see Volume 2, Chapter 25). Initial failure may be due to hypoventilation, such as that seen

with multiple rib fractures. Flail chest is defined as multiple fractures occurring in two or more places, in three or more adjacent ribs, which results in paradoxical chest wall movement. The flail segment results in pendelluft, where ventilation passes between the normal and abnormal thoraces. Disarticulation and fractures of ribs cause low tidal volume breathing and splinting, with resulting hypercapnea (Table 4). Diagnosis may be made by CXR or chest computed tomography (CT) scan. **♣ Thoracic epidural anesthesia can improve respiratory function in patients with rib injuries.** Management of chest wall injuries is primarily supportive, with pain management paramount. Epidural anesthesia has been demonstrated to improve respiratory function, and should be considered for patients with flail chest (50). Pain management should be instituted prior to the institution of mechanical ventilation, as this intervention alone may be adequate for treatment. Patients with chest trauma are at risk for other thoracic injuries, including diaphragmatic disruption. A high index of suspicion is required to identify diaphragmatic rupture, which may be hidden by herniation of the liver through the right side of the diaphragm.

#### *Pulmonary Contusion*

Pulmonary contusion commonly results from chest trauma. This injury is characterized by hypoxemia, and may result in a clinical picture indistinguishable from ARDS. The pathophysiology of this injury is from alveolar-capillary disruption. Contusion may also occur as a result of intraoperative injury, particularly with lung retraction during thoracic aortic surgery. Diagnosis is made by a constellation of clinical findings, including hypoxemia and the presence of diffuse infiltrates on CXR. The injury may be exacerbated by excessive fluid resuscitation, as the normal safety factors for the prevention of pulmonary edema have been disrupted (51).

#### *Pneumothorax and Hemothorax*

Chest trauma may cause disruption of small or large airways or blood vessels, resulting in pneumothorax or hemothorax. Although more common with penetrating trauma, pneumothorax may result from blunt trauma and airway disruption. Both of these conditions may be immediately life-threatening. Mechanical ventilation may also cause barotrauma-induced pneumothorax. Whatever the cause of pneumo or hemothorax, the result is the same: increased pleural pressure that impedes venous return and decreases ventricular filling and ejection fraction. If the injury leads to tension pneumothorax or hemothorax, then cardiovascular collapse will result. To diagnose pneumothorax, CXR and physical examination with auscultation of the chest are essential, and should be components of initial evaluation of the trauma patient. A high index of suspicion is required, especially for unsuspected hypotension, in the setting of mechanical ventilation. CXR of the supine patient may show a deep sulcus sign, representing air in the costophrenic sulcus. In hemothorax, partial or complete opacification of the thorax will be seen. Treatment should not be delayed, and tube thoracostomy should be performed. For small pneumothoraces, observation or catheter aspiration may be sufficient, however, in larger pneumothoraces, hemothoraces, and particularly hemothoraces, placement of a larger tube is required to assure drainage. These procedures are particularly urgent in a patient receiving mechanical ventilation. For example, Steier et al. (52) showed that delay of treatment for more than 30 minutes, of patients

with pneumothorax from mechanical ventilation, was associated with a mortality rate of greater than 30%. When thoracostomy was done sooner, mortality rate was 7%.

#### **Fluid Overload**

Trauma patients are particularly prone to volume overload during resuscitation. One of the most important consequences of fluid overload is hydrostatic pulmonary edema (Table 4). Early placement of a central venous catheter may help guide fluid resuscitation and minimize this complication. PA catheters do not appear to be superior in preventing this complication in normal, young, previously healthy trauma patients (53). Other conditions that predispose trauma patients to pulmonary edema include inflammatory mediator release from shock, and tissue injury from transfusion of blood and blood products. Diagnosis of fluid overload pulmonary edema must be differentiated from ARDS. This will be determined by identifying the presence of left atrial hypertension, usually associated with right atrial hypertension, recognized on the central venous pressure (46). Many patients may have a combination of syndromes, with increased vascular permeability, followed by increased hydrostatic pressure from overresuscitation. Chest radiography usually shows bilateral pulmonary edema, but is not specific for the etiology of the edema (22). Treatment consists of supportive care with oxygen, diuretic administration (only after intravascular volume adequacy is established) and, if necessary, mechanical ventilation. In the setting of renal failure, emergent hemodialysis may be required.

#### **Fat Embolism**

Fat embolism syndrome may cause respiratory failure in trauma and orthopedic patients. It is clinically indistinguishable from ARDS. This syndrome is most commonly associated with long bone and pelvic fractures, where fat from the bone marrow enters the circulation, causing inflammatory injury to the lung and a noncardiogenic pulmonary edema picture (Table 4). The reaction may be triggered by thromboplastin with complement and coagulation system activation, and activation of leukocytes. The embolization is microscopic and difficult to diagnose; essentially a diagnosis of exclusion. Clinical manifestations include neurologic changes, hypoxemia and, rarely, right heart failure. Skin manifestations include petechiae, found in 50% to 60% of patients. Treatment includes routine care of patients with ARDS, with the caveat that the long bone fractures must be stabilized surgically. Steroids after the onset of the syndrome are controversial, with at least one study showing efficacy of methylprednisolone 7.5 mg/kg/6 hrs for 12 doses for prevention, but not treatment (54).

#### **Near-Drowning**

Near-drowning (Volume 1, Chapter 35) is often a catastrophic event that is associated with high morbidity (i.e., anoxic encephalopathy) and mortality. Most victims do not aspirate large quantities of water, and aspirated water is usually reabsorbed rapidly. Most complications occur as a result of hypoxia and delayed-onset pulmonary edema. Associated pathology includes spinal cord injury, myocardial infarction, and seizures. Patients may develop late-onset cerebral edema as well. Seawater drowning results in the introduction of hypertonic water into the alveolar space, where it draws additional liquid across the alveolar epithelium from the capillaries. Cardiac output may be impeded from the increase in pulmonary vascular resistance caused by

**Table 5** Orlowski Score

Points	Factor
1	Age 3 or older
1	Submersion time greater than 5 min
1	No resuscitation attempts for at least 10 min after rescue
1	Coma on admission to emergency department
1	Arterial blood pH $\leq 7.10$

Note: One point is given for each category, and score  $\leq 3$  is associated with 90% intact recovery; if  $> 3$ , then 5% intact recovery.

alveolar compression. Fresh water does not draw additional water into the alveolar space, but the hypotonic liquid denatures surfactant and other alveolar proteins, causing atelectasis, shunting, and hypoxemia. The ultimate clinical syndrome that results is similar, whether the drowning is in fresh or seawater.

Initial resuscitation is no different than that of any trauma patient, with establishment of an airway and supplemental oxygen administration paramount. In awake, cooperative patients, NIPPV may be effective. Prognostication of outcome is reflected by the Orlowski score (Table 5) (55). An Orlowski score  $\leq 3$  is associated with a 90% chance of recovery (55).

### Burns

Burn injury is a complex form of trauma that may result in ARF due to inhalation injury or due to tissue destruction and fluid third space from the thermal injury itself (Table 4). Burn injury is covered in great detail in Volume 1, Chapter 34. The severity of inhalation injury depends on both the type and concentration of inhaled material, and where they are deposited in the lungs. Exposure to smoke in an enclosed space may result in lung injury, with severity ranging from mild to fatal. Thermal injury is usually limited to the upper airway, as the alveolar liquid layer and high blood flow rapidly dissipate high temperatures. Both thermal injury and particles may initiate an inflammatory process that results in ARDS. Full manifestation of the severity of injury may not be evident for hours, so these patients require close observation and ICU admission. Clinical presentation includes wheezing, stridor, dyspnea, and tachypnea. Physical examination of the oropharynx and nares may reveal burns or soot. Whenever there is suspicion of an inhalational injury, patients should have their airways evaluated with fiberoptic bronchoscopy, and endotracheal intubation should be undertaken immediately, before swelling causes asphyxiation. Carboxyhemoglobin levels can be measured, but are not necessarily prognostic. Treatment is supportive, with the same considerations as for those patients with ARDS. Steroids should be avoided initially, as no clinical trials have demonstrated clear efficacy, and they may increase infectious complications. Similarly, empiric antibiotic therapy has no demonstrated efficacy.

### Other Injuries Promoting or Worsening Acute Respiratory Failure

#### Head Injury

Patients with traumatic head injury are at high risk for respiratory failure (Volume 1, Chapter 23 and Volume 2, Chapter 12). These patients may develop respiratory failure as a result of multiple factors, including aspiration pneumonitis, neurogenic pulmonary edema, or increased vascular permeability, from the

release of vasoactive substances from the injured brain; this is more common in the setting of subarachnoid hemorrhage (Table 4). Patients with head injury may also develop respiratory failure from altered mental status, with resulting hypercapnea. Neurogenic pulmonary edema is a complex phenomenon, which results from specific brainstem injuries, and likely is caused by a combination of increased vascular permeability and elevated pulmonary hydrostatic pressures (56). Patients with head injury often require endotracheal intubation for airway protection, and initially have no primary cause of respiratory failure, but are at particularly high risk of ventilator-associated pneumonia (57).

#### Renal Failure

Renal failure may contribute to ARF through multiple routes (Volume 2, Chapter 41). Most commonly, acute renal failure leads to fluid overload that causes hydrostatic pulmonary edema (Table 4). Additionally, failure to clear acid results in acidemia, creating a large minute ventilation burden, and retained products of metabolism lead to leaky capillaries (noncardiogenic pulmonary edema). Critically ill patients may not be able to sustain the elevated minute ventilation required to compensate for the metabolic acidosis, and respiratory failure results. Alkalinization of the blood may be appropriate in the setting of a renal tubular acidosis, where there is bicarbonate loss into the urine. Other metabolic functions of the kidney, including failure of toxin clearance, may contribute to altered mental status and subsequent ARF. Electrolyte abnormalities may contribute to respiratory muscle weakness, and should be corrected to optimize respiratory function. A recent study of critically ill patients with acute renal failure suggests that intensive hemodialysis can decrease multiple organ failure and mortality (58).

#### Pancreatitis

Pancreatic injury and pancreatitis create a systemic inflammatory response similar to sepsis syndrome, which often results in ALI (Volume 2, Chapter 39). Release of cytokines and proteases into the circulation injures endothelial cells, causing increased pulmonary vascular permeability and pulmonary edema. The consequences of these abnormalities are not significantly different from the consequences of severe sepsis syndrome. ARDS appears commonly in patients with pancreatitis, and usually requires mechanical ventilation (59). Electrolyte abnormalities and hyperglycemia may contribute to the ARF seen with acute pancreatitis.

#### Hepatic Injury

Traumatic liver injury shock and drug intoxications may result in fulminant hepatic failure, leading to multiple organ dysfunction and ARF (Volume 2, Chapter 36). Release of vasoactive substances into the circulation creates a syndrome similar to that seen with sepsis, but with higher mortality. Hypoxemia may be seen due to intrahepatic and intrapulmonary shunting, and can be refractory (Table 4).

The hepatopulmonary syndrome is characterized by the clinical triad of advanced chronic liver disease, pulmonary vascular dilatations, and reduced arterial oxygenation (i.e., increased A-a gradient) in the absence of intrinsic cardiopulmonary disease. This syndrome is common in patients with liver cirrhosis or portal hypertension (60). The pathophysiology includes arteriovenous shunting in the lung, predominantly in the bases, and are equivalent to "spider angiomas" in the lung. Echocardiography will reveal a positive bubble study with intravenous agitated saline (61).

Increasing the  $\text{FiO}_2$  improves oxygenation, but because shunting is not the only problem, there is also a combination of  $\dot{V}/\dot{Q}$  mismatching and diffusion abnormalities.

Although permanent cure has only been achieved following liver transplantation, the role of nitric oxide (NO) was suggested in 2002, when methylene blue was found to transiently improve oxygenation in patients with hepatopulmonary syndrome (62). Recently, the role of  $\text{TNF-}\alpha$  has been implicated, with the demonstration that pentoxifyllin improves oxygenation (63). The interactions of NO, endothelin, and  $\text{TNF-}\alpha$  have been summarized in a recent editorial by Dinh-Xuan and Naeije (64). ARDS develops in approximately 30% of these patients, and the hepatopulmonary syndrome is associated with sepsis.

## COMMUNITY-ACQUIRED PNEUMONIAS CAUSING ACUTE RESPIRATORY FAILURE

Patients admitted to the ICU frequently have pre-existing respiratory infections (65). Because community-acquired pneumonia (CAP) may progress to ARF, recognition and appropriate treatment of this entity is essential. Many trauma patients will have signs and symptoms of CAP prior to their traumatic injuries, so CAP must be included in the differential diagnosis of ARF in the trauma patient. The emergence of antibiotic resistance makes careful analysis and antibiotic selection more important than ever. The recommendations in this chapter are consistent with those recommended by the American Thoracic Society for both community-acquired pneumonias (66) and hospital-acquired pneumonias (67).

Chronic illness is the largest single risk factor for CAP. Diseases of the respiratory tract, especially COPD, predispose patients to pneumonia. Other coexisting illnesses, which should raise the index of suspicion for CAP, include diabetes, renal failure, malignancy, AIDS, and chronic cardiac disease. Use of either alcohol or tobacco similarly inhibits defense mechanisms and predisposes to CAP.

Diagnosis of CAP relies on the physical examination, CXR, Gram stain sputum culture, and blood count. Patients requiring ICU admission should also have an arterial blood gas and two sets of blood cultures obtained. The presence of a number of factors predict those patients with increased risk of death: coexisting illness, shock,  $\text{WBC} < 4 \times 10^9/\text{L}$  or  $> 30 \times 10^9/\text{L}$ , coexisting acute renal failure, anemia,  $\text{pH} < 7.35$ . These factors should be taken into consideration when determining if the patient requires ICU admission. Therapy should initially be empiric and broad, with antibiotic coverage narrowed once the organism and sensitivities are known. As in nosocomial infections, current knowledge of the community antibiogram should guide antibiotic selection (Table 6).

### Bacterial Pneumonias (Community Acquired) *Streptococcus pneumoniae* (*Pneumococcus*)

*Pneumococcus* (*Streptococcus pneumoniae*) is the most commonly identified pathogen, comprising 30% to 60% of isolates in patients requiring hospitalization. The Centers for Disease Control (CDC) estimates that *S. pneumoniae* causes 40,000 deaths and 500,000 cases of pneumonia annually in the United States (68). Pneumococcal pneumonia is characterized by high fever, rigors, productive cough, dyspnea, tachypnea, pleural pain, and meningitis. *S. pneumoniae* causes approxi-

mately 20% of all bacterial meningitis, and bacteremia occurs in 25% to 30% of patients with pneumococcal pneumonia. When bacteremia occurs, it is associated with higher mortality. Diagnosis is made by Gram stain, where the organisms appear as gram-positive, lancet-shaped diplococci. Definitive identification must be made either by bacterial culture or counter immunoelectrophoresis. Antibiotic sensitivities should be obtained, as resistance is common. Treatment of sensitive *S. pneumoniae* is with penicillin, ampicillin, or amoxicillin. However, the increasing prevalence of resistant organisms (up to 40% of isolates are resistant) mandates that empiric therapy for high-risk patients admitted to the ICU include an intravenous  $\beta$ -lactam plus an intravenous macrolide (e.g., azithromycin), or an antipneumococcal fluoroquinolone alone. Lower risk patients can be treated with either azithromycin or an antipneumococcal fluoroquinolone. Patients who have undergone splenectomy are at particularly high risk of infection with this organism, and must be immunized prior to discharge.

### *Hemophilus influenzae*

*Hemophilus influenzae* is most commonly present as the type b serotype (Hib). Hib is responsible for 3% to 10% of all CAP. Children and infants are at particularly high risk for infection with Hib, which usually presents with coryza and pleural effusions; and most adults present with bronchopneumonia. Presumptive diagnosis is made with Gram stain, which shows small, gram-negative coccobacilli, and definitive diagnosis by culture. About 30% of *H. influenzae* strains produce  $\beta$ -lactamase, and are resistant to ampicillin. Thus, preferred treatment is trimethoprim-sulfamethoxazole. Fluoroquinolones and azithromycin are also active.

### *Staphylococcus aureus*

*Staphylococcus aureus* accounts for about 2% of CAP. High-risk groups include the elderly, intravenous drug users, and those with preceding viral infections. *S. aureus* pneumonia is characterized by signs and symptoms similar to those already described for pneumococcal pneumonia. *S. aureus* is particularly prone to causing abscesses and infections on prosthetic devices. Diagnosis is made by examination of sputum, blood cultures, or empyema fluid, which reveals gram-positive cocci. Differentiation from *S. epidermidis* and *S. saprophyticus* is made by the coagulase test. *S. aureus* produces a number of toxins, including toxic shock syndrome toxin, epidermolysin, and enterotoxin, all of which may cause clinically important, and often lethal, clinical syndromes. The clinical course of patients with *S. aureus* is also characterized by empyema formation, which requires tube thoracostomy. This organism is particularly adept at developing antibiotic resistance, with methicillin-resistant *S. aureus* increasingly present in the community. Treatment of *S. aureus* pneumonia in patients requiring ICU admission consists of an intravenous  $\beta$ -lactam (cefotaxime or ceftriaxone), plus either an intravenous macrolide (azithromycin) or intravenous fluoroquinolone. If methicillin resistance is present, the organism should be considered resistant to all  $\beta$ -lactam antibiotics, and should be treated with vancomycin. Linezolid, although only bacteriostatic, is effective against methicillin-resistant *S. aureus*, and in two double-blind studies, showed lower mortality than vancomycin for VAP (69). The 2005 American Thoracic Society/Infectious Disease Society of America guidelines for hospital-acquired pneumonias suggest it may be preferred, due to its higher penetration of epithelial lining fluid (67). In the case of vancomycin-resistant *S. aureus* (VISA) pneumonia, Linazolid is clearly the drug of

**Table 6** Organisms that Cause Acute Respiratory Failure Requiring Ventilatory Support

Type	Organism (Gram stain)	Presentation, diagnostic factors, other comments	Drug treatment
CAP	<i>Streptococcus pneumoniae</i> , aka: Pneumoccus (Gm Pos diplococcus—lancet shaped)	S&S: Fever, rigors, coughs, dyspnea, (meningitis may occur): increased risk following splenectomy. Causes 30–60% of CAP	Ampicillin (if sensitive), resistant organisms require azithromycin, or fluoroquinolone
CAP	<i>Staphylococcus aureus</i> (Gm Pos cocci—grapelike clusters)	S&S: Similar to pneumococcus, propensity to form abscesses and infect prosthetic devices. Common in IVDA.	Ancef or ceftriaxone (if sensitive). For MRSA, vancomycin is required <sup>a</sup>
CAP	<i>Hemophilus influenzae</i> (Gm Neg coccobacilli)	Presenting S&S: (adults) bronchopneumonia, (kids) coryza and pleural effusions	TMP-SMX or ciprofloxacin
CAP	<i>Klebsiella pneumoniae</i> (Gm Neg bacilli)	Presenting S&S: Bronchopneumonia, ↑ risk in alcoholics and elderly. “Current jelly” sputum with Gm Neg bacilli	Ceftriaxone, extended spectrum penicillin <sup>b</sup> , ciprofloxacin
CAP/NOS	<i>Acinetobacter</i> (Gm Neg bacilli)	S&S similar to <i>Klebsiella</i> , common nosocomial pneumonia source. Increasingly resistant organisms (i.e., ESBLs)	Ceftriaxone, extended spectrum penicillin <sup>b</sup> , ciprofloxacin <sup>c</sup>
NOS	<i>Pseudomonas aeruginosa</i> (Gm Neg rods)	Fever, chills dyspnea, productive cough, purulent sputum, CXR diffuse patchy infiltrates, common in burn patients. Also, increasing ESBLs	Ceftazidime <sup>d</sup> and ciprofloxacin or ceftriaxone, antipseudomonal penicillin <sup>b</sup> , and aminoglycoside <sup>c</sup>
NOS	<i>Enterobacter</i> spp. (Gm Neg rods)	Can present like <i>Pseudomonas</i> , or have primarily tracheo-bronchitis. Increasingly resistant organism (i.e., ESBLs)	Ceftriaxone and ciprofloxacin <sup>c</sup>
NOS	<i>Serratia marcescens</i> (Gm Neg bacilli)	Increased risk in immunocompromised, and following prolonged IV catheterization. Increasing ESBLs	Ceftriaxone or ciprofloxacin <sup>c</sup>
ASP	All above organisms plus mouth anaerobes	Fever, cough, and purulent sputum. Classic CXR: infiltrate superior segments of lower lobes (particularly right)	Acute aspiration may not need Rx. However, fever and purulent sputum, rx: ciprofloxacin and clindamycin
ATYP	<i>Mycoplasma pneumoniae</i> (scant bacteria on Gram stain)	Interstitial pneumonia, bronchitis, culture takes 10 days. Diagnosis by culture. Treatment only necessary if severe	Erythromycin, tetracycline, or azithromycin
ATYP	<i>Legionella pneumophila</i> (scant bacteria on Gram stain)	Headache, fevers, malaise, patchy alveolar infiltrates. Diagnosis by serology or urine antigen, or DFA	Erythromycin ↑ dose 2–3 wk, or azithromycin for 2–3 wk
ATYP	<i>Chlamydia pneumoniae</i> (scant bacteria on Gram stain)	Fever, malaise, pharyngitis, pneumonia. Diagnosis requires embryonic cell culture or DFA	Erythromycin or tetracycline 3–4 wk
ATYP	Q-fever <i>Coxiella burnettii</i> (scant bacteria on Gram stain)	Exposure to farm animals (especially sheep). Fever, chills, HA, myalgias. Diagnosis is by blood culture or serology	Tetracycline, doxycycline
ATYP	Pneumocystis Carinii (scant bacteria on Gram stain)	Fever, nonproductive cough, interstitial diffuse infiltrates on CXR immunocompromised host (especially cell mediated). Diagnosis by sputum silver stain	TMP-sulfa, pentamidine
VIRAL	Influenza A and B, RSV, CMV, VZV (scant bacteria on Gram stain)	Low WBC, few bacteria on sputum, need viral cultures or serology for diagnosis—herpetic tracheobronchitis may be suggested by bronchoscopic appearance—confirmed with viral culture	Acyclovir for—herpes tracheobronchitis or varicella, Ganciclovir for CMV, intravenous IgG and Interferon may help in some
FUNGI	Cryptococcus (massive, round, Gm Pos)	Almost never causes ARF in immunocompetent individuals. AIDS patients may develop ARF. Dx BAL or serology: cryptococcal polysaccharide capsular antigen	Fluconazole (mild disease), For advanced disease: amphotericin B or voriconazole

(Continued)

**Table 6** Organisms that Cause Acute Respiratory Failure Requiring Ventilatory Support (*Continued*)

Type	Organism (Gram stain)	Presentation, diagnostic factors, other comments	Drug treatment
FUNGI	Coccidioidomycosis (scant bacteria on Gram stain)	Fever, cough (productive, sometimes blood) pleuritis—CXR may show cavitory lesion. Hx—contact with fossils or digging in San Joaquin Valley. Diagnosis by serology	Fluconazole (mild disease), For advanced disease: ampho B or voriconazole
FUNGI	Histoplasmosis (scant bacteria on Gram stain)	S&S S/A Cocci, but Hx exposure to Mississippi River Valley. Diagnosis by serology and by urine antigens (may have retinal involvement)	Fluconazole (mild disease), For advanced disease: ampho B or voriconazole
FUNGI	Blastomycosis (scant bacteria on Gram stain)	S&S S/A Cocci, but Hx exposure to Mississippi or Ohio River Valleys	Fluconazole (mild disease), For advanced disease: ampho B or voriconazole
FUNGI	Aspergillosis (scant bacteria on Gram stain)	Fever, cough, usually fatal respiratory failure, ↑ risk in immunocompromised (s/p BMTxP)	Ampho B or voriconazole or caspofungin
TB	Mycobacterium (acid-fast bacilli) Ziel Neilson Stain (MTD) auramine	↑ risk with foreign birth on travel, immunocompromised health (epidemic in HIV infected patients). Recent PCR (MTD) test allows more rapid diagnosis	Multiple drug resistance increasing (see Volume 2, Chapter 53 and consult ID)
WMD	Anthrax aka <i>Bacillus anthracis</i> (very large Gm Pos Rods) Large cells with square ends	Inhalational anthrax almost entirely due to weaponized preparation, or occupational exposure, fever, chills, sweats, dyspnea, ↑ WBC, ↑ liver transaminases	Ciprofloxacin or doxycycline

Note: *Candida* is a cause of disseminated disease, but very rarely causes acute respiratory failure.

Also note: Daptomycin is contraindicated in pneumonia. It is inactivated by surfactant. Linezolid should be used for vancomycin resistant organisms causing pneumonia.

<sup>a</sup>Linezolid, though only bacteriostatic, is effective against MRSA, and has greater epithelial lining penetration than vancomycin.

<sup>b</sup>Extended spectrum (antipseudomonal) penicillins include piperacillin and mezlocillin.

<sup>c</sup>Extended spectrum beta lactamases (ESBLs) are increasingly prevalent, and require one of the two following carbapenems: imipenem or meropenem (ertapenem lacks activity against *Pseudomonas* or *Acinetobacter*).

<sup>d</sup>Although ceftazidime is effective against all of the gram-negative organisms, we recommend reserving it for known pseudomonal infections.

Abbreviations: Ampho B, Amphotericin B; ATYP, atypical pneumonia; CAP, community-acquired pneumonia; DFA, direct fluorescent antibody; ESBLs, extended spectrum beta lactamases; FUNGAL, fungal pneumonia; Gm Neg, gram-negative organism; Gm Pos, gram-positive organism; IVDA, intravenous drug abuse; NOS, nosocomial pneumonia; MRSA, methicillin resistant staph aureus; TB, tuberculosis; WMD, weapons of mass destruction; S&S, signs and symptoms.

choice. Daptomycin is contraindicated in the treatment of pneumonia. Although daptomycin has excellent cidal effects against VRSA, in other tissues, it is inactivated by surfactant. In addition to Linezolid, Tigecycline (a derivative of tetracycline) has activity against VRSA. Tigecycline has no activity against *Pseudomonas*, but has recently (June 2005) been approved by the FDA for skin structure infections, and will likely become useful in the treatment of resistant nonpseudomonal pneumonia.

### ***Klebsiella pneumoniae***

*Klebsiella pneumoniae* is the most important community-acquired gram-negative pathogen. Mortality can be as high as 50%, even with antibiotic treatment. Patients with CAP due to *Klebsiella pneumoniae* typically present with bronchopneumonia. This organism is more frequently associated with the elderly, alcohol use, nosocomial pneumonia, and neutropenic patients. Diagnosis is made by the presence of "currant jelly" sputum, which on Gram stain shows numerous gram-negative bacilli. False-positive cultures due to other organisms that colonize the airways are common. For definitive diagnosis, culture from other sources, such as blood or pleural fluid, should be obtained.

Treatment consists of a cephalosporin (e.g., ceftriaxone), antipseudomonal penicillin, or fluoroquinolone. Each of these drugs can be given alone, or in combination with an aminoglycoside. Aminoglycosides should not be used alone. Another class of antibiotics that can be combined with an aminoglycoside to combat *K. pneumoniae* is the monobactams (e.g., aztreonam).

### ***Acinetobacter***

*Acinetobacter* is a gram-negative bacillus, which tends to cause respiratory disease in patients with diminished host defense. Although more commonly associated with nosocomial pneumonias, it is also a significant community-acquired pathogen, and thus listed here. The clinical presentation is similar to that described for *K. pneumoniae*. Diagnosis is, similarly, difficult because of the presence of colonizing organisms. Attempts should be made to isolate the organism from the blood or other fluids. Treatment of *Acinetobacter* pneumonia consists of a cephalosporin (e.g., ceftriaxone), antipseudomonal penicillin, or fluoroquinolone. Each of these drugs can be given alone, or in combination with an aminoglycoside. Aminoglycosides should not be used alone. Other drugs that can be combined

with an aminoglycoside are a monobactam.  $\beta$ -lactams are frequently associated with treatment failure, or relapse, when used against *Acinetobacter*. Additionally, a marked increase in drug resistance due to extended spectrum beta lactamases (ESBLs), produced by gram-negative pathogens, has begun to plague many hospitals and ICUs, and are particularly expressed in *Acinetobacter*, *Enterobacter* spp., *Serratia marcescens*, and *Pseudomonas* spp. When ESBLs are causative of pneumonia, one of the two following carbapenems should be used: imipenem or meropenem (ertapenem lacks activity against *Pseudomonas* and *Acinetobacter*).

### Aspiration Pneumonitis Coinciding with Hospital Admission

Patients with aspiration pneumonitis from community-acquired organisms present with a bacterial infection of the lower airways. The most common pathogens are anaerobic bacteria that normally colonize the oropharynx. Unlike aspiration pneumonia from chemical pneumonitis, bacterial infection is more insidious. Clinical presentation is with fever, cough, and purulent sputum. CXR most commonly shows infiltration in the superior segments of lower lobes, which drain dependently (posterior) in supine patients. This is particularly common on the right, possibly due to the straighter right mainstem bronchus. Posterior segments of upper lobes may also be involved, depending on the patient's position at the time of aspiration. Anaerobic infection may lead to abscess formation or empyema, which may be visible on the CXR. Diagnosis may be difficult, as expectorated sputum will be contaminated with upper airway flora. The preferred specimen source is a transtracheal aspirate (in nonintubated patients), and BAL or protected bronchoscopic specimen in intubated patients. Additionally, pleural fluid (in presence of effusion/empyema) infections frequently include multiple organisms, particularly *S. aureus*, in addition to mouth anaerobes. For the anaerobic infection, clindamycin is usually effective. For sicker patients, an aminoglycoside or fluoroquinolone, combined with a third-generation cephalosporin or extended-spectrum penicillin is effective.

### Atypical Pneumonias (Community Acquired)

#### *Mycoplasma pneumoniae*

*Mycoplasma* infection is the most common cause of CAP in the younger age group from 5 to 35, and is often spread in epidemic form. This organism has the ability to adhere to, and destroy, ciliated epithelial cells. This characteristic results in a clinical syndrome of interstitial pneumonitis, bronchitis, and bronchiolitis. Patients initially present with symptoms of influenza, with pharyngitis, cough, and malaise. Sputum may be mucopurulent or blood-tinged. Disease progresses gradually, and most patients recover uneventfully; however, some may progress to respiratory failure. Diagnosis is difficult, as isolation from sputum culture may take up to 10 days. Gram stain shows few bacteria. Chest X ray is characterized by a patchy, infiltrative pattern, rather than dense consolidation. Treatment is often not required, and if deemed necessary, should be with erythromycin, tetracycline, or azithromycin.

#### *Legionella pneumophila*

Pneumonia from *Legionella pneumophila* is normally a limited flu-like illness. Legionnaires' disease is the more commonly recognized form, and is characterized by a more severe

pneumonia, and occasionally, soft-tissue infections. Legionnaires' disease accounts for approximately 5% of CAPs that lead to hospitalization. Patients at risk for this disorder include those that smoke, use alcohol, and are immunosuppressed, especially with steroids. There is a greater prevalence in males than females. Signs and symptoms of Legionnaires' disease include headache, fever, and myalgias initially, which then progress to a nonproductive cough and high fever. CXR is notable for patchy lobar or alveolar infiltrates. Pleural effusions and abscesses may be seen. Diagnosis may be obtained by serology, urine antigen measurement, or direct fluorescent antibody (DFA) staining. Treatment consists of high-dose erythromycin (1 g IV every 6 hours). Alternatives include a fluoroquinolone or azithromycin. Treatment should be continued for two to three weeks because of the risk of relapse. In spite of treatment, mortality may be as high as 15%, especially in immunosuppressed patients (80).

#### *Chlamydia pneumoniae*

*Chlamydia pneumoniae* can be isolated in 5% to 10% of patients with CAP. Clinical presentation of *C. pneumoniae* pneumonia is similar to other atypical pneumonias, particularly that of *M. pneumoniae*. Patients present with fever, malaise, pharyngitis, bronchitis, and variably productive sputum. Risk factors are not known, except for advanced age. Diagnosis of *C. pneumoniae* pneumonia is difficult, as it requires embryonic cell culture or DFA. More often, diagnosis is made clinically in a patient who has not responded to  $\beta$ -lactam antibiotics. Treatment should be with tetracycline or erythromycin, and continued for two to three weeks.

#### Q-Fever

Q-fever is the acute illness caused by *Coxiella burnetii*. This organism is normally associated with farm animals, particularly sheep, and an exposure history is essential. Almost all cases are those of occupational exposure, which occurs by inhalation. Signs and symptoms include high fever, chills, headache, and myalgias. Nonproductive cough is variably present. Many patients also develop hepatitis. Lobar pneumonia may occur, and the chest radiographic pattern is similar to other atypical pneumonias. Diagnosis must be made by clinical history of exposure, and may also be documented by blood culture or serology. Treatment is with tetracycline, doxycycline, or chloramphenicol (third tier due to toxicity).

#### *Pneumocystis carinii*

Pneumonia due to *P. carinii* is most frequently associated with immunocompromised patients, especially those with defects in cell-mediated immunity, including AIDS. Susceptibility to *P. carinii* pneumonia in AIDS patients is dependent on their T-cell function, which becomes inadequate when CD4 cells are below 150–200/ $\mu$ L. Symptoms of *P. carinii* pneumonia include dyspnea, fever, and nonproductive cough. CXR may show diffuse infiltrates, but is not reliable. Patients may be profoundly hypoxemic, causing dyspnea. Diagnosis is made with sputum silver staining, which may be induced or obtained bronchoscopically. Bronchoscopy is much more reliable for diagnosis, and bronchoalveolar lavage specimens should be obtained in intubated patients and considered in others that can tolerate the procedure. Treatment consists of trimethoprim-sulfamethoxazole at 20 mg/kg/day, IV for 21 days. In patients with severe hypoxemia, corticosteroids have been demonstrated to

decrease hypoxemia and duration of mechanical ventilation (70). Noninfected AIDS patients with CD4 counts  $<200/\text{mm}^3$  should receive prophylaxis with trimethoprim-sulfamethoxazole.

### Common Viral Pneumonias

Influenza A and B: In adults, the most common viral pneumonias result from influenza infection. In elderly or debilitated patients, parainfluenza, respiratory syncytial virus, cytomegalovirus (CMV), and varicella-zoster may be pathogens. The vast majority of these infections are self-limited, but patients with inadequate immune responses may develop a full-blown pneumonia. Most of these infections start as bronchitis or bronchiolitis, and then progress to pneumonia. Herpes tracheo bronchitis is commonly seen in critically ill trauma patients. Clinical diagnosis is suggested by hemorrhagic bronchial lesions seen during bronchoscopy. Viral cultures confirm the diagnosis, but acyclovir therapy can be started immediately after seeing the lesions, and continued (or stopped) on the basis of cultures.

Identification of viral pneumonia is important, as many patients will progress to a bacterial pneumonia, and present with constitutive symptoms including headache, malaise, and myalgias. CXR usually shows an interstitial pattern, rather than focal infiltrates. Laboratory findings often include a low WBC count. Diagnosis may be difficult, with sputum examination showing few bacteria. Demonstration of a rash, in conjunction with the respiratory illness, may be helpful. Only serologies or viral culture can establish a definite diagnosis. Treatment is usually supportive, but acyclovir for herpes or varicella infections, ganciclovir for CMV infections, or intravenous immune globulin have been used.

### Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is an acute form of viral respiratory illness that became recognized as a global infectious disease threat in March 2003, when the World Health Organization was called in to help evaluate and contain the epidemic. First appearing in Foshan, in the Guangdong province of southern China in November 2002, SARS became the first new serious contagious illness to emerge in the 21st century, with almost 800 people killed, and nearly 8100 suffering serious illness in 2003 alone. Outbreaks in 30 countries threw public health systems into chaos and disrupted international travel (71).

The spread of SARS illustrates how quickly infection can proliferate in the modern, mobile, global economy. Conversely, the rapid discovery of the infectious agent, as well as the containment of the epidemic and elucidation of the pathophysiologic patterns associated with SARS, illustrates the sophistication of modern epidemiological and infectious disease research capabilities (72). Indeed, in April 2003 (approximately one month after the epidemic was identified), Peiris et al. (73) had isolated the SARS-associated coronavirus (SARS-CoV). In less than one month after that, Marra et al. (74) had already sequenced the SARS-CoV genome. In November 2003, one year after the initial outbreak, Li et al. (75) had discovered the critical role of the angiotensin-converting enzyme 2 (ACE2) as a functional receptor for the SARS-CoV. The subsequent research into the role of the ACE2 receptor (and its possible role in ARF of other etiologies) is discussed in the "Eye to the Future" section (76,77). Here, the clinical characteristics of SARS will be briefly reviewed.

### Etiology

SARS is caused by a previously unrecognized coronavirus, called (SARS-CoV) (72). It is believed that the SARS-CoV jumped species from a palm civet to humans and exploited opportunities provided by crowded living conditions and the warm, humid climate in southern China, evolving into a virus that is now readily transmissible between humans via respiratory secretion droplets. Hospitals and international travel provided the "amplifiers" that facilitated the initially local outbreak to rapidly achieve global dimensions (72).

### Epidemiology

The primary method of SARS infection is by close person-to-person contact. SARS-CoV is transmitted most readily by respiratory droplets. When respiratory secretions from the cough or sneeze of an infected person are propelled a short distance (generally up to three feet) through the air, droplets are deposited on the mucous membranes of the mouth, nose, or eyes of nearby persons. The virus can also spread when a person touches a surface or object contaminated with infectious droplets, and then touches his or her mouth, nose, or eye(s). In addition, it is possible that SARS-CoV might be spread more broadly through the air (airborne spread) (72).

### Signs and Symptoms

The illness usually begins with a high fever ( $>38.0^\circ\text{C}$ ). The fever is sometimes associated with chills or other symptoms, including headache, malaise, and body aches. Some people also experience mild respiratory symptoms at the outset. However, in contrast to most respiratory viruses, minimal upper respiratory symptoms are initially present following SARS-CoV infection. Diarrhea is seen in 10% to 20% of patients. After two to seven days, SARS patients may develop a dry, nonproductive cough that usually progresses to a viral pneumonia, with variable degrees of right-to-left transpulmonary shunt. In 10% to 20% of patients, mechanical ventilation is required.

### Incubation Period and Contagious Duration

The SARS-CoV has a long incubation period for a respiratory virus: typically four to seven days and, occasionally, as long as 14 days. The illness has a relatively insidious onset, upper respiratory tract symptoms are uncommon, and lower respiratory tract symptoms worsen slowly, but steadily, during the first 10 to 15 days (78). Persons with SARS are most likely to be contagious only when they have symptoms, such as fever or cough. Patients are most contagious during the second week of illness, when their viral loads and respiratory symptoms are most severe. However, as a precaution against spreading the disease, the CDC recommends that persons with SARS limit their interactions outside of the home for an additional 10 days after the fever has dissipated and their respiratory symptoms have resolved.

### Pathology and Laboratory Testing

On gross examination, the typical lung infected with SARS virus will demonstrate diffuse hemorrhage on the lung surface (79). Several laboratory tests can now be used to detect SARS-CoV. A reverse-transcription polymerase chain reaction test can detect SARS-CoV in clinical specimens such as blood, stool, and nasal secretions. Serologic testing also can be performed to detect SARS-CoV

antibodies, produced after infection. Finally, viral culture has been used to detect SARS-CoV.

### Prognosis and Treatment

The prognosis of this infection is fair, provided that the patient is in good health and within the younger age group. But death occurs in 3% to 12% of cases. A poorer prognosis is found in those with coexisting conditions such as diabetes mellitus, renal failure, and other chronic medical conditions.

Treatment remains mainly supportive. All patients suspected of SARS infection should be admitted to the hospital, and isolated to prevent further spread of disease. The CDC recommends that patients with SARS receive the same treatment that would be used for a patient with any serious community-acquired atypical pneumonia (e.g., macrolide antibiotic), as this condition is commonly confused with SARS infection. SARS-CoV is being tested against various antiviral drugs; so far no specific antiviral remedy has been identified. Riboviron has specifically been found to be noneffective (72). Monoclonal antibodies from memory B-cells have recently been shown to neutralize SARS-CoV, but research is ongoing (72).

### Fungal Pneumonias

Fungal pneumonia may be primary, or may result from superinfection of a pre-existing bacterial or viral infection. These pneumonias are seen primarily in immunocompromised hosts, but patients on suppressive antibacterial therapy are at risk as well. These infections may be complicated by hypersensitivity pneumonitis and the formation of cavitory lesions. There are geographic considerations in fungal pneumonias; *Coccidioides immitis* causes coccidiomycosis, primarily in the Southwest of the United States and the central valley of California.

### Coccidioidomycosis

Infection with *C. immitis* is endemic to the western United States. Infection occurs with inhalation of spores, which transform into spherules at body temperature. Although usually self-limited, impaired hosts may develop invasive pneumonia. Patients develop a granulomatous pneumonia characterized by fever, pleuritis, cough, and production of sputum, which may be bloody. Cavitory lesions may form, which can be life-threatening if they erode into the pulmonary vasculature. Diagnosis of coccidiomycosis is made by culture of sputum or pleural fluid. Occasionally, the spherules can be seen with staining. Complement fixation or immunoassay testing may also demonstrate elevated titers. Treatment choice depends on the severity of infection. For milder infections, fluconazole or itraconazole are adequate, but in invasive infections, amphotericin, posiconazole, voriconazole, or caspofungin should be administered (81). In patients with concomitant meningitis, intrathecal therapy may be required.

### Histoplasmosis

Infection with *Histoplasma capsulatum* occurs globally, and in the United States, most frequently is seen in the Mississippi River Valley. *H. capsulatum* occurs naturally as a mold, but when inhaled and warmed to body temperature, transforms into yeast cells. Patients with chronic exposure, and immunocompromised hosts are those at highest risk of infection. Acute primary histoplasmosis is characterized by fever, cough, and malaise, and may cause acute pneumonia.

Progression of infection may result in disseminated infection, and in the lung may cause cavitory lesions. Diagnosis may be made by culture of sputum or biopsy samples, and occasionally, staining of the blood buffy coat will demonstrate organisms. Acute primary infection is usually self-limited, but invasive infection should be treated with amphotericin or voriconazole (82).

### Aspergillosis

*Aspergillus* sp. are ubiquitous molds that become pathogenic in immunocompromised hosts. Exposure occurs by inhalation of conidia, and invasion may occur in the setting of immunosuppression. Bone marrow transplant patients, in particular, are susceptible to invasive infections, which may be life-threatening. Symptoms range from mild fever and cough, to fatal, progressive respiratory failure. Diagnosis is complicated by the fact that these organisms are ubiquitous, so the presence of *Aspergillus* sp. in sputum or other cultures may merely represent environmental contamination. Bronchial washings are preferred over sputum, and tissue diagnosis may be required. Because of the risk of biopsy in mechanically ventilated patients, empiric therapy may be required in patients with suspected infection. Treatment is with amphotericin B, and pulmonary infection may be more effectively treated using liposome-encapsulated amphotericin. Voriconazole has recently been approved for invasive fungal infections, and may eventually replace amphotericin due to less renal toxicity.

### Mycobacterial Pneumonia

Chronic infection with mycobacteria may develop into mycobacterial pneumonia. The commonly identified organisms causing tuberculosis (TB) include *M. tuberculosis*, *M. bovis*, and *M. afrocanum*. Most patients at risk include the elderly, immunocompromised patients, and recently have appeared as an epidemic in those with HIV infection. More worrisome has been the emergence of multiple, drug-resistant organisms. Active TB may occur as a new infection, or reactivation of a chronic pulmonary infection. Awareness of the possibility of TB is essential, both for optimal patient care and to prevent exposure of health care workers and others, via inhalation of aerosol. Primary infection may result in a dormant phase, where organisms may persist a lifetime. Reactivation usually occurs as a result of an immunosuppressive insult.

Symptoms of pulmonary TB include cough, fever, and variably productive sputum. There may be associated lymphadenopathy. Diagnosis is often suspected by CXR, which may show apical scarring. If the patient is immunocompetent, skin testing may be done. Pulmonary TB is usually diagnosed by the demonstration of acid-fast bacilli on a sputum smear, and then confirmed by culture. This process may take many days, however. More recently, polymerase chain reaction testing has allowed much more rapid diagnosis. Treatment requires a full course of therapy, with at least two drugs, to prevent the emergence of resistance (see Volume 2, Chapter 53). Additional drugs may be required, depending on the risk group and degree of immunosuppression; an infectious disease consultation should be obtained by those who do not routinely treat this disease.

### Anthrax

*Bacillus anthracis* is the causative agent of anthrax, a weaponized version of which has recently been used as a biological

agent of terror (83). Early recognition of anthrax infection by health care workers is essential for early intervention, to prevent widespread exposure. Anthrax is normally pathogenic for herd animals, including cattle and deer, and vegetative bacteria have poor survival outside their hosts. Spores are hardier, and they may survive for decades. Weaponization occurs when the spores are treated, so they become more readily dispersed and inhaled. Inhalational anthrax occurs following inhalation of the spores, which then germinate. Symptoms include fever, chills, sweats, nausea, dyspnea, and chest discomfort. Physical findings include fever, tachycardia and, rarely, hypotension. Laboratory findings are largely nonspecific, with elevated WBC count and transaminases most common. CXR is usually abnormal, with mediastinal widening a fairly specific finding. Infiltrates and hemorrhagic pleural effusions are common. Chest CT may show mediastinal lymphadenopathy (responsible for the mediastinal widening seen on CXR) and pleural effusions which, when sampled, are usually bloody. The presence of a markedly widened mediastinum, in a formerly healthy patient with severe respiratory illness, should be suspicious for inhalational anthrax. Because of the rarity of this disease, diagnosis may be difficult, but therapy should be initiated while the diagnosis is pursued. *B. anthracis* is a gram-positive, encapsulated, nonhemolytic, penicillin-sensitive, spore-forming bacillus, which may be visible on peripheral blood smear. Most public health facilities now have reference laboratories in place to assist with rapid identification.

Therapy should be initiated with doxycycline or ciprofloxacin, although penicillin is usually effective and is approved by the FDA. The recommended initial dosing for adults, with clinically evident inhalational anthrax, is ciprofloxacin 400 mg administered intravenously every 12 hours (84). The use of dual initial therapy (ciprofloxacin plus penicillin) may be considered, in view of the frequent and rapid development of complicating meningitis, and the clinical experience of cerebrospinal-fluid penetration with high-dose intravenous penicillin (84). More complete recommendations for special groups, such as pregnant women, immunosuppressed patients, and children, are available elsewhere (84).

Prompt notification of public health authorities is essential, as infection control, postexposure prophylaxis, and decontamination are required to prevent widespread loss of life.

## NOSOCOMIAL PNEUMONIAS CAUSING ACUTE RESPIRATORY FAILURE

The ICU is associated with a greatly increased risk of nosocomial infection, with rates three to five times greater than that seen for patients who are not admitted to the ICU (85). These infections are associated with substantial morbidity and mortality, in addition to cost. Prevention of these infections is clearly the most effective therapy, and a strong evidence base exists that demonstrates the cost-effectiveness of such measures. Nosocomial pneumonia is most often associated with intubated patients who develop VAP. This subject is covered in detail in Volume 2, Chapter 48. Antibiotic resistance develops in the ICU as a result of exposure of organisms to broad-spectrum antibiotics. One strategy that may limit this selection pressure is the use of antibiotic rotation (86,87). In addition to *Acinetobacter* (discussed

above), the following microorganisms are commonly associated with nosocomial pneumonia.

### Nosocomial Organisms

#### *Pseudomonas aeruginosa*

*P. aeruginosa* respiratory infections occur almost entirely in patients who are immunocompromised. Patients with chronic lung disease and CHF are particularly susceptible. Along with *S. aureus*, it is the most common cause of VAP. Pneumonia occurs as a result of aspiration of *P. aeruginosa* from the oropharynx, which becomes colonized during the course of hospitalization. *P. aeruginosa* pneumonia is associated with high morbidity and mortality, in part because of the propensity of *P. aeruginosa* to cross the alveolar epithelium and cause bacteremia (88). The clinical presentation of *P. aeruginosa* pneumonia includes chills, fever, severe dyspnea, productive cough with purulent sputum, and cyanosis. CXR may reveal focal or diffuse infiltrates. Bacteremia is common, so blood cultures should be obtained in addition to sputum culture or bronchoalveolar lavage. Because of the increasing prevalence of resistant organisms, double coverage (e.g., ciprofloxacin and ceftazidime combined) is recommended in critically ill patients. Because combined, the critically ill patients are at risk for renal insufficiency, aminoglycosides are reserved for second-line therapy, in combination with a fluoroquinolone or an antipseudomonal penicillin.

#### *Enterobacter* spp.

*Enterobacter* spp. is a common cause of nosocomial pneumonia, and like *P. aeruginosa*, causes lung infection via aspiration of colonizing oropharyngeal organisms. The lung may also be infected by the intravenous route, as a result of central venous catheter infections, which are frequently caused by *Enterobacter* spp. These organisms tend to colonize patients who have been treated with antibiotics, and therefore are abundant in the ICU. Most are resistant to first-, second-, and frequently third-generation cephalosporins. Blood cultures are rarely positive, so surveillance sputum cultures should be obtained, when possible. More aggressive pursuit of VAP is discussed in Volume 2, Chapter 48. Treatment of *Enterobacter* pneumonia consists of a second-generation cephalosporin, a nonpseudomonal third-generation cephalosporin (e.g., ceftriaxone), or ciprofloxacin. When ESBLs are produced by resistant *Enterobacter*-causing pneumonia, imipenem or meropenem should be used.

#### *Serratia marcescens*

*Serratia* is a frequent cause of nosocomial infections, of both the urinary and respiratory tract. These infections are rare outside the ICU, as they are commonly associated with catheters and other foreign bodies. Antibiotic resistance is common, especially with monotherapy using cephalosporins. The combination of ceftriaxone and an aminoglycoside is recommended for serious infections requiring prolonged therapy. When ESBLs are produced by resistant *S. marcescens* causing pneumonia, imipenem or meropenem should be used.

### Factors Predisposing to Nosocomial Pneumonias

Nosocomial pneumonia is the second most common hospital-acquired infection after urinary tract infection (85). Although the majority of nosocomial pneumonias occur in nonintubated patients, the risk of pneumonia is up to 20 times greater in intubated patients (87). Other common

risk factors include age, decreased level of consciousness, the presence of a nasogastric tube, postsurgical patients, and recent bronchoscopy (89).

A number of strategies have been examined, in an effort to decrease risk of nosocomial pneumonia. Clearly, the most effective is prevention or prophylaxis. The implementation of ventilator weaning protocols that decrease the duration of mechanical ventilation, will decrease risk. VAP is discussed in detail in Volume 2, Chapter 48. Other preventive measures include aggressive infection control policies, such as hand washing, postpyloric nasogastric feeding, and appropriate antibiotic usage. Inadequate treatment of VAP may also contribute to increased prevalence of nosocomial pneumonia; if initial broad-spectrum therapy is ineffective, then treatment should be de-escalated (90). More innovative concepts like zinc-coated ETTs show promise, but await definitive clinical trials.

✎ **Decreasing duration of mechanical ventilation, through the use of weaning protocols, can reduce the incidence of VAP.** ✎

## SUMMARY OF CARE FOR THE PATIENT WITH ACUTE RESPIRATORY FAILURE

### Respiratory Insufficiency Criteria for Intensive Care Unit Admission

Triage of patients with ARF to the ICU focuses initially upon severity of the ARF. However, in patients with moderate disease, not in itself requiring ICU admission, additional factors that must be evaluated include coexisting illness in the patient, anticipated difficulty of intubation, clinical

course, and availability of monitoring and nursing. Patients requiring high-flow supplemental oxygen for hypoxemia, or those requiring noninvasive ventilatory support, require close monitoring if they are not physically admitted to the ICU.

Patients with progressive pneumonia or sepsis syndrome should be evaluated for admission to the ICU earlier rather than later, as hypoxemia, hypercapnea, and acidosis may develop rapidly in patients who do not have intact compensatory mechanisms. The Society of Critical Care Medicine has established guidelines for ICU admission, discharge, and triage (65). Table 7 describes the two major respiratory criteria (oxygenation and ventilation abnormalities) that should be considered for ICU admission. Other considerations include the availability of qualified nursing or respiratory care personnel (e.g., patient in need of frequent suctioning, encouragement to cough, deep breath, etc.).

### Intubation and Mechanical Ventilation Criteria

The decision to intubate the trachea and implement mechanical ventilation is multifactorial, and may be determined by the degree of hypoxemia, hypercapnea, respiratory distress, stridor, or altered mental status. NIPPV has been demonstrated to be efficacious in a number of settings, particularly in exacerbations of COPD. However, noninvasive ventilation should only be employed in situations where the respiratory insufficiency is expected to be transient. This is seldom the case in trauma. The various modes of mechanical ventilation are fully described in Volume 2, Chapter 27.

**Table 7** Criteria for Intensive Care Unit Admission: Emphasis on ARF, Postoperative, Post-Trauma Conditions

Priority	ICU admission criteria	Respiratory related examples
1A	Critically ill, unstable patients in need of intensive R <sub>x</sub> or monitoring that cannot be provided outside of the ICU.	ARF requiring MV. Shock requiring MV and continuous vasoactive drug infusions, etc.
1B	Postoperative or post-trauma patients requiring MV, and monitoring or R <sub>x</sub> for shock or HD instability.	S/P polytrauma, S/P TBI, S/P thoracic or major vascular surgery, S/P liver transplant, S/P major abdominal surgery, S/P surgery in critically ill patient.
2	Patients requiring intensive monitoring and may potentially need immediate intervention.	S/P neck or thoracic injuries, who are initially oxygenating and ventilating adequately. New onset pneumonia in patient with chronic comorbid condition(s).
3A	Unstable critically ill patients with a reduced likelihood of recovery because of underlying disease or nature of their acute illness.	End stage liver disease with acute severe TBI, disseminated malignancy or AIDS with major (>30% BSA) burn.
3B	Patients that might benefit from ICU to relieve acute illness, however, have set forth limits on therapeutic efforts (e.g., no intubation or CPR).	Metastatic malignancy complicated by infection, or pneumonia in patient with living will, or advanced directive that prohibits aggressive life-saving therapy.
4A	Patients not ill enough to significantly benefit from ICU care.	S/P uncomplicated peripheral vascular surgery; hemodynamically stable DKA, mild CHF, etc.
4B	Patients with terminal and irreversible illness facing imminent death (i.e., ICU therapy is considered futile). Patients with decision-making capacity (or a living will or advanced directive) that prohibits intensive care who receive comfort care only.	Brain death or severe irreversible brain injury (however, these patients may be suitable organ donors; if so they advance to priority 1 or 2). Irreversible multiorgan system failure. Patients with decision-making capacity (or a living will/advanced directive) that prohibits ICU and/or invasive monitoring or ETT.

*Abbreviations:* AIDS, acquired immunodeficiency syndrome; ARF, acute respiratory failure; BSA, body surface area; CHF, congestive heart failure; CPR, cardiopulmonary bypass; DKA, diabetic ketoacidosis; ETT, endotracheal tube; HD, hemodynamic; ICU, intensive care unit; MV, mechanical ventilation; R<sub>x</sub>, treatment; S/P, status post; TBI, traumatic brain injury.

*Source:* From Ref. 65.

Patients who continue to be hypercapneic, acidotic, or hypoxemic despite noninvasive measures should have their trachea intubated and be started on mechanical ventilation. This decision may be influenced by both the rate of disease progression, as well as the need for interventional and/or diagnostic procedures. For example, if it is deemed necessary to place a central venous catheter, many patients with tenuous respiratory status are unable to tolerate lying supine (much less in the Trendelenberg position), due to decreased functional residual capacity, and may require intubation to facilitate line placement or more complex procedures. Likewise, patients who must undergo diagnostic procedures like magnetic resonance imaging or CT scanning (where monitoring of respiratory status is compromised), or in need of cerebral angiography (where sedation and absence of movement is critical) should be intubated to protect against respiratory failure, gastric aspiration, or complications of the procedure.

Finally, patients with stridor, or airway exams that indicate intubation is likely to be difficult, should have their tracheas intubated earlier, under controlled, semi-elective conditions, rather than later, under less controlled emergent conditions. In many cases, maintaining spontaneous ventilation, and intubating the trachea using an awake-intubation technique (e.g., fiberoptic bronchoscopy) represents the optimum approach when stridor is present, or difficult intubation is anticipated (see Volume 1, Chapter 9).

## EYE TO THE FUTURE

The management of patients with respiratory failure has improved exponentially over the last decade. The future holds promising therapies, which include improved diagnostic equipment, which will allow real-time measurement of arterial blood gases, which in concert with therapist-driven weaning protocols may allow faster weaning from mechanical ventilation. As respiratory failure is often a by-product of other disease processes, such as sepsis (Volume 2, Chapter 47) and pancreatitis (Volume 2, Chapter 39), specific therapies for those diseases, currently evolving, will have a positive impact on ARF as well. Exciting new work into the molecular mechanisms of cellular regulation, immunology (Volume 2, Chapter 52), and microbial-host interactions is beginning to elucidate the fundamental mechanisms underlying the sources of some etiologies of respiratory failure. These research pursuits will yield new therapeutic tools, some of which may become available soon.

Researchers now believe that the ACE2 receptor involved in SARS has broad applicability in the pathogenesis and treatment of numerous etiologies of pulmonary edema, beyond infection with SARS-CoV. The SARS-CoV requires ACE2 to gain entry into cells (75). However, once the virus enters the cell, the expression of ACE2 is downregulated, and the subsequent paucity of ACE2 expression appears to be the mechanism that promotes respiratory failure. Insight garnered from this research has suggested methods for treating humans infected with SARS-CoV, by administering ACE2 to reverse the often deadly condition (77,91). ACE2 administration may also help alleviate pulmonary edema from other sources.

The ACE2 receptor is required for the SARS-CoV to infect cells and replicate itself. Using tissue culture, researchers have demonstrated that, in the presence of cells expressing ACE2, SARS-CoV replicate to levels 100,000 times greater than when incubated with cells not

expressing ACE2. Furthermore, compounds that inhibit ACE2 in humans decrease SARS-CoV viral replication.

The "Spike," or S proteins on SARS-CoV, are used like a hook to grab onto ACE2; this binding enables cell membranes to fuse together, a process that is critical for a virus to enter a cell (92). The unexpected secondary relationship of SARS-CoV infection and ACE2 receptors was discovered by Kuba et al. (77), who found that infections with SARS-CoV result in ACE2 downregulation, also through binding of SARS-CoV Spike protein to ACE2.

The role of ACE2 as a protector against pulmonary edema was first demonstrated when lab mice were infected with the SARS corona virus, and it was noticed that the resulting drop in ACE2 was associated with the mice lungs filling with fluid, triggering acute pulmonary edema-mediated respiratory failure. Armed with their new knowledge, the researchers theorized that if a lack of ACE2 causes respiratory failure, then restoring it should halt the process. They injected the mice with bioengineered ACE2, which, as they predicted, shut down the SARS-induced pulmonary edema (77).

Recent data in a small cohort of individuals with SARS suggested that an insertion/deletion ACE polymorphism that affects ACE function correlates with disease severity, underscoring the relevance of these findings in humans (93). Indeed, Marshal et al. demonstrated that ACE plays a likely role in the pathogenesis of ARDS (perhaps via effects on pulmonary vascular tone/permeability, epithelial cell survival, and fibroblast activation). They noted that 47% of the variance in plasma ACE activity is accounted for by the ACE insertion/deletion polymorphism, and that the D allele is associated with higher activity. Accordingly, they hypothesized that the D allele might be associated with ARDS. In their study, they demonstrated that the DD genotype was markedly increased in the patients with ARDS, compared to other ICU patients ( $p = 0.00008$ ), coronary artery bypass graft patients ( $p = 0.0009$ ), and general population ( $p = 0.00004$ ) control groups, and was significantly associated with mortality in the ARDS group ( $p < 0.02$ ), suggesting a potential role for renin-angiotensin systems in the pathogenesis of ARDS and, for the first time, implicating genetic factors in the development and progression of ARDS (94).

The aggregate analysis of this exciting aforementioned new research, regarding the molecular mechanisms of SARS-mediated infection and pulmonary edema (involving the renin-angiotensin system), has now suggested a broader role of ACE2 in lung failure and ARDS of multiple etiologies. Recombinant ACE2 protein might, therefore, not only serve as a treatment to block spreading of SARS-CoV, modulation of the renin-angiotensin system could also be used to protect individuals infected with other viruses (such as strains of avian influenza A), and other disease processes (such as pancreatitis-mediated noncardiogenic pulmonary edema), from developing acute severe lung failure and ARDS (77). Numerous additional examples of ongoing research into the molecular mechanisms of disease, and also the genetic predisposition (relating to the expression, or nonexpression of permissive or protective proteins) will continue to provide bright new avenues for treatment of respiratory failure in the future.

## SUMMARY

ARF continues to be the most common reason for admission to the ICU for both nontrauma and trauma patients.

**Table 8** Categorization of Common Sources of Respiratory Failure Based upon the Primary Physiologic Abnormality (Oxygenation or Ventilation)

Oxygenation problem	Ventilation problem
Direct pulmonary dysfunction	Airway obstruction
Pneumonia	Stridor
Atelectasis	Excessive snoring
Pulmonary contusion	
Noncardiogenic	Excessive WOB
pulmonary edema	Low compliance
(ALI/ARDS)	$\uparrow\uparrow$ Airway resistance
Sepsis, SIRS	$\uparrow$ 'd $V_D/V_T$
$\uparrow\uparrow$ Nonthoracic trauma	CO <sub>2</sub> production
Fat emboli	Inability to do the WOB
Burns	Generalized weakness
Pancreatitis	Critical illness
$\downarrow \exists \delta$ albumin <sup>a</sup>	polyneuropathy
Cirrhosis	Steroid myopathy
Acute renal failure	
Cardiogenic pulmonary edema	Lung mechanical problem
Left heart failure	( $\downarrow$ 'd ventilatory drive or strength)
Ischemia	Opiate overdose
Mitral valve disease	Brainstem injury
Viral cardiomyopathy	Spinal cord injury
Hydrostatic pulmonary edema	( $\downarrow$ 'd NMJ function)
Neurogenic pulmonary edema	Myasthenia gravis
NPPE	Botulism

<sup>a</sup>Hypoalbuminemia can result from massive blood loss and resuscitation with crystalloid, nephrosis, cirrhosis, malnutrition, excessive catabolism, etc.

**Abbreviations:**  $\downarrow$ , decrease;  $\uparrow$ , increase; ALI, acute lung injury; ARDS, acute respiratory distress syndrome; NMJ, neuromuscular junction; NPPE, negative pressure pulmonary edema; SIRS, systemic inflammatory distress syndrome;  $V_D/V_T$ , dead space to tidal volume ratio; WOB, work of breathing.

The specific diagnosis can often be categorized as primarily a problem of oxygenation or ventilation (Table 8). The precise etiology of the respiratory failure should be aggressively sought after, beginning when patients are first evaluated in the ICU, or immediately prior to transfer. Although culture data will generally take at least 48 hours, often the clues explaining the cause of respiratory failure become irretrievable 12 to 24 hours after presentation, forcing treatment to remain empirical and suboptimal for much longer durations. Even though oxygenation and ventilation problems are often coinvolvement, one form is often predominant initially, and reflects the inciting insult. It is extremely important to search for the initial trigger of respiratory failure, because it has both prognostic and therapeutic implications.

ARF can result from problems directly related to the lungs, aspiration, pulmonary emboli pneumonia, and blunt chest trauma (e.g., pulmonary contusion). However, many critically ill patients develop ARF after primary pathology in another organ system (e.g., renal failure, liver failure) or a generalized condition causing systemic inflammation (sepsis, pancreatitis, trauma, burn). Because their etiologies are covered in other chapters, this chapter has focused upon primary problems affecting the lungs and causing ARF.

The SARS-CoV Spike protein-mediated ACE2 down-regulation contributes to the severity of pulmonary edema, and explains how this family member of the normally relatively harmless coronaviruses has evolved into a lethal virus. Furthermore, the significance of the discovery of the molecular nature behind the pulmonary edema component of SARS-CoV extends beyond SARS itself. Indeed, understanding the role of ACE2 in pulmonary edema has suggested a possible means of preventing lung failure from numerous other forms of ARF and ARDS, including sepsis, anthrax, and avian flu (the agent that, many infectious disease experts believe, will launch the next flu pandemic) (95).

Finally, a more sobering thought is the continuing emergence of antibiotic resistance in the ICU. Aggressive infection control, limitation of excessive antibiotic usage and, possibly, devices like antimicrobial-coated ETTs may help stem the tide.

## KEY POINTS

- ☞ Arterial blood gas (ABG) analysis is the single most important laboratory test for defining the severity of ARF. In addition to quantifying the severity, ABG analysis assists in differentiating the cause of ARF, and is useful in decision making regarding intubation and mechanical ventilation.
- ☞ Many of the drugs used in the ICU have vasodilator properties and can worsen oxygenation by blunting HPV and exacerbating  $\dot{V}/\dot{Q}$  mismatching.
- ☞ The most common causes of right-to-left transpulmonary shunting in ICU patients are direct pulmonary pathologic entities, such as pneumonia, atelectasis, and noncardiogenic pulmonary edema.
- ☞ Many commonly used drugs can cause methemoglobinemia, which will worsen hypoxemia and acidosis. These drugs include dapsone, local anesthetics (benzocaine and prilocaine), commonly used nitrates (nitroprusside, nitroglycerin), and sulfonamides. Diagnosis may be made with co-oximetry that measures various hemoglobin species. Treatment is with methylene blue.
- ☞ Patients with acute asthma exacerbations are normally hypertensive because of catechol release. Those that are normotensive or hypotensive and tachycardic may have elevated intrathoracic pressure impeding venous return, and are at increased risk for cardiopulmonary arrest during endotracheal intubation.
- ☞ Inspiratory stridor is usually due to an extrathoracic obstruction (supraglottic or periglottic), and expiratory stridor is usually due to an intrathoracic process.
- ☞ The key principles of airway management for stridor are: (i) maintain spontaneous ventilation, (ii) avoid blind intubation techniques (may convert partial obstruction into complete obstruction), (iii) awake fiberoptic intubation is often the best diagnostic tool and method of airway intubation, and (iv) equipment and personnel capable of performing a surgical airway must be present until the airway is secured.
- ☞ Thoracic epidural anesthesia can improve respiratory function in patients with rib injuries.
- ☞ Decreasing duration of mechanical ventilation, through the use of weaning protocols, can reduce the incidence of VAP.

### DEFINITIONS AND EPIDEMIOLOGY

#### Definitions

Formally recognized over four decades ago (1), acute lung injury and the acute respiratory distress syndrome (ALI/ARDS), are defined by descriptive physiologic and clinical criteria set forth by the American-European Consensus Conference (AECC) of 1994 (Table 1) (2). Three primary features define ALI/ARDS; a profound oxygenation defect (right-to-left transpulmonary shunt), impaired carbon dioxide excretion, and the presence of noncardiogenic pulmonary edema. The oxygenation defect is characterized by the partial pressure of oxygen in the arterial blood ( $\text{PaO}_2$ )/fraction of inspired oxygen ( $\text{FiO}_2$ ) ratio (P/F ratio). When the P/F ratio is  $<300$ , the criteria for ALI is met, whereas if  $<200$ , the ARDS threshold is achieved. The AECC definitions for ALI and ARDS build upon the experience of the lung injury severity score introduced by Murray et al. (3). That scoring system combines the magnitude of physiologic impairment (severity of oxygenation defect, required level of positive end-expiratory pressure, and decreased respiratory compliance) along with the degree of alveolar consolidation on the chest radiograph (3). Several studies have compared the diagnostic accuracy between these criteria concluding statistical agreement (4). The intent of the simplified definition is to characterize a syndrome without reference to a specific etiology (5).

#### Epidemiology

An accurate incidence of ALI/ARDS has been difficult to determine. Several epidemiological studies using the AECC definition suggest an incidence of 12.6 to 18.9 cases per 100,000 population per year (6). However, new data recently generated in King's County, Washington, demonstrated the incidence may be as high as 75 cases per 100,000, or approximately 200,000 cases per year in the United States (7). Previous studies that did not apply the AECC criteria described lower estimates, ranging from 1.5 to 17.9 cases per 100,000 population per year (8).

#### Associated Clinical Disorders, Risk Factors, and Mortality

☞ Both ALI and ARDS, can result from a multitude of disorders (Table 2) with the common thread being injury to the epithelial capillary barrier of lung alveoli. ☞ This

injury can result from direct injury, or indirectly through local or systemic inflammation. The most common associations from prospective studies are sepsis syndrome accounting for 40%, aspiration and pneumonia combining for 40%, as well as trauma, and multiple transfusions (9). ☞ Because of the frequency of associated septic conditions, infectious foci must be actively pursued and treated in ARDS patients (10). ☞

Several independent predictors of mortality have been reported including comorbid states and age  $>65$  (Table 3) (8). The patient's immunological status (particularly neutrophil function) is an important determinant of ALI/ARDS severity. Patients suffering from chronic alcoholism are more susceptible to lung injury, likely a result of deranged neutrophil activation (11). Conversely, diabetics with impaired neutrophil function from hyperglycemia may be protected from lung injury, but are more likely to succumb to sepsis syndrome (12).

Interestingly, the only pulmonary-specific physiologic predictor of mortality appears to be a bedside measure of pulmonary dead-space fraction (13). Patients with diminished alveolar fluid clearance, determined by sequential samples of pulmonary edema fluid, also have a higher mortality (14).

Estimates over the past several decades for the overall mortality rate of ALI/ARDS patients range from 30% to 60% (10). Most deaths seem to be a consequence of multiorgan dysfunction rather than primary pulmonary failure. Fortunately, more recent calculations suggest a decreasing mortality trend, approximately 35% to 40% (7).

### PATHOPHYSIOLOGY

Regardless of the etiology of ALI/ARDS, the extravasation of protein-rich fluid into the alveolar space leads to pathologic, radiographic, and clinical changes that can be delineated into acute, subacute, and chronic phases (Table 4).

#### Acute Exudative Phase

☞ The acute exudative phase is a consequence of widespread protein-rich alveolar edema. ☞ In the initial hours, the permeability edema has a high alveolar to plasma protein ratio (16). Findings on bronchoalveolar lavage and

**Table 1** Criteria for Acute Lung Injury and Acute Respiratory Distress Syndrome

Acute onset
PaO <sub>2</sub> /FiO <sub>2</sub> ≤ 300 mmHg (ALI)
PaO <sub>2</sub> /FiO <sub>2</sub> ≤ 200 mmHg (ARDS)
Bilateral pulmonary infiltrates on anterior-posterior chest radiograph
Absence of left arterial hypertension (PCWP < 18 mmHg when measured)

*Abbreviations:* ALI, acute lung injury; ARDS, acute respiratory distress syndrome; FiO<sub>2</sub>, fraction of inspired oxygen; PaO<sub>2</sub>, partial pressure of oxygen in the arterial blood; PCWP, pulmonary artery capillary wedge pressure.

lung biopsy include diffuse alveolar damage with cellular infiltration by neutrophils, macrophages and erythrocytes, alveolar-epithelial disruption, and hyaline membrane deposition (17).

Radiographically, nonspecific findings predominate with bilateral infiltrates that may not be symmetrical and may be associated with pleural effusions (Fig. 1) (18). Computed tomography may further reveal a bilateral heterogeneous alveolar filling without enlargement of pulmonary vessels. It tends to occur in dependent lung zones with associated consolidation and atelectasis (19).

☛ **Alveolar flooding results in significant transpulmonary shunting and ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) imbalance causing profound hypoxemia that is refractory to supplemental oxygen.** ☛ A reduction in static lung compliance, the tidal volume divided by the plateau pressure minus the level of positive end-expiratory pressure (PEEP), leads to an increase in the work of breathing. Hypoxemia may worsen with increasing metabolic demand (e.g., fever, and high work of breathing) decreased oxygen delivery (e.g., anemia, impaired cardiac output), or derangement in acid-base status (20). The initiation of mechanical ventilation attempts to reverse the hypoxemia due to alveolar flooding and increased work of breathing by providing assisted ventilation with PEEP and supplemental oxygen. However, the oxygen delivery can be further decreased with positive pressure ventilation due to impairment of cardiac output. Accordingly, ARDS patients with impaired cardiac output often require some degree of inotropic support.

**Table 2** Clinical Disorders Associated with the Development of Acute Lung Injury and Acute Respiratory Distress Syndrome

Direct lung injury	Indirect lung injury
Pneumonia	Sepsis
Aspiration of gastric contents	Severe trauma with shock and multiple transfusions
Pulmonary contusion	Cardiopulmonary bypass
Fat emboli	Drug overdose
Near-drowning	Acute pancreatitis
Inhalational injury	Transfusions of blood products
Reperfusion pulmonary edema after lung transplantation or pulmonary embolectomy	Reperfusion of ischemic gut and extremities

**Table 3** Predictors of Increased Mortality in Acute Lung Injury and Acute Respiratory Distress Syndrome (Based on Epidemiologic Studies)

Risk factor	Examples
Severe, nonpulmonary systemic disease	Liver dysfunction/cirrhosis Sepsis Nonpulmonary organ dysfunction HIV infection Active malignancy Chronic alcoholism Renal failure
Pulmonary factors	Increased alveolar dead space Prolonged, decreased pulmonary compliance
Age-related factors	>65
Miscellaneous poor predictors	Organ transplantation APACHE II >25

**Table 4** Stages of Acute Lung Injury and Acute Respiratory Distress Syndrome

Stage	Pathophysiology/clinical presentation	Pathogenesis
Acute exudative	Onset—hours to days Hypoxemia—intra-pulmonary shunting and ventilation perfusion imbalance Static lung compliance worsening Increasing dead space Bilateral pulmonary edema on the chest radiograph	Disruption of alveolar-capillary unit from: Primary injury Secondary injury such as inflammatory and procoagulant mechanism Protein-rich alveolar edema accumulating secondary to inflammatory and procoagulant mechanism
Subacute fibrosing alveolitis	Onset—hours to weeks Hypoxemia—as above plus diffusion defect Pulmonary hypertension with right ventricular failure Susceptibility to ventilator-associated pneumonia Reticulation and distortion of bronchovascular markings and barotrauma on the chest radiograph	Interstitial and air space fibrosis from: Mesenchymal cellular infiltrate Disorganized collagen deposition
Chronic resolution	Onset—hours to months Hypoxemia improved Lung compliance improved Persistent restrictive defects and diffusion abnormalities by pulmonary function testing Long-term neuro-muscular deficits and diminished quality of life	Resolution of alveolar edema through: Regenerated alveolar-capillary integrity Apoptosis of inflammatory cells

**Figure 1** The anterior–posterior chest radiograph shows bilateral patchy alveolar infiltrates consistent with noncardiogenic pulmonary edema. This patient has acute respiratory distress syndrome from gram-negative sepsis due to a perforated duodenal ulcer. *Note:* There is an endotracheal tube in place to deliver positive pressure ventilation.

Concomitant abnormalities in pulmonary blood flow lead to mismatched ventilation–perfusion. This physiologic dead space is the component of wasted ventilation that impairs the excretion of carbon dioxide and may cause hypercapnia. As mentioned previously, increased dead-space ventilation early in the disease course is predictive of mortality (13). Interestingly, the recent therapeutic shift towards permissive hypercapnia is not associated with worse outcome (21).

### Subacute Fibrosing Alveolitis Phase

Some patients recover from the acute insult without sequelae, however, some progress to a subacute fibrosing alveolitis phase. This phase is characterized by fibrotic alteration of the interstitium and air spaces of the lung and chronic inflammatory cell infiltrate (14). The evolving fibrosis is evident on the chest radiograph as linear opacities (18). Likewise, computed tomography demonstrates interstitial reticulation and distortion of bronchovascular markings (19). Dependent lung zone barotrauma, in the form of pneumothorax and other air leaks, is anticipated in approximately 5% to 10% of patients. Surprisingly, there is not an increase in mortality associated with barotraumas (22).

Gas exchange abnormalities persist; hypoxemia, from the ongoing transpulmonary shunt and ventilation–perfusion imbalance as well as hypercapnia, from increased alveolar dead-space ventilation (20). In severe cases, the obliteration of the pulmonary capillary bed can lead to worsening pulmonary compliance, pulmonary hypertension, and ultimately right ventricular failure (23).

The clinical course of ALI/ARDS is frequently complicated by nosocomial infections, particularly ventilator-associated pneumonia (VAP). Estimates of ALI/ARDS patients suffering VAP have been as high as 60% (24). The increased risk is partly due to the consequences of endotracheal intubation and mechanical ventilation. These include the microbial colonization of the lungs and changes in alveolar epithelial integrity (25). Endotracheal tubes facilitate bacterial entry and limit physical clearance of organisms. Once established, these flora alter the innate response to infection by reducing surfactant protein secretion that is critical in the process of

clearance, and by increasing the quantity of proinflammatory cytokines (26). In the setting of VAP, specific attributable mortality increases, particularly with the presence of *Pseudomonas* and *Acinetobacter* species (27).

### Chronic Resolution Phase

Gradual resolution, typically weeks after the insult, is heralded with improving oxygenation and lung compliance, as slow radiographic resolution occurs. **Postextubation pulmonary function testing among ALI/ARDS survivors shows restrictive impairments and diffusion abnormalities.** At 6 to 12 months, lung volume and spirometric measurements normalize, however, diffusion derangements persist (28). This is accompanied by a low health-related quality of life not entirely explained by changes in pulmonary function. Some of the postrecovery sequelae of ARDS (including prolonged or chronic weakness and fatigue), result from critical illness neuromuscular disease (see Volume 2, Chapter 6) (29). Neuro-psychological deficits, another consequence of critical illness, are an additional burden to survivors (6).

## PATHOGENESIS

### Mechanisms of Lung Injury

The alveolar-capillary unit is composed of the alveolar epithelium, lined with type I and II pneumocytes, and the microvascular endothelium. The acute exudative phase of ALI/ARDS is a result of a compromised vascular and epithelial barrier allowing an influx of protein-rich edema fluid into the air space.

The pathogenesis of the alveolar edema depends on both inflammatory and coagulation-dependent mechanisms. Inflammatory mediators may be generated focally or systemically depending on the initial insult (Table 2). **The release of inflammatory mediators into the systemic circulation amplifies the injury to both nonpulmonary organs as well as the lung itself, a process referred to as innate immunity (30).** Severe alveolar epithelial injury results in disorganized collagen deposition and imbalanced apoptosis, subacute fibrosing alveolitis. Ultimately, resolution and removal of alveolar edema and cellular debris requires the restoration of the alveolar-capillary unit that actively transports fluid, electrolytes, and proteins.

### Direct Lung Injury

A large number of direct or indirect injuries to the alveolar capillary-epithelial barrier can lead to ALI/ARDS (Table 2). The most important direct exposure injuries include bacteria, aspiration, and trauma (mechanical at smoke inhalation). These more common etiologies are described in greater length here.

### Bacterial Pneumonia

Direct exposure of the epithelial–endothelial barrier to bacteria increases permeability influx while decreasing active fluid transport across the alveolar epithelial membrane. **The bacteria-causing pneumonia (particularly those associated with ALI/ARDS) possess a variety of virulence factors disruptive to alveolar epithelial cells.** The capsule surrounding *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Klebsiella pneumoniae* is designed to protect bacteria against phagocytosis (31). *Staphylococcus aureus* produces extracellular and cell wall–associated proteases (32). Gram-positive bacteria have a surface-associated adhesion molecule,

lipoteichoic acid, whereas the gram-negative bacteria express lipopolysaccharides, both potent stimuli of the host defense (33). Further, animal models with *Pseudomonas aeruginosa* demonstrate some bacterial products, including phospholipase C and exoenzyme S, which injure the epithelial barrier and impair the resolution of alveolar edema. Similarly, influenza virus alters epithelial ion transport with the enzymatic activity of phospholipase C and protein kinase C, also known to disrupt these sodium channels (34).

#### Aspiration

Similar disruption of the lung barrier is noted with aspiration of gastric contents. ⚡ **The severity of alveolar epithelial injury following gastric aspiration is a consequence of both the volume and acidity of the aspirate.** ⚡ Quantities as small as 30 mL in an adult with a pH less than 2.5 are adequate to induce ALI (35). ALI/ARDS animal studies routinely use a standard protocol with hydrochloric acid solutions. There is a biphasic lung injury. First, the direct caustic effect injures the barrier integrity, becoming evident in minutes. Hours later, a systemic response may develop (36). The sterility of gastric contents under normal conditions likely explains the findings that only one-third of those aspirating develop clinical symptoms. Even fewer patients progress to ALI/ARDS (37).

#### Trauma and Burns

Patients exposed to direct thoracic trauma will develop variable degrees of pulmonary contusions (disruptions of alveolar-capillary barrier in all areas of contusion), lacerations, etc. This direct injury may occur concomitantly with other direct lung insults (e.g., aspiration, smoke inhalation, etc.). Later, in the course of their illness, these patients may be exposed to additional direct injuries (e.g., bacterial colonization and ventilator-associated pneumonia) as well as a multitude of indirect insults (e.g., sepsis, hemorrhagic shock, and fluid overload) discussed below. The magnitude of the direct lung injury is related to the impact of the trauma, but also to the condition of the lung prior to the injury. Patients with low serum albumin, liver disease, coagulopathy, or sepsis, prior to the direct injury, suffer more severe ALI/ARDS for similar degrees of trauma. In the case of burn trauma, patients may suffer direct lung injury from smoke inhalation, as well as secondary lung injury from the systemic manifestations of thermal injury (see Volume 1, Chapter 34). The special pulmonary considerations related to lung trauma are discussed in far greater detail in Volume 2, Chapter 25.

#### Indirect Lung Injury

##### Sepsis

In both pulmonary and extrapulmonary infections, the initial response to a localized infection is a systemic release of endotoxins or exotoxins, inducing macrophages to generate inflammatory cytokines, termed innate immunity. The occurrence of ARDS in sepsis is a marker of an exaggerated inflammatory response that overwhelms the capacity of the immune system to balance between pro- and anti-inflammatory factors (also see Volume 2, Chapter 47 on Sepsis and Volume 2, Chapter 63 on SIRS).

Early on, alveolar macrophages, the first line of cellular defense, generate inflammatory cytokines [tissue necrosis factor-alpha (TNF- $\alpha$ ), interleukin 1-beta (IL-1 $\beta$ ), interleukin-6 (IL-6), and chemokines similar to interleukin-8 (IL-8)] as well as consuming, processing, and presenting foreign elements (38). This initial response activates and attracts polymorphonuclear neutrophils (PMNs) to the site of infection or

injury. Additionally, there is a systemic response through the stimulation of blood monocytes (releasing and transcribing more cytokines, growth factors, and chemokines) and endothelial cells (activating the coagulation cascade). Growth factors, such as granulocyte colony-stimulating factor, augment the production of neutrophils, whereas chemokines attract them to the peripheral organs (39).

Once activated, the PMNs, the second cellular line, express integrins that act as mediators for sequestration on small capillaries, for adhesion to endothelial cells and for migration across barriers (39). At the same time, the endothelium is stimulated to express surface receptors for adhesion of PMNs that will cross the alveolar-capillary membrane. These PMNs can release toxic products including reactive oxygen species and proteolytic enzymes that can increase endothelial permeability and alveolar epithelial damage (40). In the presence of bacteria or other foreign organisms, the PMNs assist macrophages in the process of phagocytosis and antigen presentation.

The third cell line of immunity involved in the acute response is the type II pneumocyte. These cells produce cytokines, complement growth factors, plus they express adhesion molecules and secrete several surfactant proteins (41). Some of the surfactant proteins participate in the recognition of nonself patterns, such as the gram-positive lipoteichoic acid molecule and opsonize for antigen presentation (42). Injury to the pneumocytes may be the result of PMNs producing proteolytic enzymes and reactive oxygen species in the alveoli, resulting in worse alveolar-capillary permeability and impairing edema fluid removal (43).

Endothelial cells stimulated by TNF- $\alpha$  and IL-1 $\beta$ , activate coagulation. The trigger is the expression of tissue factor (TF), a transmembrane cell surface receptor similar to a cytokine receptor. Concurrently, the endothelial cell-bound pool of TF pathway inhibitor is depleted. This leads to the formation of thrombin and fibrin clot. The procoagulant thrombin is also capable of stimulating inflammatory pathways and further suppressing the endogenous fibrinolytic system (43). These same activated endothelial cells release platelet-activating factor leading to platelet aggregation (44). The combination of systemic inflammatory cytokines and thrombin can impair the endogenous fibrinolytic pathway resulting in obstruction, injury to small capillaries, tissue hypoxia, and alveolar injury. The compromised epithelial barrier facilitates alveolar flooding.

#### Hemorrhagic Shock

Massive hemorrhage impacts distal alveolar fluid clearance. With acute blood loss of greater than 30% blood volume, there is a sharp rise in plasma epinephrine leading to a doubling of alveolar fluid clearance. Similar to early sepsis, elevated epinephrine levels upregulate the epithelial fluid transport capacity. However, prolongation of either the hemorrhagic or septic shock state results in the inability to up-regulate alveolar fluid clearance, despite an intact epithelial barrier. This process probably requires both neutrophils and macrophages that trigger a systemic cascade that alters adrenergic activity and increases the release of oxidant radicals. Expression of nitric oxide synthase leads to the release of nitric oxide, further impairing the function of sodium channels and alveolar fluid transport. The mechanisms may explain part of the susceptibility to alveolar flooding after major trauma (34). Additionally, circulatory inflammatory cytokines (either released from the trauma that caused the blood loss or from blood and blood products during transfusion) can cause pulmonary capillaries to begin leaking fluid.

Massive alveolar and interstitial edema may also result from the administration of large quantities of resuscitation fluids. Also, patients who start out with low serum albumen or liver disease are more prone to ALI. Finally, patients may manifest secondary injury following massive trauma or burns due to the circulating inflammatory cytokines (see Volume 1, Chapter 34 and Volume 2, Chapter 63).

**Resolution Phase**

**Fluid Clearance**

For alveolar edema to be actively reabsorbed several factors must be overcome. Reversal of hypoxia is required. There appears to be a hypoxia-induced decrease in alveolar fluid clearance caused in part by fewer sodium transport proteins being inserted into the alveolar epithelial membranes (45). Also, mechanical ventilation-induced stretch injury in type I epithelial cells must be minimized. Lower tidal volumes are protective to both epithelial and endothelial cells and allow faster alveolar fluid clearance (46).

Another significant factor in the resolution of alveolar edema is the active ion transport of sodium and chloride from the alveoli to the interstitium. This is both catecholamine-dependent and independent. Water fluxes passively via aquaporins, epithelial water channels (47). Fluid clearance may be apparent within hours of the acute phase onset and directly correlates with improved survival and shorter duration of mechanical ventilation. Impairment of alveolar fluid clearance defined as rates of less than 14% per hour, correlate with worse outcome in ALI/ARDS patients (Fig. 2) (14).

**Protein Clearance**

In severe alveolar epithelial injury, repair of the barrier does not occur normally. The alveoli are filled with mesenchymal cells and their by-products, collagen precursors, as well as hyaline membranes and cellular debris. Within the first week, a fibrotic process stimulated in part by IL-1β is well under way (48).

Effective removal of these insoluble proteins by the epithelial cells occurs by endocytosis and transcytosis (49). This process limits the extent of hyaline membrane composition and fibrous tissue networking. Soluble proteins diffuse between epithelial cells. Meanwhile, previously

activated PMNs and other inflammatory cells appear to undergo programmed cell death, apoptosis (50). Over-activation of the apoptotic cascade may contribute to ongoing leakage of proteins, whereas inadequate apoptosis may impair removal of activated cells (51).

**Remodeling**

The type II pneumocyte is the progenitor for re-epithelialization of denuded alveoli. Proliferation and differentiation into type I cells restores the epithelial integrity, a process that is controlled, in part, by keratinocyte and other growth factors (52).

**EVIDENCE-BASED TREATMENT**

The mainstay of treatment is to stabilize the respiratory failure using mechanical ventilation, search aggressively for and treat reversible etiologies, and administer supportive care (41). Approaches to therapies have followed the theories regarding the pathogenesis of lung injury.

**Mechanical Ventilation and Gas Exchange Mechanisms**

Mechanical ventilation in patients suffering from ALI/ARDS has evolved over the past decade. ⚡ **Since the early 1990s, consensus statements began recommending lower tidal volume ventilation and airway pressures allowing for permissive hypercapnia and hypoxemia (53).** ⚡ The strategy was based on growing awareness of ventilator-induced lung injury, probably a consequence of cyclic opening and closing of atelectatic lung zones that trigger an inflammatory cascade (54). This therapeutic approach was definitively supported by the publication of the National Institutes of Health (NIH)/National Heart Lung and Blood Institute (NHLBI) ARDS Network Ventilation Protocol (Table 5) (21). The study compared ventilation with lower tidal volumes (6 mL/kg predicted body weight and plateau pressures <30 cm H<sub>2</sub>O) to traditional tidal volumes (12 mL/kg

**Figure 2** Percent hospital mortality versus alveolar fluid clearance in patients with acute lung injury and acute respiratory distress syndrome. Maximal clearance >14%/hr; impaired/submaximal <14%/hr.

**Table 5** National Institutes of Health/National Heart Lung and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Network Lower Tidal Volume Ventilation for Acute Lung Injury/ARDS Protocol Summary

Variables	Protocol
Ventilator mode	Volume assist-control
Tidal volume	<6 mL/kg predicted body weight
Plateau pressure	<30 cm H <sub>2</sub> O
Ventilation set rate/pH goal	6–35/min, adjusted to achieve arterial pH > 7.30 if possible
Inspiratory flow, I:E	Adjust flow to achieve I:E ratio of 1.1–1.3
Oxygenation goal	55 mm Hg < PaO <sub>2</sub> or 88% < SpO <sub>2</sub>
F <sub>I</sub> O <sub>2</sub> /PEEP (mmHg) combinations	0.3/5, 0.4/5, 0.4/8, 0.5/8, 0.5/10, 0.6/10, 0.7/10, 0.7/12, 0.7/14, 0.8/14, 0.9/14, 0.9/16, 0.9/18, 1.0/18, 1.0/22, 1.0/24
Discontinuation	Attempts to wean by pressure support required when F <sub>I</sub> O <sub>2</sub> /PEEP < 0.4/8

*Abbreviations:* F<sub>I</sub>O<sub>2</sub>, fraction of inspired oxygen; I:E, inhalation to exhalation ratio; PaO<sub>2</sub>, partial pressure of oxygen in the arterial blood; PEEP, positive end-expiratory pressure.

and pressures  $<50$  cm  $H_2O$ ). ✎ **The critical finding of the NIH/NHLBI study was a 22% reduction in mortality using the lung protective strategy, regardless of the clinical etiology (55).** ✎ The number of patients needed to be treated with this strategy, to prevent one death from ARDS, was 12.5 patients (21). The strategy was effective in patients with different clinical risk factors for ALI/ARDS (55).

The relationship of  $F_{I,O_2}$  to oxygen-induced lung injury is not clearly understood. A  $F_{I,O_2} <0.6$  has been considered safe (56). PEEP may allow for lower  $F_{I,O_2}$  levels by increasing functional residual capacity and reducing trans-pulmonary shunt (57). However, excessive PEEP may worsen cardiac output, increase pulmonary hypertension, and increase alveolar dead space. Correction of oxygenation deficits usually require a balance of  $F_{I,O_2}$  and PEEP. The protocol above, adjusts the  $F_{I,O_2}$  and PEEP by using a sliding scale (Table 5) (58). A follow-up trial by the ARDS Network reported that higher levels of PEEP did not have an additional value in reducing mortality, although this subsequent trial reported a further decrease in mortality to 27% with the 6 mL/kg low tidal volume strategy (Table 5) (59).

Despite maximal  $F_{I,O_2}$  and PEEP, patients may suffer refractory hypoxemia. Definitive trials have explored both extracorporeal membrane oxygenation (ECMO) and extracorporeal carbon dioxide removal ( $EC_{CO_2}R$ ) to counter the seemingly irreversible gas exchange (60,61). ECMO optimizes oxygenation through extrinsic circulation, whereas  $EC_{CO_2}R$  normalizes  $PaCO_2$  via filtration, thereby decreasing the amount of ventilator support and subsequent associated lung injury. Neither technique has demonstrated improvements, beyond standard mechanical ventilation and supportive care, in the adult trauma population.

## Reversal of Underlying Etiology

### Infectious Foci

Identifying and reversing an underlying cause may reduce mortality. Particular attention should focus on infection that is responsive to antibiotics and/or surgical intervention as well as the prevention of nosocomial infection (41). Empiric antibiotics should be based on hospital antimicrobial sensitivities.

### Activated Protein C

✎ **Patients suffering from severe sepsis and ALI/ARDS should be considered for the administration of recombinant human activated protein C.** ✎ Activated Protein C is an inhibitor of both the procoagulant and the inflammatory cascades that reduces absolute mortality by 6.1% in severe sepsis (62). The Food and Drug Administration (FDA) performed a subgroup analysis of the original trial. It indicates that the greatest benefit is observed in patients with Acute Physiology and Chronic Health Evaluation II scores  $>25$  (63). Recommended activated protein C dosing is a 24 mcg/kg/hr infusion for 96 hours.

### Insulin Therapy

Intensive insulin therapy (blood glucose kept between 80–110 mg/dL by exogenous insulin infusion) has been shown to improve outcomes in critically ill surgical patients and in some medical patients when admitted to the ICU beyond three days (64). Optimal blood glucose levels and most at risk patient populations are still being determined (64). Also see Volume 2, Chapter 60 for an expanded discussion of this topic.

## Supportive Care

### Hemodynamics

Hemodynamic management remains a controversial issue. Current recommendations are to restore intravascular volume to achieve euvolemia and reverse hypotension. This can be approximated by a central venous pressure of 6–12 mmHg or pulmonary capillary wedge pressure of 6–14 mmHg in patients with normal hearts and relatively mild ALI. However, patients with severe ARDS and/or pulmonary hypertension may require higher filling pressures to achieve appropriate cardiac outputs and systemic pressures [especially if higher levels of PEEP or inverted inhalation to exhalation (I:E) ratios are employed]. Accordingly, titrating filling pressures to a more physiologic endpoint, for example, stroke volume of at least 1 mL/kg, is pursued. Vasopressors are added to maintain a mean arterial pressure greater than 60 mmHg or higher. The attainment of supranormal oxygen delivery does not provide an outcome benefit (65). Instead, the clinician is guided by clinical indexes of organ perfusion (65). Currently, the NIH ARDS Clinical Trials Network is completing a large multicenter trial of 1000 patients, to evaluate a conservative versus a liberal fluid strategy guided by either a central venous or pulmonary artery catheter measurements in ALI/ARDS patients.

### Nutrition

An additional important supportive measure is early enteral nutrition using standard nutritional formulations. Using the patient's own gastrointestinal system for caloric and nutrient administration serves the dual purpose of preserving the gut barrier (an implicated source of ARDS when impaired) and allowing for nutrition to be delivered without the infection risks of total parental nutrition (see Volume 2, Chapters 47 and 49). When enteral feeding is contraindicated (e.g., small bowel obstruction), critically ill patients should receive nutrition parenterally. Nutritional goals should balance the metabolic demand and the prevention of nutrient deficiencies with complications of delivery mode and overfeeding (66). Metabolic charts can be used to measure oxygen consumption and  $CO_2$  production and can help guide caloric needs (see Volume 2, Chapter 31).

## Pharmaceutical Interventions

### Inhaled Nitric Oxide

Nitric oxide, a potent, short-acting pulmonary vasodilator, can be delivered directly to the pulmonary vasculature by inhalation with resultant reduction in pulmonary vascular resistance and improved oxygenation. Improved oxygenation occurs when the blood vessels associated with well-ventilated alveolar are vasodilated by the inhaled nitric oxide (INO). However, the pulmonary vasodilation dose of INO (20–60 ppm) is much higher than the dose recommended for improving  $\dot{V}/\dot{Q}$  mismatch ( $<1$  ppm). When higher concentrations of INO are employed, not only the vessels associated with the well-ventilated alveoli are dilated, but so too are the adjacent blood vessels (some of which are poorly ventilated), causing  $\dot{V}/\dot{Q}$  mismatch and oxygenation impairment. Furthermore, INO has no clinical mortality benefit nor does it seem to reduce the duration of mechanical ventilation (67). Thus, INO is no longer widely used for ARDS but, rather, is used in rare individual cases.

### Surfactant

Supplemental treatment with surfactant for ALI/ARDS has been driven by the successful application in neonatal

pulmonary failure. Surfactant reduces wall stress across the alveoli, thereby reducing potential stretch injury. To date, however, replacement strategies with aerosolized exogenous surfactant have only resulted in transient clinical benefits in ALI/ARDS (68,69). However, as part of a multimodal therapeutic regimen, surfactant may have some merit, but these studies are yet to be performed.

### Glucocorticoids

Recognition of the inflammatory nature of ALI/ARDS has prompted interest in glucocorticoid therapy. There has been no convincing outcome benefit in early nor late course ALI/ARDS (70). A recently completed NHLBI, ARDS Network randomized clinical trial showed no mortality benefit in patients treated with glucocorticoid (71).

### Antioxidants

Intrinsic antioxidants or oxygen free-radical scavengers play a role in mediating endothelial injury caused by reactive oxygen species. Scavengers interrupt parts of the neutrophil-mediated inflammatory cascade. Encouraging results in phase II clinical trials utilizing procysteine, one such scavenger, have been tempered by a placebo-controlled trial failing to show significant benefit (41).

### Conservative Fluid Management

A recent randomized clinical trial demonstrated a significant increase in ventilator-free days with a fluid conservative versus a fluid liberal strategy for patients with acute lung injury. After patients had been treated so that they were no longer in shock (did not require vasopressors for 12 hours), they were randomized to a fluid liberal or fluid conservative strategy. The fluid conservative strategy, which included fluid restriction and diuretic therapy to reduce pulmonary vascular pressures, was successful in improving oxygenation, reducing airway pressures, and decreasing the duration of positive pressure ventilation (72).

### $\beta$ 2-Adrenergic Agonists

More recently, there is interest in pharmaceutical strategies that accelerate removal of pulmonary edema (73). In the intact epithelial barrier,  $\beta$ 2-agonists can stimulate the resolution of edema and surfactant secretion. When given prophylactically, salmeterol, a long-acting  $\beta$ 2-agonist, reduces high-altitude pulmonary edema (74). Clinical trial will be done to test the value of this therapy in ALI/ARDS by The ARDS Network.

## EYE TO THE FUTURE

### Targeting Epithelial Growth Factors

Ultimately, effective lung function depends on the reconstruction of the alveolar unit. Growth factors modulate alveolar epithelial function and enhance its repair; in particular, keratinocyte and hepatocyte growth factors. These growth factors serve as mitogens of type II alveolar epithelial cells. Coupled with this cellular proliferation is improved alveolar fluid clearance (75). Intratracheally administered, these growth factors decrease the severity of injury in animal models challenged with caustic agents. Clinical trials are anticipated.

### $\beta$ 2-Adrenergic Agonist

As already discussed,  $\beta$ 2-adrenergic agonist therapy may be effective as a treatment to enhance the resolution of alveolar edema and to decrease lung endothelial injury (37,73,76). Clinical trials are needed to test this possibility.

### Applied Genomics in Screening and Therapeutics

Predicting an individual patient's susceptibility to certain microorganisms or their clinical response to medications, particularly antibiotics, is now a major research focus. The completion of the Human Genome Project has modified the fundamental paradigm of a "reaction" to illness, to "screening, predicting, and preventing" illness. This paradigm includes the critically ill. The future intensivist may have the ability to identify patients who have an unchecked inflammatory cascade in response to an infectious organism like *Pseudomonas* and host DNA-sequence variations to choose the most efficacious anti-*Pseudomonas* therapy (77,78). A recent NHLBI conference summarized several future directions that are needed to advance basic and clinical research in ALI/ARDS (79).

## SUMMARY

The simplified definition of ALI/ARDS (Table 1), has allowed for considerable progress in understanding the epidemiology of ALI/ARDS as well as conducting clinical trials. Advances in delineating the pathogenesis have revealed new leads into the potential role of targeted therapies that interrupt or redirect the procoagulant and inflammatory cascades, such as activated protein C, insulin, and glucocorticoids. However, reversal of the underlying infectious process and institution of supportive care measures remain paramount.

Finally and most importantly, there is now a lung-protective ventilator strategy using low tidal volumes, which reduces mortality (Table 5). These combined efforts are a direct result of the creation of and support from, the NIH ARDS Network (21). Forthcoming trials hope to clarify optimal volume status, the role of invasive monitoring, and therapies that target the repair of the alveolar unit and the resolution of pulmonary edema in lung injury.

## KEY POINTS

- ☞ Both ALI and ARDS can result from a multitude of disorders (Table 2) with the common thread being injury to the epithelial capillary barrier of lung alveoli.
- ☞ Because of the frequency of associated septic conditions, infectious foci must be actively pursued and treated in ARDS patients.
- ☞ The acute exudative phase is a consequence of widespread protein-rich alveolar edema.
- ☞ Alveolar flooding results in significant transpulmonary shunting and ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) imbalance causing profound hypoxemia that is refractory to supplemental oxygen.
- ☞ Some patients recover from the acute insult without sequelae; however, most progress to a subacute fibrosing alveolitis phase.
- ☞ Postextubation pulmonary function testing among ALI/ARDS survivors shows restrictive impairments and diffusion abnormalities.

- 9 The release of inflammatory mediators into the systemic circulation amplifies the injury to both nonpulmonary organs as well as the lung itself, a process referred to as innate immunity.
- 9 The bacteria-causing pneumonia (particularly those associated with ALI/ARDS) possess a variety of virulence factors disruptive to alveolar epithelial cells.
- 9 The severity of alveolar epithelial injury following gastric aspiration is a consequence of both the volume and acidity of the aspirate.
- 9 Since the early 1990s, consensus statements began recommending lower tidal volume ventilation and airway pressures allowing for permissive hypercapnia and hypoxemia.
- 9 The critical finding of the NIH/NHLBI study was a 22% reduction in mortality using the lung protective strategy, regardless of the clinical etiology.
- 9 Patients suffering from severe sepsis and ALI/ARDS should be considered for the administration of recombinant human activated protein C.
- 9 There does appear to be a survival benefit of one in seven when steroids are used as an adjuvant in hypotensive septic patients suffering from "relative" adrenal insufficiency.

### INTRODUCTION

Injuries to the chest are often serious, resulting in significant morbidity and prolonged stays in the intensive care unit (ICU). Several reasons account for the serious and debilitating nature of these injuries. First, trauma significant enough to injure internal organs, protected by the semirigid bony thorax, is typically quite severe. Second, the organs contained within the thoracic cavity (i.e., heart and lungs) are required for survival, and when these vital structures are injured, the flow of oxygenated blood to the systemic tissues is impaired. Third, although small, solitary stab wounds may damage only a single organ or structure within the thoracic cavity (e.g., intercostal artery, lobe of lung, etc.), blunt trauma and high-velocity missile injuries may destroy or injure large quantities of intrathoracic tissue and adjacent organ systems.

The acute resuscitative management and intraoperative care of thoracic wounds is discussed in Volume 1, Chapter 25, whereas this chapter provides an overview of the special ICU management considerations related to chest injuries. This review begins with a survey of the common mechanisms of lung and thoracic trauma, including both direct injury (see the section on direct trauma to the thorax) as well as indirect lung injury (see the section on, lung injury resulting from trauma-associated conditions). The acute lung injury and adult respiratory distress syndrome section briefly reviews the pathophysiology of acute lung injury (ALI) and the adult respiratory distress syndrome (ARDS) as these entities relate to trauma and trauma-associated pulmonary conditions. The mechanical ventilation considerations section provides a brief summary of mechanical ventilation considerations for thoracic trauma, and special analgesic techniques for thoracic trauma are surveyed in the acute lung injury and adult respiratory distress syndrome section. The chapter concludes with an eye to the future section that previews methods of pulmonary diagnosis, monitoring, and support.

### DIRECT TRAUMA TO THE THORAX

Direct injuries to the lungs or thoracic structures may result from penetrating or blunt trauma. Major life-threatening injuries should be diagnosed and treated during the primary survey (Table 1). Although other critical injuries that are not immediately life-threatening are evaluated and

treated during the secondary survey, there are multiple mechanisms for chest injury yielding pathophysiology unique to the particular injury, and requiring injury-specific interventions. The etiology of chest injury also bears upon the prognosis for successful resuscitation, intensive care management, and eventual recovery. For example, cardiopulmonary arrest in the field after blunt chest trauma has a much worse prognosis for recovery than transient arrest following a penetrating injury (1).

### Penetrating Trauma

Penetrating chest trauma is increasingly common as urban unrest and regional conflicts escalate. These injuries may be temporized in the field and must be definitively managed in a trauma facility (Volume 1, Chapter 25). Penetrating chest trauma should always be considered a potentially lethal injury. However, if appropriately managed, even some victims arriving in profound shock can be rescued. **The most common etiologies of shock from penetrating chest injury include tension pneumothorax, massive hemothorax, cardiac wounds, and cardiac tamponade.**

Stab wounds to the chest may present anywhere in the continuum between solitary peripheral injury to the chest wall, or lung injury requiring only a chest tube, versus severe hemorrhagic shock and death from injury to a great vessel, or one of the abovementioned common etiologies. These individual injuries are briefly discussed later in this chapter and more fully covered in Volume 1, Chapter 25. Stab wounds and other low-velocity penetrating chest injuries may injure only the internal mammary artery, or intercostal artery, and classically present with a slightly delayed onset of hemorrhagic shock. Resuscitative thoracotomy (Volume 1, Chapter 13) is indicated for patients presenting in extremis, or arrest following penetrating trauma.

Gunshot wounds (GSWs) and shrapnel injuries have a combination of blunt and penetrating trauma components, with a wide area of adjacent tissue at risk. **The magnitude of destruction resulting from the secondary shock wave occurring with high-velocity GSWs and shrapnel injuries may not be initially apparent.** Accordingly, GSWs and shrapnel injuries require sequential monitoring for progression of injury, and complete evaluation of all organs and tissues in proximity of the GSW or shrapnel injury. These injuries often require prolonged periods of mechanical ventilation and supportive care in the ICU. Specific injuries are discussed below.

**Table 1** Thoracic Injuries that Should Be Detected During the Primary and Secondary Surveys

Injury category	Specific injury
Immediate threat to life— should be detected in primary survey	Airway obstruction
	Tension pneumothorax
	Open pneumothorax
	Flail chest
	Massive hemothorax
Critical injuries— generally identified during secondary survey	Cardiac tamponade
	Simple pneumothorax
	Hemothorax
	Pulmonary contusion
	Tracheobronchial disruption
	Myocardial contusion
	Aortic laceration
	Diaphragmatic rupture
Wounds transversing the mediastinum

## Blunt Trauma

### Pulmonary Contusion

Pulmonary contusion accompanies deceleration injuries, blast wounds, crush injuries, and blows to the chest. It is often associated with bony trauma to the chest involving rib, scapula, thoracic spine and/or clavicle fracture. Contusion-induced lung dysfunction can be accompanied by bronchial or vascular disruption in the chest. Hemothorax due to chest wall or lung bleeding can compound the pulmonary dysfunction and also contribute to hemodynamic compromise in the chest trauma patient.

Lobar collapse and atelectasis frequently accompany pulmonary contusion. Atelectasis and collapse occur when aspirated secretions become inspissated in the airway. Aspiration is more common, following a lapse in consciousness. Additionally, secretions become increasingly difficult to clear from the airway in patients with an impaired ability to take deep breaths and cough (due to pain or flail chest). Impaired ventilation after lung contusion, particularly in those with chest wall fracture, can ultimately lead to respiratory failure. The respiratory failure results from decreased lung and chest wall compliance to increased right-to-left transpulmonary shunt (see below).

Compliance (C) is defined as volume/pressure, and is usually expressed in liters (or milliliters) per centimeter of water, that is, the volume of air moved by each centimeter of water pressure applied. The total respiratory compliance ( $C_T$ ) may be diminished either via alterations in the chest wall compliance ( $C_{CW}$ ), for example, in the patient with massive chest wall edema or eschar due to burn, or due to alterations in compliance of the lung ( $C_L$ ) itself. However, the values are not merely additive. Rather, compliance is analogous to electrical capacitance. Accordingly, total compliance is calculated in a similar fashion to total capacitance for capacitors in series (the individual reciprocals are added to obtain the reciprocal of the total value), thus:

$$\frac{1}{C_T} = \frac{1}{C_L} + \frac{1}{C_{CW}}$$

Gastric distention associated with thoracoabdominal trauma may further impair pulmonary compliance, if severe and

untreated. Gastroparesis can be treated with gastropropulsive drugs (i.e., erythromycin or metoclopramide) and by minimizing systemic opiates. Gastric distention is managed by nasogastric (NG) tube placement and intermittent gastric suction.

Hypoxemia and frank respiratory failure require airway instrumentation and mechanical ventilation. Bronchoscopy may be required to alleviate airway obstruction from inspissated secretions and blood. Additionally, bronchoscopy is required to assess for evidence of tracheal or bronchial disruption. After thoracic injury, an increase in right-to-left transpulmonary shunt occurs due to abnormalities of lung parenchyma from pulmonary contusion, atelectasis, pulmonary edema, or ARDS. This is reflected by a widening of the alveolar-arterial oxygen gradient. The factors affecting shunt fraction are reviewed in Volume 2, Chapter 2.

Dead-space ventilation may be markedly increased as well after thoracic injury, such as when pain after chest wall injury yields a state of rapid and shallow respiration, or when hypotension results in an increase in the extent to which alveoli are ventilated but not perfused. The factors increasing dead-space ventilation are further reviewed in Volume 2, Chapter 2.

Thoracostomy tube drainage is commonly required to eliminate collections of air, fluid, or blood from the chest cavity. Ideally, these procedures are done under strict sterile precautions; however, because of the emergency nature of such interventions, bacteria may enter the chest cavity resulting in the later development of empyema (Figs. 1 and 2). In our experience, empyema is rare following emergency thoracostomy. However, rarely, when infection and true empyema do develop, or the viscous fluids and coagulated blood in the chest do not drain well via thoracostomy tubes, open or thoracoscopic removal of these contents may be required.

Primary blast injury is a common mechanism of injury in urban warfare. Naturally, these patients are at high risk for

**Figure 1** Radiographic appearance of empyema of the right chest.

**Figure 2** Computed tomograph demonstrating empyema in the right chest.

pulmonary contusion. Blast lung injury occurs under circumstances of contained explosions, for example, those occurring on civilian buses, when explosive materials are detonated in an enclosed space.

Thoracoabdominal injuries and common associated injuries, especially ear drum perforation, are the result of high amplitude air pressure waves as great as 5 atm exerted for several seconds (2). In addition, abdominal blast wounds can be associated with bowel perforation.

### **Rib Fractures/Flail Chest**

Rib fractures are problematic for several reasons. First, rib fractures are painful, particularly with movement. This leads to “splinting,” the process whereby the patient (both voluntarily and involuntarily) limits movement of the fracture site during position changes and respiratory effort. **☞ Atelectasis will develop as a result of splinting of the chest and will compound the shunt attributable to lung contusion itself.** ☞ Lobar collapse may also occur, resulting in severe hypoxia and a radiographic picture of unilateral or bilateral volume loss in the area of the lobar collapse.

Pain is stressful and leads to sleep deprivation if untreated. Hypoxemia will become exacerbated when confusional states develop, particularly in patients who are not receiving adequate analgesia (becoming increasingly fatigued and sleep deprived). Therefore, it is imperative that the pain cycle be interrupted by intervention. Such intervention may be simply the administration of oral or intravenous analgesics in the most minor of injuries. However, parenterally administered sedatives and analgesics may occasionally contribute to confusional states. Accordingly, thoracic epidural analgesia (or another form of regional analgesia) is recommended for solitary chest wall injuries in hemodynamically stable patients with a normal coagulation system. When regional analgesia is initiated the first few hours following admission to the trauma center, the cascade of splinting, atelectasis, hypoxemia, and respiratory failure can be markedly diminished (see later discussion on analgesia, in the analgesia for thoracic trauma section, as well as Volume 2, Chapter 5).

A “flail segment” is generally defined as three or more ribs broken in two or more places. Some clinicians consider a “flail chest,” as any mechanical chest dysfunction resulting from thoracic trauma where the patient is unable to ventilate adequately due to that injury, even in the absence of a true flail segment. Additionally, a flail segment can be

missed upon admission to the trauma center, as a weak or “splinting” patient may not be capable of generating sufficient inspiratory forces to cause an inward and paradoxical movement of the chest in the area of the contiguous rib fractures. The extent of the underlying lung contusion in flail injury is probably the most important aspect of the lung dysfunction under these circumstances. It must therefore be understood that even with perfect analgesia, patients with flail chest will almost invariably progress to respiratory failure. Furthermore, when the pulmonary contusion itself is severe, the consequent right-to-left transpulmonary shunt worsens and respiratory failure will ensue (see Volume 2, Chapter 24).

When respiratory insufficiency due to flail chest and/or significant pulmonary contusion is present, intubation and mechanical ventilation are warranted. Indeed, an older study by Sankaran and Wilson (3) found that early intubation in these patients resulted in only 6% mortality, whereas delayed intubation (waiting until the patient developed clinical evidence of hypoxia or hypercapnea) led to >50% mortality. Although modern techniques may provide lower mortalities today, early intubation and mechanical ventilation remain as a cornerstone of therapy.

Analgesia is another critical element in the management of these patients. Mechanically ventilated patients do not benefit from regional anesthesia to the same degree as nonintubated patients. Accordingly, intravenous analgesia and sedation is initially more appropriate in these mechanically ventilated patients.

### **Hemothorax and Pneumothorax**

Pneumothorax can result from blunt trauma due to compression of the air-filled alveoli and airways, as well as from puncture following rib fractures. Hemothorax due to chest wall or lung bleeding can compound pulmonary dysfunction and contribute to hemodynamic compromise in the chest trauma patient. Both hemothorax and pneumothorax can be diagnosed by clinical and radiological methods (Volume 1, Chapters 8 and 25). Typically, these injuries are diagnosed and treated during the primary survey (Volume 1, Chapter 8). However, they may have a delayed presentation in the operating room (OR) or ICU, with abrupt hypotension or by a sudden increase in peak inspiratory pressures and concomitant decreased breath sounds in the affected hemithorax. These clinical findings are often associated with subcutaneous emphysema (pneumothorax) and/or decreased hematocrit (hemothorax). However, they also present occultly, with subtle changes in vital signs, and the only clinical clue being decreased breath sounds on the affected side.

### **Specific Intrathoracic Injuries**

#### **Airway Injury (Trachea and Bronchi)**

Airway injury may result from blunt trauma or penetration from a knife, GSW, or a piece of shrapnel, causing injury to the larynx, trachea, bronchi, or more distal airway. **☞ Bronchoscopy is an essential part of the evaluation of the victim of thoracic or neck trauma whenever there is a suspicion of airway disruption.** ☞ The author, Hanowell, has diagnosed airway injury or disruption by fiberoptic bronchoscopy on numerous occasions, and has even had to remove a bullet from the mainstem bronchus of a GSW victim via the use of bronchoscopy. Airway disruption may be heralded by finding of subcutaneous emphysema and/or an unusual or persistent pneumothorax accompanied by an obvious air leak after placement of a thoracostomy tube (so-called broncho-pleural fistula). The majority of

tracheo-bronchial lesions associated with blunt trauma occur in the intrathoracic portion of the major airways within a few centimeters of the carina (4). Surgical correction is required, and failure to promptly diagnose such injuries can lead to grave pulmonary complications or death.

Blunt thoracic trauma may also be associated with disruption of the smaller airways and pulmonary veins, leading to an alveolar-pulmonary venous communication that is associated with air embolism to the left heart. At the time of thoracotomy for major trauma, the first sign of this may be the surgeons' observation of air in the coronary arteries.

☞ **When left heart air embolism is recognized, the team must prevent further entry of air into the left heart. The first maneuver is isolation of the injured lung via one-lung ventilation (1LV).** ☞ Placement of a double lumen tube (DLT) is one way to accomplish 1LV, but should be done by a skilled anesthesiologist, with precision and speed, augmented by bronchoscopic positioning. Alternatively, intubated patients in respiratory failure may not tolerate changing to a DLT (presence of airway swelling, cardiopulmonary instability). In these cases, advancing a bronchial blocker through an existing endotracheal tube and into the injured bronchus with fiberoptic bronchoscopy is the method of choice (5). Use of the Arndt bronchial blocker has made this procedure far less cumbersome (5). For a complete review of lung separation techniques, including the use of DLTs and various bronchial blockers, the reader is referred to the review by Wilson et al. (5). When a bronchial blocker is not available, a lifesaving maneuver may entail simply directing the existing single lumen tube into the mainstem bronchus of the uninvolved lung with the aid of bronchoscopy. In the case of the need for left lung isolation, the anesthesiologist can even attempt at blindly advancing the single lumen tube into the right mainstem. However, positioning and verification with a fiberoptic bronchoscopic technique is always recommended. Definitive treatment is surgical with bronchial repair or exclusion of the injured lung. Initial surgical control may involve cross-clamping the involved bronchus to prevent further ingress of air from the alveoli into the pulmonary venous system (Table 2).

**Table 2** Clinical Features of Air Embolism in Thoracic Trauma

Clinical feature	Description/comments
Predisposing conditions and presentation	Lung laceration, airway disruption Hypotension (R/O tamponade, pneumothorax, hemorrhage) Onset of hypotension during mechanical ventilation
Diagnosis	Air visualized in coronary arteries/fundi Air bubble seen in heart on TEE
Treatment	Close the fistula connecting lung bronchi to vasculature Avoid nitrous oxide when air embolism suspected Administer pure oxygen: favors elimination of nitrogen
Sequelae of air embolism	Cerebrovascular air embolism and stroke Coronary air embolism and coronary insufficiency

Abbreviations: R/O, rule out; TEE, transesophageal echocardiogram.

## Esophageal Injuries

Esophageal injuries are extremely lethal, particularly those resulting from high-velocity missiles and those associated with any delay in diagnosis. Understanding esophageal anatomy explains much of the morbidity associated with these injuries. ☞ **Early evaluation and prompt management are the most critical factors in optimum outcomes following esophageal injury.** ☞ Because of the high morbidity and relative rarity of injuries, some debate continues regarding the best techniques and algorithms for evaluation and management. However, none debate the need for early, prompt diagnosis and treatment.

### Anatomy

The adult esophagus is approximately 25 cm in length, extending from the cricopharyngeus muscle in the neck to the fundus of the stomach. The esophagus descends in the midline of the neck, behind the membranous portion of the trachea, continues downward through the esophageal hiatus of the diaphragm, and enters the stomach. Three anatomic areas of narrowing occur in the esophagus: (i) at the level of the cricoid cartilage (pharyngoesophageal sphincter), (ii) in the mid-thorax, from compression of the aortic knob and the left mainstem bronchus, and (iii) at the esophageal hiatus of the diaphragm (gastroesophageal junction).

The musculature of the pharynx and upper third of the esophagus is the skeletal type, the remainder being smooth muscle. The muscular alignment is similar to the rest of the gastrointestinal tract (inner circular and outer longitudinal). The entire esophagus lies in a loose areolar tissue bed, which communicates with the entire mediastinum. Accordingly, any contaminated spillage is highly likely to develop into mediastinitis.

The arterial supply to the esophagus is consistent, but quite segmental, with little collateralization. The upper portion is supplied by branches of the inferior thyroid arteries. The thoracic portion is supplied by both branches of the bronchial arteries and esophageal segmental arteries (emanating directly from the aorta). Occasionally, intercostal arteries contribute. The diaphragmatic and abdominal portions of the esophagus are nourished by branches of the left gastric artery. The venous drainage is quite variable and complex. The most important veins are those draining the inferior portion. These empty into the coronary vein, a tributary of the portal vein. This connection results as esophageal varices in cirrhotic patients.

### Clinical Presentation

The vast majority of esophageal injuries result from penetrating trauma and caustic ingestion. When blunt traumatic esophageal injuries occur, they are located almost exclusively in the neck. Classical signs of esophageal injury include pain, fever, and crepitus, but these become increasingly predominant when diagnosis is delayed. Hamman's sign, mediastinal crunching, may be present in thoracic esophageal injuries. Some signs are more prominent in particular regions of the esophagus (e.g., dyspnea and vomiting are common in thoracic esophageal injuries, but rare in cervical esophageal injuries). Additionally, the mechanism of trauma affects the prevalence of clinical signs (present in only 50% of patients following stab wounds, and nearly 100% of patients following GSWs) (6). Because these signs and symptoms are nonspecific, a high degree of suspicion must accompany any injury with proximity to the esophagus.

### **Radiographic and Endoscopic Evaluation**

Plain films of the neck or chest are abnormal in 80% of perforations, but are nonspecific. Contrast studies are needed with specificities ranging between 94% and 100% (6). Endoscopy does pose a risk of worsening injury (e.g., converting a trivial perforation into a frank perforation with contamination). However, combining esophagoscopy (in experienced hands) with contrast esophography, improves diagnostic accuracy, with some series reporting no missed injuries (7).

### **Operative Management**

Care of the commonly associated injuries to the major airways and vasculature naturally take precedence. However, because delayed treatment results in far worse outcomes, diagnosis and treatment of esophageal injuries must occur as soon as the patient's condition allows. Indeed, the rate of esophageal anastomotic leak and esophagocutaneous fistula rose from 20%, when treatment occurred within 12 hours of injury, to 100% when treatment was delayed beyond 24 hours (8).

A complete review of operative techniques for esophageal repair is beyond the scope of this chapter. However, the following general considerations should be reviewed. For stab wounds, primary repair may follow irrigation and debridement, whereas following high-velocity GSWs or shrapnel injuries, a portion of the esophagus may need to be resected. A closed suction (i.e., Jackson Pratt) drainage device is usually employed, and perioperative antibiotics with efficacy against mouth and skin flora should be initiated immediately following diagnosis. In the presence of combined esophageal and tracheal injuries, it is advisable to interpose one of the strap muscles to decrease the delayed fistula rate.

### **Postoperative Management and Nutrition**

Some advocate placing a NG tube to decompress the esophagus, relying on total parental nutrition (TPN). Others advocate early enteral feeding through the NG tube. The duration of NG tube insertion (for those advocating TPN) is as variable as the number of surgeons performing the procedure. Analgesia is often problematic, especially for thoracic esophageal repairs, and pain should be aggressively treated. However, excessive postoperative pain in the face of fever and leukocytosis should warn of an esophageal leak.

### **Cardiac Injuries**

Thoracic trauma victims must be evaluated for cardiac injuries whenever wounds have proximity to the heart. Discovery may require echocardiographic and electrocardiographic, radiographic and/or biochemical findings depending upon the mechanism of injury.

In the case of suspected cardiac contusion, guidelines that define the extent to which victims are appropriately evaluated and monitored, are based upon the overall severity and likelihood of injury. In minor trauma, a normal electrocardiogram and transthoracic echocardiogram will generally be adequate to screen for significant injury. When these tests are negative, no further specific measures are indicated. In the patient with more severe injuries and high suspicion of myocardial contusion, the use of electrocardiography (ECG), troponin I measurements, and transesophageal echocardiography (TEE) are indicated (9). Patients with positive findings on these tests are at increased risk of serious dysrhythmias, and deserve a higher level of monitoring to include at least ECG telemetry. Perioperative

evidence of myocardial contusion is also important in planning anesthesia and surgery for the multiple trauma victim.

✎ **Assessment of structural abnormalities of the heart and pericardial effusion (blood) and possible early or frank cardiac tamponade, can be quickly evaluated with transthoracic echocardiography (TTE) as part of the FAST exam (Volume 1, Chapters 14, 16, and 25). However, TEE is preferable to TTE whenever structural lesions or valve abnormalities are to be evaluated.** ✎

### **Great Vessel Injuries**

Chest trauma may entail injury to any vessel in the thorax or contiguous areas including the neck or abdomen. Tears of the thoracic aorta occur after sudden deceleration injury and constitutes one of the most common and important injuries following blunt thoracic trauma. The most common site of aortic injury is adjacent to the ligamentum arteriosum, where the thoracic aorta is fixed and most subject to the shearing forces of sudden deceleration. However, thoracic aortic rupture or dissection may occur at other sites as well.

Diagnosis should be considered in the presence of shoulder harness marks on the patient, or a steering wheel imprint in unrestrained drivers. Pulses in the left upper or lower extremities may be diminished compared to the right upper extremity, but this is not universally present. The diagnosis of thoracic aortic rupture should also be considered when any of the following findings are noted on chest radiography: first or second rib fractures, a wide mediastinum, blurring of the aortic knob, left hemothorax, downward deflection of the left mainstem bronchus, or a rightward-shifted trachea or NG tube.

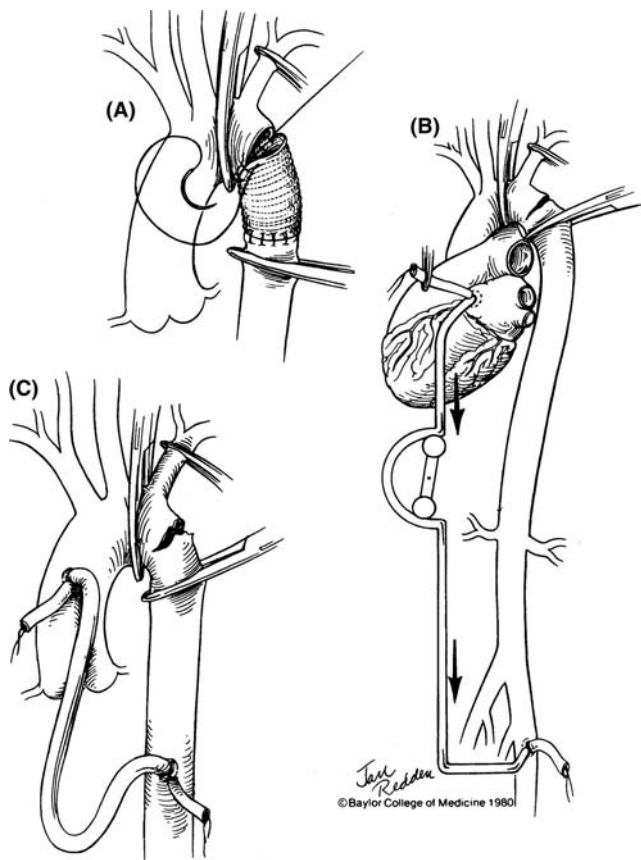

Evaluation of the aorta and arch structures should proceed following suspicion of injury with computerized tomography or aortogram. The TEE can also demonstrate aortic defects, and given that TEE is extremely useful in diagnosing multiple cardiac lesions associated with blunt thoracic trauma, the concomitant evaluation of the aorta is warranted in all of these patients. However, certain areas in the aorta are poorly visualized via TEE; thus it is an imperfect screening tool. Cinnella et al. (10) believe the TEE should be considered as a first-line evaluation tool to evaluate aortic injury following blunt trauma, but they acknowledge that randomized trials are lacking.

The current standard is spiral computed tomographic (CT) imaging for aortic injury, and some still prefer arteriography for aortic branch lesions (11). The rapid development in CT scanning technology has resulted in dramatic improvement in anatomic clarity in recent years. When one includes three-dimensional reconstructions for aortic lesions and injuries to the great vessels, it is difficult to beat CT angiography, though this continues to be a rapidly changing area.

Due to the propensity of aortic tears to progress to rupture in a large percentage of nonoperated patients, treatment of thoracic aortic rupture has traditionally involved urgent replacement with a synthetic aortic conduit. However, endovascular approaches are increasingly being utilized with success (especially in patients with concomitant injuries) (12). Some patients require delayed operative management due to contraindications to blood pressure perturbations and/or systemic heparinization (e.g., intracranial hemorrhage/hematoma), or the need to manage other higher-priority lesions (e.g., exploratory laparotomy for hemorrhage, or evacuation of intracerebral hematoma). For patients requiring delayed management, beta blockade

associated with significant opioid analgesia, sedation, and judicious vasodilator therapy should be a main pillar of critical care management.

Patients without contraindications to immediate treatment generally go to the OR as soon as the surgical and anesthetic teams are assembled, and the patient has been resuscitated and fully worked up for intercurrent injuries. Aortic tears at or distal to the left subclavian artery may be treated by short-term clamping and resection of the damaged aortic tissue, with repair utilizing a short segment of Dacron tube graft with or without heparin or shunts (Fig. 3A–C). When clamp time is  $\leq 30$  minutes, paraplegia rates are  $< 7\%$  (comparable to bypass rates). For these patients, a left lateral thoracotomy and DLT are utilized, and require close communication and cooperation between the surgeon and anesthesiologist to optimally manage these cases (see below—*anesthetic management*). Several commonly employed adjuncts for descending thoracic tear repair include atriofemoral bypass (Fig. 3B), and passive proximal to distal aortic shunts (Fig. 3C). More proximal aortic tears involving the ascending aorta or arch will require full heparinization and cardiopulmonary bypass. The anesthetic

**Figure 3** Techniques used for repair of blunt injuries to the descending thoracic aorta. (A) Clamp and sew technique (sometimes accomplished without heparinization or shunting). (B) Atriofemoral (partial) bypass, provides perfusion to the spinal cord and structures below the level of the aortic clamp, and diverts some blood away from the native heart, thus decreasing the stress on the left ventricle and possibility of very elevated ascending aortic blood pressure (requires heparinization). (C) Passive shunt bypass (Gott shunt), requires a small amount of heparinization. *Source:* Courtesy of Baylor College of Medicine.

management for these cases is similar to that utilized for repair of aortic aneurysms or dissections in these areas (and is beyond the scope of this chapter). The interested reader is referred to standard cardiothoracic anesthesia textbooks for further information.

Anesthetic management for repair of distal aortic tear includes the attainment of adequate intravenous access, volume infusion for associated hemorrhage, and placement of central venous access. Optimally, two arterial lines are placed, one in the right radial artery to reflect proximal aortic and cerebral blood flow pressures, and one in either femoral artery to reflect distal pressures and spinal cord perfusion pressures. The other femoral arterial area is prepped into the field in case needed during the operation (e.g., atrial femoral bypass). In the absence of an associated esophageal or cervical spine injury, TEE is an extremely useful monitor, reflecting ventricular preload and contractility, and can often be used to help determine the extent of aortic tear.

Blood pressure control with beta-blockers, opioids, and vasodilators can be employed preoperatively in hypertensive patients to decrease the incidence of further injury or frank rupture. Induction of anesthesia without triggering hypertension and tachycardia is essential to avoid further shearing of the aorta. However, many of these patients present in hemorrhagic shock from their other injuries and require massive volume resuscitation. Accordingly, avoiding myocardial depressants and or vasodilators in the hemorrhagic shock patient is equally mandatory.

A DLT or bronchial-blocking device is used to isolate the lungs and to facilitate surgical exposure to the left chest. A lumbar cerebral spinal fluid (CSF) drain can occasionally be placed even in the trauma setting if the patient is sufficiently stable. The goal of CSF drainage is to decrease retrograde pressure on the spinal cord and limit neurological sequela resulting from the sacrifice of any aortic branches to the spinal cord. This measure may be precluded by the emergency nature of these surgeries and instability of the severely injured patient. Mannitol infusion may be utilized for suprarenal clamping to promote urinary flow and as an antioxidant so as to avert acute tubular necrosis. Prior to aortic cross-clamping, vasodilators and beta-blocker infusion can be utilized to attenuate the rise in blood pressure associated with this surgical manipulation.

Prior to aortic unclamping, appropriate volume loading by monitoring central venous pressure, pulmonary artery occlusion pressure, and/or left ventricular cavity dimension by TEE is essential to avoid hypotension. Additionally, vasodilation therapy should be weaned off. Heparinization and various circulatory bypass techniques may be utilized to assure continued perfusion to the vital organs and spinal cord during vascular repair. As patients undergoing surgical repair of the thoracic aorta require left thoracotomy, appropriate measures to postoperatively manage pain are necessary (see later discussion).

After exsanguinations, paraplegia is the most dreaded and significant complication. Paraplegia results from insufficient perfusion of the anterior spinal cord. In a large meta-analysis of 1742 patients, Von Oppell (13) found that 2.9% of patients with thoracic aortic injuries had already developed paraplegia preoperatively. Postoperative paraplegia was found in 19.3% of clamp/repair patients, 6.1% of bypassed patients, 11.1% of passive shunt patients, and in 2.3% of active shunted patients (13). He also reported that full heparinization in patients with multiple injuries yielded a higher mortality compared to no heparin.

Renal failure and/or mesenteric ischemia may also complicate the postoperative course of these patients.

### Traumatic Asphyxia

Traumatic asphyxia is a rare condition which results from massive increased intrathoracic and venacaval pressure due to a thoracic crush injury in the presence of a closed glottis. The syndrome was first described by D'Angers in 1837 (14). Retrograde flow of blood through valveless veins of the head and neck results in swelling and petechiae or cyanotic discoloration of the face and neck. Neurological manifestations frequently include transient loss of consciousness, but rarely involve focal neurological deficits or cord syndromes, unless additional injuries are present (15).

No specific lung injuries may occur from traumatic asphyxia, rather, neurological impairment is the concern. Although the patient may appear moribund upon initial presentation, emergent airway management and supportive care can result in remarkable improvement in patient status in the first 48 hours, providing the duration of asphyxia is brief and the associated injuries are not severe.

### Initial Management of the Patient in Extremis

The primary survey, reviewed in Volume 1, Chapter 8, should identify most life-threatening injuries (Table 1), and these must all be promptly treated. Immediate recognition and treatment of the thoracic trauma patient in extremis (impending death) provides the best chance for survival. Some thoracic trauma patients, particularly those following penetrating trauma, will require an emergency department resuscitative thoracotomy for survival. However, most are initially managed with a thoracostomy tube, and later (if bleeding persists) may require urgent thoracotomy.

### Resuscitative Thoracotomy

The term "resuscitative thoracotomy" is used to mean a thoracotomy performed on a patient in extremis, typically outside the OR (in the emergency department or resuscitation bay). However, many of these patients are sent directly to a prepared trauma OR (Volume 1, Chapter 5). Thus, from a nomenclature perspective, the physical location of the thoracotomy is not as important as the reason and timing. The concept underlying a resuscitative thoracotomy (Volume 1, Chapter 13) is to improve perfusion to both cerebral and coronary circulation by performing open cardiac massage and cross-clamping of the descending aorta. Additional benefits of resuscitative thoracotomy include control of intrathoracic bleeding, release of pericardial tamponade, control of the pulmonary hilum to minimize bleeding, and air leaks.

Rhee et al. (16) have recently reviewed the combined data from 24 previously published series. This study confirmed the importance of mechanisms of injury, location of injury, and signs of life during transport (and upon arrival), on predicting survival (Table 3). Although the overall survival rate was only 7.4%, normal neurological function at discharge was observed in 92.4% of these surviving patients (16). An important factor that correlated with survival was successful tracheal intubation in the field. A complete review of resuscitative thoracotomy is provided in Volume 1, Chapter 13, and interested readers are referred there for additional information.

### Thoracostomy Tube Alone vs. Urgent Thoracotomy

The decision to place a thoracostomy tube for hemothorax versus urgent operative thoracotomy is a fundamental

**Table 3** Survival Factors for Patients Following Resuscitative Thoracotomy

Survival factor	Specific category and survival (%)
Mechanism of injury	Blunt trauma (1.4) Gunshot wound (4.3) Stab wound (16.8)
Location of major injury	Multiple major injuries (0.7) Abdominal (4.5) Thoracic (10.7) Cardiac (19.4)
Signs of life	Absent in the field (1.2) Present during transport (8.9) Absent on arrival (2.6) Present on arrival (11.5)

Source: Adapted From Ref. 16.

determination that needs to be made in every thoracic trauma patient who presents with hemodynamically unstable hemothorax. The current Advanced Trauma Life Support® (ATLS®) guidelines call for urgent operative thoracotomy to control bleeding and allow full lung expansion when the initial chest tube output exceeds 1500 mL of blood, or when the hourly output exceeds 250 mL for three consecutive hours (though we do not believe anyone should wait this long). Other indications for urgent and non-urgent thoracotomy following trauma are provided in Table 4. The surgical approach for urgent thoracotomy is beyond the scope of this chapter, and is found in standard surgical texts.

## LUNG INJURY RESULTING FROM TRAUMA-ASSOCIATED CONDITIONS

In addition to direct wounding of the heart, lung, and chest wall, secondary injuries can afflict the trauma patient due to multiple associated conditions including aspiration, burns, inhalation injury, near-drowning, fat embolization, pulmonary embolization, and acute respiratory distress syndrome (ARDS). Each of these injuries increase morbidity and have their own special considerations for managing the thoracic trauma patient, and will be discussed below.

### Aspiration of Gastric Contents

Trauma patients may aspirate blood or gastric contents before, during, or immediately after their injury. Aspiration during airway management is also common and problematic. The rate of aspiration after urgent intubation ranges from less than 1% in the OR under controlled circumstances, to almost 40% in other circumstances (17–21). Patients at risk for aspiration include those with a full stomach, a history of reflux, a decreased level of consciousness, depressed laryngeal reflexes, morbid obesity, emergency abdominal surgery following alcohol consumption, or in the presence of pain or stress (18). Trauma victims often have one or more of these risk factors.

### Prevention

☞ The proper use of cricoid pressure (Sellick's maneuver) may help prevent regurgitation of gastric contents into the trachea during intubation (22). ☞ However, no studies

**Table 4** Indications for Urgent and Nonurgent Thoracotomy

Indications for urgent thoracotomy	Cardiac tamponade	
	Acute hemodynamic deterioration	
	Initial chest tube output >1500 mL	
	Ongoing chest tube output > 250 mL/hr for >3 hr	
	Vascular injury at the thoracic outlet	
	Traumatic thoracotomy (loss of chest-wall substance)	
	Massive air leak from the chest tube	
	Known or suspected tracheal or bronchial injury	
	Esophageal injury	
	Great vessel injury	
	Mediastinal traverse with a penetrating object	
	Significant missile embolism to the heart or pulmonary artery	
	Transcardiac placement of inferior venal caval shunt for hepatic vascular wounds	
	Indications for nonurgent thoracotomy	Nonevacuated clotted hemothorax
		Chronic traumatic diaphragmatic hernia
		Traumatic cardiac septal or valvular lesions
		Chronic traumatic thoracic aortic pseudoaneurysms
Nonclosing thoracic duct fistula		
Chronic (or neglected) post-traumatic empyema		
Traumatic lung abscess		
Missed tracheal or bronchial injury		
Tracheoesophageal fistula		
Innominate artery/tracheal fistula (often urgent)		
Traumatic arterial venous fistula (often urgent)		

have confirmed the effectiveness of cricoid pressure in reducing aspiration and its associated morbidity and mortality. Another strategy to minimize the risk of aspiration is inserting a nasogastric tube (NGT) into the patient, prior to induction, to reduce the volume of gastric contents (orogastric tubes are placed in patients with maxillofacial trauma). Many of these same practitioners will remove the NGT, after emptying the stomach, to decrease the incidence of gastroesophageal reflux (23,24). However, others prefer leaving the NGT in place, using the rationale that it may help drain residual gastric contents (25). If the NGT is left in place, Salem et al. (26) have shown that the NGT does not impair the efficacy of cricoid pressure. However, the effect of the NGT on laryngoscopic view and ease of intubation has not been studied. Accordingly, patients with anticipated difficult intubation (see Volume 1, Chapter 9) should be intubated without the NGT in place. The use of histamine-2 receptor antagonists has been shown to decrease gastric volume and acidity; this option may rarely be implemented effectively in the trauma patient who is presented for urgent or emergent surgery (27). Additionally, metoclopramide may be administered to promote gastric emptying (as long as there is no bowel obstruction).

### Diagnosis and Management

Up to 40% of patients who aspirate during intubation may subsequently developed a clinical pneumonitis (16,19). When aspiration-induced pneumonitis does occur, it is more often associated with greater than 0.4 mL/kg of gastric contents and a gastric content pH of 2.5 or less (16,19). Of those patients who do develop aspiration pneumonitis, about half may require mechanical ventilation (16,19). The patients who develop aspiration pneumonitis often have symptoms of wheezing or coughing, decreased oxygen saturation, or abnormalities on chest roentograms, within two hours of aspiration (19). Patients who suffer an aspiration should have bronchial suctioning performed, especially if the aspirate contains particulate matter. Corticosteroids do not appear to be beneficial when given prophylactically. Similarly, antibiotics should not be given unless the aspirate is grossly contaminated (e.g., patient with upper gastrointestinal obstruction), or the patient has been institutionalized for more than 72 hours, or after a sputum culture returns positive with specific organisms (28,29).

However, aspiration of gastric contents can account for up to 20% of ARDS patients (30,31). Aspiration is one of the most common conditions associated with the development of ARDS. Therefore, patients symptomatic after aspiration should be carefully monitored for progressive respiratory failure, because the mortality rate increases up to 50% (16,19).

### Burns and Inhalation Injury

#### Incidence and Etiology

Although it is less common for a trauma patient to also have sustained a thermal injury (32), up to 7% of patients who suffer burns have concomitant nonthermal injuries (32–34). Burn victims suffer concomitant inhalation injury up to 35% of the time (35,36). Inhalation injury should be suspected in patients who have a history of smoke or flame exposure in a closed space, a history of loss of consciousness, facial burns, carbonaceous particles in their nares, carbonaceous sputum, or a carboxyhemoglobin level greater than 10% (36). However, even when the burn patient does not have an inhalation injury, respiratory complications occur in 18% to 33% of all burn patients (36). When a burn patient has an inhalation injury, there is a significant increase in respiratory complications and mortality can be as high as 77% (35–39). Interestingly, Hollingsed (36) found that burn patients with an inhalation injury but no additional respiratory complications (e.g., pneumonia) had no higher mortality than those without an inhalation injury. Instead, Hollingsed noted that burn patients who develop respiratory failure have a higher mortality rate (27–50%) than those without pulmonary failure (0–3%), regardless of the history of inhalation injury. There is, nonetheless, a propensity for respiratory failure to develop in those who have suffered inhalation injury (see Volume 1, Chapter 34).

#### Pathophysiology and Treatment

Inhalation injury can occur in several forms and affect different portions of the airway. The most obvious consequence of inhalation injury is hypoxemia and its attendant complication of ischemia. Hypoxemia should be immediately treated with a high-inspired concentration of oxygen. Patients may also develop severe tissue edema of the oropharyngeal and laryngeal areas, secondary to direct thermal injury (40,41). Since the edema may take over 12 hours to develop, patients suspected of having an inhalation injury should be closely monitored (42). These patients

often benefit from early intubation and mechanical support until the edema resolves.

The various components found in smoke may cause carbon monoxide or cyanide toxicity, as well as a chemical pneumonitis marked by sloughing of the mucosa and plugging of the airways (41). Patients suffering from carbon monoxide or cyanide poisoning may present with metabolic acidosis and neurological symptoms progressing from headache and confusion to hallucinations and coma (42,43). **✎ The treatment of carbon monoxide toxicity involves the use of a high-inspired concentration of oxygen.** **✎** Depending on the severity of the carbon monoxide poisoning, the patient may require intubation or, if available, hyperbaric oxygen treatment (also see Volume 1 Chapter 34 and Chapter 73 in this Volume). In addition to mechanical ventilation and circulatory support, the patient with cyanide toxicity may benefit from the intravenous administration of sodium thiosulfate or sodium nitrite to bind the cyanide molecules. Patients with a chemical pneumonitis require ventilatory support with vigorous pulmonary toilet to minimize the risk of secondary complications such as pneumonia. Prophylactic antibiotics and corticosteroids should be avoided (44). However, appropriate antibiotics should be initiated when an infection is identified by Gram stain and culture data.

Trauma patients who sustain a thermal injury may also have pulmonary complications aside from inhalation injury. The burn itself may result in the formation of a thick eschar circumferentially around the thorax, which may impede chest wall excursion until the patient undergoes escharotomy. The fluid resuscitation needed for burns with inhalation injury are about twice those needed for thermal injury without inhalation injury, but this additional fluid requirement has rarely been associated with the development of pulmonary edema (45). Inhalation injury itself is not associated with a large accumulation of extravascular lung water, though this too varies (45,46). Finally, the development of sepsis in a burn patient may also be accompanied by the development of increasing lung water (47,48).

### Fat Embolism Syndrome

Fat embolism is defined as the presence of fat droplets in the circulation, usually after a major trauma or long-bone fracture (49,50). The fat embolism syndrome results in a constellation of clinical signs and symptoms, including tachypnea, hypoxemia, tachycardia, petechial rash, thrombocytopenia, fever, and deteriorating neurological status, associated with fat globules in the circulation (49–51). Diagnosis of fat embolism syndrome is made by exclusion of other etiologies, given the nonspecific nature of many of the signs and symptoms. Although fat embolism is very common, with over 90% of patients suffering from a long-bone fracture found to have some degree of fat embolism, the fat embolism syndrome is much less common with an incidence ranging from 0.5% to 19% (49–55).

### Pathophysiology

The clinical course of fat embolism syndrome proceeds in one of two variants: a fulminant form and a progressive form. The severe form begins within 12 hours of injury is associated with significant neurological deficits and cardiovascular compromise, and has a higher mortality rate compared to the progressive form that presents 24 to 72 hours after injury, and has a wide range in severity of signs and symptoms (54–57).

The precise mechanism by which the fat enters the systemic circulation remains unclear. There is evidence that fractures as well as repair of fractures with reamed intramedullary nails, increase the intramedullary pressure with resultant fat embolization (58,59). The fat may enter the systemic circulation either through the venous drainage of the femur, via a shunt between the arterial and venous systems in bone, or through the pulmonary capillaries (50,58).

Once in the circulation, fat may cause hypoxia and respiratory compromise by either mechanically occluding pulmonary capillaries or by participation in a biochemical chain of events related to the presence of fat in the pulmonary vasculature. The latter includes the possibilities that lipase converts the fat into free fatty acids that subsequently cause vasculitis and alveolar damage; fat provides a surface for the activated platelets to adhere and coagulation to occur; and fat enhances the inflammatory process triggered by trauma (50,58–61).

Fat embolism syndrome can occur without respiratory effects, however, it is more commonly associated with hypoxemia (49). Fat embolism syndrome may also be associated with severe respiratory failure accompanied by chest radiographs demonstrating bilateral diffuse infiltrates indistinguishable from ARDS. In these patients with ARDS, the mortality of fat embolism syndrome is about 10% (49,62).

### Treatment

Randomized studies treating fat embolism syndrome with corticosteroids have had limited success with improving the respiratory effects (62–66). In one study, up to 45% of patients suffering from fat embolism syndrome required ventilatory support either due to severe hypoxemia or significant central nervous system depression (49). The same study documented 96% of patients as having some degree of hypoxia. Given the prevalence of respiratory involvement, patients with fat embolism syndrome should be closely monitored for hypoxemia and supported with mechanical ventilation as medically indicated.

### Thromboembolism and Pulmonary Embolism

#### Incidence and Etiology

Deep venous thrombosis (DVT) and pulmonary embolism (PE) are major factors of morbidity and mortality in trauma patients (see Volume 2, Chapter 56). DVT occurs in 6% to 80% of trauma patients (67–71), whereas PE occurs in 0.3% to 2.3% of trauma patients (69,72–76). DVTs may result in morbidity, due either to recurrent DVTs or to the development of post-thrombotic syndrome. Although DVTs may recur in trauma patients, the risk of recurrence is significantly less than in patients who develop DVTs secondary to inherited coagulation disorders and malignancy (77). Post-thrombotic syndrome occurs in approximately 30% of patients with DVT and is characterized by leg pain, pretibial edema, induration of the skin, hyperpigmentation, venous ectasia, and ulceration that occur within the first two years after acute DVT (77,78). Although fatal PE occurs rarely in trauma patients, PEs (fatal and subclinical) occur in up to 50% of patients with DVTs (79,80). Equally concerning is the fact that despite a PE mortality rate between 20% and 50% (72,80,81), up to 70% of patients who die of PE are not clinically suspected of having suffered a PE (82–84). **✎ For patients who survive the first 24 hours after traumatic injury, PE is the third leading cause of death (76).** **✎**

Patients at risk for DVT and for PE include those who have sustained direct venous trauma, a spinal cord injury,

severe head injury, pelvic fracture, fracture of the lower extremities, or severe trauma with subsequent shock or multiple transfusions (67,70,72,74). These conditions result in varying combinations of prolonged immobilization, stasis, endothelial damage, and hypercoagulability. Consequently, these patients may develop DVTs that can then embolize.

### Diagnosis

Patients with DVTs are frequently asymptomatic until they suffer a fatal PE. Consequently, clinical findings, such as a swollen and painful leg, palpable cord, and erythema, are unreliable for the diagnosis of DVT (70,75,80). Similarly, PE can be difficult to diagnose clinically because the symptoms and signs of pleuritic chest pain, dyspnea, tachypnea, and hemoptysis are nonspecific (80,85). A high index of suspicion for PE should be maintained in any trauma patient who subsequently develops dyspnea, hypoxemia, and respiratory failure without obvious pulmonary pathology. PEs can occur in trauma victims as early as within the first 24 hours after injury or as late as two weeks after trauma (75,86).

The most common methods used to detect the development of DVTs include contrast venography, impedance plethysmography, and duplex ultrasound (80,85). Although venography is considered the gold standard for diagnosing DVT, its use is limited by its invasiveness and cost. Impedance plethysmography and duplex ultrasound have the advantage of being noninvasive in nature, however, they require trained personnel to perform and can be limited by technical difficulties (67). Of these two methods, duplex ultrasound is considered to be superior to impedance plethysmography in detecting DVT (80,85). Knudson et al. (67) found that serial duplex ultrasound venous examinations of trauma patients serve as an ideal noninvasive surveillance method for patients deemed to be at risk for developing DVTs. However, routine surveillance has not been proven to reduce the incidence of PE and is more costly than DVT prophylaxis (76,87). Techniques used to diagnose PE include pulmonary angiography, ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) lung scan, and spiral CT angiography (85).

**✎ Pulmonary angiography had been the gold standard for diagnosing PE. As with contrast venography, pulmonary angiography is limited by its invasiveness and cost. Spiral CT is emerging as the new gold standard. However, some patterns of PEs such as distal small vessel disease are better seen by angiography, whereas others are better seen by CT (85). ✎**

The  $\dot{V}/\dot{Q}$  lung scan was evaluated in the landmark Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, and determined to be useful in diagnosing PE primarily when the  $\dot{V}/\dot{Q}$  scan was considered to be of high probability and correlated with a high clinical suspicion of PE (88). At the same time, the  $\dot{V}/\dot{Q}$  scan was also noted to be useful in excluding the diagnosis of PE when the  $\dot{V}/\dot{Q}$  scan was of low probability and associated with a low clinical suspicion of PE (88). Overall, the  $\dot{V}/\dot{Q}$  scan is diagnostic in 30% to 50% of the patients (88). Consequently, spiral CT angiography is increasingly viewed as the best technique to diagnose PE. Early studies suggest that spiral CT angiography is more accurate than  $\dot{V}/\dot{Q}$  scan and less invasive and expensive than pulmonary angiography (85,89). However, spiral CT angiography is limited when evaluating for PE in the subsegmental arteries (85). Hopefully, an ongoing PIOPED II study to evaluate spiral CT angiography will provide more definitive answers (90).

### Treatment

The primary treatment for thromboembolism and PE remains prophylactic anticoagulation in patients identified as being at risk for developing DVT. Numerous studies have demonstrated the effectiveness of early prophylactic anticoagulation in decreasing the incidence of DVT (69,91,92). According to the American College of Chest Physicians recommendations, trauma patients should be started on prophylactic low-molecular-weight heparin (LMWH) if they have no contraindications, such as active hemorrhage, intracranial hematoma, partial spinal cord injury, uncorrected coagulopathy, and development of major complications related to heparin (76,93). Prophylactic treatments in order of decreasing efficacy are LMWH, such as dalteparin and Lovenox, fixed low-dose unfractionated heparin, and low-dose warfarin at fixed dose or titrated to increase the prothrombin time by 1.5 to 3 seconds (94). If LMWH is contraindicated, the patient should be placed on a mechanical treatment such as sequential pneumatic compression devices (SCD) (76). Potential problems with SCD include limited use in patients with lower extremity trauma requiring dressings, casts, or traction (67,68,95). In these patients, an SCD can be placed on an upper extremity.

Prophylactic inferior vena cava (IVC) filters are often employed in trauma patients who meet the following three conditions: (i) are at high risk for DVT and PE, (ii) are not candidates for anticoagulation, and (iii) for whom SCDs are either not feasible or considered insufficient prophylaxis. Conflicting studies exist regarding the efficacy of prophylactic IVC filters in preventing PE in high-risk trauma patients (72,73,87,93,96–98). However, most authors agree that when IVC filters are placed prophylactically, it should occur early in the patient's hospital course (72,93,97). Less controversial is the use of IVC filters in trauma patients who have already developed DVTs and who also have contraindications to anticoagulation, or who have suffered a PE despite standard DVT prophylaxis (76,93). IVC filters, however, do not guarantee the prevention of future PEs (76,93). Therefore, the efficacy of prophylactic IVC filters must be weighed against potential complications associated with IVC filters including migration of the filter, IVC occlusion, new DVT or propagation of previous DVT, venous insufficiency, and erosion of filter into adjacent viscera (93,96,98,99). The interested reader is referred to Volume 2, Chapter 56 for further review of DVT management.

### Neurogenic Pulmonary Edema

#### Incidence and Etiology

Neurogenic pulmonary edema (NPE) may develop in patients following traumatic brain injury (TBI), or a subarachnoid hemorrhage (100,101). The true incidence of NPE is unknown (102–105), although one study suggests it may be as high as 50% of patients with severe TBI (106). Similarly, the overall mortality rate of NPE is difficult to define, with rates from 9.5% to over 90% found in the literature (103,105,107).

The pathophysiology of NPE remains unclear. One animal study suggests that the brainstem may be the neuroeffector site responsible for a massive sympathetic discharge (108). However, several other specific areas in the medulla, including the area postrema, Area A1 (a cluster of adrenergic receptors) of the ventrolateral medulla, the medial reticular nucleus, and the nucleus tractus solitarius are also possible sites (109–111). As a result of the massive

outflow of sympathetic activity, the patient undergoes systemic and pulmonary vasoconstriction, hypertension, ventricular wall stress, and damage to endothelial cells (101,104,109,110,112).

### **Diagnosis**

The patient with NPE presents with tachypnea, hypoxemia, tachycardia, hypertension, and frothy sputum. The signs and symptoms may appear within minutes to hours of the central nervous system injury, or develop gradually over the course of several days (112,113). Although the patient has pulmonary edema, the pulmonary capillary wedge pressure is usually low (112). Accordingly, NPE is a subset of noncardiogenic pulmonary edema. The chest X ray demonstrates diffuse patchy alveolar infiltrates, similar to those seen in patients with ARDS in the majority of patients (105).

### **Treatment**

Fortunately, NPE is frequently a self-limited process (105,109,113). The patients require ventilatory support with positive end-expiratory pressure (PEEP) to prevent hypoxemia until the NPE resolves, which can be as quickly as within several hours of instituting mechanical ventilation (112). Some recent studies suggest that the use of dobutamine may be useful in resolving NPE in those patients with left ventricular dysfunction (114,115).

### **Fluid Overload**

#### **Incidence and Etiology**

The true incidence of fluid overload in trauma patients is difficult to determine. One retrospective review of patients sustaining thoracic trauma had 2.6% rate of pulmonary edema in 187 patients (116), whereas a prospective review of pulmonary complications in trauma patients showed a 0.2% incidence of pulmonary edema in the 3289 patients analyzed (117). Pulmonary edema can be defined as the presence of clinical or radiographic findings that responds to fluid restriction or diuresis (117).

The etiology of fluid overload is related to the trauma patients receiving significant crystalloid resuscitation as well as massive transfusion to treat hemorrhagic shock. At the same time, respiratory failure due to fluid overload may be partially attributed to pulmonary contusions sustained at the time of injury, new onset or exacerbation of pre-existing cardiac failure, and the development of sepsis (118).

#### **Pathophysiology**

The pathophysiology of fluid overload remains controversial. Pulmonary edema may be the result of increased pulmonary capillary permeability, which can occur due to trauma itself (118,119), due to hemorrhagic shock (118), or due to the development of sepsis (118,120). However, several studies show that despite an increase in pulmonary microvascular permeability, pulmonary edema has not consistently occurred (121,122). Fluid overload may occur in some trauma patients, because they have a decreased compliance in the interstitial compartment that is exacerbated by decreased renal perfusion (123). The third and most popular theory is that pulmonary edema develops because massive fluid resuscitation, particularly with crystalloid solutions, results in a decrease in the plasma colloid oncotic pressure, with subsequent movement of fluid from the intravascular space to the interstitial compartment (124–126).

Once again, several studies dispute this idea (118,127–131). However, this theory has been critical to the still unresolved issue of whether colloid solutions are better than crystalloid solutions when massive fluid resuscitation is required in patients. Multiple studies suggest that colloids do not significantly improve pulmonary function or decrease the incidence of pulmonary edema when compared to crystalloids (128,132,133). In fact, several studies and reviews suggest that colloids may actually worsen pulmonary function and survival in trauma patients (129,132,134,135). More rigorous, randomized clinical trials, however, are still needed to better understand the phenomenon of fluid overload, and the role played by crystalloids and colloids.

### **Near-Drowning**

#### **Definition, Incidence, and Etiology**

Near-drowning is reviewed in detail in Volume 1, Chapter 35, and has been defined by Modell (136) as “survival, at least temporarily, after suffocation by submersion in water.” The exact incidence of near-drowning can only be estimated from data regarding drownings, but is at least double the incidence of drowning (137,138). According to the World Health Organization, at least 450,000 people drown annually world wide (139). However, since not all drownings are reported, this figure is undoubtedly an underestimation (140,141). Less than 10% of drowning accidents occur in salt water (141).

Drownings, and thus also near-drownings, are associated with a variety of causes including swimming, cramps while swimming, the consumption of alcohol and drugs near bodies of water, epilepsy or cardiac attacks while in the water, lapse of supervision around bodies of water, the use of hyperventilation to increase the duration of underwater swimming, and the immersion syndrome (141–145). The immersion syndrome occurs when a person is suddenly exposed to water 5°C less than body temperature and develops arrhythmias and syncope (144). Drownings can also be associated with boating accidents, car-in-water accidents, diving accidents, and suicide.

#### **Pathophysiology**

When drowning, victims may or may not have initially aspirated water (145). Regardless, the person experiences laryngospasm severe enough to cause not only panic but also hypoxemia. As hypoxia eases the laryngospasm, the victim swallows as well as aspirates water (144). Contrary to previous theories, the impact of the aspirated water on the respiratory system is more a function of the volume rather than the composition of fluid (144). The aspirated fluid, whether salt or fresh water, destroys surfactant resulting in decreased pulmonary compliance and the development of alveolitis and noncardiogenic pulmonary edema (141,144). All of these developments interfere with normal alveolar-capillary gas exchange, increase intrapulmonary shunting, and subsequently worsen the near-drowning victim’s hypoxemia (146). Increasing hypoxia leads to high pulmonary vascular resistance, compromised cardiac function, and systemic hypotension despite severe peripheral vasoconstriction (144). Eventually, the near-drowning victim develops both metabolic and respiratory acidosis. Although rare, the aspirated water may cause electrolyte disturbances, hemolysis, and subsequent arrhythmias (144,147–149).

## Management

Immediately upon rescuing a drowning victim, pulmonary resuscitation should be promptly begun without first attempting to drain the aspirated water from the lungs (e.g., using the Heimlich maneuver) (150). Restoration of oxygenation and ventilation is the key to convert a drowning victim to a near-drowning survivor (142). If the water is fresh water, it will rapidly be absorbed into the vascular system (151,152). If the water is seawater, pulmonary edema fluid will be exuded into the alveolar spaces (143,144,149). The priority should be to re-establish oxygenation and ventilation, with or without mechanical support. The near-drowning victim's pulmonary status may be further complicated by emesis and aspiration of gastric contents (153). Treatment for aspiration should be judiciously begun only when infection is suspected and cultures are pending, unless the near-drowning victim is known to have aspirated grossly contaminated water (142,154).

Although the near-drowning victim's initial chest X ray on admission to the hospital may be normal, it does not necessarily correlate with the patient's arterial oxygen concentration or pulmonary artery to inspired oxygen concentration ratio (147). More importantly, a later radiograph may reflect the pulmonary edema that can develop up to 12 hours after the drowning accident (144,155). The pulmonary edema that occurs may be the result of the process described above or the onset of either NPE or ARDS (156). Regardless, the patient often requires mechanical ventilatory support to ensure adequate oxygenation and that ventilation is maintained. (For greater specifics regarding the respiratory management of the patient with NPE or ARDS, please see the corresponding sections.) The use of steroids has not been shown to be of benefit (147).

The near-drowning patient's pulmonary status may be further compromised by the development of cardiac failure. Cardiac dysfunction occurs as the severe hypoxemia experienced during drowning produces increased pulmonary vascular resistance that decreases the cardiac output and increases central venous pressure (157,158). Subsequently, the patient develops cardiogenic pulmonary edema in addition to the ongoing pulmonary edema secondary to drowning (159). These patients may benefit from either increased intravascular volume or dobutamine to improve cardiac function and oxygen delivery (160). The use of furosemide, however, is strongly discouraged (144).

Although not addressed in detail here, there are other potential medical concerns to be considered when treating a near-drowning victim. These include hypothermia due to exposure in the water and cerebral edema secondary to cerebral hypoxia; both should be individually addressed (141,142,144). For additional study on near-drowning, the reader is referred to Volume 1, Chapter 35.

## ACUTE LUNG INJURY AND ARDS

☞ **ALI can result from all of the lesions that progress to the ARDS (also see Volume 2, Chapters 23 and 24).** ☞

Indeed, ALI, by recent definition, merely means that the  $\text{PaO}_2/\text{F}_i\text{O}_2$  is  $<300$ , whereas ARDS has a  $\text{PaO}_2/\text{F}_i\text{O}_2 <200$  (161). Typically, ALI begins with an injury to both components of the alveolar-capillary barrier: the alveolar epithelium and the pulmonary capillary. The loss of alveolar epithelium has multiple effects (162). First, the increased permeability of the alveolar epithelium permits

the development of alveolar edema. Next, the impaired fluid and ion transport inhibits the normal reabsorption of fluid and, further, enhances the development of alveolar edema. Finally, decreased surfactant production and turnover further compromises the gas exchange function of the alveoli. Surfactant diminution results in increased surface tension of alveoli that are still open, causing them to collapse and develop atelectasis.

Simultaneously, an increase in pulmonary vascular permeability leads to an influx of protein-rich edema into the alveoli (163–166). Hence, this phase of the injury process is known as the exudative phase. Besides proteins, the alveolar edema fluid also contains a high concentration of neutrophils (167). Studies of neutrophils show that their activation causes lung injury and their depletion can prevent or reduce injury (168,169). However, ARDS can develop in neutropenic patients (170). Recent work has focused on preventing adhesion of neutrophils to endothelial and epithelial cells, in an effort to decrease their migration from the vascular lumen and slow their injurious interaction with epithelium (171). The exact role of neutrophils remains unclear, however, they do participate in the pulmonary inflammatory process (162,172).

The combination of alveolar edema and surfactant dysfunction increases intrapulmonary shunting, increases dead-space ventilation, and decreases lung compliance. Shunting can increase to 25% to 50% of cardiac output and present as severe refractory hypoxemia (173). Increased dead-space ventilation results from the rapid shallow breathing, even when the alveoli are relatively normal. The decrease in lung compliance is due to increased lung water edema and a reduction in the aeratable lung volume to 20% to 30% of normal (174). CT studies of the lungs of patients diagnosed with ARDS show localization of densities to dependent areas, correlating with loss of gas volume rather than edema (174). As ARDS progresses from the exudative to the proliferative and, finally, the fibrotic phase, the decrease in lung compliance begins to result from a change in the intrinsic elastic properties of lung tissue.

For many of these complications, ARDS is the final common pathway. ☞ **ARDS-incident events may be associated with primary injuries to the lung, such as aspiration, pneumonia, pulmonary contusions, near-drowning, and toxic inhalation (160,161). On the other hand, the initiating event may be an extrapulmonary illness that injures the lungs through activation of systemic inflammation response syndrome.** ☞ Examples of indirect causes of ARDS include sepsis, shock, multiple emergency transfusions, major multiple fractures, pancreatitis, burns, cardiopulmonary bypass, and disseminated intravascular coagulation (161,162). Seventy to eighty percent of ARDS is accounted for by sepsis, aspiration, and trauma (163,164). The onset of ARDS varies with approximately 80% of patients developing ARDS within 48 hours after an inciting event, 90% of patients developing ARDS in the first 72 hours, and the remaining patients developing ARDS over the next several days (164,165). Mortality ranges from 10% to 90%, with average mortality slightly greater than 50%. Death is primarily due to multiorgan dysfunction syndrome and sepsis, rather than pulmonary failure or hypoxia.

Ashbaugh (166), first described ARDS in 1967 as an acute onset of severe respiratory distress with cyanosis refractory to oxygen therapy, decreased lung compliance, and diffuse infiltrates on chest radiograph. In 1994, the American-European Consensus Conference on ARDS simplified the definition to improve the determination of

incidence and mortality and their response to interventional strategies. ALI is defined as “a syndrome of inflammation and increased permeability that is associated with a constellation of clinical, radiologic, and physiologic abnormalities that cannot be explained by, but may coexist with, left atrial or pulmonary capillary hypertension” (161). ARDS is reserved for the most severe form of ALI. The defining criteria for both include acute onset, chest X rays consistent with bilateral infiltrates, pulmonary artery occlusion pressure of less than 19 mm Hg or no clinical evidence of congestive heart failure, and a low PaO<sub>2</sub>/FiO<sub>2</sub> ratio. The cut-off for ALI is a PaO<sub>2</sub>/FiO<sub>2</sub> ratio of less than 300, whereas that for ARDS is less than 200 (161).

## MECHANICAL VENTILATION CONSIDERATIONS

Mechanical ventilation for trauma and critical care is reviewed extensively in Volume 2, Chapter 27. ARDS-affected lungs can be further traumatized by mechanical ventilation when a high fraction of inspired oxygen (FiO<sub>2</sub>) is used, plateau pressures exceed 30–40 cm H<sub>2</sub>O causing barotrauma, and high tidal volumes are used resulting in volutrauma (175). **Current ventilation management for ARDS involves an open lung technique with tidal volumes in the 6 cc/kg range and enough PEEP to keep alveoli open at end exhalation.**

Maintaining the PEEP at a level that keeps alveoli open allows ventilation to occur above the lower inflection point on the P/V curve (see Volume 2, Chapter 27). Similarly, by keeping the tidal volume less than 7 cc/kg, the ventilation is typically occurring below the upper inflection point on the P/V curve. This is the so-called “lung protective strategy.”

### Best PEEP

Best PEEP decreases or abolishes the lower inflection point to prevent cyclic alveolar collapse and recruitment, whereas minimizing overdistension of alveoli already open (176). At the same time, best PEEP permits decreases in the FiO<sub>2</sub> and minimally affects the cardiac performance of a patient with adequate intravascular volume. Gattinoni (177) demonstrated on computed tomography that PEEP has an immediate effect on lung densities by acting as a counterforce to hydrostatic pressure. The effect of PEEP, therefore, reopens dependent alveoli and reduces the amount of nonaerated tissue. His studies show that the maximal amount of PEEP should not exceed ventral to dorsal height of lung in centimeters when applied in the supine patient (178).

### Small Tidal Volumes

Amato (179) defines the open lung approach as the use of (i) PEEP above the lower inflection point of the pressure-volume curve, (ii) tidal volumes <6 mL/kg, (iii) static peak pressures <40 cm H<sub>2</sub>O, (iv) permissive hypercapnia, and (v) stepwise use of pressure-limited modes. Their study shows that using the open lung approach improved lung compliance, increased PaO<sub>2</sub>/FiO<sub>2</sub> and decreased shunt, decreased periods of high FiO<sub>2</sub> use and resulted in faster weaning from the ventilator. Unfortunately, Amato was unable to demonstrate any significant difference in mortality. A study by the National Institutes of Health (NIH) ARDS Network also supports the use of small tidal volumes, which were associated with a decreased plasma concentration of IL-6, an increased number of early extuba-

tions, an increase in ventilator-free days, and decreased mortality (180). This study reinforces earlier research demonstrating ventilator-associated lung injury (181–183). A more recent trial by the NIH ARDS Network corroborates the results of the earlier work and suggests that small tidal volumes should be used in patients with ALI or ARDS, regardless of its etiology (184).

### Prone Position

Having the patient in prone position can improve oxygenation and decrease shunt without deleterious effects on hemodynamics. The beneficial effects of prone position include: changes of chest wall compliance, changes in gravitational ventilation/perfusion distribution, changes in regional diaphragmatic motion, improvement of postural drainage of bronchial secretions, and compliance of thoracoabdominal cage decreased. Prone position may cause gas to be distributed toward the ventral, dependent portion of the lung resulting in a more homogeneous regional inflation and improved oxygenation.

Perfusion of the lung continues to be greater in the dorsal area than the ventral area, even after the patient has been in the prone position for a prolonged period of time (185). The beneficial effect of the prone position does not immediately disappear on return to the supine position.

### Partial Liquid Ventilation

Partial liquid ventilation involves filling the functional residual capacity volume with perfluorocarbons (PFC) in combination with conventional mechanical ventilation (186). The PFC acts as the carrier for oxygen and carbon dioxide. PFC improves gas exchange by decreasing surface tension and thus increasing compliance, promoting recruitment of previously collapsed dependent lung regions, facilitating the use of lower ventilator pressures to achieve desired tidal volumes, and facilitating removal of airway secretions (185,187). Recruitment also occurs by physical distension by a noncompressible fluid. PFC preferentially re-expands gravity-dependent dorsal alveoli and simultaneously redirects blood flow toward the nondependent lung. Recruitment of alveoli improves ventilation/perfusion matching and, thus, decreases intrapulmonary shunting. Studies are under way to evaluate the efficacy of this treatment modality. The reader is referred to Volume 2, Chapter 27 for further study.

## ANALGESIA FOR THORACIC TRAUMA

Patients with thoracic trauma are at significant risk of respiratory morbidity and mortality (188). Respiratory failure and/or pneumonia can be prevented with aggressive respiratory care; however, this is limited by the adequacy of pain control (188,189). Pain from rib fractures due to blunt thoracic trauma can severely limit patient mobilization, deep breathing, and cough. First-line pain management predominantly consists of a patient-controlled analgesia (PCA) deliverance of parenteral opioids, with or without other adjuncts such as nonsteroidal anti-inflammatory drugs (NSAIDs). Unfortunately, systemic analgesics may be ineffective, or result in oversedation and a decrease in the cough reflex (190). Patients who are failing first-line (systemic analgesic) therapy or who are at high risk for respiratory failure can derive benefit from several different regional

anesthetic techniques (Fig. 4) available for the treatment of thoracic pain.

Although invasive, regional blocks tend to be more effective than systemic opioids and produce less systemic side effects. However, the current literature does not support the application of any particular method of analgesia for all circumstances, for patients with multiple fractured ribs (191). Rather, the data supports having superbly trained trauma anesthesiologists and surgeons that understand the strengths and weaknesses of the various analgesic techniques (191). In this setting, the clinician can weigh the risks and benefits and individualize the pain management based on the clinical setting and the extent of trauma.

The following regional analgesic options should be considered along with systemic opioids: epidural analgesia, thoracic paravertebral block, intercostal nerve block, and interpleural analgesia. These have all been used effectively, and will be reviewed sequentially next.

### Epidural

Thoracic epidural analgesia is a commonly employed mode of pain management for thoracic trauma. The use of a thoracic epidural analgesia has been shown to decrease the amount of opiate utilized, increase tidal volumes, and improve negative inspiratory force (191–193). When started within 24 hours of admission, thoracic epidural

analgesia with bupivacaine and fentanyl have been shown to provide superior analgesia than intravenous PCA morphine (188).

Several forms of epidural analgesia have been used and are acceptable for the treatment of thoracic trauma. Debate continues concerning the level of placement (lumbar vs thoracic) and the ideal epidural solution (opiate vs local anesthetic or combination). However, the general consensus is that a combined (opiate and local anesthesia) technique tends to be optimal by providing superior analgesia with fewer side effects (188). Although technically more difficult, a thoracic epidural with a local anesthetic/opiate mixture is superior, especially if using a local anesthetic-based technique. If a lumbar epidural catheter is placed, an opiate without local anesthetic should be used for pain management. The addition of patient-controlled epidural analgesia, along with continuous epidural drug infusions, has further increased the effectiveness of this technique. Thoracic epidural is considered by many to be the most effective of the regional techniques available to treat thoracic trauma (194). However, several known complications of thoracic epidural need to be considered (188). Epidural analgesia is contraindicated in patients with significant ongoing hemorrhage, abnormalities in coagulation factors, thrombocytopenia, or hypotension for any reason, systemic infection, and neurological trauma (i.e., spinal cord damage). The most common side effect of epidural analgesia is hypotension

**Figure 4** Regional analgesic techniques available for patients with thoracic trauma (including rib fractures). The figure shows the basic anatomy including the intercostal nerve, pleura, muscle, and fascial layers, as well as the anatomic target location for each of the regional techniques. *Source:* From Ref. 191.

that usually responds to volume infusion. There is also always the rare risk of epidural hematoma or abscess.

✎ **Placement of an epidural catheter in the trauma victim, especially at the thoracic level, takes significant expertise and should only be performed by an appropriately trained anesthesiologist.** ✎ Furthermore, management should be conducted by an established and dedicated pain management team.

Trauma patients who have suffered unilateral chest trauma, with or without neurological compromise, are good candidates for pain management with thoracic paravertebral block. This regional technique should be performed by an appropriately trained anesthesiologist. Several variations of this technique can be utilized in the thoracic trauma patient. A continuous catheter can be placed or a “single-shot” can be performed. Advantages over an epidural technique include not interfering with neurological examinations, a decreased incidence of hypotension, and coagulopathy is only a relative contraindication (195). Risks of this technique include pneumothorax, vascular puncture, hypotension and, occasionally, epidural spread resulting in pulmonary compromise.

### Intercostal Block

Easy to perform and not requiring an anesthesiologist, the intercostal nerve block is a popular technique for management of trauma localized to the seventh rib and below. Performance of this block on higher ribs is problematic due to interference from the scapula. Due to the dual innervation of ribs, the inner space above and below each rib must be injected. The block can be repeated as often as needed but one study found that 89% of patients required only two interventions and subsequently did well with systemic opiates (196). The predominant risk of this technique is pneumothorax, which is roughly 1.5% per block. This technique is most appropriate for patients with isolated lower rib fractures who do not suffer from other injuries. Catheter placement has been described and is successful, especially if the catheters are actually intentionally placed extrapleural as described by Haenel et al. (190). Increased spread is achieved and additional levels can be covered by a single catheter placed in this manner.

### Intrapleural Block

Extremely easy to perform and only limited by local anesthetic toxicity secondary to absorption, interpleural analgesia can be utilized if the previously described regional techniques cannot be performed. Unfortunately, the efficacy of this technique is suspect, and certainly is not as effective as the aforementioned ones (197,198).

## EYE TO THE FUTURE

The future management of thoracic trauma will integrate methods to enhance delivery of care via use of mobile systems, incorporate newer technology and pharmacological agents, and strive for less invasive surgical and monitoring techniques. There continues to be a need for solutions for common trauma-related complications. For example, there is a need for enhanced methods for protection of the spinal cord in circumstances of direct cord injury, as well as prevention of anterior spinal cord injury occurring during surgical repair of thoracic aortic rupture and/or

dissection. Additionally, newer methods of airway management, with the utilization of bronchial-blocking devices and enhanced bronchoscopic imaging, will be welcome advances in perioperative management of thoracic trauma. Echocardiographic assessment of hemodynamics can permit a less invasive alternative to pulmonary artery catheterization. More effective technology and miniaturization of TEE devices could enhance diagnosis of injury and perioperative hemodynamic monitoring of the thoracic trauma victim. The development of safe and effective blood substitutes will be important as the risk of blood-borne pathogens lingers. Recombinant blood factors may enhance the treatment of coagulopathy and provide solutions for trauma-related coagulopathies. For example, recombinant factor VIIa has treated bleeding refractory to other interventions, and there is now experimental and early clinical evidence that these recombinant factors can be effective in the treatment of trauma-related hemorrhage (199). Thoracoscopic diagnosis and repair of injury is more prevalent in trauma care. Analgesic methods, though good, are not yet optimal. New strategies of mechanical ventilation and sedation during ICU care are necessary. Triage and field management of casualties may save more lives as more prompt care requires training of individuals in immediate proximity to the trauma scene, to utilize portable systems of resuscitation and trauma care. Endovascular management of thoracic aortic injury is now becoming available clinically (200).

## SUMMARY

Thoracic trauma is a common problem in both urban trauma and military conflicts. Optimal management requires early diagnosis and prompt treatment of life-threatening injury (hemothorax, pneumothorax, pericardial tamponade, etc.). Besides treatment of the primary injury, outcome is improved when secondary injury (e.g., aspiration, fluid overload, etc.) is prevented or minimized. When feasible, the use of thoracoscopic technology speeds recovery, because additional trauma and pain is minimized. Lung-protective ventilation strategies allow for oxygenation and ventilation without causing exacerbation of the existing lung injury.

Analgesia must be optimized to facilitate early return to spontaneous ventilation and minimize splinting-related atelectasis and pneumonia. Patients capable of breathing on their own, despite extensive rib or chest-wall trauma, are optionally managed with thoracic epidural analgesia. Those requiring prolonged mechanical ventilation can receive intravenous opiates during the most painful period (first two to four days following injury).

Optimum care of the thoracic trauma patient requires a unifying management approach which includes the above concepts. By so doing, the significant morbidity and prolonged ICU stays common so those injuries can be minimized.

## KEY POINTS

- ✎ The most common etiologies of shock penetrating chest injury include tension pneumothorax, massive hemothorax, cardiac wounds, and cardiac tamponade.
- ✎ The magnitude of destruction resulting from the secondary shock wave occurring with high-velocity GSWs and shrapnel injuries may not be initially apparent.

- ✎ Atelectasis will develop as a result of splinting of the chest and will compound the shunt attributable to lung contusion itself.
- ✎ Bronchoscopy is an essential part of the evaluation of the victim of thoracic or neck trauma whenever there is a suspicion of airway disruption.
- ✎ When left heart air embolism is recognized, the team must prevent further entry of air into the left heart. The first maneuver is isolation of the injured lung via one-lung ventilation (ILV).
- ✎ Early evaluation and prompt management are the most critical factors in optimum outcomes following esophageal injury.
- ✎ Assessment of structural abnormalities of the heart and pericardial effusion (blood) and possible early or frank cardiac tamponade, can be quickly evaluated with TTE as part of the FAST exam (Volume 1, Chapters 14, 16, and 25). However, TEE is preferable to TTE whenever structural lesions or valve abnormalities are to be evaluated.
- ✎ The proper use of cricoid pressure (Sellick's maneuver) may help prevent regurgitation of gastric contents into the trachea during intubation (22).
- ✎ The treatment of carbon monoxide toxicity involves the use of a high-inspired concentration of oxygen.
- ✎ For patients who survive the first 24 hours after traumatic injury, PE is the third leading cause of death (76).
- ✎ Pulmonary angiography had been the gold standard for diagnosing PE. As with contrast venography, pulmonary angiography is limited by its invasiveness and cost. Spiral CT is emerging as the new gold standard. However, some patterns of PEs, such as distal small vessel disease, are better seen by angiography, whereas others are better seen by CT (85).
- ✎ Acute lung injury (ALI) can result from all of the lesions that progress to the ARDS (also see Volume 2, Chapters 23 and 24).
- ✎ ARDS-iciting events may be associated with primary injuries to the lung, such as aspiration, pneumonia, pulmonary contusions, near-drowning, and toxic inhalation (160,161). On the other hand, the initiating event may be an extrapulmonary illness that injures the lungs through activation of systemic inflammation response syndrome.
- ✎ Current ventilation management for ARDS involves an open lung technique with tidal volumes in the 6 cc/kg range and enough PEEP to keep alveoli open at end exhalation.
- ✎ Placement of an epidural catheter in the trauma victim, especially at the thoracic level, takes significant expertise and should only be performed by an appropriately trained anesthesiologist.

## Respiratory Care

William T. Peruzzi and Kenneth D. Candido

Department of Anesthesiology, Northwestern University Medical School, and Department of Respiratory Care, Northwestern Memorial Hospital, Chicago, Illinois, U.S.A.

### INTRODUCTION

Trauma and critically ill patients routinely require respiratory care ranging from supplemental oxygen administration to lung separation and unilateral or independent lung ventilation. Respiratory support encompasses a wide range of prophylactic, therapeutic, and diagnostic interventions, including airway mucus clearance, increasing lung volumes, improving oxygenation, and recruiting collateral airway units. Expectorants, mucolytics, mucokinetics, and modifiers of airway water transport may each have a role in the management of these patients. Anti-inflammatory agents, anticholinergics, and some macrolide antibiotics may prove to be mainstays in the care and treatment of certain cases.

Airway management is one of the foundations of resuscitation from trauma of all types, and may pose a formidable challenge for the caregiver called upon to urgently stabilize such patients. A variety of complications may develop following the securing of the airway and the implementation of respiratory care, necessitating prolonged vigilance and a high degree of skill to minimize the potentially severe morbidity associated with these scenarios. One of the goals of respiratory care is to maximize the quantity of oxygen ( $O_2$ ) arriving at the sites of intracellular utilization.

This chapter concerns itself with the optimization of  $O_2$  delivery ( $DO_2$ ) and carbon dioxide ( $CO_2$ ) elimination, as therapeutic goals in the management of trauma patients. The application of the correct respiratory care modality at the appropriate time will often result in a favorable outcome with minimization of the inherent risks. Inappropriate or delayed application of the necessary respiratory care modality may result in serious clinical morbidity and the need for more extensive supportive measures at a later time.

### DISORDERS OF OXYGENATION

By definition, hypoxemia is an abnormally low  $PO_2$  in arterial blood ( $PaO_2$ ). Hypoxia exists when oxygen tension at the cellular level is inadequate for cellular function (tissue oxygen deprivation). Distinguishing the terms is important because each may exist without the other. Pulmonary conditions associated with hypoxemia may be routinely associated with trauma and include hypoventilation, diffusion impairment, shunt, and ventilation-perfusion inequalities. Blood-related conditions including anemia and carbon monoxide (CO) intoxication, among others can

be seen in trauma patients. Tissue factors associated with hypoxemia, notably cyanide toxicity, are rarely associated with general trauma, yet can occur in structural fires, and must be considered in any presentation of hypoxemia that is unresponsive to supplemental oxygen administration—because all the previously mentioned factors do, indeed, respond in some measure to supplemental oxygen.

The alveolar oxygen tension ( $P_{AO_2}$ ) is determined by a balance between the rate of removal of  $O_2$  by the blood and the rate of replenishment of  $O_2$  from alveolar ventilation. The  $O_2$  removal is a function of the metabolic demands of tissues, which may be quite high as a result of endogenously or exogenously administered catecholamines in the trauma patient. Hypoventilation is said to occur when abnormally low alveolar ventilation causes a rise in  $PCO_2$  and a fall in  $PO_2$ . Trauma patients intoxicated with opioids, barbiturates, or ethanol are at risk for developing hypoxemia from hypoventilation. Similarly, victims of trauma to the chest wall, or those in whom the respiratory muscles are paralyzed as a result of a central nervous system injury, can also suffer hypoventilation. As  $PO_2$  falls,  $PCO_2$  rises in hypoventilation, and this relationship is expressed by the alveolar gas equation:

$$P_{AO_2} = P_{iO_2} - \frac{P_A CO_2 + F}{RQ}$$

where  $P_{AO_2}$  is the alveolar oxygen tension,  $P_{iO_2}$  the partial pressure of humidified oxygen,  $P_{iO_2} = F_{iO_2} (P_B - P_{H_2O})$ ,  $F_{iO_2}$  the inspired oxygen concentration,  $P_A CO_2$  the alveolar  $CO_2$  tension,  $RQ$  the respiratory quotient ( $CO_2$  production/ $O_2$  consumption) (typically 200/250 mL/min, or 0.8), and  $F$  is a small correction factor (typically = 2 mmHg).

Similarly, the relationship between alveolar ventilation and  $PCO_2$  demonstrates why hypoventilation increases alveolar (and arterial)  $PCO_2$ :

$$PCO_2 = \frac{\dot{V}CO_2 \times K}{\dot{V}_A}$$

where  $PCO_2$  is the arterial  $CO_2$ ,  $\dot{V}CO_2$  the  $CO_2$  production,  $\dot{V}_A$  the alveolar ventilation, and  $K$  is a constant.

Diffusion impairment is another factor potentially associated with hypoxemia in trauma. Under ideal conditions, the  $PO_2$  difference between alveolar gas and end-capillary blood resulting from incomplete diffusion is exceedingly small, yet this difference may become larger during stressful states such as trauma, or if the blood-gas barrier becomes thickened, or if an oxygen-poor admixture is administered to a patient. Although this mechanism of

hypoxemia may not be routinely present in the trauma patient, it remains a practical concern in respiratory care, because it may be one presentation of the patient who manifests low oxygen tension in the face of normal  $PCO_2$ . This type of insult is typically responsive to the administration of supplemental oxygen.

The  $P_{AO_2}$  results from a dynamic equilibrium between oxygen delivery to the alveolus and oxygen extraction from the alveolus. Oxygen delivery to the alveolus is a function of the minute ventilation ( $\dot{V}_E$ ) and the inspired oxygen fraction ( $F_{IO_2}$ ), whereas oxygen extraction from the alveolus is a function of the de-oxygenation status of blood presented to the alveolus ( $SVO_2 \times Hgb = CVO_2$ ) and the capillary blood flow ( $Q_C$ ). If the factors governing oxygen extraction remain static, a decrease in alveolar ventilation or  $F_{IO_2}$  will result in less oxygen delivery to the alveolus. Since the alveolar contents of nitrogen and water vapor remain essentially unchanged, the  $P_{AO_2}$  must decrease; therefore, the capillary blood will equilibrate with a lower  $P_{AO_2}$ .

If factors determining alveolar oxygen delivery remain constant, a decrease in pulmonary artery oxygen content ( $CVO_2$ ) or an increase in capillary blood flow, will result in more oxygen extraction from the alveolus. There are three major reasons for mixed venous blood to have decreased oxygen content. First, an increase in metabolic rate increases oxygen consumption ( $\dot{V}O_2$ ). If there is no increase in perfusion, the tissues will extract more oxygen from each deciliter of blood and thereby decrease the venous blood oxygen content. Second, decreased oxygen delivery at a constant  $\dot{V}O_2$  requires that the tissues extract more oxygen from each deciliter of blood, thereby decreasing the venous blood oxygen content. Third, a decreased arterial oxygen content will result in a lower venous oxygen content after the normal extraction of oxygen by the tissues. A compensatory mechanism for all three scenarios is an increase in cardiac output ( $Q$ ). The above presentation expresses the gas-exchange factors that are traditionally referred to as the ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) relationship. Low  $\dot{V}/\dot{Q}$  refers to perfusion in excess of ventilation, leading to a decreased alveolar oxygen tension and hypoxemia. It is important to recognize that changes in  $F_{IO_2}$  and  $SvO_2$  can change the alveolar  $PO_2$  without changing the  $\dot{V}/\dot{Q}$  relationship. Therefore, arterial oxygenation deficits must be considered beyond the scope of  $\dot{V}/\dot{Q}$  relationships.

Anatomic right-to-left shunting is defined as blood that goes from the right side to the left side of the heart without traversing pulmonary capillaries. Capillary shunting is defined as blood that goes from the right side to the left side of the heart by traversing pulmonary capillaries that are adjacent to unventilated alveoli. In both circumstances, right heart blood enters the left heart without an increase in  $O_2$  content. This phenomenon is traditionally referred to as zero  $\dot{V}/\dot{Q}$ , or true shunting, because the blood does not interact with alveolar gas.

Shunting and hypoxemia are not synonymous terms, nor do they have linear relationships. The hypoxemic effect of any shunt will depend both on the size of the shunt and on the oxygenation status of the blood that is shunted. A small shunt in a patient with a low  $SvO_2$  may have profound hypoxemic effects, whereas a large shunt in patients with a high  $SvO_2$  may cause only mild hypoxemia.

Oxygen diffusion defects, due to edema fluid or fibrous tissue between the alveolar epithelium and the capillary epithelium, can impose a significant impediment to  $O_2$  diffusion and inhibit equilibration between pulmonary

capillary and alveolar  $O_2$  tensions. This impaired  $O_2$  exchange is worsened as blood transit time decreases (blood traverses the lung more rapidly). Arterial hypoxemia secondary to diffusion defects is not common in trauma but is responsive to an increase in  $P_{AO_2}$ .

$\dot{V}/\dot{Q}$  mismatch, not infrequently, occurs in trauma and can result from retained bronchial secretions, bronchospasm, obstructive endobronchial lesions, chronic obstructive pulmonary disease, pulmonary edema, or other pulmonary pathology. The hallmark of hypoxemia due to  $\dot{V}/\dot{Q}$  mismatch is that it is responsive to oxygen therapy. In order to determine  $O_2$  responsiveness, an appropriate oxygen challenge must be given (1). If, at sea level, the  $F_{IO_2}$  is increased by 0.2 (i.e., from 0.2 to 0.4, or 0.3 to 0.5), the  $PAO_2$  of all ventilated alveoli should increase by 90–100 mmHg. Subsequently, the  $PAO_2$  will increase by significantly more than 10 mmHg if less than 15% true right-to-left shunt is present; however, it will increase by significantly less than 10 mmHg if greater than 30% true shunt exists.

True right-to-left shunt can result from several different pathological conditions—intracardiac shunt; alveolar collapse, as occurs in acute lung injury (ALI); pulmonary consolidation associated with lung infections; segmental or lobar lung collapse due to retained secretions or other lung pathology; pulmonary arterial-venous malformations or pulmonary-capillary dilatation, as is sometimes seen in liver disease; and large vascular lung tumors. Oxygen therapy has limited effect on blood traversing true shunt units. The reason for this is that, regardless of the  $F_{IO_2}$  or  $P_{AO_2}$ ,  $O_2$  transfer cannot occur when blood does not come into contact with functional alveolar units. Therefore, true shunt pathology is refractory to  $O_2$  therapy. Functional alveolar units may be impaired or destroyed by penetrating chest wall trauma, among other causes. For several types of pathology resulting in true shunt, there is little or no available therapy; antibiotics or surgical interventions may help other types of true shunt-producing disease. The type of lung pathology that is the most responsive to therapy is that involving diffuse or focal lung collapse. Segmental or lobar lung collapse can often be reversed with appropriate bronchial hygiene or removal of the source of obstruction.

Diffuse alveolar collapse often results from destabilization of the alveolar architecture due to disruption of the surfactant layer and alveolar epithelial damage associated with ALI (2,3). This type of pathology is responsive to positive end expiratory pressure (PEEP) (4). PEEP levels of 5 to 10 cm  $H_2O$  will increase alveolar size and redistribute interstitial lung water from the interstitial regions between the alveolar epithelium and pulmonary-capillary endothelium to the peribronchial and hilar regions of the lung (5,6). PEEP levels >15 cm  $H_2O$  no longer increase alveolar size; rather, these levels of PEEP “recruit” nonfunctional and collapsed alveoli to expanded and functional alveolar units (7).

☞ **The three major reasons for mixed venous blood to have low  $O_2$  content include: (i) metabolic rate; (ii)  $\downarrow$   $O_2$  delivery; and (iii)  $\downarrow$  arterial  $O_2$  content.** ☞

## OXYGEN ADMINISTRATION

In order to understand the indications for  $O_2$  therapy, the physiologic responses to hypoxemia and hypoxia must be appreciated. First, there is an increase in minute ventilation that increases alveolar ventilation and the work of breathing. Second, there is an increase in  $Q$ , which maintains  $DO_2$  in the

face of a decreased arterial O<sub>2</sub> content, but increases the stress placed on the cardiovascular system. Therefore, the goals of oxygen therapy are to improve arterial O<sub>2</sub> content and subsequently decrease the work of breathing and myocardial stress.

### Oxygen Content

☞ The primary determinants of oxygen content are the Hgb concentration and the degree of Hgb saturation. ☞

Oxygen content is determined by the concentration of Hgb in the blood, the percentage of the Hgb that is saturated with oxygen, the maximal amount of oxygen that can be bound to Hgb (constant of 1.34 mL O<sub>2</sub>/g Hgb), and the amount of O<sub>2</sub> dissolved in the plasma (0.003 mL O<sub>2</sub>/mL Hg). Thus,

$$CaO_2 = [Hgb] \times [SaO_2] \times [1.34] + [PaO_2] \times [0.003]$$

Obviously, the primary determinants of O<sub>2</sub> content are the Hgb concentration (g/dL) and the degree of Hgb saturation (expressed as a decimal). At atmospheric pressure, the amount of O<sub>2</sub> dissolved in the plasma ([PaO<sub>2</sub>][0.003]) is usually negligible. The value of 1.34 mL/g Hgb represents the amount of O<sub>2</sub> that can be bound to Hgb contained within the red blood cell membrane; a value of 1.39 mL/g Hgb is sometimes used and represents the amount of O<sub>2</sub> that can be bound by stroma-free Hgb, which occurs when cells are lysed during co-oximetry measurements (8).

### Oxygen Delivery Systems

There are three basic types of gas delivery systems: rebreathing systems, nonrebreathing systems, and partial rebreathing systems. Rebreathing systems collect exhaled gases into a reservoir on the expiratory limb of the system, which contains a CO<sub>2</sub> absorber (permitting the re-entry of expiratory gases into the inspiratory gas flow without rebreathing of CO<sub>2</sub>). This system is used primarily for the delivery of anesthetic gases in order to conserve expensive volatile anesthetics. Such systems have little or no use in current critical care settings.

A partial rebreathing system is one in which the initial portion of the expired gases, consisting mainly of gas from the anatomical dead space, is expired into a reservoir, whereas the latter portions of the expiratory gases are vented in the atmosphere through one-way valves. The expiratory gases from the anatomic dead space contain very little CO<sub>2</sub> and, therefore, can be rebreathed without significant consequences. The reservoir also receives fresh inspiratory gas flow; thus, the patient breathes both expiratory gas containing little CO<sub>2</sub> and fresh inspiratory gas.

Most oxygen-delivery systems are nonrebreathing systems in that all expiratory gases are vented in such a fashion that exhaled CO<sub>2</sub> is not rebreathed during subsequent breaths. This is often accomplished with one-way valves to prevent mixing of inspired and expired gases.

☞ Nonrebreathing systems are divided into high-flow (fixed performance) and low-flow (variable performance) systems. ☞ A high-flow system means that the inspiratory gas flow rate delivered to the system is sufficient to meet the peak inspiratory-flow demands of the patient. Thus, all inspiratory gas is supplied by the O<sub>2</sub>-delivery system and the F<sub>I</sub>O<sub>2</sub> is both known and stable. In order to accomplish this, the inspiratory gas flows must be three to four times the measured minute ventilation (9). The use of high-flow O<sub>2</sub>-delivery systems is indicated whenever there is a need

**Table 1** Low-Flow Oxygen-Delivery Devices, Flow Rates, and F<sub>I</sub>O<sub>2</sub>

Low flow system	Oxygen flow rates (L)	F <sub>I</sub> O <sub>2</sub>
Nasal cannula	1	0.24
	2	0.28
	3	0.32
	4	0.36
	5	0.40
Simple facemask	6	0.44
	5–6	0.40
	6–7	0.50
Partial rebreathing mask	7–8	0.60
	6	0.60
	7	0.70
Nonrebreathing mask	8	0.80
	9	0.80 +
	10	0.80 +
	10	0.80 +
	–15	0.90 +

Note: Predicted F<sub>I</sub>O<sub>2</sub> values for low-flow systems assume a normal and stable pattern of ventilation.

Source: From Ref. 95.

for a consistent and predictable F<sub>I</sub>O<sub>2</sub>, especially in patients with unstable ventilatory patterns.

Conversely, a low-flow system delivers a fixed amount of O<sub>2</sub> to the patient, and entrainment of room air is necessary in order to meet the patient's peak inspiratory-flow rates. In this setting, the F<sub>I</sub>O<sub>2</sub> is variable and unpredictable if the patient has an abnormal or changing pattern of ventilation. If the patient has a stable, normal pattern of ventilation, however, low-flow O<sub>2</sub>-delivery systems can deliver a relatively predictable and consistent F<sub>I</sub>O<sub>2</sub> (Table 1).

It must be understood that use of a low-flow O<sub>2</sub>-delivery system does not imply delivery of low O<sub>2</sub> concentrations. For example, it is possible to calculate the F<sub>I</sub>O<sub>2</sub> for a low-flow system, such as a nasal cannula, if certain assumptions are made as follows: (i) the anatomic reservoir (nose, nasopharynx, and oropharynx) is approximately 50 mL or one-third of the anatomic dead space (150 mL); (ii) the O<sub>2</sub> flow rate is 6 L/min (100 mL/sec) via the nasal cannula; (iii) the patient's respiratory rate of 20 breaths/min results in a one-second inspiratory phase and a two-second expiratory phase; and (iv) there is negligible gas flow during the terminal 0.5 seconds of the expiratory phase, thus allowing the anatomic reservoir to completely fill with O<sub>2</sub>. Using the above assumptions, the F<sub>I</sub>O<sub>2</sub> can be calculated for variable tidal volumes (V<sub>T</sub>) (Table 2). This variability in F<sub>I</sub>O<sub>2</sub> at 6 L/min of O<sub>2</sub> flow clearly demonstrates the effects of a changing ventilatory pattern on F<sub>I</sub>O<sub>2</sub>. In general, the larger the V<sub>T</sub> or the faster the respiratory rate, the lower the F<sub>I</sub>O<sub>2</sub>; the smaller the V<sub>T</sub> or lower the respiratory rate, the higher the F<sub>I</sub>O<sub>2</sub>. With a stable, unchanging ventilatory pattern and O<sub>2</sub> flow rate, low-flow systems can deliver a relatively consistent F<sub>I</sub>O<sub>2</sub>.

### Low-Flow Systems

Low-flow O<sub>2</sub> devices are the most commonly employed O<sub>2</sub>-delivery systems because of their simplicity, ease of use, familiarity, low cost, and patient acceptance. In most clinical situations, low-flow systems are acceptable and even preferable.

**Table 2** Variability in  $F_{I}O_2$  with Low-Flow  $O_2$ -Delivery Systems and Variable Patterns of Ventilation

	$V_T = 500$ cc	$V_T = 250$ cc
Anatomic reservoir	50 cc $O_2$	50 cc $O_2$
Inspiratory phase (1 sec)	100 cc $O_2$	100 cc $O_2$
Entrained room air	350 cc	100 cc
$O_2$ from entrained room air (21% oxygen)	70 cc $O_2$	20 cc $O_2$
Total volume $O_2/V_T$	220 cc/500 cc	170 cc/250 cc
$F_{I}O_2$	0.44	0.68

Source: From Ref. 96.

### Nasal Cannula

The nasal cannula is the most frequently used  $O_2$ -delivery device because of its simplicity and comfort. To be effective, the patient's nasal passages must be patent in order to allow filling of the anatomic reservoir; however, the patient does not need to breathe through the nose. Oxygen will be entrained from the anatomic reservoir even in the presence of mouth breathing. If the  $O_2$  flow rate exceeds 4 L/min, the gases should be humidified to prevent drying of the nasal mucosa. Flow rates greater than 6 L/min will not increase the  $F_{I}O_2$  significantly above 0.44, and are often poorly tolerated by the patient.

### Simple Facemask

A simple facemask consists of a mask with two side ports. The mask provides an additional 100–200 mL oxygen reservoir and will provide a higher  $F_{I}O_2$  than will a nasal cannula. The open ports in the sides of the mask allow entrainment of room air and venting of exhaled gases. **A minimum flow of at least 5 L/min is necessary to prevent  $CO_2$  accumulation and rebreathing during facemask-assisted breathing.** Flow rates greater than 8 L/min will not increase the  $F_{I}O_2$  significantly above 0.6.

### Partial Rebreathing Mask

A partial rebreathing mask (Fig. 1) is similar in construction to the simple facemask, but it also incorporates a 600–1000 mL reservoir bag into which fresh gas flows. The first one-third of the patient's exhaled gas fills the reservoir bag. Because this gas is primarily from the anatomic dead space, it contains very little  $CO_2$ . With the next breath, the patient inhales a mixture of the exhaled gas and fresh gas. If the fresh gas flows are equal to or greater than 8 L/min and the reservoir bag remains inflated throughout the entire respiratory cycle, adequate  $CO_2$  evacuation and the highest possible  $F_{I}O_2$  should occur. The rebreathing capacity of this system allows some degree of  $O_2$  conservation that may be useful while transporting patients with portable  $O_2$  supplies.

### Tracheostomy Collars

Tracheostomy collars are primarily used to deliver humidity to patients with artificial airways. Oxygen may be delivered with these devices, but, similar to other low-flow systems, the  $F_{I}O_2$  is unpredictable, inconsistent, and depends upon the ventilatory pattern.

### High-Flow Systems

Although high-flow systems are more complex, more labor intensive to initiate and maintain, and more expensive,

**Figure 1** Air flow during inspiration and expiration through a partial rebreathing mask. Note the first part of the exhaled gas from the anatomic dead space enters the respiratory bag to be inspired with the next breath. Source: From Ref. 93.

clinical situations in which it is important to deliver a precise  $F_{I}O_2$  require their use.

### Venturi Masks

These masks entrain air using the Bernoulli principle and constant pressure-jet mixing (10). This physical phenomenon is based on a rapid velocity of gas (e.g.,  $O_2$ ) moving through a restricted orifice (Fig. 2). This movement produces viscous shearing forces, which create a subatmospheric pressure gradient downstream relative to the surrounding gases. This pressure gradient causes room air to be entrained until the pressures are equalized. In this manner, flows high enough to meet the patient's peak-inspiratory demands can be generated. As the desired  $F_{I}O_2$  increases, the air-to- $O_2$ -enainment ratio decreases with a net reduction in total gas flow. Therefore, the probability of the patient's needs exceeding the total flow capabilities of the device increases with higher  $F_{I}O_2$  settings. Occlusion of or impingement on the exhalation ports of the mask can cause backpressure and can alter gas flow ("Venturi stall"). In addition, the  $O_2$ -injector port can become clogged, especially with water droplets. Therefore, aerosol devices should not be used with Venturi masks; if humidity is necessary, a vapor-type humidifier should be used. There are two basic types of Venturi systems: (i) a fixed- $F_{I}O_2$  model, which requires specific color-coded inspiratory attachments with labeled jets that produce a known  $F_{I}O_2$  with a given flow, and (ii) a variable- $F_{I}O_2$  model, which has graded adjustments of the air-entrainment port that can be set to allow variation in delivered  $F_{I}O_2$ .

### Nonbreathing Masks

A nonbreathing mask (Fig. 3) is similar to a partial rebreathing mask, but with the addition of three unidirectional valves. Two of the valves are located on opposite sides of the mask. They permit venting of exhaled gas and prevent entrainment of room air. The remaining

**Figure 2** Principle of an air-entrainment device. Pressurized  $O_2$  is forced through a constricted orifice; the increased gas velocity distal to the orifice creates a shearing effect that causes room air to be entrained through the enainment ports. The high flow of gas fills the mask; holes allow both exhaled and delivered gases to escape. Insets (A) and (B) illustrate that the size of the enainment ports (EP) determines the amount of room air to be entrained; OS is the  $O_2$  source. Large ports (A) result in relatively low  $F_{I}O_2$ ; small ports (B) result in relatively higher  $F_{I}O_2$ . For any size EP, the  $F_{I}O_2$  is stable; however, the total gas flow will vary with the pressurized  $O_2$  flow (see text). *Source:* From Ref. 94.

unidirectional valve is located between the mask and the reservoir bag, and prevents exhaled gases from entering the fresh-gas reservoir. As with the partial rebreathing mask, the reservoir bag should be inflated throughout the entire ventilatory cycle in order to ensure adequate  $CO_2$  clearance from the system and the highest possible  $F_{I}O_2$ .

**Figure 3** Air flow during inspiration and expiration through a nonrebreathing mask. Note that all expired gas exits through one-way valves on the sides of the mask and is precluded from entering the reservoir bag by an additional one-way valve. *Source:* From Ref. 93.

To avoid air entrainment around the mask and dilution of the delivered  $F_{I}O_2$ , masks should fit snugly on the face, but excessive pressure should be avoided. If the mask is fitted properly, the reservoir bag should respond to the patient's inspiratory efforts. Unfortunately, if fresh-gas flows and the volume of the reservoir bag are insufficient to meet inspiratory demands, the patient could be compromised. Therefore, masks may be fitted with a spring-loaded tension valve that will open and allow entrainment of room air as needed, to meet inspiratory demands. If such a valve is not present, another option is to remove one of the unidirectional valves that prevent room air entrainment. If the total ventilatory needs of the patient are met by the nonrebreathing system, the system then functions as a high-flow system. If room air entrainment occurs, then a low-flow system is operating.

### Aerosol Mask and T-Piece

An  $F_{I}O_2$  greater than 0.40 with a high-flow system is best provided with a large-volume nebulizer and wide-bore tubing. Aerosol masks, in conjunction with air-entrainment nebulizers or air/ $O_2$  blenders, can deliver a consistent and predictable  $F_{I}O_2$  regardless of the patient's ventilatory pattern. A T-piece is used in place of an aerosol mask for patients with an endotracheal or tracheostomy tube. An air-entrainment nebulizer can deliver an  $F_{I}O_2$  of 0.35 to 1.0, produce an aerosol, and generate flow rates of 14–16 L/min. As with Venturi masks, a higher  $F_{I}O_2$  results in less room air entrainment and lower flow rates. Should a greater total flow be required, two nebulizers can feed a single mask and increase total flow. In addition, large diameter corrugated tubing can be placed on one or both exhalation holes on a standard facemask to serve as  $O_2$  reservoirs, and further decrease the chance of entraining room air. Air/oxygen blenders can deliver a consistent  $F_{I}O_2$  in the range of 0.21 to 1.0, with flows up to 100 L/min. These devices are usually used in conjunction with humidifiers. Oxygen therapy should never be withheld from a patient with respiratory failure for fear of respiratory drive suppression.

## COMPLICATIONS OF OXYGEN THERAPY

### Suppression of Respiratory Drive

When patients who retain  $CO_2$  receive  $O_2$  therapy, they may exhibit a depression in their respiratory drive. The resultant decrease in minute ventilation produces an increase in the  $PaCO_2$ ,  $CO_2$  narcosis, and further depression of the respiratory drive. Oxygen should be administered with caution to patients who retain  $CO_2$ . More recent studies indicate that the increase in  $PaCO_2$  is often due to an increase in  $VD/V_T$  with  $O_2$  therapy, rather than a decrease in respiratory drive. Oxygen therapy should never be withheld from a patient with respiratory failure for fear of respiratory drive suppression.

### Oxygen Absorption Atelectasis

Absorption atelectasis occurs when high alveolar  $O_2$  concentrations cause alveolar collapse. Normally, nitrogen, which is at equilibrium with the blood, remains within the alveoli and "splints" alveoli open. When a high  $F_{I}O_2$  is administered, nitrogen is "washed out" of the alveoli, and the alveoli are filled primarily with oxygen. In areas of the lung with reduced  $\dot{V}/Q$  ratios,  $O_2$  will be absorbed into the blood faster than ventilation can replace it. The alveoli then become progressively smaller until they reach the critical volume at which surface-tension forces cause alveolar collapse. This phenomenon is precipitated primarily by the

**Figure 4** The general relationship between intrapulmonary shunt fractions ( $\dot{Q}_{SP}/\dot{Q}_T$ ) and increasing inspired  $O_2$  concentration ( $F_{I}O_2$ ). The shunt fraction diminishes as the  $F_{I}O_2$  is increased from 0.21 (room air) towards 0.50. This diminution is readily attributed to the decreasing hypoxemic effect of low ventilation-perfusion ( $\dot{V}/\dot{Q}$ ) as the alveolar  $PO_2$  increases. As the  $F_{I}O_2$  is increased from 0.50 toward 1.0, the shunt fraction increases. Broken line depicts what would be anticipated if all low  $\dot{V}/\dot{Q}$  alveoli remained open as the  $F_{I}O_2$  increased. The observed increase in shunt fraction must be attributed to increased zero  $\dot{V}/\dot{Q}$ . *Source:* From Ref. 95.

administration of an  $F_{I}O_2$  greater than 0.5 and is illustrated in Figure 4.

### Oxygen Toxicity

A high  $F_{I}O_2$  can be injurious to the lungs. The mechanism of  $O_2$  toxicity is related to production of  $O_2$  free radicals such as superoxide anions ( $O_2^-$ ), hydroxyl radicals (OH), hydrogen peroxide ( $H_2O_2$ ), and singlet oxygen ( $^1O_2$ ). These radicals affect cell functions by inactivating sulfhydryl enzymes, interfering with DNA synthesis, and disrupting the integrity of cell membranes. During periods of lung-tissue hyperoxia, the normal oxygen-radical-scavenging mechanisms are overwhelmed, and toxicity results (11). The  $F_{I}O_2$  at which oxygen toxicity becomes important is controversial and variable depending upon animal species, degree of underlying lung injury, ambient barometric pressure, and duration of exposure. ⚡ **In general, it is best to avoid exposure to an  $F_{I}O_2$  of 0.5 or greater for more than 24 hours.** ⚡

### AIRWAY CLEARANCE TECHNIQUES

Bronchial hygiene is useful and effective when the patient is carefully evaluated, the goals of therapy are clearly defined, and the appropriate modalities are applied. Normal respiratory secretions include mucus, surfactant, and periciliary fluid. Airway mucus is a secretory product of goblet cells and submucosal glands. It is a nonhomogeneous, adhesive, viscoelastic gel composed of water, carbohydrates, proteins, and lipids. In health, the mucus gel is primarily composed of a three-dimensional tangled polymer network of mucus glycoproteins or mucin.

Airway mucus is moved by three basic mechanisms: slug flow, which describes how airflow may push forward a mucus plug obstructing an airway; annular flow, describing mucus moving along the walls of an airway by expiratory air flow or cilia; and mist flow, describing aerosolized mucus that is exhaled as suspended droplets (12). Mucus transportation can be affected by traumatic lung injury

or damage to the oropharynx or nasopharynx. ⚡ **Disruption of normal secretion or mucociliary clearance impairs pulmonary function and lung defenses, and predisposes the individual to infection.** ⚡

Extensive ciliary damage and mucus hypersecretion render the individual dependent upon airflow-assisted mucus clearance mechanisms such as cough, to maintain airway hygiene (13). Likewise, acute and chronic airway inflammation may lead to ciliary dysfunction and sloughing of the ciliary epithelium, effectively disrupting the "mucociliary elevator" system of mucus clearance. Because the trauma patient may have an impaired cough mechanism due to central or peripheral abnormalities, they may need assistance in mobilizing and expelling retained airway secretions.

### Prophylactic vs. Therapeutic

Prophylactic bronchial hygiene therapy is administered to trauma patients who are essentially free of acute pulmonary pathology, with the intent of preventing inadequate bronchial hygiene. Therapeutic bronchial hygiene therapy is aimed at the reversal of pre-existing inadequate bronchial hygiene, specifically, the mobilization of retained mucus and secretions, and the reinflation of atelectatic lung regions.

### Humidification

⚡ **Humidification of inhaled gases is required to maintain normal respiratory epithelial function.** ⚡ Air inspired through the nose is warmed and nearly 90% humidified by the time it passes through the pharynx. The administration of dry  $O_2$  lowers the water content of the inspired air, and the use of artificial airways bypasses the nasopharynx and oropharynx where the humidification of gases primarily takes place. If adequate humidification of inspired gases is not provided before the gas enters the trachea, the deficit of humidity is provided by moisture from the mucus blanket of the tracheobronchial tree. Thus, both  $O_2$  administration and the use of artificial airways can increase the demands on the lung to humidify inspired gases. If humidification of inspired gases is not appropriately addressed, drying of the tracheobronchial tree, ciliary dysfunction, impairment of mucus transport, inflammation and necrosis of the ciliated pulmonary epithelium, retention of dried secretions, atelectasis, bacterial infiltration of the pulmonary mucosa, and pneumonia may occur. To prevent these complications, a humidifier or nebulizer should be used to increase the water content of inspired gases. Humidification can be accomplished by passing gas over heated water (heated pass-over humidifier); by fractionating gas into tiny bubbles as gas passes through water (bubble humidifiers); by allowing gas to pass through a chamber that contains a heated, water-saturated wick (heated-wick humidifier); or by vaporizing water and selectively allowing the vapor to mix with the inspired gases (vapor-phase humidifier).

A nebulizer increases the water content of the inspired gas by generating aerosols (small droplets of particulate water) of uniform size, which become incorporated into the delivered gas stream and then evaporate into the inspired gas as it is warmed in the respiratory tract. There are two basic types of nebulizers. Pneumatic nebulizers operate from a pressurized-gas source and are either jet or hydronomic; electric nebulizers are powered by an electrical source and are referred to as "ultrasonic." There are several varieties of the above nebulizers, which are more dependent on design differences than on the power source.

### Incentive Spirometry

✎ The incentive spirometer is an effective and inexpensive prophylactic and therapeutic bronchial hygiene tool. ✎ This device provides a visual goal or “incentive” for the patient to achieve and sustain a maximal inspiratory effort. When performed on an hourly basis, this modality provides optimal lung inflation, distribution of ventilation, and improved cough. Thus, atelectasis and the retention of bronchial secretions are minimized. Incentive spirometry can also be helpful in the diagnosis of acute pulmonary pathology, in which a sudden decrease in a patient’s ability to perform at a previously established level may herald the onset of severe atelectasis, pneumonia, or other pulmonary pathology. For incentive spirometry to be effective, the patient must be cooperative, motivated, and well instructed in the technique (by the respiratory therapist, nurse, or physician); the patient should be able to obtain a vital capacity greater than 15 mL/kg or an inspiratory capacity greater than 12 mL/kg; and the patient should not be tachypneic or receiving a high  $F_{I}O_2$ .

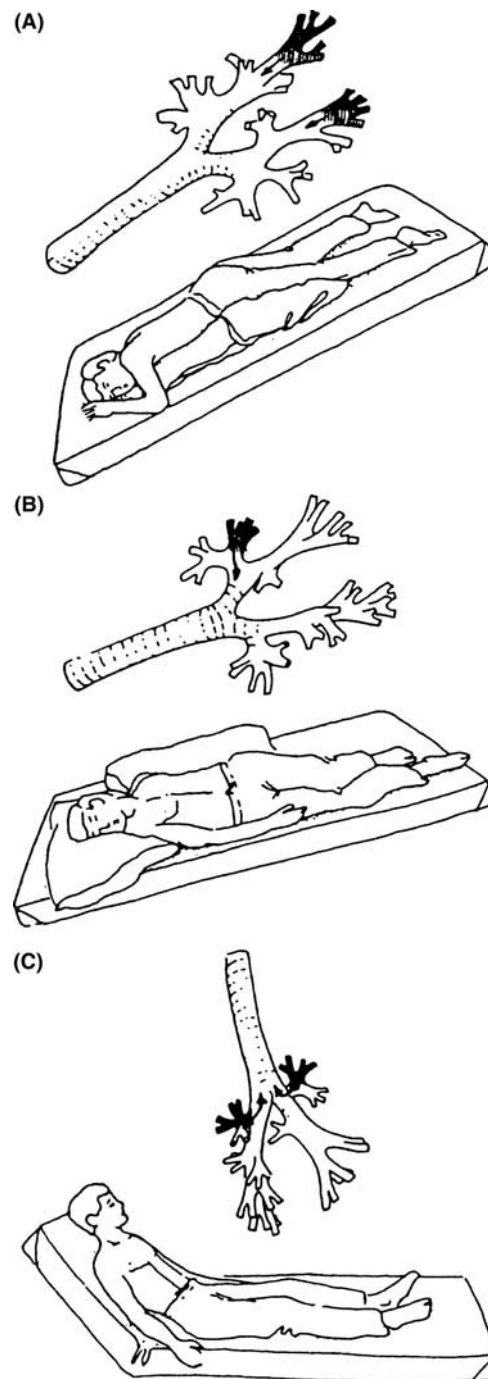

### Chest Physical Therapy

Chest physical therapy (CPT) techniques can be classified into those that promote bronchial hygiene, improve breathing efficiency, or promote physical reconditioning. The CPT techniques considered here will be those concerned with bronchial hygiene. Chronic mucus hypersecretion is associated with a high mortality and a rapid decline in pulmonary function (14,15). In asthma, secretions may worsen  $\dot{V}/Q$  mismatch, and result in more severe or life-threatening exacerbations (16,17). For these reasons, CPT is a valuable tool in combating pulmonary morbidity in trauma patients.

### Postural Drainage

Postural drainage is a technique that uses different body positions to facilitate gravitational drainage of mucus from various lung segments (Fig. 5). Although gravity is not a primary mechanism for normal secretion clearance, it plays a major role in depth and pattern of ventilation, perfusion, and lymphatic drainage (18). Postural drainage improves mobilization of secretions, but requires a considerable investment of time. ✎ The key elements of postural drainage are posture, time, breathing, and cough. ✎ Although postural drainage may be the gold standard to which all other bronchial hygiene techniques are compared, it has limited applicability in victims of trauma except for those who have excessive sputum production, and in spinal cord injured, and/or spine/thoracic trauma where both mobilization and cough are diminished. This is because the viscosity of the normal mucus blanket is such that it does not typically flow into gravity-dependent terminal airways (18). On the other hand, diseases that are amenable to postural drainage therapy include cystic fibrosis, bronchiectasis, COPD, acute atelectasis, and lung abscess, among others.

In hospitalized trauma patients, the basilar lung regions can often benefit from postural drainage, because most hospital bed positions do not permit adequate drainage of these segments. The patient should be positioned so that the affected lung segments are superior to the carina, with each position maintained for 3 to 15 minutes (18). Simply turning the patient may be a primary technique for lung expansion and for matching ventilation with perfusion. When performing postural drainage in unilateral lung disease, the healthier lung should be initially placed down to improve oxygenation and to follow with drainage of the contralateral lung. The reason for this is that

**Figure 5** Common postural drainage positions for (A) posterior basilar segments; (B) middle lobe and lingual; (C) apical segments of upper lobes. *Source:* From Ref. 93.

crosscontamination of the nondiseased lung is always a possibility.

It is also important to avoid inappropriate positioning during postural drainage. Patients with increased intracranial pressure (ICP) or congestive heart failure (CHF) may not tolerate head-down positioning to facilitate drainage of the basilar lung segments. Shifting of abdominal and thoracic contents with gravity in the Trendelenburg position may be deleterious for patients at risk for aspiration with uncontrolled airways, distended abdomens, or recent esophageal injury. Also, it is important to avoid direct pressure on sites

of injury, operations, or burns. The technique has been associated with hypoxemia, bronchospasm, acute hypotension, increased ICP, pulmonary hemorrhage, pain, vomiting, and aspiration (18).

### Percussion and Vibration

☞ **Percussion assists secretion mobilization by loosening adherent secretions and centralizing them for more effective expectoration or easier suctioning.** ☞ External manipulation of the thorax, in the form of percussion and vibration, is used to facilitate the process of postural drainage. Theoretically, percussion assists secretion mobilization by shaking secretions loose, like “shaking ketchup from a bottle” (18). The goal of therapy is to intermittently apply kinetic energy to the chest wall and lung, to loosen and mobilize secretions that adhere to bronchial walls and improve airflow-dependent clearance by moving secretions from the periphery of the lung to more proximal airways, where greater secretion depth and higher expiratory air flow can improve expectoration. Mucus transport by expiratory air flow (including cough) is the primary transport mechanism in patients with pulmonary diseases when mucociliary transport is damaged (19).

Chest percussion is accomplished by rhythmically striking the thorax with cupped hands or a mechanical device placed directly over the lung segment to be drained. Percussion and vibration should be cautiously considered for trauma patients suffering burns, open wounds, skin infections, recent skin grafts, subcutaneous emphysema, recently placed pacemakers, or recent injection of local anesthetic through continuous-infusion epidural catheters. Mechanical percussion devices are available and have some theoretic advantages in that they apply vibratory or percussive forces in a more consistent, uniform fashion, and they are not subject to fatigue. Clinically, however, there is no demonstrable advantage between the two approaches (20).

Vibration normally follows percussion and involves the application of a fine tremorous action that is manually performed by pressing in the direction of the ribs and soft tissue of the chest. Chest vibration is accomplished by placing the hands on the chest wall and generating a rapid vibratory motion in the arms (from the shoulders), and gently compressing the chest wall in the direction that the ribs normally move during exhalation (21–23). Vibrations should be delivered over the draining area during the patient’s expiration for optimal effect.

Overall, percussion and vibration appear to be relatively ineffective, and do not seem to add to the effectiveness of the combination of coughing, breathing exercises, and postural drainage—whereas forced expiratory technique, even without postural drainage, enhances tracheobronchial clearance (18).

### Indications and Contraindications

Indications for the use of CPT are the inability or reluctance of a patient to change body position (i.e., during mechanical ventilation or in paralyzed patients); the presence of segmental atelectasis; physical evidence of retained secretions; and the presence of diseases, such as cystic fibrosis, bronchiectasis, or cavitating lung disease, that result in increased mucus production.

Contraindications to the use of CPT include situations in which proper positioning cannot be safely accomplished, when a patient’s injuries would preclude appropriate

percussion or vibratory maneuvers, or when pre-existing disease processes could be exacerbated during the procedure (23). Specifically, contraindications to the Trendelenburg position include increased ICP; recent neurosurgical procedures; unclipped cerebral-artery aneurysms; uncontrolled hypertension; pulmonary edema associated with CHF; abdominal distension; increased risk for gastroesophageal reflux or aspiration (e.g., esophageal operations, altered airway-protective reflexes, or decreased mental status); ongoing epidural opioid or anesthetic infusions; and recent eye surgery. The reverse-Trendelenburg position is contraindicated for use in patients with hypotension or other hemodynamic instability.

External manipulation of the thorax, such as percussion and vibration, is contraindicated in patients with subcutaneous emphysema; a recent skin graft or myocutaneous flap procedures on the thorax; thermal injuries, open wounds or skin infections of the thorax; flail chest or fractures, osteomyelitis, or osteoporosis of the ribs; soft-tissue injuries to the thorax or complaints of chest-wall pain due to other causes; temporary transvenous pacemakers or recently inserted permanent pacemakers; suspected pulmonary tuberculosis, pulmonary embolism, pulmonary contusions, or a bronchopleural fistula; large pleural effusions or an undrained empyema; increased ICP or other unstable intracranial pathology; unstable spine injuries or recent spine operation; active hemorrhage with hemodynamic instability; severe or uncontrolled coagulopathies; and confused or combative patients who do not tolerate physical manipulation.

Another hazard associated with CPT is the development of hypoxemia during the procedure. In many cases, hypoxemia can be treated by initiating oxygen therapy or increasing the oxygen concentrations during CPT. The decision to use CPT requires that the physician assess potential benefits versus potential risks and limitations. Therapy should be provided for no longer than is necessary to obtain the desired therapeutic results.

### ALTERNATIVE AIRWAY-CLEARANCE TECHNIQUES

In addition to the traditional CPT techniques, alternative airway-clearance methods, such as positive-expiratory-pressure (PEP) therapy, forced-expiratory technique, autogenic drainage (AD), and high-frequency oscillation (HFO), have recently gained support in the literature and are widely used in Europe (21,24–26). These techniques either serve as replacement for the traditional CPT or are used in conjunction with CPT to remove retained secretions and promote aerosol deposition. These techniques focus on controlled breathing and modified coughing techniques, but patients require significant training before they can adequately master the various maneuvers. Patients who actively participate in alternative airway-clearance methods are usually those with long-standing pulmonary processes, such as cystic fibrosis patients who can cooperate and tolerate the maneuvers. ☞ **Trauma patients in the intensive care unit (ICU) or those with long-term pulmonary complications, such as spinal cord injury, severe ARDS, etc., may also be good candidates for treatment with alternative airway-clearance methods.** ☞

HFO of the air column in the conducting airways is designed to facilitate secretion removal in select individuals. A variety of devices are available that generate HFO by

applying forces either at the airway opening or across the chest wall (27). HFO reduces the viscosity of sputum, potentially influencing its clearance by a cough. HFO may also increase the volume of air distal to airways partially obstructed with mucus.

Devices used to administer HFO include the Flutter valve (VarioRaw SA, Scandipharm, Birmingham, Alabama, U.S.A.), which is shaped like a pipe with a steel ball in a “bowl” that is loosely covered by a perforated cap. The weight of the ball serves as an expiratory positive airway pressure (EPAP) device, creating a pressure of approximately 10 cm H<sub>2</sub>O. The shape of the bowl permits the ball to repeatedly move on or off the bowl in a flutter movement, thereby generating oscillations at about 15 Hz (range: 2–32 Hz). The proposed mechanism of action includes a shearing of mucus from the airway wall by oscillatory forces, preventing early airway closure by stabilizing the airways with EPAP. This facilitates the cephalad flow of mucus. Oscillations may decrease mucus viscoelasticity at frequencies and amplitudes achievable with the Flutter device (27).

A pneumatic device called the Percussionator is used to provide intrapulmonary percussive ventilation (IPV). IPV treats diffused patchy atelectasis, enhances mobilization and clearance of secretions, and delivers nebulized medications and wetting agents to the distal airways (27). Patients using this device breathe through a mouthpiece delivering a high flow of “mini-bursts” at rates of >200 Hz. Impaction pressures of 25–40 PSI are delivered with a frequency between 100 to 225 percussive cycles/min.

High-frequency chest wall compression is designed to increase tracheal mucus clearance and improve ventilation by reducing viscoelastic and cohesive properties of mucus. The vest (Advanced Respiratory, St. Paul, Minnesota, U.S.A.) is a device originally designed to promote secretion clearance and, more recently, for sputum induction (27). It is intended for self-administered therapy and consists of a large-volume variable-frequency air-pulse delivery system attached to a nonstretching, inflatable vest worn by the patient over the entire torso. The patient uses a foot pedal to control pressure pulses, during expiration or the entire respiratory cycle. Pulse frequency is adjustable from 5 to 25 Hz, with pressure in the vest ranging from 28 to 39 mmHg.

The Hayak Oscillator is an electrically powered, microprocessor-controlled, noninvasive oscillator ventilator, which applies negative and positive pressures to the chest wall to deliver noninvasive oscillation to the lungs. Frequency range, inspiratory–expiratory ratios, and inspiratory pressures may be adjusted.

### Intermittent Positive Pressure Breathing

Intermittent positive pressure breathing (IPPB) is the application of inspiratory positive pressure to the airway in order to provide a significantly larger tidal volume than the patient can produce spontaneously. IPPB should not be confused with positive-pressure ventilation delivered with a mechanical ventilator, which is intended to provide ventilatory support. It should also not be confused with IPV, a therapeutic technique of CPT that utilizes a pneumatic device called the Percussionator. IPPB is most useful in disease states in which the patient’s depth of breathing is limited. This type of therapy is very expensive; therefore, for this mode of therapy to be indicated, the patient’s vital capacity should be less than 15 mL/kg and the IPPB treatment should augment this volume by at least 100%. In addition, some end point should be planned for the

therapy. The use of IPPB should be limited to those patients with severely compromised respiratory reserves who are suffering an acute illness, or an exacerbation of a chronic condition that causes a temporary deterioration in their overall respiratory state. Patients with more severe and chronic ventilatory-reserve limitations will often require a chronic artificial airway (i.e., tracheostomy) in order to maintain consistent bronchial hygiene.

### Suctioning

Removal of bronchial secretions via suction catheters is a commonly employed bronchial-hygiene technique. Performed appropriately, this procedure is safe and effective. Performed without appropriate caution, it can result in significant complications or death. Airway suctioning can be accomplished safely in patients with artificial airways (endotracheal or tracheostomy tubes) in place. In these circumstances, the patient should be ventilated with a manual resuscitation bag and a high F<sub>I</sub>O<sub>2</sub>. This “preoxygenation/denitrogenation” will minimize the hypoxemia that is induced by removing the patient from an O<sub>2</sub> source and applying suction to the airways. A sterile suction catheter should then be placed into the airway and advanced, without the application of vacuum, beyond the tip of the artificial airway until the catheter can no longer be easily advanced. The catheter should then be withdrawn slightly before suction is applied. Suctioning is then accomplished by the intermittent application of vacuum and the gradual withdrawal of the catheter in a rotating fashion. The duration of the entire procedure should not exceed 20 seconds. Following the completion of suctioning, the patient should be manually ventilated with an O<sub>2</sub>-enriched atmosphere to ensure adequate lung re-expansion and oxygenation. The patient should be monitored for signs of distress, bronchospasm, hemodynamic instability, or dysrhythmias throughout the entire procedure.

In the mechanically ventilated patient whose condition creates concerns of infection, either to the patient or to the healthcare professional who is rendering care, a closed-system suction catheter may be of benefit (28). Unlike open-system suction catheters, the closed-system suction catheters can be reused and physically incorporated into the patient’s ventilator circuit at the connection between the ventilator circuit and the artificial airway. This closed-system suction catheter can also be used when any disconnection from mechanical ventilation or intermittent discontinuation of high levels or PEEP may result in pulmonary compromise.

In the closed system, the catheter itself is shrouded in a protective sleeve that allows the versatility of advancing or retracting the catheter in the patient’s airway without interrupting mechanical ventilation. Although preoxygenation is not as critical with closed-system suctioning, it should still be used. Hypoxemia is best avoided by temporarily increasing the F<sub>I</sub>O<sub>2</sub> to 100% shortly before and during any suction maneuver. When fully retracted, the closed-system suction catheter does not create airway interference or obstruction and can be left in line for extended periods of time, usually 24 to 48 hours, or as determined by an institution’s infection-control policy.

Suctioning of the tracheobronchial tree without an artificial airway in place (i.e., nasotracheal suctioning) is practiced in many centers but carries several risks. Because the patient cannot be manually ventilated and “preoxygenated” before the procedure, hypoxemia and hemodynamically significant arrhythmias can occur (29,30). In addition, passing

the suction catheter through the vocal cords can result in laryngospasm or vocal-cord injury with subsequent airway obstruction. In many patients who have impaired but reasonable ventilatory reserves, this technique is often carried out without significant problems. However, patients with extremely marginal ventilatory reserves are at the greatest risk for the aforementioned complications.

Suctioning of the tracheobronchial tree should only be undertaken when appropriately indicated. The primary indication is the presence of bronchial secretions that can be identified visually or on auscultation. Rising airway pressures in mechanically ventilated patients may also indicate the presence of retained bronchial secretions. Mucosal irritation, trauma, and bleeding can be precipitated by frequent and aggressive suctioning in the absence of bronchial secretions. Routine suctioning of the airway is, however, required in intubated patients including adults, and especially in neonates, where small airways can be acutely obstructed by a small accumulation of secretions.

### Bronchoscopy

♣ **Therapeutic bronchoscopy is indicated for clearance of secretions or when atelectasis persists despite aggressive bronchial-hygiene maneuvers, or for retrieval of aspirated foreign bodies.** ♣

Bronchoscopy can be used for both diagnostic and therapeutic purposes in various clinical settings. In the trauma critical care setting, the indications for bronchoscopy tend to be focused on diagnosing infections, removing retained secretions or foreign bodies, and assessing and controlling hemoptysis. In the ICU, bronchoscopy is often performed on patients undergoing mechanical ventilatory support and necessitates a different approach than that taken with awake, stable, spontaneously ventilating patients. Observations of the patient during bronchoscopy are essential and should be delegated to personnel other than the bronchoscopist or the immediate assistant. It is often best to have a respiratory therapist provide manual ventilation during the procedure and also monitor the patient for adverse physiological effects. Introduction of a bronchoscope into the airways of a mechanically ventilated patient will often result in increased airway pressures, interference with distribution of ventilation, and inhibition of ventilator function. Manual ventilation of the patient by a respiratory therapist during bronchoscopy can be useful, because the therapist can instantly feel changes in airway resistance, alter the pattern of ventilation to compensate for the problem, inform the bronchoscopist that a problem exists, and assist with maneuvers that will alleviate the compromising situation before a deterioration in the patient's condition can occur.

There are several relative contraindications to bronchoscopy, but no absolute contraindications exist. The decision to perform the procedure must be based upon the balance of potential risks and benefits. Considerations that should be taken into account include: (i) the hemodynamic stability of the patient; (ii) the patient's respiratory status, including oxygenation, ventilation, PEEP level, airway pressures, etc.; (iii) the presence of coagulopathies and the potential for their correction or amelioration before the procedure; and (iv) the patient's mental status. Bronchoscopy may be life-saving in the presence of these factors, and should never be omitted if determined to be indicated for emergency clearance of the airway.

Therapeutic bronchoscopy is indicated for clearance of secretions when radiographic studies show evidence of segmental or lobar atelectasis, and the patient's clinical condition requires urgent intervention or when atelectasis is persistent despite aggressive bronchial-hygiene maneuvers (i.e., postural drainage, percussion, and vibration), and is likely to result in detrimental sequelae such as pneumonia or lung abscess. In such circumstances, inspissated bronchial secretions may not be effectively mobilized by any means other than direct visualization, lavage, and manual removal. Therapeutic bronchoscopy is also useful in the retrieval of aspirated foreign bodies. Such foreign bodies may range from particulate food material, which may not be evident on chest radiographs, to any number of inanimate objects. The degree of difficulty encountered with the location and removal of a foreign body depends upon several factors, such as its size, consistency, location, and the duration of time it has been in the bronchial tree. Various foreign-body-retrieval tools (Fig. 6) are designed to be passed through the suction channel of the bronchoscope and grasp or snare objects of various size, shape, and consistency.

The localization and control of bleeding in the airways is one of the most difficult challenges in bronchoscopy for several reasons. Depending upon the severity of the bleeding, visualization is often difficult. One of the risks of bronchoscopy is mucosal injury and its associated additional hemorrhage. Once located, the source of bleeding may not be amenable to control via bronchoscopic techniques. Despite all of these problems, bronchoscopy can be important in obtaining information that is useful in the planning of procedures necessary to further diagnose and control sites of pulmonary hemorrhage, such as localizing the bleeding to a specific lung, lobe, or segment for more rapid angiographic

**Figure 6** (A) Protected bronchial microbiology brush in the retracted position with the protective diaphragm in place. (B) Protected bronchial microbiology brush in the extended sampling position before retraction into the protective sleeve. (C) Foreign-body-retrieval forceps with "teeth." location and intervention. Bronchoscopy is also useful in diagnosis and treatment of retained clots in the airway (31) and for stent placement needed to alleviate bronchial obstruction due to tumor or collapse (32).

In the critical care setting, diagnostic bronchoscopy is useful for the detection and characterization of bacterial and opportunistic lung infections. However, the use of bronchoscopy for the diagnosis of nosocomial pneumonia, especially ventilator-associated pneumonia, is controversial. The methods by which cultures are obtained, the use of quantitative or semiquantitative culture techniques, the threshold of bacterial growth necessary for the diagnosis of pneumonia versus colonization, and the other factors that are most useful in differentiating bacterial colonization from pneumonia in different patient populations, are all debated (33–35).

There are several reasons to perform bronchoscopy for the diagnosis of lung infections. Cultures of endotracheal aspirates may not yield results consistent with the pathologic organism because of oropharyngeal contamination or tracheal colonization. The use of clinical (fever, leukocytosis, and purulent secretions) and radiologic (focal infiltrates) criteria for differentiation of pneumonia from airway colonization is generally limited, especially in intubated patients (33–35). Microbiologic specimens obtained from localized areas of the lung, especially if they include samples of alveolar contents, provide more specific information regarding the pathologic process (36); however, sensitivity and specificity for the diagnosis of pneumonia can be influenced greatly by the type of pathology present, the bronchoscopic technique, and interpretive thresholds (33,37).

Bronchoscopy permits the direct visualization of the airways so that anatomic abnormalities, such as tumors or aberrant bronchial anatomy which can predispose the patient to developing airway obstruction and infection, can be detected. Occasionally, it is important to obtain tissue samples via transbronchial biopsy in order to further elucidate the pathologic process when culture results alone are insufficient.

The diagnosis of lung infections can be accomplished with various bronchoscopic techniques, including protected bronchial brushing, bronchoalveolar lavage (BAL) (protected or unprotected), or transbronchial biopsy. Each of these methods has indications and limitations, which must be considered when planning diagnostic procedures. Protected bronchial brushing is useful for the diagnosis of bacterial pneumonia, because this technique permits the avoidance of contaminated upper-airway secretions and more select sampling of the region of lung of interest. This technique has limitations because the potential for contamination with upper-airway secretions continues, but it is much more likely that positive cultures from the area of the lung in question will be representative of the pathologic process.

The type of protected brush and the methods used to obtain samples will vary, but it is primarily the ability to obtain quantitative cultures (38) that justifies the risks and expense of this procedure. This technique allows the retrieval of 0.001–0.01 mL of lung secretions (39). The level of bacterial growth used to diagnose a ventilator-associated pneumonia with protected bronchial brushing is generally accepted as  $>10^3$  colony-forming units (cfu)/mL (40).

BAL also permits sampling from a specific region of lung and has several added advantages compared to protected bronchial brushing. BAL samples a large area of the distal airways and alveoli, is appropriate for all types of

microbiological diagnoses [bacterial, fungal, *Pneumocystis carinii* (PCP), etc.], and provides a sample volume that is adequate for a large number of tests (35).

BAL can be performed either in a nonprotected or a protected manner. The nonprotected technique involves isolating the bronchus of interest from the remainder of the tracheobronchial tree, by wedging the tip of the bronchoscope into an airway lumen and lavaging with a large-volume (approximately 120–200 mL in 5–10 aliquots) of nonbacteriostatic saline.

One may expect to obtain a return of less than 50% of the lavage fluid that will contain approximately 1 mL of actual lung secretions (35). The first lavage sample is likely to be contaminated with central-airway secretions and is often discarded or treated as bronchial washings (41). **Protected BAL has been developed to decrease the potential contamination of the lavage fluid with secretions contained within the lumen of the bronchoscope.** This technique uses a protected transbronchoscopic balloon-tipped catheter to lavage from the level of third-generation bronchi following expulsion of the protective polyethylene-glycol diaphragm and occlusion of the bronchi with the air-filled balloon (42).

When using BAL, the level of bacterial growth accepted as being consistent with a ventilator-associated pneumonia is  $10^4$  cfu/mL because of dilution of the alveolar secretions (33,40). Some clinicians would use a higher diagnostic threshold ( $10^5$  cfu/mL) with nonprotected BAL, because of the increased chance of sample contamination, and would accept the fact that this threshold will increase the specificity but decrease the sensitivity of the test.

The use of “blind” (nonbronchoscopic), nonprotected BAL in order to monitor and diagnose ventilator-associated pneumonia in trauma patients has been advocated (43). Although this use may be generally appropriate and cost-effective for pneumonia surveillance in this group of patients, the results may be misleading in patients with chronic lung disease or who are immunocompromised. Thus, the patient population must be considered carefully when diagnostic bronchoscopic techniques are chosen.

A special nonbronchoscopic catheter for BAL has been developed and proven to be useful in the diagnosis of PCP (44). This device is also useful in circumstances, such as mechanical ventilation with high PEEP when the risks of bronchoscopy are considered to be too high; however, bleeding and pneumothorax can occur with the use of this device. The use of transbronchial biopsy in the critical care setting is most often not necessary and is frequently contraindicated, especially for patients who are being treated with positive-pressure ventilation.

Bronchoscopy remains a valuable diagnostic tool in these clinical settings: (i) immunocompromised patients (i.e., HIV infected and organ transplant patients), (ii) ventilator-associated pneumonia, and (iii) severe persistent community- or hospital-acquired pneumonia. Fiberoptic bronchoscopy is especially useful in the diagnosis of atypical pneumonia (i.e., cytomegalovirus, *Mycobacterium tuberculosis*, *Pneumocystis carinii*) (37). Again, risks and benefits must be weighed before choosing the diagnostic technique.

The administration of antibiotic therapy before obtaining bronchoscopic bacterial cultures has been shown both to decrease sensitivity (likely due to inhibition of growth) and to decrease specificity (probability due to increased airway colonization) (35). Obviously, the preferred method is to obtain culture samples before instituting antibiotic therapy, but if antibiotics have already been administered,

the only recourse is to interpret the culture results accordingly. When lidocaine is used during bronchoscopy from which bacterial cultures are to be obtained, the lidocaine may inhibit the growth of some microorganisms (45), but this finding has not been noted with lidocaine used in nebulization (35,36).

## AEROSOL THERAPY

An aerosol is a suspension of fine particles of a liquid in a gas. Aerosols have three basic applications in respiratory care: as an aid to bronchial hygiene, to humidify inspiratory gases, and to deliver medications. When dealing with medical aerosols for inhalation, particle size should be 5 mm or less in order for gravitational effects to be sufficiently small to permit deposition in the pulmonary tree (46).

### Bland Aerosol Therapy

When used as an aid to bronchial hygiene, water is one of the most important physically active agents. Aerosol therapy can be useful in the hydration of dried, retained secretions and the restoration and maintenance of the mucus blanket. This hydration, in conjunction with appropriate cough mechanisms and other bronchial-hygiene techniques, will permit the mobilization of retained secretions. Care must be taken, however, because bland (i.e., without medication) aerosols used for these purposes can result in the patient's clinical deterioration due to either increased airway resistance (bronchospasm) or swelling and expansion of dried secretions (47). These detrimental effects may be ameliorated by the administration of a bronchodilator or the use of techniques to mobilize the expanding secretions. Although bland-aerosol therapy is widely used, evidence to support the utility of such therapy is not available (46,48). Generally, it appears that there is a need to reassess the clinical utility of this modality.

The major indication for nebulized saline, either hypotonic or hypertonic, is for induction of sputum specimens. The administration of high-volume aerosolized saline for 30 minutes via a continuous ultrasonic aerosol is appropriate to achieve sputum induction, provided the patient has a strong effective cough and there is sputum in the airways that can be mobilized and expectorated.

Obtaining sputum specimens for the diagnosis of PCP in immunocompromised individuals requires a special procedure. The diagnosis is confirmed by visualization of the organisms in samples of sputum, BAL fluid, or lung tissue obtained on biopsy. Sputum samples should be obtained after the patients have brushed their teeth and rinsed their mouths. The patient inhales an ultrasonic mobilization of 3% sodium chloride through his or her mouth to promote a vigorous cough and produce a sample containing alveolar cells and contents. With this technique, the diagnosis can be obtained in 50% to 80% of patients with PCP due to the acquired immunodeficiency syndrome (AIDS) (49–51). This diagnostic yield may be decreasing in light of current inhaled and systemic antibiotic prophylaxis of PCP.

Complications associated with ultrasonically nebulized aerosols include wheezing or bronchospasm, infection, overhydration, and patient discomfort. Other individuals in the room may be exposed to droplet nuclei of *M. tuberculosis* or other airborne infections produced as a consequence of coughing particularly during sputum induction. The use of sputum induction for diagnostic purposes is only effective

if the patient has a productive cough and is able to produce a "deep specimen" that is not contaminated. Success in obtaining quality sputum specimens is best accomplished early in the morning after the patient has been supine for several hours. In the presence of an effective cough and adequate hydration, which is possible after using an ultrasonic nebulizer for 30 minutes, a patient should, in most cases, successfully mobilize any retained secretions to the level where an adequate specimen can be expectorated, collected, and sent to the laboratory for analysis.

### Aerosolized Medications

The airway mucosa responds to infection and inflammation in several ways. These include goblet cell and submucosal gland hyperplasia and hypertrophy, with resultant mucus hypersecretion. Mucoactive medications either increase the ability to expectorate sputum or decrease mucus hypersecretion. The delivery of medications for the reversal and prevention of bronchoconstriction is an important application of aerosol therapy. PEP and aerosol therapy done simultaneously, either by hand-held nebulizer or metered-dose inhaler (MDI) can improve the response to bronchodilators (52). Table 3 provides data on the most commonly used aerosolized pharmacologic agents.

These medications include  $\beta$ -agonists, anticholinergic agents, and anti-inflammatory agents. The  $\beta$ -agonists and anticholinergic agents act primarily by enhancing bronchodilation through increases in intracellular cyclic adenosine monophosphate levels or decreases in intracellular cyclic guanosine monophosphate levels. The use of anti-inflammatory agents has gained popularity in the treatment of bronchospastic disorders because the disease process has been demonstrated to be of an inflammatory nature.

When delivered in aerosolized form, antibiotic medications, such as pentamidine isethionate and amphotericin B, have been found to be effective for the prophylaxis and treatment of opportunistic pulmonary infections, such as PCP and pulmonary aspergillosis (53–56). Nebulized pentamidine decreases the frequency, severity, and occurrence of PCP in patients with AIDS (57). Pentamidine aerosolization should generate particles with a mass median aerodynamic diameter (MMAD) of less than 3.0  $\mu$ m in order to ensure adequate penetration to the lung parenchyma and to minimize the irritation associated with deposition in the airways. The currently recommended dosage regimen is 300 mg, administered via an ultrasonic nebulizer (Fisoneb<sup>®</sup>) or a jet-type nebulizer (Respigard II<sup>®</sup>) every month (57,58).

Invasive pulmonary fungal infections are significant problems in immunocompromised patients, especially those undergoing bone marrow transplantation during their neutropenic stages. Aerosolization and inhalation of amphotericin B has been investigated as a method to provide prophylaxis against pulmonary fungal infections while minimizing the adverse side effects of the drug (55,59). Aerosolized amphotericin appears to be well tolerated and has minimal systemic absorption (54,60); however, well-controlled outcome data are not available. Aerosolized antibiotic therapy for infections associated with cystic fibrosis has also been explored, but found to be of equivocal efficacy (61).

Ribavirin has been recommended for the treatment of respiratory syncytial virus (RSV) in children, especially those with congenital heart disease, immunodeficiency, or bronchopulmonary dysplasia (61). This drug has also been used in certain immunocompromised adults;

**Table 3** Aerosolized Bronchodilators and Antiasthmatic Drugs

Drug	Method	Adult dosages <sup>a</sup>	Frequency action (hr)	Duration of effects	Intended effect (side effect)	Mechanism
<i>Sympathomimetics</i>						
Albuterol 0.5% (Ventolin <sup>®</sup> , Proventil <sup>®</sup> )	MDI <sup>b</sup> Nebulized	2 puffs (90 µg/puff) 2.5–5.0 mg in 4 mL	q4-6h or qid	≤6	Bronchodilation	β <sub>2</sub> -agonist, increase in cAMP
Isoetharine hydrochloride 1% (Bronkosol <sup>®</sup> )	Nebulized MDI <sup>b</sup>	0.25–0.50 mL in 4.0 mL 2 puffs (10 mg/puff)	q2-4h	1.5–3.0	Bronchodilation (tachycardia)	β <sub>2</sub> -agonist, increase in cAMP
Isoproterenol 0.5% (Isoprel <sup>®</sup> )	Nebulized	0.25–0.50 mL in 3.5 mL	q2-4h	1.5–2.0	Bronchodilation (tachycardia, vasodilation, flushing)	Prototype β-agonist; significant β <sub>1</sub> side effects
Metaproterenol sulfate 5% (Alupent <sup>®</sup> )	Nebulized MDI Rotocaps <sup>®b</sup>	0.3 mL in 4.0 mL 2puffs (0.655 mg/puff) 1–2 capsules (200 µg/cap)	q4-6h or qid	≤5	Bronchodilation	β <sub>2</sub> -agonist, increase in cAMP
Racemic epinephrine 2.25%	Nebulized	0.5 mL in 3.5 mL	q1h, prn	≤1	Mucosal decongestion	Weak β <sub>2</sub> agonist and mild a mucosal vasoconstrictor
Terbutaline 0.1% (Brethane <sup>®</sup> , Bricanyl <sup>®</sup> )	Nebulized	2–5 mg in 2–5 mL	q4-6h	4–6	Bronchodilation	β <sub>2</sub> -agonist
<i>Anticholinergic drugs</i>						
Atropine sulfate 2% or 5%	Nebulized	0.025 mg/kg up to 2.5 mg in 2–5 mL	q6-8h	4–6	Bronchodilation	Cholinergic blocker, decreases cGMP
Ipratropium bromide 0.02% (Atrovent <sup>®</sup> )	MDI Nebulized	2 puffs (18 µg/puff) 0.5 mg in 2.5 mL	q4h or qid tid or qid	3–4	Bronchodilation	Cholinergic blocker, decreases cGMP
<i>Anti-allergy agents</i>						
Beclomethasone acetone (Vancril <sup>®</sup> , Beclvent <sup>®</sup> )	MDI	2 puffs (42 µg/puff)	q6h or qid	6	Anti-inflammatory	Anti-inflammatory; inhibit leukocyte migration; potentiate effects of β-agonists
Cromolyn sodium (Intal <sup>®</sup> )	Nebulized MDI Spinhaler <sup>®b</sup>	20 mg in 2–4 mL 2–4 puffs (800 µg/puff) 1 capsule (20 µg/cap)	q6h or qid	6	Stabilization of mast cell membranes	Suppression of mast cell response to Ag-ab reactions; used prophylactically
Dexamethasone sodium phosphate (Decadron <sup>®</sup> )	Nebulized	1 mg in 2.5 mL	q6h	6	Anti-inflammatory	Anti-inflammatory; inhibit leukocyte migration; potentiate effects of β-agonists
Flunisolide (Aerobid <sup>®</sup> )	MDI <sup>b</sup>	2–4 puffs (250 µg/puff)	bid		Anti-inflammatory	Anti-inflammatory; inhibit leukocyte migration; potentiate effects of β-agonists
Triamcinolone (Azmacort <sup>®</sup> )	MDI <sup>b</sup>	2 puffs (100 µg/puff) 4 puffs (100 µg/puff)	tid–qid bid		Anti-inflammatory	Anti-inflammatory; inhibit leukocyte migration; potentiate effects of β-agonists

<sup>a</sup>Dosages may vary. References to specific drug inserts are recommended.<sup>b</sup>Rotocaps and Spinhaler = inhaled powder.

Abbreviations: Ag-ab, antigen-antibody; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; MDI, metered dose inhaler.

however, because of the high expense of treatment and the rarity of severe RSV infections in adults, the diagnosis of RSV infection should be confirmed with rapid laboratory testing before commencing therapy.

The U.S. FDA has recommended the "Small Particle Aerosol Generator" (SPAG) for aerosolization of ribavirin for the treatment of RSV in children, but SPAG may also be used for adults if such therapy is deemed appropriate. The SPAG system will generate particles with a MMAD of less than 1.5  $\mu\text{m}$ . The delivery of bronchodilators and antibiotics, and the use of aerosolization, are being investigated as means by which to deliver other drugs, such as insulin (62), that otherwise require chronic parenteral administration.

Unfortunately, a high incidence of bronchospastic reactions is associated with the administration of aerosolized antibiotics and other medications. These reactions necessitate either pretreatment or concurrent treatment with an aerosolized  $\beta$ -agonist. In addition, these agents potentially have toxic effects for healthcare-delivery personnel who are administering the treatments; therefore, appropriate exhaust, scavenging, or filtering systems should be used during administration of the treatments.

### Small-Volume Nebulizers, Metered-Dose and Dry-Powder Inhalers

The delivery of medications via small-volume nebulizers (SVN) has historically been the standard for aerosol-medication delivery. Small and relatively easy to use, the SVN does require a gas source that can produce a flow of 5–10 mL/min. Optimal gas-source flow settings and specific design characteristics of a particular SVN are variables that determine aerosol particle size. As such, this method of drug delivery is expensive and potentially inefficient (63) and requires a significant time commitment on the part of the respiratory therapist.

Recent variations in the SVN design that incorporate a reservoir bag to collect and suspend aerosol particles of desired therapeutic size, and the addition of a PEP valve to promote better aerosol deposition, have been engineered to improve SVN efficiency. Advocates of these design changes suggest that the result is better aerosol-particle size, less systemic absorption of medication, and more medication targeted and deposited to the airways; however, no published clinical studies have supported this claim.

A functional alternative to the SVN is the MDI. The MDI is a device that permits the patient to rapidly self-administer an inhaled drug. The delivery of drug to the lower airways, with appropriate use of the MDI, has been demonstrated to be approximately 10% of the total dose and is comparable to that attained with the SVN (64–66). However, in contrast to the SVN, with which 66% of the drug is deposited in the apparatus and 2% is deposited in the mouth and stomach, MDI administration results in only 5% to 10% of drug deposition in the apparatus, with 80% deposited in the mouth and stomach (64,67). This factor carries implications pertaining to local side effects and tissue toxicity (i.e., oral thrush associated with inhaled-steroid use) (64).

✎ In terms of clinical effects, no differences between MDI and SVN therapy have been found for peak expiratory-flow rates or severity of symptoms in stable patients treated with either modality (68). ✎ In addition to having clinical efficacy equal to that of SVN devices, administering bronchodilator therapy with MDI devices requires less manpower and offers significant cost savings to the hospital (69).

Studies suggest that there can be a substantial benefit from the increased use of MDI with spacer and a percentage of patients can replace SVN with MDI using a spacer device (70,48,49,71). The effective use of an MDI requires that the patient meet certain clinical criteria. The patient must be able to appropriately position and actuate the device, inspire deeply, and coordinate the inspiratory effort with the device actuation.

In order to ensure efficacious use, a successful coordination of efforts is necessary, which requires appropriate instruction, training, and practice (72). Problems with proper technique are especially pronounced with patients who are either young or elderly (73). In order to ameliorate some of the problems associated with MDI use, "spacer devices" have been developed (74). A spacer effectively acts as a reservoir into which the drug is discharged by attaching and actuating the MDI device (Fig. 7). The use of spacer eliminates the need for significant coordination of hand, mouth, and breathing functions and improves delivery of the drug to the airways.

A breath-activated variation to the MDI is the Autohaler<sup>®</sup>. This device addresses concerns related to particle deposition and coordination issues inherent to the use of conventional MDI devices (75). Objectively comparing the conventional MDI devices and the Autohaler is difficult, because the Autohaler is limited to use with one drug (pirbuterol acetate) in the United States. As do conventional MDI devices, the Autohaler uses chlorofluorocarbons (CFC) as a propellant, a factor that is of environmental concern and strictly regulated by the government. A comparison of therapy with an MDI-spacer system versus SVN treatments indicated that a greater spirometric response was initially obtained with SVN, but this response

**Figure 7** Illustration of a spacer with a metered-dose inhaler (MDI). (A) Demonstrates the aerosol suspension dispersing equally in the gas volume within the spacer following ejection from the MDI. (B) The patient takes a deep, slow inhalation of the medication. *Source:* From Ref. 93.

equalized over time to hospitalization (76). A study comparing MDI versus SVN delivery of albuterol in mechanically ventilated patients indicated equal clinical responses in both groups (77). In light of such information, it is reasonably clear that SVN administration of bronchodilators should be reserved for those patients who are unstable or otherwise incapable of using an MDI device. Patients can be assigned to MDI-spacer therapy if they meet the following criteria (78):

1. Respiratory rate <25 breaths/min.
2. Ability to breath-hold for 5 seconds or more.
3. Vital capacity >15 mL/kg.
4. Ability to understand verbal and visual instructions.
5. Appropriate hand-mouth-inspiratory coordination.
6. Peak expiratory flow rates of 150 mL/min for females and 200 mL/min for males.

Patients should be instructed in MDI-spacer use by a properly trained respiratory therapist. Before patients completely switch to this device, their technique should be evaluated, and additional training should be given if necessary.

Delivery of bronchodilators to patients undergoing mechanical ventilation can be effective but is also problematic. The use of an SVN to deliver bronchodilation during mechanical ventilation can result in bacterial contamination of the ventilator circuit, alteration in the delivered  $V_T$ , increased work of breathing during patient-initiated modes of ventilation, and damage to flow-measurement devices incorporated into some ventilator circuits (79). In addition, administration of aerosols via an endotracheal tube will reduce penetration to the lower airways (80). MDIs, in conjunction with mechanical ventilatory supports, have been evaluated for use in delivery of bronchodilators and have been shown to be comparable to SVN delivery systems—without the associated problems (79).

The use of MDI devices with spacers has undergone nonclinical bench testing with evidence of increased aerosol delivery; however, trials to document an improvement in clinical response are not yet available (73). Improved aerosol delivery can also be accomplished by adapting a nozzle-extension system to the MDI and extending the nozzle tip beyond the end of the endotracheal tube (81,82). Again, clinical studies to support the improved efficiency of this method of aerosol delivery are lacking, and the results of animal studies indicate that tracheal epithelial injury may occur when this system is used (73,83).

Another method of inspired-drug delivery is the dry-powder inhaler (DPI). DPIs create aerosols by drawing air through an aliquot of dry powder. The powder contains either micronized (<5  $\mu\text{m}$  in diameter) drug particles bound into loose aggregates or micronized drug particles that are loosely bound to large (>30  $\mu\text{m}$  in diameter) lactose or glucose particles (1). Patients using a DPI must be able to generate an inspiratory flow rate of greater than 30 to 60 L/min to be effective, and DPIs are not recommended for patients in acute bronchoconstriction or for children under the age of six years. DPIs are recommended for prophylactic and maintenance therapy because of the inspiratory flow requirements (84). These devices have two major advantages over SVN or MDI devices: they are activated by the patient's inspiratory effort and, therefore, do not require a high degree of hand-mouth-inspiratory-effort coordination, and they do not use fluorocarbon propellants.

This drug-delivery method appears to have equal efficacy compared to MDI and SVN delivery systems (64). The

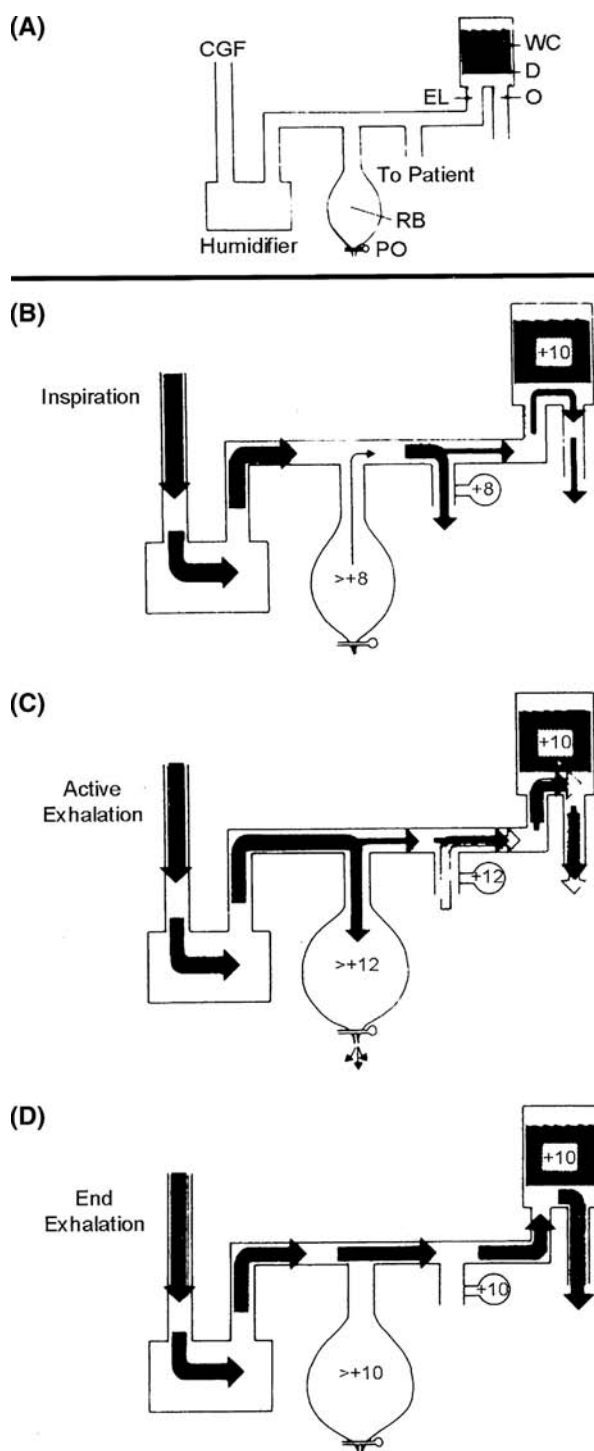

use of these devices may increase as the concern for environmental protection results in the elimination or severe restriction of CFC propellants (46). Although patients can find DPIs more convenient and easier to use than MDIs, one report suggests that as many as 25% of patients may use DPIs improperly (46). Clinicians must understand the required technique involved with DPIs and provide the necessary instruction and periodic review of technique, for patients to receive the benefits of medication delivery utilizing a DPI (47,48,70).

## CONTINUOUS POSITIVE AIRWAY PRESSURE

Positive airway pressure has been used since the 1930s to improve oxygenation, increase lung volumes, and reduce venous return. More recently, continuous positive airway pressure (CPAP) has been identified as an effective method of splinting airways during expiration, improving collateral ventilation, increasing response to inhaled bronchodilators, and aiding secretion clearance in patients with various lung disorders. CPAP bronchial hygiene techniques may be effective alternatives to CPT for expanding lungs and mobilizing secretions (52). CPAP therapy may be more effective than spirometry and IPPB in the management of postoperative atelectasis (86). CPAP is the application of positive airway pressure during both inspiration and expiration, during spontaneous breathing. A typical continuous-flow CPAP system includes a medium-volume, high-compliance reservoir bag (5–10 L) and maintains system flow in excess of the patient's peak inspiratory flow demands (Fig. 8). Characteristically, system-continuous flows are maintained at 60–90 L/min. The adequacy of continuous flow is evaluated by observing gas continuously exiting from the system, even during peak inspiratory-flow periods. A system-pressure manometer and, ideally, an  $\text{O}_2$  analyzer should be included in all CPAP circuits. A threshold resistor is located on the expiratory limb of the pressurized circuit. Finally, a pressure pop-off valve is included in all systems to prevent excessive pressure (such as occurs with system obstruction or when the patient coughs with a high-flow resistance or PEEP device) from building up in the system. With all circuits, some fluctuations in system pressure are noted, with the acceptable range being about  $\pm 2$  cm  $\text{H}_2\text{O}$ . Fluctuations of greater magnitude during inspiration may be corrected by increasing system flow, increasing the size of the circuit reservoir, or increasing the flow and the size of the reservoir. Changes in baseline pressures during exhalation are primarily affected by the flow-resistance properties of the PEEP device.

CPAP, applied by full-face mask or nasal mask, has been used for respiratory support in patients with various types of pulmonary pathology, ranging from CHF to obstructive sleep apnea. The primary respiratory effects of CPAP are that it increases functional residual capacity; improves distribution of ventilation, lung compliance, and oxygenation; and decreases work of breathing. CPAP applied with a nasal mask is more comfortable, often better tolerated, and allows the patient to communicate more effectively than does CPAP applied with a full-face mask. Additionally, should vomiting occur, nasal-mask CPAP does not present an obstacle to airway clearance. However, in severely hypoxemic patients, nasal CPAP may not permit a seal sufficient to sustain the airway pressure necessary to maintain oxygenation. Conditions in the trauma patient, such as sinusitis, ear infection, epistaxis, or recent facial, oral or skull injury, should be individually

**Figure 8** (A) Schematic representation of a continuous positive airway pressure device. The continuous gas flow must be great enough to force some gas to continuously enter the reservoir bag except during peak inspiratory flow. Through adjustment of the pop-off mechanism, the pressure in the bag is maintained equal to or greater than the threshold pressure. Thus, gas will always flow through the outlet port of the PEEP device. Note that the patient's airway pressure fluctuates no more than  $\pm 2$  cm H<sub>2</sub>O of the threshold pressure. (B) Inspiration: most of the gas flow will enter the patient's airway without added impedance, whereas the remainder of the gas flows through the outlet port of the PEEP device. Note that at the moment of the patient's peak inspiratory flow, there may be a small amount of gas entering the patient from the reservoir bag. (C) Active exhalation: airway pressure is greater than threshold, causing more of the continuous gas flow to enter the reservoir bag. The increased expiratory flow may create increased pressure if the PEEP device has orificial resistor properties and thus increases the work of breathing. (D) End exhalation: the continuous gas flow and reservoir bag maintain the circuit pressure at the threshold pressure. *Abbreviations:* CGF, continuous gas flow source; D, diaphragm of the PEEP device; EL, exhalation line of the patient circuit; OP, outlet port of the PEEP device; PEEP, post end expiratory pressure; PO, pop-off mechanism, which is an open nipple with an adjustable clamp; RB, elastic reservoir bag; WC, water column determining the threshold pressure of 10 cm H<sub>2</sub>O. *Source:* From Ref. 93.

evaluated prior to considering a decision to initiate this therapy. Those with hemoptysis or unresolved pneumothorax are not candidates for this treatment modality (52).

Biphasic-airway-pressure (BiPAP) therapy is effectively the combination of CPAP with pressure-support augmentation of spontaneous inspiration. This method permits mechanical support of spontaneous ventilatory efforts without the need for intubation. This method of “noninvasive” ventilatory support has been demonstrated to be efficacious in patients demonstrating hypoxemia, hypercapnia, or hypercapnia and hypoxemia due to COPD, CHF, ARDS, and PCP (86–88). Although pressure injury to the nose has been reported with the use of biphasic airway pressure, the potential complications of gastric distention and aspiration do not appear to be significant. Of course, this mode of ventilatory support would not be appropriate for patients with a compromised ability for airway protection or glottic pathology (i.e., supraglottitis, thermal injury, or laryngeal edema). Additionally, patients must be observed carefully to ensure that the device does not become displaced and that spontaneous ventilation continues.

🐉 **BiPAP therapy combines CPAP with a pressure-support augmentation of spontaneous inspiration.** 🐉

## EYE TO THE FUTURE

Impaired mucus clearance or mucus hypersecretion have potentially grave consequences for the individual. Aside from discomfort and dyspnea, excess mucus in the airway may lead to airway obstruction, atelectasis, infection, bronchiectasis, and other pulmonary morbidity (83). Concepts regarding airway secretion clearance are continuing to evolve. Included in any discussion of these evolving techniques is ultra-low-frequency airway oscillation, also known as the Insufflator/Exsufflator. This device, admittedly not newly developed, may be uniquely suited to assist in airway clearance in trauma victims, as well as in those individuals who have neuromuscular weakness and other infirmities. It may prove to be a valuable adjunctive measure when added to postural drainage and lung expansion therapy. Other new modalities include AD, active cycle of breathing technique, PEP methods, high-frequency airway oscillation (flutter), high-frequency chest-wall oscillation (The Vest), and IPV. Patient motivation and understanding of the disease process may greatly affect outcomes when utilizing devices such as these. The greatest challenge may be in educating our patients in the relative risk-benefit and alternative paradigms of care available to them.

## SUMMARY

The practice of respiratory care has always been integral to the practice of critical care medicine. The advancements of technology and medical science have made this role even more important, but, also more complex and difficult. These advancements require appropriate training and understanding of the equipment now used to deliver state-of-the-art respiratory care. Also, the complexity of patients requiring critical care necessitates the inclusion of individuals capable of making complicated clinical assessments and decisions. The complexity of this situation will only increase as medical science advances. Therefore, the training and capabilities of respiratory care practitioners must advance to keep pace with these changes.

## KEY POINTS

- 🐉 The three major reasons for mixed venous blood to have low O<sub>2</sub> content include: (i) metabolic rate; (ii) ↓ O<sub>2</sub> delivery; and (iii) ↓ arterial O<sub>2</sub> content.
- 🐉 The primary determinants of oxygen content are the Hgb concentration and the degree of Hgb saturation.
- 🐉 Nonrebreathing systems are divided into high-flow (fixed performance) and low-flow (variable performance) systems.
- 🐉 Flow rates greater than 6 L/min will not increase the F<sub>I</sub>O<sub>2</sub> significantly above 0.44 and are often poorly tolerated by the patient.
- 🐉 A minimum flow of at least 5 L/min is necessary to prevent CO<sub>2</sub> accumulation and rebreathing during facemask-assisted breathing.
- 🐉 In general, it is best to avoid exposure to an F<sub>I</sub>O<sub>2</sub> of 0.5 or greater for more than 24 hours.
- 🐉 Disruption of normal secretion or mucociliary clearance impairs pulmonary function and lung defenses, and predisposes the individual to infection.
- 🐉 Humidification of inhaled gases is required to maintain normal respiratory epithelial function.
- 🐉 The incentive spirometer is an effective and inexpensive prophylactic and therapeutic bronchial hygiene tool.
- 🐉 The key elements of postural drainage are posture, time, breathing, and cough.
- 🐉 Percussion assists secretion mobilization by loosening adherent secretions, and centralizing them for more effective expectoration or easier suctioning.
- 🐉 Trauma patients in the ICU or those with long-term pulmonary complications, such as spinal cord injury, severe ARDS, etc., may also be good candidates for treatment with alternative airway-clearance methods.
- 🐉 Therapeutic bronchoscopy is indicated for clearance of secretions or when atelectasis persists despite aggressive bronchial-hygiene maneuvers, or for retrieval of aspirated foreign bodies.
- 🐉 Protected BAL has been developed to decrease the potential contamination of the lavage fluid with secretions contained within the lumen of the bronchoscope.
- 🐉 In terms of clinical effects, no differences between MDI and SVN therapy have been found for peak expiratory-flow rates or severity of symptoms in stable patients treated with either modality (68).
- 🐉 BiPAP therapy combines CPAP with a pressure-support augmentation of spontaneous inspiration.

### INTRODUCTION

The ability to provide mechanical ventilation (MV) is the cornerstone of critical care medicine. More than 50 years of clinical experience with MV has shaped current understanding of the four fundamental relationships involved in an MV breath (time, pressure, volume, and flow). These factors affect more than merely MV, as manipulation of these values will affect both oxygenation and CO<sub>2</sub> elimination, but also affects patient comfort, secondary lung injury, ventilator-associated pneumonia (VAP), and hemodynamic stability.

Despite the one half century of experience with MV, controversy exists regarding many aspects [e.g., benefit of high-frequency ventilation (HFV), inverse ratio, pressure control ventilation, proning, permissive hypercapnia, etc.]. The controversy results from the paucity of randomized controlled trials (RCTs) investigating MV, the variety of patients and disease processes requiring MV, the plethora of ventilators and modes available, as well as the confusing and inconsistent terminology.

### HISTORY

Although the scientific basis of oxidative metabolism was not established until the 1900s, ancient Egyptian, Chinese, and Greek medical papyri provide evidence that physicians in early civilizations understood the need for air to move into the airway to sustain life. Indeed, an engraving of the tracheostomy procedure was chiseled into Egyptian tablets dating back to 3600 B.C. (1). The earliest known textual references to tracheostomy are found in the *Rigveda*, a sacred Hindu book, published around 2000 B.C. (1). Hippocrates (460–370 B.C.) is quoted in his corpus to have said: “Whoever wishes to investigate medicine properly, should consider the pulsations of veins and breathing of the lungs according to age, harmonious and inharmonious, signs of disease more than health, for breath too is nutrient.” Furthermore, in his “Treatise on Air,” Hippocrates may have provided the first written description of endotracheal intubation when he instructed that: “One should introduce a cannula into the trachea along the jawbone so that air can be drawn into the lungs” (2).

Aristotle (384–322 B.C.) demonstrated the essential requirement of fresh air for the maintenance of life when he showed that animals placed in airtight boxes perished. Although his deduction on the cause of death (that the animals died due to their inability to cool themselves) was incorrect, he established that fresh air was required to sustain life. The first written account of mouth-to-mouth resuscitation is attributed to the prophet Elisha in the Old Testament (~800 B.C.), though the mechanism of resuscitation was attributed to divine intervention.

Galen (130–200), surgeon to the gladiators of Pergamos and later physician to the emperor Marcus Aurelius, performed vivisection and understood the role of the airway as a conduit to move air into the lungs, as evidenced in his writings: “If you take a dead animal and blow air through its larynx (using a reed), you will fill its bronchi and watch its lungs attain the greatest dimension” (3). However, Galen incorrectly deduced, and others were wrongly taught for over 1500 years that the function of the lungs was to cool the heart.

Andreas Vesalius (1514–1564) published an anatomically correct sequel to Galen’s writings, in his opus “*De Humani Corporis Fabrica*, 1543” in which an ornate wood cutting depicts a group of cherubs performing a tracheostomy on a sow. Vesalius is credited with popularizing the notion that resuscitation is possible when he introduced a reed into a dying animal’s trachea and through the intermittent application of positive pressure ventilation, successfully restored its heartbeat (4). In *Fabrica*, he wrote: “But that life may be restored to the animal, an opening must be attempted in the trunk of the trachea, into which a tube of reed or cane should be put; you will then blow into this, so that the lung may rise again and take air.”

In 1530, Paracelsus (1493–1541) experimented with lung function using a fire bellows connected to a tube inserted in a patient’s mouth as a ventilation device (4). Interestingly, William Harvey (1578–1657) solved the riddle of the circulation, but never went on to clearly speculate on the importance of respiration. Harvey did, however, cite references from Galen and others that addressed respiration in the incomplete and inaccurate fashion that was understood at the time.

Robert Hooke (1635–1703) became interested in establishing the cause of death that results when the thorax is opened to atmospheric air (5). He experimented with dogs

and found that he was able to sustain an animal's life by using a fire bellows connected to an opening in the trachea. Hooke presented his results to the Royal Society of England in 1667. However, his technique would not be applied to human surgery until nearly two centuries later (5).

In 1744, John Fothergill of England reported a successful incident of mouth-to-mouth resuscitation. In 1767, the Dutch formed the "Society for the Rescue of Drowned Persons" later known as the "Human Society" (also see Volume 1, Chapter 1). One of the more progressive techniques was to keep the victim warm, give mouth-to-mouth breathing, and compress the chest and stomach to assist exhalation (4). Although there was no apparent focus or intention to increase inhalation, these maneuvers did have this effect.

In 1775, John Hunter of London developed a double bellows system for resuscitation: one for blowing air in and the second for drawing the "bad air" out. He also recommended the use of finger pressure over the larynx to help prevent gastric inflation with air. This maneuver predated the description attributed to Sellick (6) by 200 years. This technique was adapted for patient use by the Royal Humane Society in 1782.

In 1911, Dräger designed an artificial breathing device that fire and police units used for resuscitation. The Dräger "Pulmotor" held the head of the victim in the head-tilt position. Pressure by the operator on the cricoid cartilage (as described by John Hunter) helped prevent gastric inflation (4).

From the mid-1800s to the early 1900s, an incredible number of ventilator assist devices were invented that applied negative pressure (pressure below ambient) around the body (7). Cuirass is a French word, which was used to describe the part of a suit of armor that covered the front of the chest. It has also come to mean a type of negative pressure ventilator that covers the anterior thorax and sometimes the abdomen as well. In Austria, Hungary, and the United States, Ignaz von Hauke (1874), Rodolf Eisenmenger (1901), and Alexander Graham Bell (1882), respectively, constructed various early models of chest cuirass-negative pressure ventilators. The first really successful negative pressure ventilator was designed in 1928 by Engineer Philip Drinker, physiologist Louis Agassiz Shaw, and Dr. Charles F. McKhann at the Department of Ventilation, Illumination, and Physiology of the Harvard Medical School (8).

The use of endotracheal intubation and MV in the operating room (OR) was used sparingly after the introduction by Jackson, but accelerated after 1934 when Gudel (9) popularized the use of a cuffed endotracheal tube (ETT) (see Volume 1, Chapter 1) and controlled ventilation during anesthesia, facilitating operations on the upper abdomen and also making possible open chest thoracic procedures. But the skills of anesthesiologists in providing positive pressure ventilation via tracheostomy or translaryngeal intubation were virtually unknown outside the walls of the OR. The tank respirator ("iron lung") or cuirass respirator were the only ventilators available for use on patients with respiratory failure due to polio. Other patients with respiratory failure severe enough to require intubation and MV simply did not survive.

The Copenhagen polio epidemic of 1952 provided the setting for the union for the expertise of anesthesiologists (with their knowledge of cardiopulmonary physiology) and the need for widespread MV. This need served as the birth of the specialty of critical care medicine.

From August to December of 1952, over 2200 patients with the documented diagnosis of polio (345 with respiratory failure) were admitted to the Blegdam Infectious Disease Hospital in Copenhagen. At the beginning of the

epidemic, only one tank respirator and six cuirass respirators were available at this hospital. After 27 of the first 31 patients with respiratory failure died, Dr. H.C.A. Lassen (chief physician of Blegdam Hospital) asked an anesthesiologist, Dr. Bjorn Ibsen, for consultation to determine whether positive pressure ventilation used during anesthesia might be of benefit (10).

Almost overnight, the management of choice for polio became tracheostomy with cuffed ETT and manual ventilation using an anesthesia bag and a to-and-fro system fitted with a CO<sub>2</sub> absorber. At the height of the epidemic, the medical schools in Copenhagen were closed and up to 250 medical students took daily shifts to hand ventilate the tracheotomized polio victims. At the end of the epidemic, valved systems without CO<sub>2</sub> absorbers were employed and a number of manufacturers modified their OR ventilator machines (previously only used in surgery) for use as long-term positive pressure ventilators.

Several North American anesthesiologists visited Denmark during the epidemic and news of the Copenhagen experience spread rapidly. It was soon recognized that the techniques used to treat the polio victims could be applied to respiratory failure due to other ailments (drug overdose, tetanus, myasthenia gravis, etc.). This recognition led to the opening of the first respiratory intensive care units (ICUs). Subsequently, surgical intensive care units (SICUs) developed as a natural progression for patients who were ventilated postoperatively in the recovery room. Ventilating patients outside of the OR for prolonged periods, for other processes began as well (e.g., pulmonary contusions, various traumatic injuries) which caused a paradigm shift in thinking. All of these factors served as the impetus to create the first respiratory ICUs.

The founding fathers of critical care medicine in North America were these same anesthesiologists who spread the lessons learned from the Copenhagen experience, and who were attending in large teaching programs. Indeed, several well-known anesthesiologist-intensivists opened the first ICUs in North America including Safer (11) in Baltimore, Fairley (12) in Toronto (later at San Francisco General Hospital and Stanford), and Pontoppidan and Bendixen (13) at Massachusetts General Hospital, then at UCSD (later at Columbia).

Dr. Bendixen was recruited to UCSD in 1969 to run the newly established department of anesthesiology. He in turn was responsible for the recruitment of pulmonary physiologists Eric Wahrenbrock, Jonathan Benumof, along with past editor of *Anesthesiology*, Larry Saidman, to the department of anesthesiology at UCSD.

These pioneering respiratory physiologists collaborated with others at UCSD, such as John B. West and Peter D. Wagner, to shape the thinking about both the research and the teaching of pulmonary physiology for decades to come. Since then, many leaders in pulmonary physiology, airway management, and MV have contributed new ventilator modes and strategies for patient care. These investigators continue to push the threshold of knowledge forward. The fruit of their labors are reviewed in this chapter.

## INDICATIONS FOR MECHANICAL VENTILATION

Indications for MV are distinct from indications for intubation (see Volume 2, Chapter 9). The two most basic

**Table 1** Indications for Mechanical Ventilation

Hypoxic respiratory failure	Hypercapnic respiratory failure
Low $F_{I}O_2$ (i.e., high altitude)	Spinal injury, denervation injury (i.e., spinal cord transection, phrenic nerve injury)
Hypoventilation (i.e., flail chest, opioids)	Respiratory center depressants (i.e., opioids, anesthetics, CNS injury)
$\dot{V}_A/\dot{Q}_t$ mismatch (i.e., hypovolemia, hyperinflation)	Neuromuscular disease (i.e., myasthenia gravis)
Shunt $R \rightarrow L$ ( $\dot{Q}_s/\dot{Q}_t$ ) (i.e., pneumothorax, pulmonary contusion)	Myopathy (i.e., critical illness myopathy)
Diffusion abnormality (i.e., ARDS, pulmonary edema)	Pleural cavity (i.e., hemothorax, pleural effusion)
Anemia (i.e., hemorrhage)	Abdominal compression (i.e., ascites, surgical packing)
Low cardiac output (i.e., ischemia, tamponade)	COPD (i.e., COPD exacerbation, status asthmaticus)
Histocytic hypoxia (i.e., cyanide poisoning)	Chest wall (i.e., flail chest, splinting)

*Abbreviations:* ARDS, acute respiratory distress syndrome; CNS, central nervous system; COPD, chronic obstructive pulmonary disease;  $F_{I}O_2$ , fraction of inhaled gas due to oxygen;  $\dot{Q}_s/\dot{Q}_t$ , transpulmonary shunt/total cardiac output;  $R \rightarrow L$ , right to left.

indications for MV include (i) conditions where the patient is unable to oxygenate the blood without a very high  $F_{I}O_2$  and/or elevated continuous positive airway pressure (CPAP), and (ii) conditions where the patient is unable to do the work of breathing without MV (Table 1) (11–14).

## VENTILATOR TYPES

☞ Ventilators can be categorized into two major types: (i) negative pressure, and (ii) positive pressure ventilators. ☞ This section reviews the differences between positive and negative pressure ventilators.

### Negative Pressure

Negative pressure ventilators, such as the “iron lung” or the chest cuirass, were known since the turn of the last century. The operational mechanism of negative pressure ventilators involves the development of negative extrathoracic pressure, which expands the chest wall and in so doing, initiates flow of gas into the lungs. Exhalation occurs when the pressure inside the iron lung increases, transmitting positive pressure to the external chest and abdomen.

This technology is suitable for patients who are unable to breathe due to skeletal muscle paralysis or weakness, but possess otherwise normal lung parenchyma and function. In this situation, when the lung parenchyma and airways are essentially normal and chest wall compliance is normal, iron lung ventilation is satisfactory. However, negative pressure ventilation has the following disadvantages compared to positive pressure ventilation: (i) airway protection

relies solely on the patient’s reflexes; (ii) when the lungs and chest wall are noncompliant, massive pressures are required to promote airflow; (iii) in the iron lung and the cuirass, there is impaired access to the patient for hygiene, examination, or resuscitation purposes.

Despite these distinct disadvantages, negative pressure ventilation via the iron lung continues to be a successful ventilation modality for patients with poliomyelitis and less commonly for chronic obstructive pulmonary disease (COPD) patients (14,15).

The cuirass functions in a fashion similar to the iron lung, but is physically less bulky and more portable. Negative pressure ventilation using a body cuirass is uncommon today. However, this mode of ventilation has been successfully used in the OR, where the airway is part of the surgical field, as occurs during bronchoscopies (16,17). Negative pressure ventilators became aggressively developed and widely distributed to support polio victims during the pandemics of the 1940s and 1950s.

### Positive Pressure

Although negative pressure devices (described earlier) were the first widely applied apparatus for MV, their limitations along with progress in anesthetic techniques led to the development of improved airway and ventilatory control in the OR, the recovery room, and into modern SICUs. Instrumental in this progress was the introduction of the laryngoscope in 1913 by Jackson and, in 1943, Gudel (9) introduced the cuffed ETT. These tubes featured a high pressure–low volume cuff, which caused tracheal mucosal ischemic problems during long-term placement. Cuffs with a higher volume and low pressure (high compliance) replaced the original tubes in the 1970s. Nonetheless, these devices ushered in the use of positive pressure ventilators (described in the remainder of this chapter).

Intubation of the trachea can be accomplished using a variety of routes and techniques as described in Volume 1, Chapter 9. The standard intubation in the OR or ICU consists of an ETT, inserted into the trachea via the mouth or nose. Other possibilities include percutaneous cricothyroidotomy or tracheotomy, mainly used in emergency situations or for prolonged intubations.

Placement of a cuffed ETT protects the airway from major aspirations, although ETT cuffs do not reliably prevent subglottic fluid from passing to the tracheobronchial tree. Microaspiration, which occurs along the longitudinal folds within the wall of an inflated cuff, is directly linked to VAP (18). A recent study showed a reduced incidence of aspiration when the cuff was lubricated with gel (19). In a small number of tracheostomy patients, the protection lasted for a mean duration of 42 hours (19).

Once a cuffed tube seals the trachea, a closed system is made of the lungs, breathing circuit, and the ventilator. In this situation, it is possible to apply positive airway pressures to the airway without inflating the stomach. Changes in flow and/or pressure generated by the patient can be easily detected by the ventilator sensors in such a closed system.

## FOUR PHASES OF MECHANICAL VENTILATION

☞ Mechanically ventilated breaths can be divided into four distinct phases to best understand the changes that occur in pressure, flow, and volume of the inhaled and

**exhaled gases.** The terminology used in this chapter is that most consistently used in clinical medicine today, initially adopted at a 1992 consensus conference on MV (Fig. 1) (20).

Phase 1 (trigger phase) is defined as the changeover from exhalation to inhalation, and phase 2 (inhalation phase) is the period when gas flows into the lungs increasing both alveolar pressure and lung volume. Phase 3 (cycle phase) is the changeover from inhalation to exhalation, and phase 4 (exhalation phase) extends between phase 3 until the next breath occurs. In most modes of MV, gas exits the lungs passively during phase 4. Understanding these four phases and how they are manipulated is fundamental to comprehending the mechanisms used in modern ventilations. Each of these phases will be further characterized below using a pressure versus time graphic, useful in describing these four phases (Fig. 1).

**Phase 1, “Trigger Phase” (Changeover from Exhalation to Inhalation)**

The “trigger phase” refers to a point in time (P1 in Fig. 1) when the ventilator initiates the positive pressure breath (changes over from exhalation to inhalation). The mechanism used by the ventilator to trigger a machine-generated

**Figure 1** Phases of mechanical ventilation. Phase 1 (P1) “trigger phase” is the changeover from exhalation to inhalation. The trigger phase is just a point in time (P1) when the machine initiates the positive pressure breath. The jargon used to describe the trigger phase also commonly referred to as the “mode of ventilation” [i.e., synchronized intermittent mandatory ventilation (SIMV), assist- controlled, etc.]. The ventilator can be triggered by the patient in the SIMV or assist controlled mode, whereas the breath is triggered by a timer circuit in the controlled mode or during the machine-initiated portions of the assist control and SIMV breaths. The variable that triggers the ventilator to deliver a patient initiated breath include: (i) a sensed pressure drop in the system (pressure sensitivity) or (ii) a sensed change in flow (flow-by sensitivity), whereas machine-triggered breaths are initiated by a timer. Phase 2 is the “inhalation phase.” This is the period of time extending between the initiation of inhalation to the start of exhalation (i.e., between P1 and P3). During the inhalation phase, most ventilators will control either flow (volume-controlled) or pressure (pressure-controlled). Phase 3 (P3) “cycle phase” is the changeover from inhalation to exhalation. In short, how the ventilator decides to end the breath and cycle into exhalation. The cycle phase is just a point in time (P3). This changeover can be pressure cycled, time cycled, volume cycled, or flow cycled. Phase 4 is the “exhalation phase,” is generally passive but can be influenced by positive end-expiratory pressure (PEEP) or by the placement of a retarding mechanism.

breath can either be patient triggered (where the ventilator senses a negative inspiratory pressure or flow profile) or time triggered (where the ventilator delivers breaths at a rate set by the clinician). Ventilator terms that describe the trigger phase of the mechanical ventilatory cycle include: (i) controlled mechanical ventilation (CMV), (ii) assist control (A/C), (iii) synchronized intermittent mandatory ventilation (SIMV), and so on. These conventional modes of triggering MV are shown diagrammatically in Figure 2, and are discussed in detail below.

**Controlled Mechanical Ventilation**

When inhalation is triggered by a computer-generated signal from a respiratory rate timing mechanism, it is referred to as CMV (Fig. 3). This is the trigger methodology used on most OR ventilators. ICU ventilators with

**Figure 2** The conventional modes of mechanical ventilation (MV) are shown in this figure with a series of pressure versus time graphs. Note that with spontaneous ventilation, airway pressure is negative during inhalation and positive during exhalation, whereas in the controlled mechanical ventilation (CMV) mode, airway pressure is positive during inhalation and exhalation, beginning and ending at zero (also see Fig. 3). The patient will only receive the set number of breaths in the CMV mode, and cannot trigger additional breaths. If positive end expiratory pressure were applied, the end-exhalation pressure would be positive in each of these modes. In the assist control (A/C) mode of MV, the machine provides a certain number of positive pressure breaths (number set by the clinician); however, the patient can trigger the ventilator to provide additional breaths by making a negative inspiratory pressure effort. In the intermittent mandatory ventilation (IMV) mode the machine will provide a certain number of positive pressure breaths (number set by the clinician). However, in contrast to A/C, if the patient cares to take any additional breaths s/he must do all the work of breathing. In the standard (non-synchronized) IMV mode, the ventilator can trigger a machine breath when the patient does not want one, and cause ventilator-patient dyssynchrony. In the synchronized IMV mode (SIMV), the machine-delivered breaths are synchronized with the patient’s intrinsic ventilatory efforts, thus markedly minimizing patient-ventilator dyssynchrony.

**Figure 3** Controlled mechanical ventilation (CMV). Pressure, flow, and volume versus time during volume-controlled CMV mode. *Source:* From Ref. 150, p. 58.

automatic timing mechanisms, called controllers, can also trigger the inhalation phase on the ventilator. In the control mode, the patient will receive the set rate of mandatory positive pressure breaths, regardless of his/her own respiratory efforts. This feature is satisfactory for deeply sedated or anesthetized patients and essential in caring for patients without any ventilatory drive of their own. However, patients capable of triggering some breaths on their own can become extremely agitated if maintained on CMV mode. This is because in the pure CMV mode, patients are “locked out” of initiating inhalation. However, the true CMV mode as described here is only available on older ICU ventilators and on anesthesia machines. No modern-day ICU ventilators are solely controllers, hence, all currently produced ventilators have escape mechanisms so that patients can receive some ventilatory support in response to their efforts.

### Assist Control

Ventilator devices that trigger a machine delivered breath in response to patient-initiated ventilatory efforts are called assistors. In the A/C mode, the patient may initiate a machine-delivered breath as frequently as he/she would like, merely by making minimal ventilatory effort which is immediately sensed by the machine as a negative inspiratory pressure or flow change (depending upon the trigger sensing mode employed) (Fig. 4). The A/C mode allows the patient to increase their minute ventilation by triggering additional breaths at a rate higher than set. However, if the patient on the A/C mode becomes heavily sedated or anesthetized and does not trigger any breaths of her/his own, s/he will only receive the baseline number of breaths set by the rate control. In this situation, A/C is

**Figure 4** Assist control ventilation (A/C). Pressure, flow, and volume versus time during volume-controlled AC ventilation. *Source:* From Ref. 150, p. 60.

indistinguishable from the CMV mode. Later, when the patient recovers from deep sedation or anesthesia and begins to seek additional breaths, full machine-delivered breaths can be triggered by the patient’s efforts, when ventilated using the A/C mode.

### Synchronized Intermittent Mandatory Ventilation

The intermittent mandatory ventilation (IMV) mode was initially developed as a weaning tool. In the IMV mode, the patient will receive a preset number of machine-delivered breaths but is allowed unrestricted ability for spontaneous breathing (although with increased work, as the patient does not get any assistance for the spontaneous breaths taken above the background set rate). The rudimentary IMV mode is problematic because the machine can deliver a controlled breath just after the patient has taken their own spontaneous, nonassisted breath. Thus, stacking of breaths can occur resulting in barotrauma/volutrauma and patient distress from patient-ventilator dyssynchrony.

Because of these considerations, SIMV was developed (Fig. 5). The SIMV mode allows the ventilator to sense when the patient takes a non-machine-aided breath and will space the preset machine-assisted breaths so as not to stack breaths. If the patient on SIMV becomes sedated or anesthetized, then s/he will only receive the number of breaths programmed into the machine. However, once the patient begins to take additional breaths, they must perform all of the work required to achieve the supplemental breaths. The baseline pressure waveforms generated when patients fail to trigger additional SIMV or A/C breaths are indistinguishable from those occurring with the CMV mode.

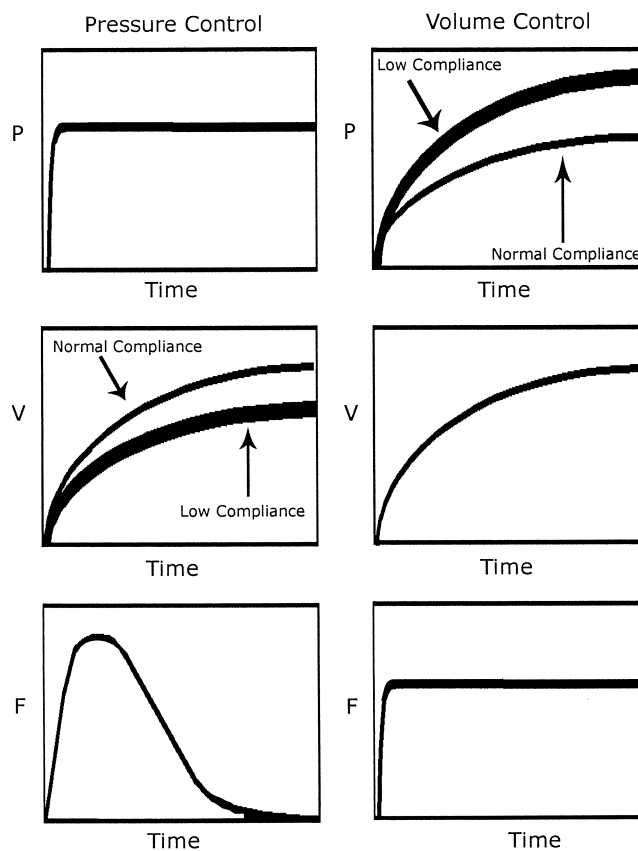

### Phase 2, “Inhalation Phase”

✎ The inhalation phase is characterized as that period of time when gas is flowing into the lungs, as well as that time when

**Figure 5** Synchronized intermittent mandatory ventilation (SIMV). Pressure, volume, and flow versus time waveforms during SIMV ventilation. The first breath is a machine time-triggered breath. At the *second arrow*, the patient is exhaling after a spontaneous breath. At this time, the mandatory (assisted) breath is synchronized with the patient's spontaneous exhalation. The *bottom arrow* indicates the mandatory breath time based on set respiratory frequency. *Source:* From Ref. 150, p. 63.

already delivered gas remains in the lungs (i.e., until the ventilator cycles into exhalation). As gas flows into the lungs, ventilators use one of two basic mechanisms to control the physical characteristics of pressure, flow, and volume (volume control and pressure control). These two major types of control systems characterize the active (gas flow) portion of the inhalation phase. The differences between volume control and pressure control are shown graphically in Figure 6 and are summarized in Table 2.

**Figure 6** Pressure control and volume control ventilation differences, showing the pressure, volume, and flow versus time waveform profiles. *Abbreviations:* F, flow; P, pressure; V, volume.

**Volume Control (Set Volume with Constant Flow Generation)**

The volume set/flow-controlled ventilators maintain a constant preset volume with every machine-delivered breath, whereas the flow rate is constant, and the pressure required to attain this volume will increase until the preset volume is delivered (Fig. 6, right side panel). The advantage of a volume set/flow-controlled ventilator is that a constant volume will be delivered with each machine-generated breath regardless of changing airway resistance or

**Table 2** Volume Control Versus Pressure Control Breaths

Variable	Volume control breath	Pressure control breath
Tidal volume	Set by clinician; remains constant	Variable with changes in patient effort and respiratory system impedance
Peak inspiratory pressure	Variable with changes in patient effort and respiratory system impedance	Set by clinician; remains constant
Inspiratory time	Set directly or as a function of respiratory frequency and inspiratory flow settings	Set by clinician; remains constant
Inspiratory flow	Set directly or as a function of respiratory frequency and inspiratory flow settings	Variable with changes in patient effort and respiratory system impedance
Inspiratory flow waveform	Set by clinician; remains constant; can use constant, sine, or decelerating flow waveform	Variable with changes in patient effort and respiratory system impedance; flow waveform always decelerating

compliance (as can occur in a patient with bronchospasm, a kinked ETT, the acute development of a pneumothorax, or decreased pulmonary compliance). This is why most ventilators in current usage are volume set/flow-controlled ventilators. Of course, if the set high-pressure limit is reached during the delivery of a volume set flow-controlled breath, inhalation will terminate on some ventilators and the set volume will not be delivered. If undetected, this could result in under-ventilation, however, alarms should alert the clinicians of this occurrence so that the problem can be rectified.

Volume control is often considered the conventional mode of controlling the pressure, volume, and flow of gas during the inhalation phase. It is also somewhat of a misnomer as it is really the flow that is controlled, whereas the volume is fixed. The advantage of the volume control mode is that tidal volume remains stable with changes in compliance or resistance. The disadvantage is that increased peak inhalation pressure occurs as lungs become less compliant or airway resistance increases. The newer variants of volume control provide options for variable flow profiles during the inhalation phase, but Figure 6 describes the classic waveform patterns.

### Pressure Control (Constant Pressure)

Pressure control is a mode of controlling the inhalation phase so that pressure remains stable (square wave) throughout inhalation. Typically, flow occurs as a decelerating wave in this mode (Fig. 6, left side panel). The overriding attractive feature in this mode of inhalation control is the fact that pressure remains constant throughout. The downside is that as compliance decreases or resistance increases, the tidal volume delivered to the patient will decrease.

Pressure-controlled ventilators have the pressure maintained at a preset level. Thus, the volume delivered varies depending on the resistance and compliance characteristics of the patient's lungs (Fig. 6). Accordingly, hypoventilation can occur. Therefore, if CO<sub>2</sub> elimination is a major concern, pressure control may not be the optimal choice. If on the other hand, limiting the pressure applied to the airways and alveoli is of particular interest, this ventilator mode guarantees control. This may be the case in lung diseases like acute respiratory distress syndrome (ARDS), where the lung involvement is heterogeneous with the risk of damaging healthy areas.

In addition, patient-ventilator synchrony can be achieved easier with pressure control compared to the volume control mode (21). Another small study showed that pressure control ventilation tends to require a lower work of breathing than the volume control mode (22).

### Phase 3, "Cycle" (Changeover from Inhalation to Exhalation)

☞ The cycle phase represents the changeover from inhalation to exhalation. ☞ The ventilator can cycle into exhalation via a number of mechanisms (pressure, time, volume or flow). Pressure-cycled ventilators terminate inhalation when a preset pressure is reached in the ventilator circuit, regardless of what tidal volume has been delivered. This is the way the old-fashioned intermittent positive pressure breathing (IPPB) ventilators used to work; and, because of this variable volume delivery, it is a rarely used mode today. In contrast, time-cycled ventilators will continue in the inhalation phase for a preset time interval. Most commonly, a set volume is delivered, then a passive inhalation hold period will occur

until the preset time elapses, at which time the ventilator cycles into exhalation. The time until exhalation in this mode is dependent upon respiratory rate and the set I:E ratio. This is the method of cycling used in the pressure-controlled, inverse ratio mode of ventilation, and on OR ventilators.

☞ **Volume-cycled ventilators terminate inhalation after a preselected volume has been delivered to the patient.** ☞ Volume-cycled ventilators are most commonly employed for phase 3. However, decreased patient's lung or chest wall compliance or increased airway resistance will decrease the amount of volume delivered to the patient's airways. Flow-cycled ventilators terminate inhalation when a preselected flow is reached (this is the method of cycling used in the pressure support mode of MV).

### Phase 4, "Exhalation Phase"

☞ The exhalation phase is the time period when the previously inhaled gas is exhausted, and is generally passive (i.e., occurs by natural recoil if elastic forces in lung and in chest wall). ☞ However, early prototypes of positive pressure ventilators applied a negative pressure (suction) during exhalation called negative end-exhalation pressure. This feature has been abandoned on all modern ventilators due to the propensity to decrease functional residual capacity (FRC), cause atelectasis, and increase right-to-left transpulmonary shunt. Modern day oscillator ventilators actually provide a "to and fro" function during ventilation. However, this occurs on top of a standing wave of pressure.

### Positive End Expiratory Pressure

Whenever the pressure in the airways at end-exhalation is greater than ambient, this is referred to as positive end expiratory pressure (PEEP). The application of PEEP increases the FRC—the lung volume at end-exhalation during normal tidal breathing. Increasing FRC recruits alveoli during inhalation and prevents closure of airways at end-exhalation thus increasing the number of lung units participating in gas exchange. Prevention of airway closure and recruitment of alveoli improves the ventilation-perfusion relationships, reverses atelectasis, and thus decreases right-to-left transpulmonary shunt (23–26).

☞ **Although the application of PEEP will decrease shunt, it can also increase alveolar dead space, particularly in West's zone 1 regions.** ☞ West's zone 1 is the portion of the lung in which the intra-alveolar pressure exceeds the arterial pressure ( $P_A > P_a$ ); these are high  $\dot{V}/\dot{Q}$  regions. Furthermore, the application of PEEP can reduce cardiac output ( $\dot{Q}$ ) (27). This can occur through several mechanisms including a decrease in venous return (28,29), an increase in pulmonary vascular resistance (30), right ventricular dysfunction (30), leftward displacement of the intraventricular septum (31), and decreased transmural ventricular filling pressures.

Through these mechanisms, the application of excessive PEEP can actually worsen the delivery of oxygen (DO<sub>2</sub>) to the body tissues, since  $\dot{Q}$  is a major determinant:

$$\dot{D}O_2 = \dot{Q} \times 1.34 [\text{Hb}] \times \text{SaO}_2 + 0.003 \times \text{PaO}_2$$

The net effect of PEEP on  $\dot{D}O_2$  depends on the relative changes on both the increase in SaO<sub>2</sub> and the decrease in  $\dot{Q}$ .

The end point of PEEP application should be the lowest level of PEEP that allows an adequate PaO<sub>2</sub> with an F<sub>I</sub>O<sub>2</sub> of 0.5 or less. Some have called this the "best PEEP"

**Figure 7** Continuous positive airway pressure (CPAP). Pressure, flow, and volume versus time during CPAP. Abbreviations: E, exhalation; I, inhalation. Source: From Ref. 150, p. 69.

(32). An “adequate  $\text{PaO}_2$ ” is approximately 60 mm of mercury. A  $\text{PaO}_2$  of 60 mmHg is just above the steep part of the oxyhemoglobin dissociation curve. In other words, an increase in  $\text{PaO}_2$  will not correlate with an improvement in  $\dot{\text{V}}\text{O}_2$ , when the mechanisms used to increase the  $\text{PaO}_2$  decrease  $\dot{Q}$  too much. Also, the ideal level of PEEP should cause the least amount of hemodynamic change when increasing oxygenation. Therefore,  $\dot{Q}$  and  $\dot{\text{V}}\text{O}_2$  should be monitored when high ( $>10$  cm  $\text{H}_2\text{O}$ ) PEEP levels are used.

### Continuous Positive Airway Pressure

In continuous positive airway pressure (CPAP) breathing both the inspiratory and expiratory limbs of the ventilator are pressurized to a set level (frequently 5 cm  $\text{H}_2\text{O}$ ) (Fig. 7) (33). The patient provides all of the ventilatory work. The mean airway pressure (mPaw) is increased but, if effective, the work of breathing can be less and oxygenation improved because of recruitment of previously atelectatic alveoli. For the temporary prevention of upper airway closure at night in patients with obstructive sleep apnea, CPAP delivered via nasal mask is widely used.

### Bilevel Positive Airway Pressure

Bilevel positive airway pressure (BiPAP) ventilatory support system is used in spontaneously breathing patients (34). As the name bilevel implies, two different levels of pressure flow, inspiratory and expiratory positive airway pressure (IPAP and EPAP), can be chosen to support the patient's ventilation. The upper (inspiratory) and lower (expiratory) pressures are set by the clinician. The gradient between the EPAP and IPAP levels determines the degree of tidal volume augmentation, or pressure support. The patient determines the time that the higher and lower airway

pressures are applied by their spontaneous respiratory cycle. BiPAP can be administered noninvasively utilizing various types of masks; however, some devices are also approved for use with intubated patients (34,35).

## SUPPORT MODES

### Pressure Support

Pressure support ventilation is a pressure-triggered and flow-cycled mode of ventilatory support. The trigger mechanism of pressure support ventilation is similar to the A/C mode because both trigger on when a negative pressure (or decreased flow in some models) is sensed. The inhalation phase is similar to pressure control (square wave pressure, decelerating flow). However, the method of cycling into exhalation is unique for pressure support (using flow rate to determine exhalation point).

In pressure support ventilation, flow is delivered to the patient until the inspiratory flow decreases below a preset value (such as 25% below the peak inspiratory flow). Thus, the delivered tidal volume will depend on the resistance and compliance of the lungs and chest wall.

The inspiratory pressure is maintained by a computer-controlled servomechanism in the ventilator that continually adjusts the inspiratory flow to maintain the desired pressure. Therefore, there is a square wave pressure and decelerating flow pattern with each machine-delivered breath. Most of the newer ICU ventilators are capable of providing the pressure support mode of ventilation. **Pressure support ventilation can be used as the sole method of ventilation or, more frequently, as a method to support weaning.**

As the level of pressure support is decreased, more patient effort is required to maintain the minute ventilation. This makes pressure support ventilation a suitable ventilation setting for weaning from MV (36). With pressure support weaning, the level of pressure support is decreased as tolerated by the patient. Pressure support has shown to be well tolerated in COPD patients (37,38), and can be used as a noninvasive method in these patients (e.g.) BiPAP (39).

### Volume Support

As pressure support provides a constant level of positive pressure during the inhalation phase of every spontaneous breath, volume support provides variable levels of positive pressure for a constant, preset tidal volume (40). Using a closed-loop control system, ventilators adapt the level of inspiratory pressure support required to deliver the volume, despite changes in the patient's inspiratory effort or the compliance and resistance characteristics of the lungs. The triggering mechanism is the same as pressure support (pressure-triggered), but phase 3 occurs once the inspiratory flow decreases to 5% of the peak flow. Volume support is thought to be a potential automated ventilator weaning approach (41).

## VENTILATOR-INDUCED LUNG INJURY

### Evidence for Ventilator-Induced Lung Injury

Positive pressure ventilation was first linked to damage of the lung, in as early as the 1940s, where a study by Macklin and Macklin (42) showed interstitial emphysema of lungs and the mediastinum, which the authors linked to

alveolar rupture caused by critically high-pressure gradient between alveolus and surrounding interstitium.

In 1974, Webb and Tierney (43) first showed positive pressure-induced lung damage in the form of edema, hyaline membrane formation, and hemorrhage, similar to the findings in ARDS. Other studies demonstrated complications like bacterial translocation from the respiratory tract (44) or an increase in circulating cytokines (45) from positive pressure ventilation in ARDS patients.

Other mechanisms found to cause lung damage and possibly contribute to ventilator-induced lung injury (VILI) include surfactant depletion and ventilation at low-end-expiratory lung volumes (46).

## VOLUTRAUMA VS. BAROTRAUMA CONTROVERSY

### Evidence for Barotrauma

For lung pathologies caused by the presence of extra-alveolar air in abnormal locations like pneumothorax, pneumomediastinum, pneumopericardium, pulmonary interstitial air, pneumatoceles, and venous air emboli, both terms barotrauma and volutrauma can be found in the literature. These complications affect 4% to 15% of all mechanically ventilated patients, however, more common in patients with ARDS, status asthmaticus, and aspiration pneumonia (47). Several studies looked for whether the predominant factor for VILI was excessive volume or pressure (48,49).

A relationship between high peak inspiratory pressures (PIP) and barotrauma has been suggested by findings in some studies (49–51), whereas others found poor correlation (52–54). There are also studies that found an inverse relationship between PIP and barotrauma, showing a lower incidence of barotrauma in the study groups with higher PIP (55–57). A similar controversy can be found in reviewing the literature for correlations of PEEP and barotrauma (54,55,58). The role of PEEP in lung protective ventilation strategies will be reviewed later.

☞ **One explanation for the confounding relationship between PIP and barotrauma is that the actual pressure applied at the alveolus is lower than that measured at the ventilator tubing, and it is the pressure distending the alveolus that is most injurious.** ☞

### Evidence for Volutrauma

Abundant animal and human data now exists supporting the concept of volutrauma (59–61). Studies in dogs, rabbits (60), and rats (61) showed induction of volutrauma by high inflation pressures during MV. This could be prevented by drastically reducing the lung compliance by strapping or banding of the thorax and/or the abdomen.

The amount of lung distension is dependent on the transalveolar pressure rather than airway pressure. Transalveolar pressure is the difference between airway pressure and intrapleural pressure. For a normal pleural pressure (0 mmHg), depending on the moment in the respiratory cycle, the transpulmonary pressure needed to achieve vital lung capacity is around 35–40 mmHg.

Thus for patients with normal compliant lungs, the pressure limit during MV should be set at 35–40 mmHg to avoid volutrauma. Higher alveolar pressures may not cause volutrauma in situations where there is reduced chest wall or abdominal compliance, resulting in transpulmonary pressures below potential harmful values (62).

## LUNG PROTECTIVE VENTILATION STRATEGY: DEFINED

### Different Approaches

After it was established that MV could prolong or cause lung injury, a significant effort has been expended in searching out ventilation strategies that minimize stress on the lung.

Variations of PIP, PEEP levels, tidal volumes (VTs), and the use of HFV and inverse I:E ratio ventilation are several of the most commonly employed strategies that have been examined to determine their impact on VILI. Most of these studies use acute lung injury (ALI)/ARDS models or patients, since these pathologies are most prone to lung injury. In these syndromes, the lung is affected in a patchy, heterogeneous matter, leaving some areas densely consolidated, and others virtually normal. This leads to decreased surfactant function, diffuse atelectasis and alveolar consolidation and flooding (63).

Traditionally, the goal of MV had been to keep the PaCO<sub>2</sub> in a physiologic normal range and to apply adequate oxygenation using tidal volumes of 10–15 mL/kg to achieve this. In lungs with pathologies like ARDS, this often results in very high PIP. The recognition that this ventilation regimen can injure the already damaged lung further, led to an approach of using reduced tidal volumes and a pressure limit.

Hickling and Henderson (64) showed that the use of a tidal volume of 5 mL/kg and a PIP of less than 30 cm H<sub>2</sub>O was associated with a reduced mortality rate among subjects with ARDS. Three large multicenter, randomized clinical trials followed, and failed to show a decrease in mortality by using low tidal volumes in the study group compared to a group with traditional higher tidal volumes (62,65,66).

### National Institutes of Health–National Heart, Blood, and Lung Institute Study: First Investigation to Show Decreased Mortality with a Mode of Ventilation

☞ **The first trial showing a decrease in mortality for a low tidal volume strategy compared with traditional, higher tidal volumes was conducted by the National Institutes of Health–National Heart, Blood, and Lung Institute ARDS Network Study (67).** ☞ In this multicenter, randomized clinical trial, a total of 861 patients were assigned to either a starting tidal volume of 12 mL/kg predicted body weight (traditional) or 6 mL/kg (low tidal volume group). Ventilation had to be established no later than 36 hours after ALI criteria were met. Adjustments to lower tidal volumes were made in both groups if needed to avoid excessive end inspiratory plateau pressures.

The mortality rate in the traditional tidal volume group was 40% compared with only 31% in the low tidal volume group. The low tidal volume group had statistically significant more ventilator-free days and more days without nonpulmonary organ failures. Explanation as to why this study could demonstrate an outcome difference, where previous studies failed, may include the larger study population. Another reason could be the larger differences in tidal volume between groups as compared to some of the previous studies.

### Open Lung Approach

In addition to high tidal volumes and lung stretch causing VILI, ventilator patterns promoting increased amounts of atelectasis have been shown to be harmful. Mechanical forces that occur in small bronchioles and alveoli that repeatedly

**Figure 8** Static pressure–volume curve. The lower inflection point defines optimal PEEP level, whereas the upper inflection point defines the maximal lung inflation pressure (end inhalation pressure). *Abbreviations:* LIP, lower inflection point; UIP, upper inflection point. *Source:* From Ref. 151.

snap open and close may play a role in the development of the injury (68). In addition, the region between normal and atelectatic lung may be affected by physical stress (68).

☞ **In the open lung approach, the patient is ventilated between the upper and lower inflection points on the pressure–volume curve.** ☞ Pressure–volume (P–V), aka “elastance” curves, can be useful in determining the optimal PEEP that prevents atelectasis at end-expiration and does not cause overdistension (Fig. 8) (69). The term “lower inflection point” describes the point on the lower portion of the P–V curve where the flat slope becomes more steep (first knee in the curve). The upper inflection point marks the point where the steep curve becomes flat again (second knee in the curve). The optimal ventilation would theoretically lie in-between those two points in order to avoid atelectasis and overdistension. Studies by Amato et al. (70,71) suggest beneficial outcomes in ARDS patients who were ventilated with a PEEP above the lower inflection point.

This approach in determining the optimum amount of PEEP has some limitations: First, the P–V curve represents the combined elastance of both lung and chest wall (72). Second, not every static P–V curve shows a clearly distinguished inflection points (69). Also, a single point on the P–V curve does not represent the global events throughout the lung. The determination of a P–V curve is labor intensive and several studies have demonstrated the wide variability in measuring and reporting the upper and lower inflection points.

Furthermore, the P–V curve shows hysteresis: at each level of airway pressure, volume is greater during deflation than during inflation. Hysteresis can be accounted for by the differences in surface tension and pressures of small bronchioles and alveoli during inflation and deflation (73). So, after initial opening of a lung unit, lower pressures are needed to maintain ventilation. This phenomenon has led to the newly developed interest in intermittent recruitment maneuvers. Overall, it seems that there is no straightforward answer to the question of the ideal amount of PEEP. However, most experienced intensivists agree that the best PEEP is the least PEEP required to maintain an “open lung” strategy during ventilatory support.

## NEWER MODES: AIMED AT LUNG PROTECTIVE VENTILATION

### Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a newer mode of ventilatory support, which combines CPAP with a release valve on the expiratory limb that can open at end-exhalation. The patient is breathing spontaneously during APRV and this modality can be used either invasively or noninvasively. The putative advantage of this mode of ventilation is less positive pressure transmitted to the cardiovascular system. ARDS patients showed improved cardiopulmonary function and oxygenation in spontaneous breathing patients receiving APRV, compared to similar patients on standard MV (74–76). The benefit may result from improved recruitment of nonventilated lung units. Improved oxygenation with APRV was again shown recently in an animal study on pigs with induced lung injury (77).

### Time-Cycled, Pressure-Controlled Inverse Ratio Ventilation

Time-cycled, pressure-controlled inverse ratio ventilation (TCPCIRV), is a mode of MV used for patients with ARDS (78–80). This ventilatory mode was developed to counteract three major pathologic findings associated with ARDS: (i) decreased compliance ( $C_L$ ), (ii) increased transpulmonary shunt ( $\dot{Q}_s/\dot{Q}_t$ ), and (iii) the inhomogeneous (i.e., diffuse, but scattered) alveolar involvement associated with ARDS. By controlling the pressure and increasing the I:E ratio, gas flows into the lungs in a more physiologic way, decreasing barotrauma previously prevalent with ventilation of lungs with low  $C_L$ . Increasing the I:E ratio keeps alveoli open longer to participate in gas exchange longer, thus decreasing the  $\dot{Q}_s/\dot{Q}_t$ . Because of the heterogeneity of the lung injury associated with ARDS, some long inhalation time-constant alveoli do not expand when conventional I:E ratios are employed. By increasing the I:E ratio, the long inhalation time-constant alveoli (that would otherwise be atelectatic) are able to contribute to gas exchange. Since ARDS lungs are extremely stiff, they empty quickly, and the shorter exhalation time is generally well tolerated. When conventional ventilation with PEEP is used, the normal, compliant lung units may become overdistended, leading to  $\dot{V}/\dot{Q}$  inequality with worsening gas exchange.

☞ **In severe ARDS, the concept of applying PEEP preferentially to the diseased lung units is hypothesized to improve gas exchange.** ☞ By prolonging inspiratory time (inverse of the usual I:E ratio), the expiratory flow time is decreased, and with extreme inverse I:E, exhalation flow does not complete before the next delivered breath occurs. This results in alveolar gas trapping or “intrinsic” (auto) PEEP. Because the diseased alveolar units are the slowest to empty, the intrinsic PEEP will mainly be present in these units, that is, the normal units will have already emptied. This “selective” PEEP is hypothesized to improve  $\dot{V}/\dot{Q}$  matching (i.e., decreased shunt and dead space), resulting in improved oxygenation and  $\text{CO}_2$  elimination. However, if too much intrinsic PEEP is used, alveolar dead space can increase just as it can when too much extrinsic PEEP is used. The initial setup for TCPCIRV is shown in Table 3.

☞ **Because of improved gas exchange with TCPCIRV, one can generally ventilate and oxygenate patients at lower peak airway pressures.** ☞ The risk of barotrauma is then theoretically reduced. However, because inspiration is prolonged, mPaw increases. Hence, significant decreases in  $\dot{Q}$  can occur, especially in hypovolemic patients, as has been described by Perel (81). Thus, all patients treated with

**Table 3** Initial Setup for Time-Cycled, Pressure-Controlled, Inverse Ratio Ventilation

Step	Parameter	Comments
1	F <sub>I</sub> O <sub>2</sub>	Temporarily increases F <sub>I</sub> O <sub>2</sub> to 1.0 (may be there already), then wean down as tolerated. Same as during previous mode
2	Set PEEP	Maintain at value used during conventional MV
3	Inspiratory pressure	Start with inspiratory pressure = peak pressure during volume controlled breath—set PEEP (e.g., if patient is receiving 10 of PEEP and peak pressure is 45–50, initial inspiratory pressure should be 35–40 with PEEP at 10 cm H <sub>2</sub> O)
4	RR	Generally not adjusted during TCPCIRV. Usually an initial rate of 15–25 is common
5	I:E ratio	The normal I:E ratio is 1:2. Increasing the I:E ratio increases the time alveoli are pressurized and the time for oxygen to diffuse across the alveolar epithelium
6	Inspiratory time	Determined by the I:E ratio. If the patient is set on a RR = 20 and an I:E ratio of 1:1, then a 1.5 sec inhalation time and a 1.5 sec exhalation time results

*Note:* The effects of TCPCIRV on PaCO<sub>2</sub> and  $\dot{V}O_2$  are less predictable than the effects on PaO<sub>2</sub> (see text). Accordingly, frequent monitoring of blood gases and  $\dot{V}O_2$  is necessary.

*Abbreviations:* F<sub>I</sub>O<sub>2</sub>, fraction of inhaled gas due to oxygen; MV, mechanical ventilation; PEEP, positive end-expiratory pressure; RR, respiratory rate; TCPCIRV, time-cycled, pressure-controlled, inverse ratio ventilation.

TCPCIRV should have invasive arterial pressure monitoring (and when unstable either a TEE or pulmonary artery catheter). In addition, high levels of sedation and (usually supplemental) paralysis are required to effectively ventilate patients in this mode. Although TCPCIRV is a beneficial mode for ventilating ARDS, guidelines for initiating TCPCIRV in less severe forms of ARF are less well defined and further studies are needed.

### High-Frequency Ventilation

☞ HFV has several variants defined in the literature, but in general terms describes a form of MV utilizing high ventilatory rates and low tidal volumes (82). ☞ The  $V_T$  used in HFV is usually at, near, or below the anatomic dead space volume; accordingly, gas exchange occurs by bulk flow, coaxial flow, pendelluft, Taylor dispersion, or facilitated molecular diffusion (83). The Food and Drug Administration (FDA) considers HFV to occur when the rate of ventilation is >150 breaths/min.

Because HFV uses much smaller tidal volumes and lower peak inspiratory airway pressures than conventional ventilation, it possesses many of the attributes required for lung protective ventilation of ARDS patients. Its main clinical use has been for neonatal patients with respiratory failure (84,85). Indeed, HFV has only been shown to be superior to

conventional ventilation for pediatric respiratory distress syndrome (RDS). HFV can be categorized into five separate types by using criteria of ventilation rate and type of gas delivery mechanism.

#### High-Frequency Positive Pressure Ventilation

High-frequency positive pressure ventilation (HFPPV) utilizes conventional positive-pressure ventilators with low compliance circuits set at high rates and small tidal volumes. The  $V_T$  is usually in the range of 3–4 mL/kg with a set frequency of 60 to 120 breaths/min (1–2 Hz). HFPPV does not meet the FDA threshold for HFV because the rates are typically <150.

#### High-Frequency Jet Ventilation

In high-frequency jet ventilation (HFJV), a high-velocity pulse of gas is delivered into the lungs through a narrow cannula (usually within the lumen of a conventional ETT). The respiratory frequency typically ranges from 1.5 to 10 Hz. Originally developed in the 1970s, HFJV results in delivery of  $V_T$  smaller than the  $V_D$  (2–5 mL/kg). The consequent minimized tidal movement of the operative field led to its use in the OR for patients undergoing thoracic surgery (e.g., bronchopleural fistula repair) and for surgery on the upper airway (e.g., trachea, carina, and mainstem bronchus) (86). Today HFJV is mainly used in pediatrics and flow is delivered via a specially made triple-lumen ETT (National Catheter Corporation). Ventilators designed specifically for HFJV include the Bunnell Life Pulse (Bunnell, Inc., Salt Lake City, Utah, U.S.A.). Under most conditions, gas entrainment occurs around the jet, increasing the  $V_T$  by a physical process termed jet mixing.

#### High-Frequency Flow Interruption

High-frequency flow interruption (HFFI) is similar to HFJV, achieving frequencies as high as 15 Hz. This is the HFV apparatus invented by Emerson, which uses interrupted bulk gas flow using a ball moving back and forth across a nozzle. The ball alternates between obstructing the output flow and allowing the flow. The HFFI device can be used as a bulk flow device connected to an ETT or with a jet catheter in the airway when a high-pressure source is intermittently interrupted. This technology is not widely used clinically.

#### High-Frequency Oscillatory Ventilator

Utilizing an oscillator (piston pump) to create rapidly changing positive and negative pressure fluctuations is called high-frequency oscillatory ventilation (HFOV). High frequencies of 5–50 Hz are commonly used with this modality. HFOV aims to maintain an open lung volume by the application of a stable mPaw. The F<sub>I</sub>O<sub>2</sub> and the mPaw are the main determinants of oxygenation during HFOV, whereas the effectiveness of ventilation (CO<sub>2</sub> elimination) is dependent upon the magnitude of pressure fluctuations and the set frequency.

The role of HFOV in treatment of neonates with RDS is well established (84,85). In early case studies (86,87) and later in clinical trials (88–90), HFOV was used as a rescue therapy for adults with severe ARDS not responding to conventional MV (91). HFOV improved oxygenation best when used in combination with recruitment maneuvers (92,93).

A recent review by Derdak (94) using HFOV in adult ARDS patients suggests it may benefit patients who require both a high F<sub>I</sub>O<sub>2</sub> (>0.6) and high mPaw (≥20 cm

H<sub>2</sub>O). Whether HFOV actually reduces mortality compared to other ventilation modes that also increase with mPaw (e.g., TPCIRV) and its role outside of the rescue and/or research setting remains to be determined in future RCTs (95–97).

### High-Frequency Percussive Ventilation

High-frequency percussive ventilation (HFPV) is a recent ventilatory mode, which combines conventional cycles with high-frequency percussions. HFPV was initially instituted as salvage therapy after acute respiratory failure following smoke inhalation injury achieving in each case a dramatic improvement of oxygenation, PaCO<sub>2</sub>, and ventilatory pressures.

Complications of HFV common to all five basic modes include pneumothorax, drying of the airways, and airway injury including necrotizing tracheobronchitis. In addition, significant potential for air trapping and auto-PEEP exists [especially in the elderly COPD population, and other patients with reactive airways disease (RAD)]. Therefore, monitoring of airway pressure is extremely important in high-frequency ventilation.

The use of any or all of the five major types of HFV for the treatment of ARDS is still unproven in adults. However, many of the attributes of HFV seem ideal for adult ARDS, since the principles of lung-protective ventilation, including an open lung strategy with low tidal volume, peak pressure limitation, maintenance of an adequate end-expiratory lung volume, and the use of the low F<sub>I</sub>O<sub>2</sub>. However, large RCTs comparing HFV to conventional protective ventilation are still needed to prove HFV as effective, or more effective than conventional ventilation.

### Liquid Ventilation

The use of perfluorocarbons as a respiratory medium was used as early as the 1960s (98). These colorless fluids have a greater density, lower surface tension, and higher solubilities for oxygen and CO<sub>2</sub>, than water. This mode of ventilation in the form of total liquid ventilation (complete filling of the lung with liquid requiring a special ventilator) or partial liquid ventilation (usually to functional residual capacity using a conventional ventilator), has been successfully used in pediatric and adult patients (99–104). The results so far suggest that it is safe and efficacious in improving gas exchange by recruitment of dependent, atelectatic alveoli (liquid PEEP) and minimizing lung injury by requiring lower ventilator pressures and improving lung compliance in regions of lung injury. Disadvantages include the inability to assess lung parenchyma by chest radiography, because the liquid-filled lungs appear “white” on the chest film. Also, minimal data exists describing possible long-term toxicity. Results from ongoing and future studies will determine its adaptation into clinical practice.

### Permissive Hypercapnia

Minimizing overdistension of the diseased lung and reducing the risk of stretch injury have become predominant goals in ventilating patients with lung disease like ARDS (105,106). This usually necessitates the use of small tidal volumes and lower minute ventilations to keep maximal transpulmonary pressures low. The resulting low minute ventilation often leads to hypoventilation with increased PaCO<sub>2</sub> and respiratory acidosis. Willingness to tolerate this respiratory acidosis is referred to as permissive hypercapnia

(105,106). Most patients can tolerate pH values in the range of 7.1 to 7.2 (106). Deep sedation is often required to decrease the respiratory drive caused by the hypercarbia. The role of NaHCO<sub>3</sub> as a buffering agent is controversial. High doses are required at low pH, and this may lead to paradoxical intracellular acidosis and increased intracellular CO<sub>2</sub> production. The clinician should also carefully consider potential harmful effects of permissive hypercapnia like central nervous system depression, increased intracranial pressure (ICP), dysrhythmias, myocardial ischemia or myocardial depression, and pulmonary hypertension.

### Prone Ventilation

Placing ventilated patients with ARDS in the prone position to improve oxygenation was initially used in the early 1970s (107), and has been shown to improve oxygenation in patients with severe ALI/ARDS (108,109). The reason for underutilization of this ventilation technique is related to the special nursing and technical requirements, and the increased risk of dislodging the ETT and other important lines during the repositioning.

The improved oxygenation in the prone position is thought to be at least partially due to: (i) improved  $\dot{V}/\dot{Q}$  matching by redistribution of perfusion to the better ventilated lung areas; (ii) better clearance of secretions by gravity; (iii) increased FRC; and (iv) a favorable change in regional diaphragm motion (110).

A large multicenter, randomized trial confirmed the improved oxygenation in the prone group but did not show a significant difference in outcome (111). Criticism of this study (112) included the short time spent in the prone position (at least six hours). It has been shown that the benefit from the proning increases with time spent in the prone position (113).

### Inhaled Nitric Oxide

Since the endogenous vasodilator, endothelium derived relaxing factor, has been identified as nitric oxide (NO), it is not surprising that inhaled NO selectively vasodilates the pulmonary vasculature and has been used for patients with ARDS (114).

☞ **The potential benefit of inhaled NO in ARDS patients lies in improving the shunt fraction in the diseased lung.** ☞ Since it only dilates vessels in areas of ventilated alveoli, it diverts blood flow to these alveoli. The effects are kept local by its very short half-life and rapid inactivation. Although improved oxygenation with NO has been observed, prospective trials in ARDS showed no improved long-term outcome (115–118). As of this publication, FDA has only approved NO for the treatment of neonatal hypoxemia.

These results have led to the controversy about its use. Further studies need to show favorable outcome to prove it as a beneficial adjunct in the treatment of severe lung injury before its recommended routine use.

### Noninvasive Positive-Pressure Ventilation

Noninvasive positive-pressure ventilation (NIPPV) has been shown to be beneficial in settings where the patient is not intubated, but needs ventilatory support. NIPPV is a technique in which the ventilator is connected to the patient via a tightly fitting facemask, potentially avoiding complications from endotracheal intubation (i.e., VAP). But NIPPV has its own disadvantages, including potential air leaks from suboptimal mask fit, pressure-induced skin

damage where the mask and face contact, and intolerable discomfort. Furthermore, patients should be sufficiently oriented, committed, able to handle their secretions, and capable of working with the NIPPV system.

Successful use of NIPPV in decreasing the need for endotracheal intubation has been shown to be the case in patients with acute respiratory failure (119), cardiogenic pulmonary edema (120), as well as in patients with acute hypercapnic respiratory failure from COPD (121,122). However, this technique has minimal application during the initial resuscitation and MV phase of critically injured trauma and burn patients.

## WRITING VENTILATOR ORDERS

Initial ventilator orders should include the mode of ventilation (usually A/C or SIMV), the set tidal volume calculated based on the patient's weight, the backup set respiratory rate, the  $F_{I}O_2$ , and the amount of PEEP desired. Ventilator parameters typically determined by the respiratory therapist include the inhalation waveform, the I:E ratio (generally 1:2), trigger sensitivity, peak inhalation flow (usually 70–110 L/min is adequate), pressure limit, and P–V alarms. However, the responsible physician must understand the ramifications of improperly setting any of these variables. Furthermore, whenever TCPCIRV is used, the responsible physician should also order I:E ratio, and discuss the plan of care with the respiratory therapist.

Rarely used ventilatory settings include the use of an inflation hold, expiratory retard, and/or sigh. Indeed, most modern ventilators no longer have these capabilities. The reason these lung recruitment functions are no longer used is because in awake patients these maneuvers are uncomfortable and distressful.

The choice of ventilatory mode is based on the physician preference, but typically A/C offers the advantage of decreasing work of breathing and allows patients with respiratory muscle weakness to increase ventilation without performing the work of breathing on their own. With A/C, there is a theoretical increased risk for respiratory alkalosis because with each patient effort, a full machine-delivered breath results. The IMV mode offers the advantage of lower  $mPaw$  (since patient-initiated breaths are negative pressure breaths) allowing the patient to perform a greater portion of their work of breathing (if desired). However, the increased work of breathing with the IMV mode is often excessive in patients in severe respiratory failure.

The initial  $V_T$  can be calculated based on the patient's lean body weight, typically between 10 to 12 mL/kg in young healthy patients without lung injury. It is recommended that patients with a low FRC (such as those with ARDS) receive  $V_T$  ranging from 5–7 mL/kg with supplemental PEEP to keep the exhalation volume above the lower inflection point of the P–V curve. In addition, patients with a high FRC, resulting from bronchospasm (such as a patient with COPD or asthma) should also be ventilated with a smaller tidal volume in the range of 5–7 mL/kg in order to avoid hyper inflation, or any further increase in intrinsic PEEP.

The respiratory rate is set to assure an adequate  $\dot{V}_E$  and to avoid respiratory acidosis or alkalosis. In a normal patient with normal lungs, an arterial carbon dioxide tension ( $PaCO_2$ ) of 40 mm of mercury is usually achieved with an initial rate of 8 to 12 breaths/min.

The initial fractional inspired oxygen concentration ( $F_{I}O_2$ ) should be 1.0 in order to document a level of right to-left shunt (by measuring the alveolar to arterial oxygen tension difference) and at the same time, minimize the risk of hypoxemia during transport and the initial ventilator set-up period in the ICU. Administration of 100% oxygen for a short period of time (i.e., <4 hours) is nontoxic. Later, based upon arterial blood gases, the  $F_{I}O_2$  should be decreased by titrating the PEEP up. The goal should be to decrease the  $F_{I}O_2$  into the nontoxic (<0.5) range as soon as possible.

The amount of PEEP initially set for most patients without elevated ICP should be 5 cm water, as this is thought to be physiologic and should decrease the incidence of atelectasis by increasing FRC. However, in the case of severe hypoxemia, the PEEP may need to be increased to as high as 15–20 cm  $H_2O$  pressure. The goal should be to use the least amount of PEEP possible, although still allowing the  $F_{I}O_2$  to be 0.5 or less and obtain a  $PaO_2 \geq 60$  mmHg.

## COMPLICATIONS OF MECHANICAL VENTILATION

Complications of MV can be classified into those that cause an increase in airway pressure and those that cause a decrease in airway pressure (Table 4). Differentiation of peak versus plateau pressures can further differentiate the source of certain high-pressure problems. For instance, if the patient has a very high PIP but only a modest plateau airway pressure, an increase in airway resistance should be suspected. An increase in airway resistance may result from increased secretions, too small of an ETT, or bronchospasm.

✎ When the patient seems to be “fighting the ventilator,” an appropriate first diagnostic and therapeutic step is to separate the patient from the ventilator and hand-ventilate the patient with 100% oxygen. ✎ Separating the patient from the ventilator assures that the ETT is properly placed and functioning in the patient and that the patient him/herself is not the problem. While the patient is receiving hand-generated bag/mask ventilation, attention can be turned to the ventilator to correct problems.

### Complications of Prolonged Tracheal Intubation

There are also complications that arise simply as a result of endotracheal intubation. Although this review does not specifically address intubation, it is extremely uncommon

**Table 4** Complications of Mechanical Ventilation

High pressure	Low pressure
Kinked ETT	Tube disconnect
ETT migration (mainstem)	Extubation
Increased secretions	Air leak around the cuff
Tension pneumothorax	Balloon rupture
Light anesthesia	TE fistula
Worsening of lung disease	BP fistula (early)
Fighting the vent	
Intrinsic (“auto”) PEEP	

*Abbreviations:* BP, broncho-pleural; ETT, endotracheal tube; PEEP, positive end expiratory pressure; TE, tracheo-esophageal.

**Table 5** Complications of Tracheal Intubation

---

*During intubation*

- Trauma to the C-spine, nose, teeth, lips, tongue, oropharynx, larynx, and trachea
- Aspiration (blood, tooth, gastric contents, etc.)
- Esophageal intubation
- Endobronchial intubation
- Hemodynamic instability
- Hypnotic drugs: myocardial depression, vasodilation
- Relative hypovolemia: decreased venous return
- Loss of sympathetic tone: hyperventilation (CO<sub>2</sub> elimination), administration of sedatives
- Exaggerated ANS reflexes
  - Sympathetic (hypertension, tachycardia, myocardial ischemia)
  - Vagal (hypotension, bradycardia, cardiac arrest)

*Endotracheal tube in place*

- Bronchospasm
- Tracheomalacia
- Tracheal perforation (by cuff, by tip of tube)
- Inadequate removal of secretions (possible ETT obstruction)
- Trauma to areas of contact (exacerbated by patient movement)
- Excessive inflation of cuff causing tube lumen narrowing
- Ruptured cuff causing air leak or aspiration

*During extubation*

- Trauma to the glottis by inflated cuff
- Aspiration of supraendotracheal tube cuff secretions
- Laryngospasm
- Respiratory obstruction by immediate edema of any part of the airway previously in contact with the endotracheal tube

*After extubation*

- Sore throat, dysphagia
- Aphonia
- Paralysis of the hypoglossal and/or lingual nerves
- Vocal cord paralysis
- Ulceration, inflammation, infection, edema of any part of the airway previously in contact with the endotracheal tube
- Laryngeal granulomas and polyps
- Laryngeal membranes and webs
- Tracheal stenosis

---

*Abbreviations:* ANS, autonomic nervous system; C-spine, cervical spine; ETT, endotracheal tube.

that we perform MV without concomitant endotracheal intubation (Table 5). For an expanded discussion of the complications of endotracheal intubation and tracheostomy, see the review by Stauffer et al. (123).

### **Pathologic Airway Injury**

The presence of an ETT in the larynx causes characteristic pathology. The incidence of laryngeal complications after prolonged intubation is between 4% and 13%. The earliest of these changes are nonspecific hyperemia and edema due to mucosal irritation. Edema within the submucosa in the subglottis at the level of the cricoid may increase slowly, leading to delayed airway obstruction hours after the removal of the ETT.

As the tube remains in place, ulceration occurs with varying degrees of granulation tissue formation. The most susceptible site to irritation from the ETT is in the posterior

larynx, especially the mucosa overlying the vocal processes of the arytenoids (124).

Subglottic stenosis, which is more easily recognized, may be coexistent with posterior glottic stenosis. Prolonged intubation is the most common cause of subglottic stenosis in both adults and children. By definition, subglottic stenosis is a narrowing of the subglottic space above the inferior margin of the cricoid cartilage and below the level of the glottis.

True vocal cord paralysis may occur as a result of endotracheal intubation. The paralysis is most commonly unilateral, but bilateral paralysis with airway obstruction has been reported. Brandwein et al. (125) examined the course of the anterior branch of the recurrent laryngeal nerve and discovered it to be vulnerable to compression between the inflated cuff of the ETT, the lateral projection of the abducted arytenoid, and the thyroid cartilage. Injury to the recurrent laryngeal nerve most commonly results in the cord lying in the paramedian position. Occasionally, true vocal cord edema persists long after extubation.

### **Obstruction of the Endotracheal Tube**

Due to the plastic nature of the ETT, bending can occur at any time. Kinking can lead to hypoventilation and high peak airway pressures. The ventilator alarm should alert the clinician to a sudden increase in ventilator circuit resistance. Appropriate vigilance must be taken to avoid this occurrence.

Adequate pulmonary toilet and clearance of secretions is difficult in the mechanically ventilated patient. Secretions can be due to an inflammatory process (i.e., pneumonia, tracheitis) or mobilization of third space fluids. Nevertheless, the need for airway suctioning and pulmonary toilet should be assessed on a regular basis and achieved by in-line suctioning to minimize the risk of contamination. Mucous plugs can cause airway obstruction as severe as segmental and lobar collapse. Also, bronchospasm can occur in the patient with reactive airway disease.

### **Complications Related to Endotracheal Tube Securement**

Once the position of the ETT is confirmed, there are multiple methods to prevent movement of the ETT. Tape, umbilical tape, and cloth Velcro contraptions have been used to maintain the position at the level of the vermilion border of the lips. Unfortunately, complications can arise from the mere securing of the ETT. Patients with sensitive skin and tape allergies can develop rashes or skin ulcers. The tape adhesive can be compromised by virtue of moist secretions and sweat, which can result in ETT migration and potential extubation. Umbilical tape that wraps around the neck of the patient can occlude the venous outflow and cause facial plethora. Special care must be taken to prevent such catastrophes associated with securing the ETT.

### **Complications Related to Breach of Airway Protection Atelectasis and Impaired Clearance of Secretions**

Atelectasis is a major contributor to postoperative respiratory failure in critically ill trauma patients, especially following thoracic and high abdominal trauma. Lung collapse secondary to decreased respiratory muscle tone, cephalad displacement of the diaphragm, compression of lung tissue, and splinting, all contribute to a reduction of FRC (126). Postoperative persistence of atelectasis often results secondary to postoperative pain, decreased cough, inability

to clear secretions, and inability to take deep breaths; all of which can be improved with adequate analgesia (126).

### **Ventilator-Associated Pneumonia**

VAP is the most frequent ICU-acquired infection among patients receiving MV. VAP is defined as an inflammation of the lung parenchyma caused by infectious agents occurring >48 hours after the time MV was started. Cook et al. (127) found, in a larger series of 1014 mechanically ventilated patients, that the cumulative risk of VAP was 3% per day up to day 5, 2% per day up to day 10, and 1% per day thereafter. The attributable mortality for VAP has been reported to be as high as 33% to 55% (128). Independent predictors, in decreasing order, were a primary admitting diagnosis of burn, trauma, central nervous system disease, respiratory disease, cardiac disease, and witnessed aspiration (127–129).

Sources of infection for VAP include inoculation by healthcare workers, aspiration of oropharyngeal pathogens around the ETT cuff, and invasive respiratory devices (129). Many preventive strategies have been prescribed, such as hand washing, semi-recumbency, ventilator device care, subglottic suctioning, noninvasive ventilation, and intensive insulin therapy. Treatment is focused at early recognition, broad-spectrum antibiotics, antibiotic de-escalation at three to five days, and curtailing therapy duration to eight days if there is clinical improvement (130).

### **Barotrauma/Volutrauma**

Barotrauma refers to complications of MV, such as pneumothorax, pneumomediastinum, and other forms of extra-alveolar air (131–134). It became clear in the 1990s that the production of high pressures is not the only reason for formation of extraalveolar air (135). However, controversy continues regarding the term barotrauma, because it implies that injury is related only to pressure. Other investigators will use volutrauma to denote that lung injury associated with positive pressure is from high distending volumes rather than high pressures. Evidence is increasing that volume, not pressure alone, causes overdistension and is associated with iatrogenic lung injury (136–137). Thus, the term VILI (described earlier) is now used when referring to lung injury that can result from either barotrauma or volutrauma (138).

Types of conditions that predispose to barotrauma include: high PIPs, bullous lung disease such as may occur with emphysema, high levels of PEEP, high tidal volumes, aspiration of gastric acid, and ARDS. The result of this overdistension can be pneumothorax, pneumomediastinum, subcutaneous emphysema, systemic air embolism, and bronchopleural fistula. Ways of reducing the likelihood of alveolar rupture during MV include: setting smaller tidal volumes, decreasing tidal volume when high PEEP is used, maintaining alveolar pressures below 30 cm H<sub>2</sub>O, omitting use of sigh breaths with high tidal volumes, monitoring for auto-PEEP when present, and considering permissive hypercapnia and lung-protective ventilation strategies when necessary (139).

## **EYE TO THE FUTURE**

Today's ventilators are primarily microprocessor driven. As rapid as there are advances in information technology, so too will advances be made in the features and capabilities of

tomorrow's ventilator devices. As with information systems and other electronics, ventilators continue to be smaller, incorporate expanded capabilities, and process and display information better and faster as time progresses.

### **Closed-Loop Ventilation**

We have discussed the breath-delivery phases of MV and several modes of ventilation that are available. Closed-loop ventilation is now possible with the ability of technology to rapidly sense and respond to patient-generated variables. In its simplest form, Auto-Flow (Drager Medical, Telford, Pennsylvania, U.S.A.) and Volume Control Plus (Puritan Bennett, Tyco Healthcare, Pleasanton, California, U.S.A.) represent forms of closed-loop ventilation in which there is automatic next breath changes in pressure using tidal volume as the feedback control, with the objective of keeping tidal volume constant. Manufacturer's engineering teams continue to devise more sophisticated methods to provide closed-loop ventilation to improve the responsiveness of breath delivery to patients needs. However, there is no uniformity regarding how manufacturers name or classify these new modes. This leads to confusion among caregivers, and training programs have become more focused on understanding manufacturer-specific vocabulary. Closed-loop systems do provide for pressure support, volume targeted pressure control, mandatory minute ventilation, and other modes commonly found on ICU ventilators.

Manufacturers are quickly responding to gain a clinical advantage by partnering with clinicians to develop new modes of closed-loop ventilation. Adaptive support ventilation (ASV) is designed to titrate ventilator output on a breath-to-breath basis. The level of support is determined by the mechanical characteristics of the patient and their own breathing efforts. Based on ideal body weight and the % minute ventilation control, a target minute ventilation is determined. By delivering a series of "test breaths" the ventilator measures respiratory system compliance, airway resistance, and intrinsic PEEP. From those measures and the % minute volume setting, the ventilator will determine the target breath rate and tidal volume. Campbell et al. (140) evaluated ASV and determined that the ventilator would self-adjust to achieve a lower PIP, lower V<sub>T</sub>, and higher rate than clinician-selected settings, but was associated with an improved efficiency of ventilation and reduction in dead space when compared to conventional ventilation.

Proportional assist ventilation (PAV) is not currently available in the United States and remains limited to investigational use. PAV is a form of closed-loop ventilation designed to increase or decrease airway pressure in proportion to the patient's effort (141). PAV is an intrabreath, positive feedback controller that amplifies airway pressure proportional to inspiratory flow and volume (142). Puritan Bennett (Puritan Bennett, Tyco Healthcare, Pleasanton, California, U.S.A.) will be the first manufacturer to release PAV in the United States. The feature will be incorporated in their 840 series ventilator in which the clinician sets the % support, tube size and type, an expiratory sensitivity, the high and low tidal volume limits, and the ventilator—and on every 4 to 10 breaths the ventilator will measure resistance, compliance, flow, and volume every five milliseconds. Studies have validated the feasibility of PAV in a variety of patient conditions (143–145).

Closed-loop advances include the use of occlusion pressure measures to control the level of pressure support (146,147), the use of end tidal CO<sub>2</sub> to control the level of pressure support (148), and the concept of neurally-adjusted ventilator assist using diaphragm electrical activity to trigger the ventilator (149).

### Decision-Making Algorithms

Although technology advances continue to arm the clinician with new options for ensuring that MV and breath delivery meet the needs of the patients, decisions about the selection of these modes and changes in clinician set parameters will remain important.

Monitoring systems will continue to evolve so that ventilator information is displayed in ways that the clinician can configure, that allows storage of selected information, that allows breath-to-breath comparisons of measured parameters to assess the effectiveness of MV.

Nearly all modern-day ICU ventilators allow connectivity with information systems so that clinicians can spend less time charting, and data is integrated and stored. Point of care access to such information will assist future clinicians in making critical decisions about the patient's plan of care.

With the increasing number of monitored and derived parameters, clinicians will also need new tools to assist in making safe and appropriate changes in the patient's ventilator care plan. Decision-based algorithms are being investigated and incorporated in new technology. The ability to preconfigure facility-specific algorithms to target initial settings, adjust those settings based on user-selected inputs, and to manage the liberation from MV are incorporated in emerging technology.

### SUMMARY

A strong understanding of the ventilator is paramount when taking care of the critically ill patient. Because so many machines are made for the same purpose, the stratification of phases of ventilation enhances one's understanding of the ventilator. Choosing the appropriate mode of ventilation depends on the patient's clinical situation. The vast majority of patients in the SICU are appropriately placed on volume control ventilation. However, in the patient with severe respiratory failure, multiple lung protective modes should be used to minimize the risk of barotrauma/volutrauma and other forms of secondary lung injury.

Knowledge of the complications surrounding the procedures involved with MV is very important. Placement of an ETT and delivering positive pressure to the critically ill patient is not a benign process. In the future, newer modes will be available to further improve morbidity and mortality associated with MV by minimizing the risk of secondary lung injury.

### KEY POINTS

- ✎ Ventilators can be categorized into two major types: (i) negative pressure and (ii) positive pressure ventilators.
- ✎ Mechanically ventilated breaths should be divided into four distinct phases to best understand the changes that occur in pressure, flow, and volume of the inhaled and exhaled gases.

- ✎ The "trigger phase" refers to a point in time (P1 in Fig. 1) when the ventilator initiates the positive pressure breath (changes over from exhalation to inhalation).
- ✎ The inhalation phase is characterized as that period of time when gas is flowing into the lungs, as well as that time when already delivered gas remains in the lungs (i.e., until the ventilator cycles into exhalation).
- ✎ The cycle phase represents the changeover from inhalation to exhalation.
- ✎ Volume-cycled ventilators terminate inhalation after a preselected volume has been delivered to the patient.
- ✎ The exhalation phase is the time period when the previously inhaled gas is exhausted, and is generally passive (i.e., occurs by natural recoil if elastic forces in lung and in chest wall).
- ✎ Although the application of PEEP will decrease shunt, it can also increase alveolar dead space, particularly in West's zone 1 regions.
- ✎ Pressure support ventilation can be used as the sole method of ventilation or, more frequently, as a method to support weaning.
- ✎ One explanation for the confounding relationship between PIP and barotrauma is that the actual pressure applied at the alveolus is lower than that measured at the ventilator tubing, and it is the pressure distending the alveolus that is most injurious.
- ✎ The first trial showing a decrease in mortality for a low tidal volume strategy compared with traditional, higher tidal volumes was conducted by the National Institutes of Health—National Heart, Blood, and Lung Institute ARDS Network Study (67).
- ✎ In the open lung approach, the patient is ventilated between the upper and lower inflection points on the pressure–volume curve.
- ✎ In severe ARDS, the concept of applying PEEP preferentially to the diseased lung units is hypothesized to improve gas exchange.
- ✎ Because of improved gas exchange with TCPCIRV, one can generally ventilate and oxygenate patients at lower peak airway pressures.
- ✎ HFV has several variants defined in the literature, but in general terms describes a form of MV utilizing high ventilatory rates and low tidal volumes (82).
- ✎ The potential benefit of inhaled NO in ARDS patients lies in improving the shunt fraction in the diseased lung.
- ✎ When the patient seems to be "fighting the ventilator," an appropriate first diagnostic and therapeutic step is to separate the patient from the ventilator and hand-ventilate the patient with 100% oxygen.

## Weaning from Mechanical Ventilation

Ulrike B. Eisenmann, Anushirvan Minokadeh, and William C. Wilson

Department of Anesthesiology and Critical Care, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

Weaning from mechanical ventilation describes the process of progressively reducing mechanical ventilatory support until the patient is entirely capable of performing the work of breathing (WOB) on his/her own. Severely injured and critically ill patients are increasingly dependent upon mechanical ventilation for their survival, and their subsequent weaning from ventilatory support has become increasingly complex. These conditions have evolved from our improved resuscitation capabilities, the increasing complexity of surgical corrective procedures, and the increased baseline comorbidities associated with our aging population (1–7).

The art and science of weaning from mechanical ventilation has continued to evolve since the widespread use of mechanical ventilators for intensive care began in the late 1960s (8,9). Optimization of the weaning process is aimed at diminishing the time on the ventilator, and reducing the adverse complications associated with prolonged mechanical ventilation. Some authors object to the term “weaning” (10–13). Accordingly, Hall and Wood (10) introduced and promoted the term “liberating” from mechanical ventilation. In more recent publications, the term “discontinuing” from mechanical ventilation is increasingly used (14). This chapter will review the important concepts and use the terms weaning, liberating, and discontinuing from mechanical ventilation, interchangeably.

In the simplest terms, ventilatory dependence occurs whenever the WOB exceeds the patient’s ability to perform that work. However, there are a host of other factors that may intervene and prolong ventilatory dependence in addition to the simple WOB supply/demand relationship (15–18). The section “Weaning Sequence: Seven-Step Pathway to Extubation” provides an overview of the seven goals that must be achieved to accomplish successful weaning from mechanical ventilation and safe extubation. This section serves as an in-depth overview of the entire process, whereas the subsequent sections review the data supporting the seven-step approach. All major recommendations in this chapter are in concert with the recent American College of Chest Physicians (ACCP)/American Association for Respiratory Care (AARC)/Society of Critical Care Medicine (SCCM) evidence-based guidelines for weaning and discontinuing ventilatory support (18).

### WEANING SEQUENCE: SEVEN-STEP PATHWAY TO EXTUBATION

☞ **The weaning sequence should proceed along a logical stepwise evaluation pathway.** ☞ The successful achievement of each goal in the pathway leads to the next step in the

sequence (Table 1). The first step in the weaning process begins when the clinician judges that the patient’s condition has improved, and the underlying disease process (requiring mechanical ventilation) is improving or has resolved (Table 1). The second step is to verify that the patient is free of any intercurrent conditions that might complicate weaning.

Once these first two goals are achieved, the clinician ensures that the patient can oxygenate adequately, defined as being capable of maintaining  $\text{PaO}_2 > 60$  mmHg on an  $\text{FIO}_2 \leq 0.4$  with  $\leq 5$  to 8 cm positive end expiratory pressure (PEEP) (step 3). The fourth and fifth steps (or weaning goals) are the verification that the patient does not have an excessive WOB and that he/she is capable of performing that work. Once these thresholds are met (as demonstrated by various weaning parameters), the clinician must verify that the patient is able to protect his/her airway (step 6). Finally, prior to extubation, a determination is made regarding whether extubation, and possibly reintubation, will be easy or difficult (step 7). If reintubation is expected to be difficult, the trachea should be extubated over an airway exchange catheter (AEC), and/or with a fiberoptic bronchoscope (FOB). Patients with tracheostomies in place need not achieve goals 6 and 7 prior to advancing to tracheostomy collar. Furthermore, many neurologically impaired patients will not be capable of achieving step 6; and some pathologic processes causing tracheal stenosis (or airway swelling) obviate safe breathing through their natural airway. Whenever steps 6 and 7 cannot be safely accomplished, a tracheostomy should be considered.

☞ **Clinicians should closely review the contributors to respiratory failure at the moment the patient is intubated, and commence optimization of all anticipated impediments to weaning from the beginning.** ☞ The details of this seven-step process and the weaning goals required to proceed down the pathway from full ventilatory support to weaning and extubation are reviewed below.

### Improvement in Primary Disease Process Requiring Ventilatory Support

Without resolving or significantly improving the original disease process that triggered the need for mechanical ventilatory support, it is illogical to expect successful liberation from mechanical ventilation. Assessing the degree to which the patient has improved and adequately reversed the process that required mechanical ventilation involves the interpretation of weaning parameters discussed in this chapter, and an overall application of the art and science of medicine reviewed in other chapters of this textbook.

**Table 1** Weaning from Mechanical Ventilation Goals

Weaning goal	Pathophysiologic process requiring normalization	Demonstrated by
1	Reversal/recovery from primary disease causing ARF	Determined by appropriate evaluation
2	Absence of acute processes that may impede weaning Afebrile Stable hemodynamics Stable metabolism and electrolytes	Temperature $\leq 38^{\circ}\text{C}$ HR and MAP within 20% of baseline with no or minimal vasoactive agents Laboratory data
3	Oxygenation adequacy demonstrated	$\text{F}_i\text{O}_2 \leq 0.4$ $\text{PEEP} \leq 5\text{--}8 \text{ cmH}_2\text{O}$ $\text{PaO}_2 \geq 60 \text{ mmHg}$ $\text{PaO}_2/\text{F}_i\text{O}_2 > 150\text{--}200$
4	WOB not excessive	$\dot{V}_E < 12 \text{ L/min}$ (70-kg patient) $V_D/V_T < 0.6$ $C_L > 30 \text{ mL/cmH}_2\text{O}$ Absence of wheezing or prolonged exhalation time
5 <sup>a</sup>	Demonstrated ability to perform the required WOB	$\text{RR} < 25 \text{ min}^{-1}$ during SBT $V_T > 5 \text{ cm}^3/\text{kg}$ during SBT $\text{RSBI} < 100$ during SBT $P_{\text{IMAX}} > 25 \text{ cmH}_2\text{O}$ $P_{0.1}$ $P_{0.1}/P_{\text{IMAX}}$
6	Verify patient's ability to protect airway	Awake and following commands Intact gag reflex, vigorous cough, empty stomach (relative requirement)
7	Ensure reintubation not anticipated to be difficult	History, exam of airway If reintubation is likely difficult, should be extubated with AEC and only after evaluation with FOB

<sup>a</sup>Patients with existing tracheostomies need only to achieve above to goal 5 prior to advancing to a tracheostomy collar. However, the tracheostomy site should be evaluated for maturity, and the ease of tracheostomy recanalization (in the event of cannula dislodgment) should be evaluated.

**Abbreviations:** AEC, airway exchange catheter; ARF, acute respiratory failure;  $C_L$ , compliance;  $\text{F}_i\text{O}_2$ , inspired fraction of oxygen; FOB, fiber-optic bronchoscope; HR, heart rate; MAP, mean arterial pressure;  $\text{PaO}_2$ , arterial oxygen tension; PEEP, positive end-expiratory pressure; RSBI, rapid shallow breathing index ( $\text{RR}/V_T$  expressed in Liters);  $P_{\text{IMAX}}$ , maximum inspiratory pressure;  $P_{0.1}$ , mouth occlusion pressure;  $P_{0.1}/P_{\text{IMAX}}$ , ratio of mouth occlusion pressure to maximum inspiratory pressure; RR, respiratory rate; SBT, spontaneous breathing trial;  $V_D/V_T$ , deadspace to tidal volume ratio;  $\dot{V}_E$ , minute ventilation;  $V_T$ , tidal volume; WOB, work of breathing.

Determining the patient's level of recovery from respiratory failure (Volume 2, Chapter 26) and fitness for weaning requires insight into the underlying process that

required mechanical ventilation. Recovery from respiratory failure, resulting from a primary pulmonary event, is generally easier to gauge because only one organ system is involved. Evaluating recovery from respiratory failure that occurred secondary to dysfunction of another organ (e.g., renal failure), or as sequelae of sepsis (Volume 2, Chapter 47), multiple trauma, or the systemic inflammatory response syndrome (Volume 2, Chapter 63), requires both an evaluation of the pulmonary system and a review of the injured organs that initiated the event (14). When multiple organs are injured, the weaning sequence is even more complicated than when failure of only one organ initiated respiratory failure (15–17). In severely ill patients, the duration of weaning may extend for weeks or even months after the primary insult, as multiple systems and the lungs recover.

### Absence of Intercurrent Processes that Impede Weaning

Although the patient may have substantially recovered from the primary disease that required mechanical ventilatory support, the physician must also ensure the absence of intercurrent disease processes (e.g., renal failure, or congestive heart failure) that may complicate the primary injury, and doom the weaning process. Similarly, acute disease states that increase the WOB (e.g., sepsis, fever, etc.) or decrease the patient's ability to do that work (e.g., chronic bed rest, muscle wasting, critical illness polyneuropathy, steroid myopathy, malnutrition, etc.) must be addressed and treated prior to expecting any significant progress in weaning. Finally, the patient should be optimized from a respiratory care perspective, receiving nutrition, hemodynamically stable (defined as in a stable rhythm—preferably sinus, and off or on minimal doses of vasoactive drips), as per weaning goal 2 in Table 1.

### Adequacy of Oxygenation Demonstrated

☞ **The patient is not ready to proceed with weaning until he/she can maintain adequate oxygen saturation, both at rest and with modest exertion (i.e., during weaning).** ☞ The generally accepted oxygenation threshold required to safely commence weaning is the demonstrated ability to maintain  $\text{PaO}_2/\text{F}_i\text{O}_2 \geq 150$  to 200; or a  $\text{PaO}_2 \geq 60 \text{ mmHg}$  (i.e.,  $>90\%$  saturation) on an  $\text{F}_i\text{O}_2 \leq 0.4$  with a minimal ( $<5\text{--}8 \text{ cmH}_2\text{O}$ ) of PEEP.

The acceptable oxygenation threshold listed in Table 1 (step 3) is far below the normal resting oxygen status of healthy patients. Indeed, normal individuals maintain a  $\text{PaO}_2$  ranging between 100 and 70 mmHg when breathing room air and not receiving exogenous PEEP. However, because of the immense physiologic reserve within the normal mammalian oxygen delivery system (Volume 2, Chapter 2), these lower oxygenation threshold criteria will generally allow for the provision of adequate oxygenation to tissues during the weaning process. This subnormal threshold of the  $\text{PaO}_2/\text{F}_i\text{O}_2$  ratio is also adequate for supplying tissue oxygenation following extubation, and provides latitude for minor setbacks (e.g., transient atelectasis or fever).

### Work of Breathing Is Not Excessive

☞ **When the WOB is excessive (Fig. 1), even young and otherwise healthy patients can develop respiratory failure.** ☞ Accordingly, an assessment of the WOB must demonstrate that it is not too excessive prior to commencing the weaning process (Table 1, goal 4).

Numerous weaning parameters and clinical measures have been used. These will be thoroughly reviewed in the

**Figure 1** Patient in respiratory distress. Clinical signs include tachypnea (with a rapid shallow breathing pattern), increased accessory muscle (sternocleidomastoid and strap muscle) activity, diaphoresis, nasal flaring, abdominal paradox (especially when spinal cord injury or flail chest present), and when severe, cyanosis may develop (especially when supplemental oxygen is insufficient). *Source:* From Ref. 222.

following section. However, it is useful at this point to identify some of the weaning parameters that specifically assess the WOB [e.g., minute ventilation ( $\dot{V}_E$ ), the dead space to the tidal volume ratio ( $V_D/V_T$ ), compliance ( $C_L$ ), airway resistance ( $R_{AW}$ ), etc.].

To increase the predictive power of weaning parameters, multiple factors should be evaluated (discussed further subsequently). One way to conceptually combine the clinically important parameters reflecting the WOB into a single formula is with the WOB equation:

$$\frac{\dot{V}_E \times R_{AW}}{C_L} = \text{WOB} \quad (1)$$

The three components of the WOB equation ( $\dot{V}_E$ ,  $R_{AW}$ , and  $C_L$ ) have been defined above. The factors that contribute to altering these fundamental measures of the WOB will be discussed subsequently. The  $\dot{V}_E$  for a normal 70-kg patient is approximately 6 L/min. When  $\dot{V}_E$  is  $\leq 12$  L/min, and there are minimal additional coincident factors known to increase the WOB (e.g., wheezing, chest wall stiffness, etc.), patients with normal strength should be considered weanable. The normal  $V_D/V_T$  is approximately 0.3; when it is  $\geq 0.6$ , patients are seldom weanable due to the excessive WOB. The  $\dot{V}_E$  is comprised of both alveolar ventilation ( $\dot{V}_A$ ) and dead space ventilation ( $\dot{V}_D$ ). Accordingly, the  $V_D/V_T$  does not need to be specifically measured unless the  $\dot{V}_E$  is extremely elevated especially in the absence of

fever, obvious hypermetabolism, or overfeeding (Volume 2, Chapter 31).  $R_{AW}$  is normally negligible. However, patients with reactive airway disease, COPD, bronchitis, or a current cold will have an increased  $R_{AW}$  reflected in the clinical exam as wheezing. Similarly, kinks in the ET, or inspissated secretions on the endotracheal tube (ETT) may increase the  $R_{AW}$ . Ventilated patients demonstrating a large increase in the peak airway pressure compared to the plateau pressure on volume control ventilation reflect significantly increased  $R_{AW}$ . Those ventilated on the pressure control mode will show a decreased in tidal volume at any set inhalation pressure when the  $R_{AW}$  is elevated. The clinical exam should reveal the absence of bronchospasm or wheezing indicating  $R_{AW}$  is negligible, prior to commencing a trial of weaning.

The  $C_L$  is defined as a change in volume divided by a change in pressure (typically expressed as mL air/cmH<sub>2</sub>O). The normal  $C_L$  is  $>80$  mL/cmH<sub>2</sub>O; however, following trauma, resuscitation, and critical care,  $C_L$  is often decreased (especially in the setting of lung injury). The lower the  $C_L$ , the greater the WOB. When the  $C_L$  is  $<30$  mL/cmH<sub>2</sub>O, the WOB is often too great to allow weaning from mechanical ventilation unless the patient is also very fit.

### Ability to Perform the Work of Breathing Demonstrated

Once the patient's WOB has been evaluated and determined to be "reasonable" (i.e., not so high that weaning is impractical), the next goal is to determine if the patient can perform

the required work (Table 1, weaning goal 5). The easiest way to assess this is by having the patient perform a spontaneous breathing trial (SBT). For example, place the patient on a T-piece or on a continuous positive airway pressure (CPAP) of 5 cmH<sub>2</sub>O, without or with minimal (i.e., 5 cmH<sub>2</sub>O) of pressure support, and assess if he/she can do the WOB.

The most clinically useful (and predictive) weaning parameter used at the beginning and end of an SBT is the rapid shallow breathing index (RSBI), defined as the respiratory rate (RR) (expressed in breaths/min) divided by the tidal volume ( $V_T$ ) (expressed in liters) (9,13,18). Other weaning parameters have less predictive power, but are still instructive in determining why a patient may have a high RSBI during an SBT. Some of the more commonly employed weaning parameters are the maximum inspiratory pressure ( $P_{IMAX}$ ), also known as the maximum inspiratory force (MIF), both are typically expressed as negative cmH<sub>2</sub>O pressure; the vital capacity (VC), expressed either as mL or L; and the maximal voluntary ventilation (MVV) previously known as the maximal breathing capacity. The MVV is determined by asking the patient to perform their maximal  $\dot{V}_E$  for 12 to 30 seconds. The threshold goal is achieved if the patient can breathe twice their baseline  $\dot{V}_E$  for the entire 12- to 30-second duration. Patients able to accomplish this MVV goal demonstrate that they possess significant cardiopulmonary reserve, and are more likely to tolerate weaning.

### Airway Protection Intact and Reintubation Difficulties Fully Evaluated

After the patient meets all of the criteria for weaning from mechanical ventilation (Table 1, goals 1–5), the clinician must verify that the patient can safely have their trachea extubated by fulfilling goal 6 (demonstrating ability to protect their airway) and goal 7 (verification that reintubation is not anticipated to be difficult). If the patient has a pre-existing tracheostomy, then after fulfillment of goal 5, the patient may advance to tracheal collar. Conversely, if the patients cannot fulfill goals 6 and 7, a tracheotomy is often warranted (discussed in the tracheostomy section).

The ability to protect one's airway (Table 1, goal 6) is demonstrated by verifying: (i) the patient is awake and follows commands and (ii) that the patient has an intact gag and cough [sensory limb of the reflex is mediated by cranial nerve (CN) IX, and motor response is mediated by CN X]. As an additional margin of safety, it is best to ensure that the patient has an essentially empty stomach at the time of extubation (in case reintubation is required). For example, tube feeds should be held two to six hours prior to extubation. Patients at high risk for aspiration (i.e., those with altered mental status) should have tube feeds held the full six hours prior to extubation. Note that high gastric outputs ( $\geq 1500$  cm<sup>3</sup>/day) from a nasogastric or orogastric tube represent a relative contraindication to extubation (Table 1, goal 6), because the relative gastric outlet obstruction increases the patient's risk of regurgitation and aspiration, and is a sign that pathological processes are not fully resolved.

The final hurdle to be cleared, prior to extubation of the trachea, is determining if the airway would be difficult to reintubate urgently. For example, if the patient was a difficult intubation preop, or has a halo in place for cervical immobilization postop, he/she would be considered difficult to reintubate using conventional means (i.e., direct laryngoscopy). When the airway is anticipated to be difficult to

reintubate, extubation should occur over an AEC as described in greater detail in "The Patient is Weaned, Can the Trachea Be Safely Extubated?" and more fully in Volume 2, Chapter 29. Additionally, in situations where airway swelling has been problematic (e.g., following neck surgery/trauma), the vocal cords and supraglottic structures should be evaluated with an FOB prior to and during extubation.

### WEANING PARAMETERS: WHICH ARE PREDICTIVE?

Weaning parameters are bedside tests developed to assess the patient's readiness to be weaned from mechanical ventilation. **Some weaning parameters reflect the WOB that must be performed by the patient (e.g.,  $\dot{V}_E$ ,  $C_L$ ,  $R_{AW}$ ), whereas others reflect the patient's ability to perform that work (e.g., MIF, VC, RSBI).** When properly performed and interpreted, weaning parameters help in the decision-making process to liberate the patient from the ventilator (15). Since the introduction of artificial ventilation, weaning parameters have been developed and modified. The early parameters included simple measures of ventilation status, such as RR and  $V_T$  (while breathing spontaneously), as well as the VC and MIF (16,17). Over the last 40 years, more than 60 weaning parameters have been evaluated (18,19).

When clinical researchers investigate the statistical relationship between weaning parameter results and the success of weaning, the data for each weaning parameter threshold can be plotted in a  $2 \times 2$  table (Table 2). Chi-square analysis can be applied to the data in order to assess the statistical significance of the association between the weaning parameter and the success or failure of weaning. It is also useful to express the data in ways that are clinically relevant in order to communicate the results in a consistent manner. In this regard, the definitions summarized in Table 2 have been developed.

A true positive is a patient who achieves a positive result on the weaning parameter (at some threshold set by the researcher), and successfully weans from mechanical ventilation. A false positive is a patient who achieves a positive result on the weaning parameter (at a given threshold), but does not successfully wean. A true negative is a patient who fails to achieve the threshold weaning parameter value, and also fails to wean from mechanical ventilation. A false negative is a patient who fails to achieve the threshold weaning parameter value, but actually does successfully wean.

**Table 2** Comparing Weaning Parameter Results with Success of Weaning Using a  $2 \times 2$  Table

		Weaning	
		Success	Failure
Weaning parameter result	Positive	True positive	False positive
	Negative	False negative	True negative

Sensitivity = True Positives/(True Positives + False Negatives).

Specificity = True Negatives/(False Positives + True Negatives).

Positive Predictive Value = True Positives/(True Positives + False Positives).

Negative Predictive Value = True Negatives/(True Negatives + False Negatives).

Accuracy = (True Positives + True Negatives)/(True Positives + False Positives + True Negatives + False Negatives).

Sensitivity is the probability that a weaning parameter test is positive given that the person actually weans successfully. Sensitivity is also known as the true positive rate. Specificity is the probability that a weaning parameter test is negative given that the person fails to wean from mechanical ventilation. Specificity is also known as the true negative rate (Table 2).

The positive predictive value is the probability that a person successfully weans given a positive weaning parameter result is achieved at some threshold. The negative predictive value is the probability that a person fails to wean given a negative weaning parameter result is achieved. Accuracy, the most important statistical measure, reflects the combined positive and negative predictive values (Table 2).

When reviewing clinical trials that purport to compare various weaning parameters with the success of weaning, only those studies that provide a  $2 \times 2$  table of the data should be trusted. The remainder (unfortunately most studies) are less useful in terms of providing meaningful data that can be compared with your own practice, or with other studies. A review of the clinically employed weaning parameters is provided in the following sections.

### No Weaning Parameter Is Perfect—Most Are Useful

None of the clinically available weaning parameters are perfect; they all have their drawbacks. However, most are useful in clinical practice, and they tend to be complementary (Table 3) (20–62). The best weaning parameters are those that are easy to measure, can be obtained at the bedside, and have the greatest predictive power (63).

Unfortunately, no single weaning parameter test yields 100% accuracy. The reason for the imperfect predictive power of weaning parameters is that: (i) numerous factors are involved in ventilatory dependence (steps 1–5, Table 1), (ii) no single weaning parameter reflects all these factors, and (iii) clinicians have often already considered the weaning parameter results prior to selecting patients for trials of weaning (9,18).

Weaning parameters should only be used as supportive tests to bolster the clinical appraisal, and should never be used as a substitute for clinical judgment (64). If the clinical picture does not support the weaning parameter data reported by respiratory therapists (RTs), then either the data is flawed or the clinical picture has changed from when the weaning parameters were obtained. In this setting, it is best to carefully reassess the situation, and either obtain the parameters oneself, or ask the RT to obtain them while the clinician is present at the bedside. Finally, if the clinician habitually relies on only one weaning parameter to decide likelihood of weaning success, errors will inevitably occur. It is far better to obtain several weaning parameters to improve the overall predictive power. It is also important to clearly understand the data being obtained; some weaning parameters reflect an increased WOB, whereas others demonstrate a decreased ability to do that work (as explained earlier).

### Survey of Traditional Weaning Parameters

This section reviews all the commonly employed weaning parameters from the perspective of both “normal” and

**Table 3** Commonly Used Weaning Parameters

Parameter	Typical threshold required	Element evaluated
SaO <sub>2</sub> on F <sub>I</sub> O <sub>2</sub> = 0.4	>90%	Oxygenation
PaO <sub>2</sub> /F <sub>I</sub> O <sub>2</sub>	>300–350 mmHg	Oxygenation
$\dot{Q}_s/\dot{Q}_t$	<20%	Oxygenation (as reflected in right-to-left transpulmonary shunt)
$\dot{V}_E$	≤12 L/min (70 kg)	Demand component of WOB
C <sub>L</sub>	>40 mL/cmH <sub>2</sub> O	Demand component of WOB
R <sub>AW</sub>	Absence of bronchospasm Minimal P <sub>PK</sub> vs. P <sub>PL</sub> difference	Demand component of WOB
V <sub>D</sub> /V <sub>T</sub>	<0.6	Demand component of WOB
MIF or P <sub>IMAX</sub>	≤−20 cmH <sub>2</sub> O (if thin with compliant lung) <sup>a</sup> ≤−35 if the C <sub>L</sub> is decreased	Strength
VC	≥15 mL/kg	Strength/C <sub>L</sub>
P <sub>0.1</sub>	≤−5 cmH <sub>2</sub> O	Strength of respiratory fitness
P <sub>0.1</sub> /P <sub>IMAX</sub>	<0.09 (see text for details)	Strength and respiratory fitness
RR	≤35 breaths/min	Ability to tolerate the WOB
V <sub>T</sub>	≥5 mL/kg	A measure of strength/C <sub>L</sub> , and ability to tolerate the WOB
RSBI	RR (breaths/min)/V <sub>T</sub> (L) ≤100	Ability to perform the WOB
CROP	>13 (incorporates multiple factors)	Oxygenation and WOB
MVV	>2 × $\dot{V}_E$ for 12–30 sec	Measure of ventilatory reserve
$\dot{V}_E$ recov time	<3–5 min	Measure of ventilatory reserve

<sup>a</sup>The MIF is a negative number; the more negative the number the stronger the patient.

**Abbreviations:** C<sub>L</sub>, compliance; CROP, index composed of C<sub>L</sub>; F<sub>I</sub>O<sub>2</sub>, inspired fraction of oxygen; MIF, maximal inspiration force; MVV, maximum voluntary ventilation; PaO<sub>2</sub>, arterial oxygen tension; P<sub>0.1</sub>, mouth occlusion pressure (maximum inspiratory pressure 0.1 sec after airway occlusion); P<sub>0.1</sub>/P<sub>IMAX</sub>, ratio of P<sub>0.1</sub> to P<sub>IMAX</sub>; P<sub>IMAX</sub>, maximal inspiratory pressure;  $\dot{Q}_s/\dot{Q}_t$ , right-to-left transpulmonary shunt; R<sub>AW</sub>, airway resistance; RR, respiratory rate; RSBI, rapid shallow breathing index (RR/V<sub>T</sub> expressed in Liters); SaO<sub>2</sub>, oxygen saturation; VC, vital capacity; V<sub>D</sub>, dead space;  $\dot{V}_E$ , minute ventilation; V<sub>T</sub>, tidal volume; WOB, work of breathing.

“acceptable” values; recognizing that “acceptable” values almost always reflect a level of function far below “normal.” The first parameter most often assessed clinically is the RR. A normal, healthy, nonintubated 70-kg adult at rest has an RR of 12 to 14 breaths/min. However, the general acceptable threshold for a patient weaning from mechanical ventilation is an RR of 30 to 35 (9,18). This upper limit of 30 to 35 is a threshold that makes sense for otherwise healthy adults, but will have variable predictive power in other patient populations. Indeed, stable, nonintubated patients with pulmonary fibrosis (a restrictive lung disease) often have a baseline RR in the 20 to 30 range. A patient without any previous underlying lung disease presenting with a resting RR above 30 likely represents acute respiratory failure (14). The RR is also age dependent; a newborn’s normal RR ranges from 30 to 40, and rates above 60 to 80 are required to represent respiratory failure in this population (65). Similarly, temporarily hypermetabolic patients will have an expected increased  $\dot{V}_E$  (66,67).

The RR can be normalized to some degree by adding the patient’s  $V_T$ , as occurs with the RSBI ( $RR/V_T$  in liters). When the RSBI is  $<50$  at the end of a two-hour SBT, patients are almost always capable of being weaned from the ventilator. When the RSBI is  $>100$  to 105, they often are incapable of being liberated from mechanical ventilation (but what about the patients with RSBI in between?). Many weaning trials have used an RSBI threshold of 100 to 105, and thus do not have perfect predictive power (9,18). If the predictive threshold were decreased to the 50 to 65 range for the RSBI, then the positive predictive value would increase dramatically, but the negative predictive value would suffer (i.e., many patients who could actually tolerate weaning would still be receiving mechanical ventilation). Conversely, increasing the RSBI threshold to some number  $>105$  would increase the negative predictive value (i.e., few patients with higher indices would tolerate extubation), but the positive predictive value would be lower (i.e., many patients with RSBI just below the 105 threshold would fail to tolerate extubation).

The MIF, also known as the maximum inspiratory pressure ( $P_{IMAX}$ ), or negative inspiratory force, has been evaluated as a weaning parameter in many studies with variable predictive results (68–71). A healthy female can create an MIF of at least  $-90$  cmH<sub>2</sub>O, a male can generate less than  $-120$  cmH<sub>2</sub>O. Various clinical trials use different thresholds from  $-15$  cmH<sub>2</sub>O to  $-50$  cmH<sub>2</sub>O depending upon the average  $C_L$  and WOB of the study population.

Accordingly, simple comparisons between studies are challenging. One study demonstrated an accuracy of 66% for medical and cardiac intensive care patients capable of achieving a  $P_{IMAX}$  less negative than  $-20$  cmH<sub>2</sub>O (38). A 71% accuracy was achieved in a multidisciplinary intensive care unit (ICU) (including trauma and surgical patients) but required a  $P_{IMAX}$  of less than  $-50$  cmH<sub>2</sub>O (72).

The maximum negative pressure in the first 0.1 second ( $P_{0.1}$ ), with a threshold of  $<-5$  cmH<sub>2</sub>O is listed with an accuracy of 88%, specificity of 91%, and negative predictive value of 96% for multidisciplinary patients. However, this measurement is not readily available in most modern ICUs today (72).

The VC is determined in most ICUs before extubation with a commonly accepted threshold of 10–15 mL/kg. A healthy person generates a VC of approximately 70 mL/kg (5000 mL for a 70-kg adult). Accordingly, the minimum acceptable VC for weaning is far below the “normal” value achievable in healthy patients. The lower 10–5 mL/kg “threshold” value is often acceptable because of the

enormous reserve in the mammalian respiratory system. The 10–15 mL/kg VC target (like all weaning parameter thresholds) is a relative number, only adequate if the patient is not debilitated in areas other than those reflected in this one weaning predictor. Inability to generate the minimum acceptable VC can result from (i) a very noncompliant thorax or lungs and (ii) significant respiratory to muscle weakness. In either case, successful discontinuation from mechanical support is unlikely, and obtaining other weaning parameters (e.g., MIF,  $C_L$ ) will help explain the etiology problem.

A  $V_T$  of 6–8 mL/kg is required to maintain sufficient ventilation in a normal, spontaneously breathing patient. In ICU patients recovering from trauma and critical illness, breathing spontaneously (T-piece or C-PAP), a reasonable threshold is 4–6 mL/kg. Naturally, the RR will need to increase in patients with lower than normal  $V_T$  in order to maintain the  $\dot{V}_E$  required to exhale the normal  $CO_2$  produced.

Note that this  $V_T$  threshold is not as predictive when one is interrogating the muscle strength, and relative reversal from neuromuscular blockade drugs; in this setting,  $V_T$  measurements are not nearly as predictive as measuring the VC or evaluating a five-second head lift in a patient (Chapter 48).

Minute ventilation ( $\dot{V}_E$ ) is one of the most commonly used weaning parameters, because it is easily obtainable with today’s ventilators and serves as a gross measure of respiratory status. However, when taken in isolation, without clinical correlation,  $\dot{V}_E$  will not be as predictive (64). It is influenced by numerous clinical conditions like body weight, age (65), postoperative hypermetabolic state (66), and nutrition (67). The  $\dot{V}_E$  is, therefore, listed with a wide range of acceptable upper limits (10–15 L/min), and corresponding accuracies are lower than those resulting from other weaning parameters (62% for  $\dot{V}_E \leq 10$  L/min) (38).

The ratio of mouth occlusion pressure in the first 0.1 second to maximum inspiratory pressure ( $P_{0.1}/P_{IMAX}$ ) is a very accurate weaning parameter, in the setting of close experimental observations (Fig. 2). A  $P_{0.1}/P_{IMAX}$  ratio below 0.09 predicted successful extubation with a very high accuracy in one study (72). The authors explained these results based on ventilatory pattern changes being different in health and disease. Patients with imminent respiratory failure tend to take quick shallow breaths, as if gasping for air, which is reflected by a  $P_{0.1}/P_{IMAX}$  ratio of  $>0.09$ . This test detected successful weaning in a group of multidisciplinary critical care patients with an accuracy of 98%, PPV of 100%, and NPV of 92% (73).

Greater accuracy occurs when more than one weaning parameter is used to predict success. A formal approach by Yang and Tobin to further combine indices resulted in the index composed of  $C_L$ , RR, oxygenation, and pressure (CROP) index (73). This acronym integrates dynamic compliance  $C$ , respiratory rate  $R$ , oxygenation ( $P_aO_2/P_AO_2$ ), and maximum inspiratory pressure  $P_{IMAX}$ . The higher the CROP index, the higher the likelihood of successful weaning (73).

### The Rapid Shallow Breathing Index May Be the Single Most Useful Weaning Parameter

♣ The RSBI is the most widely used weaning parameter, because it is easy to obtain, predictive, and illustrative; patients failing to wean develop a breathing pattern characterized by small tidal volumes and increased RRs. ♣ In clinical practice, an RSBI of  $>100$  usually predicts

**Figure 2** Predictive accuracy of weaning parameters: from highest accuracy (top) to lowest accuracy (bottom) in percent. Abbreviations:  $P_{0.1}/P_{IMAX}^a$ , mouth occlusion pressure to maximum inspiratory pressure;  $P_{0.1}^a$ , mouth occlusion pressure (cmH<sub>2</sub>O);  $RSBI_{30}^b$ , RSBI after 30 minutes breathing begin;  $RSBI^a$ , rapid shallow breathing index (breaths/min/L);  $P_{IMAX}50^a$ , maximum inspiratory pressure > 50 cmH<sub>2</sub>O;  $RSBI_{100}^b$ , initial RSBI < 100;  $P_{IMAX}20^a$ , maximum inspiratory pressure > 20 cmH<sub>2</sub>O;  $\dot{V}_E^b$ , minute ventilation (cmH<sub>2</sub>O). Source: <sup>a</sup>Multidisciplinary patient group (72). <sup>b</sup>M/CICU patient group (38).

failure, and when this threshold was used the accuracy of predicting a weaning success was only 71% in MICU/CCU patients (38,74). A better prediction results when the RSBI is evaluated after 30 minutes of CPAP breathing ( $RSBI_{30}$ ), using a threshold of 100; the  $RSBI_{30}$  results in an accuracy of 85% in the same patient group. If the threshold were lowered to the 50 to 65 range, the RSBI would predict nearly 100% of patients that could be safely weaned to extubation, but (as discussed earlier) would result in far too many patients remaining ventilated who could tolerate weaning to extubation despite having  $RSBI > 65$ .

The RSBI only scored higher than the  $P_{0.1}/P_{IMAX}$  for the negative predictive value in medical/cardiac ICU patients (73,75). However, as we have discussed above, some of the differences in predictive power result from the threshold values chosen. If the experimentally derived statistical significance were the only important factor for predicting weaning success, then the arcane and cumbersome to measure  $P_{0.1}/P_{IMAX}$  ratio would be widely utilized (in some studies, the  $P_{0.1}/P_{IMAX}$  accuracy approaches 98–100%). However, the practical clinical realities require ease of use and reproducibility.

The RSBI is easy to obtain, and its use provides additional information beyond a calculated number (i.e., a description of the patient’s ventilatory status during SBT). Accordingly, the RSBI should be considered the single most useful weaning parameter. However, the threshold number used will determine the predictive power. A patient could have an RSBI of less than 100, the commonly used threshold, and still not be ready for extubation (other factors must always be considered). An RSBI less than 50 almost always successfully predicts a patient’s ability to be weaned to extubation. The threshold value chosen by the clinician will markedly alter the predictive power of any given weaning parameter.

Evaluating weaning parameters obtained by the RT results in an incomplete interpretation of data available from the patient. The clinician should be physically present at the bedside during at least part of any SBT that is being used to determine a patient’s fitness for weaning to extubation. The absence or presence of signs and symptoms of respiratory distress communicated through facial expressions, restlessness, perspiration, or hemodynamic changes all serve to supplement the weaning parameter data (in this case the RSBI), and helps the clinician determine the patient’s likelihood of tolerating weaning (Fig. 1) (75,76).

**Greatest Success Occurs When Multiple Parameters Are Combined with Clinical Judgment**

Any of the single weaning parameters used in isolation will result in many errors in management. Accordingly, multiple parameters should be used (according to Bayes’s theorem). Furthermore, when the decision to remove an ETT from a patient recovering from respiratory failure is complicated, clinical judgment that incorporates all aspects of the patient’s condition and progress is required. The acquisition and interpretation of multiple weaning parameters provide the supplemental information needed by the clinician to formulate the weaning decision-making process (64,77).

**WEANING STRATEGIES: WHICH ONE IS BEST?**

There are nearly as many weaning strategies as there are intensivists (8–13). Patients, who are not sick, rarely require weaning evaluation and may not need any special strategies (Table 4). However, patients who are debilitated

**Table 4** Strategies Employed to Facilitate Weaning

Weaning strategy	How accomplished/ comments	Likelihood of expediting weaning success
SBT	Patient placed on a T-piece or CPAP, ± supplementation with PSV and evaluated for 30–120 min; optimum duration of SBT varies with patient condition	Generally considered to be as good as any other weaning strategy
SIMV	Stepwise reduction in SIMV set rate until a set rate of 2 is achieved; SIMV set rate usually decreased 2–4 breaths/min every 12 hr	Generally considered the slowest strategy of weaning
PSV	Stepwise reduction in driving pressure until a threshold of <5–8 cmH <sub>2</sub> O is achieved; the driving pressure is usually decreased every 2–4 breaths/min every 12 hr	In some patients, PSV may facilitate weaning

Abbreviations: CPAP, continuous positive airway pressure; PSV, pressure support ventilation; SBT, spontaneous breathing trial; SIMV, synchronized intermittent mandatory ventilation.

and recovering from critical illness often need some time to both decrease their WOB (through healing) and to increase their strength (through exercise) (4). The WOB is increased following trauma and critical illness secondary to decreased  $C_L$  of the lungs and chest wall, increased  $V_D/V_T$ , and increased  $R_{AW}$ .

### Spontaneous Breathing Trial

During an SBT, the physician evaluates the patient's ability to breathe on his or her own (i.e., spontaneously) (78). To accomplish this, the patient is placed either on a T-piece or on the CPAP mode, typically set at 5 cmH<sub>2</sub>O PEEP, and supplemented with 5–10 cmH<sub>2</sub>O pressure support (Table 4) (79,80). The term "T-piece" stems from its shape. One arm of the T-shaped piece connects to the ETT, one arm connects to the fresh gas flow, and the third arm serves as the exhalation limb of the apparatus. The exhalation tubing should be at least 25 cm long to prevent entrainment of room air, and the fresh gas flow should equal at least twice the patient's spontaneous minute ventilation to eliminate rebreathing.

Although the patient performs the SBT, the RR, ventilatory pattern, and breathing efforts are closely monitored along with the SpO<sub>2</sub>, pulse rate, and blood pressure. RRs of 25 to 35 per minute are considered acceptable as long as the rate remains stable, the patient appears comfortable, and there is no deterioration in other parameters.

Most SBTs are now performed using the CPAP mode with the patient still connected to the ventilator apparatus. Advantages of this setup include the collection of more complete and continuous monitoring of many parameters, including tidal volume, RR, and minute ventilation, as well as ease of transition from baseline ventilatory support to the SBT.

✎ **Resistance created by the ETT, ventilator tubing, and circuit valves can be overcome by the addition of a minimal amount (i.e., 5 cmH<sub>2</sub>O) of pressure support.** ✎ Insufficient pressure support will result in increased WOB due to the high resistance of the relatively narrow ETTs (79,80). Too much pressure support augments the patient's spontaneous volumes and will cause a false-positive result during the SBT. The formula for determining airway resistance experienced by a patient on mechanical ventilation is shown in the airway resistance equation:

$$R_{AW} = \frac{P_{PK} - P_{PL}}{V_{INSP}} \quad (2)$$

where  $R_{AW}$  is the airway resistance,  $P_{PK}$  the peak inspiratory pressure,  $P_{PL}$  the plateau pressure, and  $V_{INSP}$  the inspiratory flow rate delivered with the breath. However, the  $R_{AW}$  equation includes the resistance of the entire system (ETT, trachea, bronchi, distal airways, etc.). The pressure support level required to counterbalance the resistive workload imposed by a narrow ETT varies widely (3–14 cmH<sub>2</sub>O) and cannot be easily measured noninvasively (79).

Historically, SBTs have been performed when the patient was deemed ready to be separated from ventilatory support (78). They can also be used as an intermittent assessment of the progress made in a patient's recovery from respiratory failure (78,81,82). Esteban et al. (82,83) showed that SBTs alternated with the assist control ventilation mode led to faster weaning when compared with pressure support ventilation (PSV) or synchronized intermittent mandatory ventilation (SIMV) weaning. Interestingly, there was no

difference in time to extubation whether SBTs were performed only once a day or multiple times per day. As both weaning methods were equally fast, the advantage of using only one SBT per day derived from saving time and human resources.

The optimal duration of the SBT for predicting weaning success is unclear because no large randomized, controlled trials (RCTs) exist. The Spanish Lung Failure Collaborative Group (83) reported a 30-minute trial to be just as effective as a two-hour trial in predicting weaning outcome (84). However, in debilitated patients who need to build muscles and ventilatory endurance, two to three SBTs per day of gradually increasing duration is more likely to result in strength training (RCTs are needed to verify). Some ICUs refer to these SBT exercise periods as "sprints" invoking the sports analogy, and a connotation that training of muscle strength and endurance is occurring.

Ultimately, the benefits of a regimented weaning strategy derived not just from the training of the respiratory muscles, but also from the organized process of exercise and progress monitoring (leading to earlier recognition of patients who are ready to be discontinued from mechanical ventilation) (84).

### Synchronized Intermittent Mandatory Ventilation Weaning

The SIMV mode of MV was described in Chapter 69. In SIMV weaning, the goal is a step-by-step reduction in mechanical support, promoting the patient's own ventilatory efforts (and strength), by sequentially decreasing the number of machine delivered breaths (Table 4). The initial set rate is progressively decreased until a rate of 2 to 4 breaths/min is achieved. The stepwise decrease in SIMV set rate typically occurs at intervals of 2 to 4 breaths/min every 12 hours, as tolerated and monitored by various parameters (i.e., the RSBI). The patient is evaluated at each level of ventilatory support, both clinically and with the use of weaning parameters, and laboratory data (i.e., arterial blood gas). The patient is considered successfully weaned and ready to evaluate for extubation if he/she is tolerating an SIMV rate of  $\leq 2$  to 4 breaths/min for at least 120 minutes. Note that Brochard et al. (85) and Esteban et al. (82) used an SIMV endpoint of 4 to 5 breaths/min for their definition of success (Tables 4 and 5). Some investigations require 24 hours of tolerating  $\leq 4$  breaths/min SIMV before meeting the weaning criteria for success (85). Pressure support (5 cmH<sub>2</sub>O) may be added to overcome the resistance created by the ventilator tubing and valves in the circuit during the spontaneous breaths.

One of the disadvantages of both SIMV weaning and T-piece weaning is the absence of automatic adjustments for changes in a patient's ventilatory demands (i.e., there is no compensation if the patient's minute ventilation declines). This implies that the patient cannot be left unattended during SIMV (or T-piece) weaning. SIMV weaning was initially promoted to prevent the patient from "fighting" the ventilator, decreasing the need for sedation, and reducing the likelihood of weaning fatigue. So far, no study has proven any of these claims or shown superiority of SIMV weaning over any other modes (82,85–87).

### Pressure Support Ventilation Weaning

As previewed above, PSV augments a spontaneous breath through a set amount of positive pressure, usually 5–20 cmH<sub>2</sub>O during inspiration. The PSV mode is a ventilation package, which is pressure triggered and flow cycled. In

addition, the pressure, flow, and volume profiles mimic the pressure control mode during the inhalation flow period (PSV is fully described in Volume 2, Chapter 27) (88–91).

Weaning with PSV usually begins by titrating the pressure support so that the patient starts with a reasonable RSBI (i.e., between 50 and 100), and is accomplished by reducing the pressure support gradually in 2–4 cmH<sub>2</sub>O decrements every 12 hours (Table 4) (82,85). Weaning is generally considered successful if the patient is tolerating a pressure support level of <5–8 cmH<sub>2</sub>O for ≥30 to 120 minutes, confirmed by adequate weaning parameters and blood gases at the end of the SBT. In a prospective, randomized controlled study, Brochard et al. (85) demonstrated PSV weaning to be faster and more successful than T-piece or SIMV weaning. However, Esteban et al. (82) failed to demonstrate any particular advantage of PSV weaning. A comparison of the Brochard and Esteban studies is provided in Table 5. Some patients tend to tolerate PSV weaning well, and for these individuals it remains a viable weaning methodology.

### Weaning Strategy Hybrids

Most intensivists currently use hybrids of the above weaning strategies (92). For example, regardless of which weaning plan is followed (once or twice a day SBTs, SIMV, or PSV), PSV is often added to compensate for the extra WOB caused by the *R<sub>AW</sub>* of the ETT during spontaneous ventilatory efforts.

Microprocessors have increased the variety of ventilation modes available both during ventilatory support and weaning from respiratory failure (Volume 2, Chapter 27) (93,94). For example, airway pressure release ventilation

(APRV) has been developed for augmentation of alveolar ventilation (95). Modes have also been developed to adapt to a patient’s change in respiratory support, like pressure-assisted ventilation (PAV) (96), automatic tube compensation (ATC) (97–103), adaptive support ventilation (ASV) (104–106), and adaptive lung ventilation (ALV) (107).

Modes purely used for ventilation of ARDS patients, such as time cycled pressure control inverse ratio ventilation (TCPCIRV), have been developed. These advanced modes add another layer of complexity to weaning because they require a transition from this aggressive level of support back to conventional mechanical ventilation before classical weaning can commence. To tolerate the TCPCIRV mode, patients require a deep level of sedation and usually neuromuscular blockade, underscoring the complexity of weaning from the TCPCIRV mode. Other options to modify oxygenation and ventilation in ARDS patients are numerous, and are fully reviewed in Volume 2, Chapter 27 (108–111).

### Summarizing Weaning Mode Trials

Three commonly applied modes of weaning a patient from ventilatory support have emerged: the SBT, where either CPAP or T-piece is utilized; SIMV; and pressure support (PSV) weaning. All three modes employ a stepwise reduction in ventilatory support as described above. Similarly, all three modes can be referred to as “sprints” when used to exercise debilitated, difficult-to-wean patients.

The literature offers hundreds of studies focusing on weaning, however, none have been conducted with sufficient power to provide a definitive answer. Only a few studies have been designed well enough to begin answering

**Table 5** Comparison of Brochard and Esteban Trials that Examined Pressure Supported Ventilation vs. Synchronized Intermittent Mandatory Ventilation vs. Spontaneous Breathing Trial Strategies of Weaning

	Brochard et al. (85)	Esteban et al. (82)
Number of patients screened	456	546
Number of patients randomized	109	130
Duration of MV before randomization	14 days	9 days
Starting condition	PSV—titrates to RR = 20–30 SIMV—half of AC rate T-piece 5–60 min as tolerated	PSV—titrates to RR ≤25 SIMV—half of AC rate T-piece as tolerated
Protocol	PSV: ↓ by 2–4 cmH <sub>2</sub> O, twice a day SIMV: ↓ by 2–4 breaths/min, twice a day T-piece: progressively increase to 2 hr	PSV: ↓ by 2–4 cmH <sub>2</sub> O, twice a day SIMV: ↓ by 2–4 breaths/min, twice a day T-piece (once): as tolerated up to 2 hr T-piece (multiple): T-piece or CPAP 5 cmH <sub>2</sub> O as tolerated multiple times per day (up to 2 hr per trial)
Criteria for success	PSV: 8 cmH <sub>2</sub> O for 24 hr SIMV: 4 breaths/min for 24 hr T-piece: 2 hr (1–3 times/24 hr)	PSV: 5 cmH <sub>2</sub> O for 2 hr SIMV: 5 breaths/min for 2 hr T-piece: 2 hr (once/24 hr)
Definition of failure	Unweaned at 21 days	Unweaned at 14 days
Results	PSV decreased percentage of patients with weaning failure (23% vs. T-piece 43%, SIMV 42%) Shorter mean duration of weaning with PSV (5.7 days) compared with pooled T-piece and SIMV patients (9.3 days)	Weaning failure: once daily T-piece (29%), multiple daily T-piece (18%), PSV (38%), SIMV (31%) Shorter mean duration of weaning with T-piece, once (3 days) and T-piece (3 days) compared with PSV (4 days) and SIMV (5 days)

some of the questions about what constitutes the most effective means of weaning (82,85,86,112,113). None of the three most commonly employed weaning modes has been consistently identified to be superior to the others (114,115). Esteban et al.'s (82) study showed the two-hour SBT using a T-piece to be at least as good, if not superior, to both PSV and SIMV (Fig. 3). In Brochard et al.'s study (85), PSV was marginally superior (Fig. 4), but as reviewed in Table 5, Brochard et al.'s protocol was more favorable to PSV than Esteban et al.'s (82,85). In both these widely referenced studies, SIMV weaning was shown to be the slowest method (8,87,116,117).

✎ **Most experienced intensivists recognize that no single mode of weaning is best for all patients in all circumstances.** ✎ Rather, the most critical elements of weaning are the repeated evaluation of the ventilator-dependent patient by both the respiratory therapist and the physician in charge; this is sometimes facilitated by protocols (118).

Patients with the need for prolonged ventilatory support may further benefit from specialized weaning facilities once they have recovered from their critical illness (119–125). In these centers, more attention can be paid to incorporating occupational and physical therapy into respiratory rehabilitation (126,127), than is possible in the acute care-centered (and more expensive) critical care unit environment (79,113,128,129). The weaning success rate ranges from 50% to 68%. It is highest within the first three months of institution of mechanical ventilation. In recent years, improved weaning techniques have accomplished separation from the ventilator in patients who were previously considered lifelong ventilator dependent, and the success rates for long-term weaning are continuing to improve (130–134).

Given that many chronic ventilator-dependent patients may have been near ventilator dependence due to poor cardiopulmonary fitness, even prior to sustaining their injury, an additional tool for improving pulmonary rehabilitation is cardiovascular fitness training.

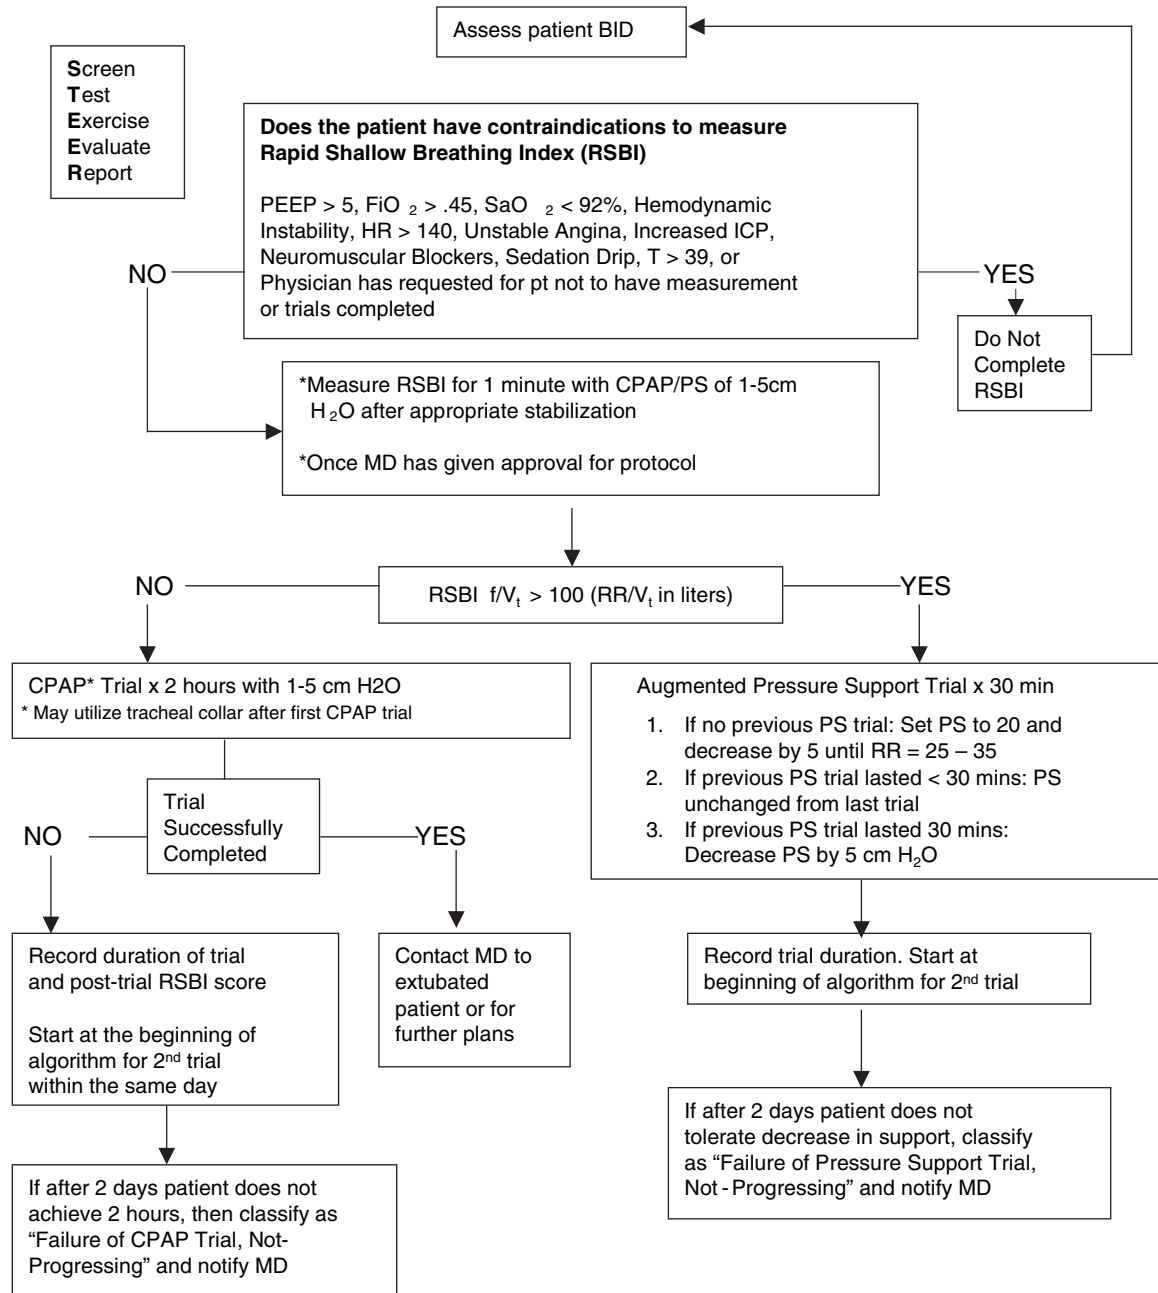

**Figure 4** Probability of remaining on mechanical ventilation in previously ventilator-dependent patients based upon the method of weaning. In this study, weaning was more rapid using a PSV weaning mode than for T-piece or SIMV weaning. See text for details. y-axis: probability of remaining on mechanical ventilation; x-axis: duration of weaning (days). *Abbreviations:* PSV, pressure support ventilation; SIMV, synchronized intermittent ventilation. *Source:* From Ref. 85.

### Weaning Protocols

An organized approach (i.e., weaning protocol) helps ensure that an organized and systematic approach is followed (118). Weaning protocols also increase the frequency and uniformity with which the patient's status is evaluated, helping to more quickly sort out the patients who are ready to be discontinued from mechanical ventilation.

The main benefit of weaning protocols is the consistent and systematic approach to weaning (135–143). When protocols are utilized, patients can be liberated from the ventilator faster (112,118). Protocols in the form of an algorithm can be followed by the RTs and/or nurses without the requirement for continuous physician presence (refer to UCSD Weaning Protocol, Fig. 5). However, review of the overall ventilatory status of the patient by the supervising physician remains indispensable in difficult-to-wean patients; and bedside presence of the clinician during SBTs provides important data that supplement weaning parameters. By employing a standardized regimen, unnecessary and potentially detrimental variations in weaning approaches are reduced and patients are extubated earlier than controls (84,105,106,108,109,144–154). Decreasing the duration of mechanical ventilation results in a reduction of adverse events secondary to mechanical ventilation and in shortening of ICU and hospital length of stay, and has been shown to improve the overall outcome (108,117,118,122,155). Earlier extubation has also been shown to decrease laryngeal damage from the ETT, and decrease the incidence of self-extubation, volutrauma/barotrauma, ventilator-associated pneumonia, ventilator-associated lung injury,

## UCSD VENTILATOR S.T.E.E.R. WEANING PROTOCOL

**Figure 5** UCSD weaning protocol. *Abbreviations:* BID, twice a day; CPAP, continuous positive airway pressure (cmH<sub>2</sub>O); F<sub>i</sub>O<sub>2</sub>, fraction of inspired oxygen; HR, heart rate (beats/min); MD, medical doctor; PEEP, positive end expiratory pressure (cmH<sub>2</sub>O); PS, pressure support (cmH<sub>2</sub>O); RSBI, rapid shallow breathing index [Respiratory rate/tidal volume (expressed in liters)]; STEER is an abbreviation for Screen, Test, Exercise, Evaluate, Report; T, temperature (°C).

cardiac compromise, patient discomfort, and respiratory muscle dysfunction (84,156).

✎ **The benefits of weaning protocols derived partly from the more frequent evaluations of respiratory status, decreasing delays caused by the false assumption that the patient is not yet weanable.** ✎ Protocols are thought to provide closer attention to the patient's respiratory status and decreased distraction from other sick patients. Part of this success is also attributable to a learning effect and

refining of management skills. If an organized weaning approach is already in place, less benefit occurs following implementation of a protocol (139,149,157). So far, mortality has not been shown to change by any specific weaning strategy, and weaning failures generally occur at similar rates in both protocol and control groups (136,137). However, an overall significant reduction of financial costs has been demonstrated using numerous protocol-driven weaning systems (84,105, 143,144,157).

### UCSD Weaning Protocol

The weaning protocol employed at UCSD (Fig. 5) has been developed through the work of several critical care practitioners over two decades. Patients are divided into two groups: (i) those that are expected to undergo an uncomplicated weaning to extubation (i.e., no focused weaning maneuvers required) and (ii) those that require a controlled weaning program. In the “uncomplicated weaning” group, the patient to be extubated fulfills steps 1 to 5 in Table 1, and is required to be awake, alert, with minimal WOB, is not expected to have difficulty controlling his/her airway, and not expected to have a difficult reintubation (i.e., also fulfills steps 6 and 7 in Table 1). The patient is placed on CPAP or T-piece, and providing that the weaning parameters are acceptable ( $RR \leq 25$ ,  $RSBI < 100$ ) and that oxygenation and ventilation are satisfactory (confirmed by arterial blood gas analysis), the trachea is extubated.

The “controlled weaning” group patient fulfills all criteria of the “uncomplicated” patient but must prove that he/she can do the WOB for a prolonged period of time. These patients, who are recovering from critical illness, frequently require strength and endurance training. They are placed on our “STEER” protocol: S for screen, T for test, E for exercise, E for evaluate, and R for report (Fig. 5). If the initial RSBI is  $< 100$ , the patient undergoes a two-hour CPAP trial, and if completed successfully is deemed ready for extubation (i.e., ready to be evaluated for goals 6 and 7, Table 1). If the patient becomes fatigued—RR of more than 30 and/or tidal volume decrease by  $50 \text{ cm}^3$  (or more than 10% below baseline) he/she is rested, but may undergo a second trial later the same day, if there is an observed likely reversible reason to explain why the patient did not tolerate the first SBT (e.g., fever spike).

If the initial RSBI is  $> 100$ , pressure support is increased to allow a CPAP trial for 30 minutes; if tolerated the pressure support is then gradually decreased. The patient is rested until a second trial later that same day if a CPAP trial is not possible, or a decrease of pressure support is not tolerated.

### Tracheostomy

Surgical airway techniques have been described for more than 5000 years (158) but the debate regarding indications in the critically ill patient has been most intense over the last 50 years. Some authors believe that early tracheostomy (within one to seven days) is associated with a reduction in duration of mechanical ventilation and shorter ICU and hospital stays when compared with translaryngeal endotracheal intubation and late (eight or more days after admission) tracheostomy (101,113,130,131). This is controversial because others cannot demonstrate any significant difference in duration of ventilatory support, ICU length of stay, frequency of pneumonia, or death in either early (3–5 days), or late (10–14 days) tracheostomy groups (132,159,160). In one study, about half of the patients underwent postextubation laryngoscopy: vocal cord ulceration and subglottic inflammation were more often present in the continued intubation group, but the difference was not significant (159). None of these patients demonstrated evidence of late vocal cord or laryngeal stenosis during the follow-up visit. Although there is a significant improvement in  $\text{PaO}_2/\text{FiO}_2$  ratios within 24 hours, there is only negligible change in  $V_D/V_T$ , if the patient remains hooked up to the ventilator tubing following a tracheostomy (73,161). However,  $V_D/V_T$  is decreased following tracheostomy when comparing

T-piece to tracheal collar. Additionally, there is a decreased WOB following tracheostomy compared to an ETT (162). In an RCT with burn patients, 26% of the conventional therapy group (continued endotracheal intubation with tracheostomy performed on postburn day 14 if necessary) were successfully extubated on postburn day 14 compared to only one patient of the early tracheostomy group (159). The authors attributed this partly to the ease of initiating or discontinuing mechanical ventilation with a tracheostomy in place decreased the rate of early tracheostomy decannulation. Additionally, the early tracheostomy group had larger full thickness burns than did the control group (159). Other benefits attributed to tracheostomy that have not been proven, but are generally accepted, include increased patient comfort, improved oral hygiene, easier airway suctioning, and greater options for oral communication.

### THE DIFFICULT-TO-WEAN PATIENT

Extubation failures and prolonged mechanical ventilation fall into the category of the difficult-to-wean patient. Most affected are elderly and COPD patients (10,163). Reinstitution of ventilatory support within 24 to 72 hours of planned ETT removal occurs in 2% to 25% of extubated patients (164,165). Failures are associated with higher incidence of hospital mortality, longer ICU and hospital stay, prolonged duration of mechanical ventilation, higher hospital costs, and increased need for tracheostomy (122,128,166,167).

Inadequacies in pulmonary gas exchange, increased WOB, and physical debility are the most common causes for failure to wean (79). If extubation fails or the patient is extubated but at risk for being reintubated, noninvasive positive pressure ventilation (NIPPV) is an alternative that can be applied successfully (Volume 2, Chapter 27) (2,106,151,168–185). However, NIPPV should not be expected to be successful if the reason for weaning failure is stridor and/or airway obstruction or any process with rapidly worsening respiratory failure. In contrast, NIPPV is particularly useful for the treatment of asthma, COPD, and cardiogenic edema, and brief episodes of hypercarbic or hypoxemic acute respiratory failure (185,186). Conversely, NIPPV is rarely successful in avoiding intubation in trauma and postsurgical surgical patients, partly because the underlying disease etiology is generally of greater severity and not quickly reversible (176,179,185).

✎ **Dysfunction of other (nonpulmonary) organ systems can also prolong weaning. Treating functional organ failures can help to turn a difficult-to-wean patient into one who can be successfully weaned.** ✎ The following survey of ventilation-associated organ system dysfunctions should be reviewed in each patient with prolonged weaning (Table 6).

### Central Nervous System (Neurological and Psychiatric) Considerations

Numerous neurologic conditions contribute to weaning difficulty (187,188). Traumatic brain injuries can impair the patient's wakefulness and ability to protect their airway; brainstem injuries can impair the respiratory drive as well as the gag and cough. Injuries to the phrenic nerve (from high cervical spine trauma) (189) and/or paralysis of thoracic cage muscles (high and low cervical spine trauma) can all impair the patient's strength, prolong

**Table 6** Special Considerations in the Difficult-to-Wean Patient: An Organ Systems Approach

Organ system	Common problems and solutions
CNS	Psychiatric/psychological: prolonged stress, fear and anxiety can lead to an acute disaster, which untreated may advance to PTSD; sleep deprivation and drug withdrawal are common problems (see text for solutions); excessive sedation and inadequate sedation can both prolong weaning, SCI can decrease the ability to do the WOB, TBI can alter the drive to breath and ability to protect the airway
Respiratory care	Secretion management and treatment of bronchospasm are frequent respiratory care problems that prolong weaning; ETTs can become kinked, or narrowed with inspissated secretions leading to significantly elevated WOB due to increased $R_{AW}$ ; positioning during the SBT can alter success; obese patients benefit from reverse Trendelenberg, SCI at C5–7 benefit from an abdominal binder (see text for explanation)
Cardiovascular	Myocardial ischemia may occur when there is an increased WOB, and or when the loading conditions on the heart change during the SBT; monitoring of ECG and evaluation with echo before and during an SBT can be diagnostic
GI/nutrition	Numerous GI and nutritional ailments can prolong weaning; severe malnutrition and excessive feeding syndromes are two ends of a spectrum that can impact weaning
Renal (electrolytes, etc.)	Fluid overload, as occurs with ARF, and deficiency in $PO_4^{2-}$ , or $Ca^{2+}$ , or $K^+$ can cause weakness, whereas excess $Mg^{2+}$ also cause weakness, deficiency of $Mg^{2+}/K^+$ are associated with dysrhythmias
ID	Fever, sepsis, and inadequately treated pneumonias or abscess, all contribute to respiratory failure
Hematological	Anemia in an already debilitated patient can increase cardiac work and lead to increase BMR and ischemia
Endocrinological	Hypothyroidism and adrenal suppression both decrease MAP and ability to do the WOB, hyperthyroidism increases WOB

*Abbreviations:* ATN, acute tubular necrosis; BMR, basal metabolic rate; CNS, central nervous system; ECG, electrocardiogram; ETTs, endotracheal tubes; MAP, mean arterial blood pressure; PTSD, posttraumatic stress disorder;  $R_{AW}$ , airway resistance; SBT, spontaneous breathing trial; SCI, spinal cord injury; TBI, traumatic brain injury; WOB, work of breathing.

weaning, and, in some cases, result in lifelong ventilator dependence (188).

Psychiatric issues also commonly contribute to the difficult-to-wean situation. Fear of respiratory failure and

death can hinder progress in some patients; this is particularly common in patients with underlying pulmonary disease and a history of prior ventilator dependence. One of the more common causes of prolonged weaning is the inappropriate titration of sedative drugs (7,190,191). Excessive sedation causes the patient to become obtunded. Inadequate drugs/doses promote increased pain, fear, anxiety, and psychosis during weaning. Delirium is present in the majority of ICU patients requiring mechanical ventilation, and its presence correlates with a prolonged duration of intubation and weaning (191).

Many institutions use relatively short-acting benzodiazepines (e.g., midazolam, lorazepam) or propofol for sedation. Newer sedatives such as the alpha-2 agonist dexmedetomidine provide excellent sedation and decrease analgesic requirements (192–197). Dexmedetomidine also maintains the respiratory drive despite the central depressant and sedative effects (Volume 2, Chapter 5). Daily evaluation and interruption of sedation have also been shown to accelerate the weaning process (198).

However, patients who are severely agitated and suffering from delirium often benefit from haloperidol. Many severely agitated patients are withdrawing from drugs, and most are extremely sleep deprived, as a result of the noisy ICU environment. Ensuring adequate sleep at night and increasing environmental stimulation during the daytime are beneficial goals. Evening efforts to promote sleep include placing less acutely ill weaning patients further away from noisy ICU doors and the main nursing desk to minimize sleep interruption from ambient noise. Newer specific benzodiazepine drugs such as zaleplon (Sonata<sup>®</sup>) or zolpidem (Ambien<sup>®</sup>) are increasingly used sleep medicines. Additionally, playing soothing music may have a positive biofeedback benefit.

Daytime stimulation is promoted by keeping the lights on and/or window shades open during the day, and reorienting patients to large clocks and calendars placed on the wall in clear view of the patient. Providing aggressive physical and occupational therapy, as well as other daytime activities also increases the environmental stimulation and daytime wakefulness of these patients. Some find the use of a bedside fan can help the patient endure SBTs. The psychological effect of cool air on the face during an SBT is analogous to jogging in a gentle cool breeze (vs. jogging on a stifling hot, humid windless day). Clinically depressed or psychotic patients should receive a psychiatric consultation and be restarted on their preinjury psychiatric medications. Review of the above neurological-, psychological-, and sedation-related causes of failure to wean comprises the first step in evaluating the difficult-to-wean patient (190,191).

### Optimize Respiratory Care

Secretion management is another, often overlooked, source of weaning failure. Although the patient may be able to oxygenate and ventilate, they may not be optimized from a respiratory care perspective. First and foremost, the clinician must ensure the absence of bronchospasm. Bronchospasm occurring in an otherwise ready to wean patient should be treated with albuterol (if COPD is prominent, ipratropium bromide should be added), and if steroid dependent, a short course of intravenous steroids in addition to aerosolized steroids should be employed.

Airway secretions are normally cleared by the tracheobronchial mucociliary system. This system is impaired in the intubated patient. In chronically intubated patients,

these stagnant pools of secretions become colonized or infected with nosocomial flora, producing an increased bacterial load in the secretions. The inability to maintain sufficient pulmonary toilet (excess respiratory secretions, inadequate cough) combined with impaired respiratory muscle capacity results in weaning failures and the need to reinstitute mechanical ventilation.

Aggressive physical therapy, including chest vibrations and pulmonary drainage, in combination with bronchodilators, frequent incentive spirometry, deep coughing, repeated suctioning, and abdominal binders (when appropriate), are all important measures for satisfactory weaning.

The ETT internal diameter (i.d.) should be evaluated in difficult-to-wean patients. A reduction in the i.d. of the ETT increases  $R_{AW}$  inversely to the fourth power of the radius. Kinks, retained secretions, and foreign bodies adherent inside the lumen of an otherwise adequately sized EET can similarly increase the WOB.

Inspiratory muscle fatigue and atrophy are common causes of failure to tolerate weaning (199–204). The use of inspiratory muscle strength training is gaining more recognition as a method to combat these changes (187,188,205–207). The proposed benefits of inspiratory training include: (i) the effect of improving the inspiratory muscle strength (206,207), (ii) standardization, (iii) routine use of beneficial breathing patterns, and (iv) other (not defined) training effects (205–207).

Patient positioning during SBTs can have a significant impact on ventilatory mechanics and weaning success. The upright position can decrease airway resistance compared with the supine position and results in increased lung volume and FRC (especially in obese patients). Most importantly, the increased FRC also protects against atelectasis and the consequent right-to-left transpulmonary shunting. Sitting a patient up in bed will achieve this goal, if their body habitus is thin. However, morbidly obese patients often need to be placed in the reverse Trendelenberg position to improve FRC. Indeed, placing morbidly obese patients in the sitting position may increase abdominal pressure and upward excursion of the diaphragm decreasing FRC.

In contrast to patients with a normally functioning thoracic cage, the supine position or slight Trendelenberg position results in superior pulmonary function (as documented by MIF and VC) in quadriplegic patients with diaphragm-sparing cervical spine injuries (i.e., C5–6, C6–7, C7–T1). These patients ventilate almost solely by the functioning diaphragm (along with a minor contribution from strap muscles). In these patients, the intercostal muscles and entire thoracic bucket handle ventilatory system is paralyzed (and paradoxically involutes during inhalation). By placing these patients supine or in slight Trendelenberg position, the diaphragm starts in the more optimized domed position (due to cephalad displacement by the weight of the abdominal contents), and has a greater excursion during diaphragmatic contraction, than occurs in the upright position. Most patients do not enjoy breathing in the reverse Trendelenberg position; accordingly, an abdominal binder can be placed and provide the same benefit (increasing abdominal pressure-mediated doming of the diaphragm prior to contraction).

### Cardiovascular Issues

Ongoing cardiac dysrhythmias, myocardial ischemia, or other cardiovascular causes of hemodynamic instability can render weaning difficult (208–215). Up to 35% of chroni-

cally ventilator-dependent patients show evidence of myocardial ischemia, which is associated with failure to discontinue mechanical ventilation (210,211). Cardiac dysfunction needs to be diagnosed and treated early, in order to maximize the likelihood of weaning success. A large variety of cardiac abnormalities can lead to weaning failure. However, myocardial ischemia is the most important cardiovascular impediment to weaning (210). Using continuous ECG monitoring, Chatila et al. (211) demonstrated myocardial ischemia in 6% of all weaning patients during SBTs. Lemaire et al. (213) first noted that intrathoracic pressure changes in patients with COPD changed markedly during the transition from positive pressure ventilation to spontaneous breathing, and that these alterations affected the cardiac loading conditions. Large, negative intrathoracic pressure swings increase both left ventricular preload and afterload. The consequent decrease in LVEF observed in COPD patients can be offset by the administration of PSV, further demonstrating the importance of heart–lung interactions during weaning (214). Patients demonstrating signs of myocardial ischemia during weaning should receive a cardiac consultation, an echocardiogram, and an examination of their coronary artery anatomy. Those with critical coronary artery lesions should be considered for treatment.

### Gastrointestinal and Nutritional Impediments to Weaning

Although any acute gastrointestinal process (e.g., small bowel obstruction, perforated viscus) will prolong weaning, these processes are normally recognized promptly, and are uncommon causes of failure to wean. Rather, malnourishment and abnormalities in essential vitamins and nutrients represent the gastrointestinal conditions that more commonly postpone weaning from mechanical ventilation. Preexisting malnourishment and debility, compounded by the delayed start of nutritional support, can prolong weaning due to muscle weakness and easy fatigability. Conversely, feeding the patient a diet too high in carbohydrates can increase the respiratory quotient (RQ), defined as  $\dot{V}CO_2/\dot{V}O_2$ . Worse still is the massive overfeeding of calories, which results in fat synthesis and an extremely increased RQ. The reader is referred to Volume 2, Chapter 31 for a review of the clinically relevant metabolic and nutritional assessment measures.

### Genitourinary Considerations

Abnormalities in fluid status and acid–base balance (controlled mainly by the lungs and kidneys) can complicate weaning. In order to compensate for acidosis (e.g., renal failure), the respiratory drive to ventilate  $CO_2$  off is increased; this will lead to higher-a-minute-ventilation (increasing the WOB) and making weaning more difficult. Conversely, metabolic alkalosis will decrease the brainstem-mediated drive to breathe causing hypercarbia, and in the absence of increased  $F_iO_2$  results in hypoxemia (Volume 2, Chapter 2). In-hospital metabolic alkalosis is most commonly due to contraction alkalosis, from aggressive diuretic therapy and/or  $H^+$ -loss secondary to continuous gastric suctioning. A decrease in minute ventilation can eventually lead to hypoxemia and persistent respiratory failure. Correction of electrolyte abnormalities [calcium, magnesium, phosphate (216,217), potassium (218–220)] and other vitamin and trace elements are likewise essential.

Renal failure almost always leads to respiratory failure when not treated. Early correction of fluid overload electrolyte and uremic toxin abnormalities increases the likelihood

of weaning success. A complete normalization of acid–base status may not be possible, except with continuous renal replacement modalities (Volume 2, Chapter 43). Unstable ICU patients with renal failure may not become weanable until these aggressive therapies are instituted.

### Infectious Disease Impediments to Weaning

Infectious conditions increase the WOB by increasing the metabolic rate (e.g., fever), increasing lung water due to capillary leak, and decreasing lung compliance. Accordingly, weaning failure can sometimes serve as the first hint of an ongoing or new infectious process. In ventilator-dependent patients, the lung is generally colonized and a common source of pneumonia and/or tracheobronchitis. Careful examination of all other potential sources (e.g., wound sites, invasive catheter sites, all body surface cavities, and fluids) is appropriate in any weaning patient showing evidence of infection (fever, leukocytosis, fluid retention, hyperglycemia, etc.). Appropriate antibiotic selection is guided by the clinical picture, Gram stain, and culture results (Volume 2, Chapter 53).

### Hematological Considerations

Abnormal hematological conditions can impair weaning and recovery from respiratory failure in a number of ways. Anemia can contribute to ischemia of multiple organs and increase the work of both the heart and lungs in compensation for the decreased O<sub>2</sub>-carrying capacity of the blood (211). The decreased O<sub>2</sub> content can also lead to generalized weakness and early fatigability of the muscles (including the diaphragm). Blood transfusion is indicated if ischemia or impaired DO<sub>2</sub> is prolonging weaning. Iron and erythropoietin are indicated in debilitated, chronically ill patients with anemia of chronic disease.

Thrombocytosis and immobility increase the risk of deep venous thrombosis (DVT) and subsequent pulmonary emboli. All critically ill trauma patients should receive DVT prophylaxis (as reviewed in Volume 2, Chapter 56).

### Endocrine Issues

Endocrine dysfunction can impair the ability to wean. The most relevant endocrinological conditions include hyperthyroidism, hypothyroidism, and adrenal suppression. Hyperthyroidism increases the metabolic rate, CO<sub>2</sub> production, and, consequently, the WOB, whereas hypothyroidism decreases the mental and physical condition, decreasing the patient's ability to do the WOB. Adrenal suppression decreases the patient's stamina and impairs the cardiovascular system. These entities are discussed in greater detail in Volume 2, Chapters 61 and 62.

## SPECIAL CONSIDERATIONS RELATED TO THORAX TRAUMA

### Direct Lung Injury

Pulmonary contusion and lung lacerations are the most pertinent direct lung injuries occurring following trauma and are fully discussed in depth in Volume 1, Chapters 25, and Volume 2, Chapters 23–25. Accordingly, only the key points affecting weaning will be outlined in the section. The contused lung is prone to shunting from alveolar damage and atelectasis, resulting in hypoxemia and increased alveolar dead space, all of which can impair weaning and result in increased WOB.

### Indirect Lung Injury

Fluid resuscitation complicates weaning following trauma. Loss of colloid oncotic pressure and consequent increased third spacing of fluid increase the diffusion distance for the oxygen molecule, resulting in increased V/Q-mismatching, shunt, and dramatically increased WOB.

Release of inflammatory mediators from sepsis and from systemic response to severe injury (Chapter 105) further exacerbates the noncardiogenic pulmonary edema. This condition impairs oxygenation through V/Q-mismatching and leads to increased WOB and a possible difficult-to-wean situation.

### Mechanical Issues

#### Flail Chest

A flail segment is defined as two or more ribs broken in two or more places, whereas a flail chest is a chest which does not function for any number of reasons (Volume 2, Chapter 25 discusses these entities in detail); pain can lead to splinting, whereas mechanical dysfunction can lead to paradoxical breathing. Both are worsened by hemo- or pneumothorax. The overall net result is a reduction in minute ventilation. Furthermore, the perfusion in the flail segment continues; however, the expansion of the lung decreases resulting in regional shunting. A patient with a flail chest typically compensates by increasing his RR and by decreasing his tidal volume rendering weaning from a respirator challenging.

#### Pneumothorax and Hemothorax

Both pneumothorax and hemothorax are discussed in Chapter 25 of both volumes. These lesions are both acutely treated with chest tubes. Prior to initiating weaning, the patient should be free of any acute process.

#### Spinal Cord Injury

Site, mechanism of injury, and clinical findings of secondary spinal cord injury determine whether a patient is at risk for respiratory failure and/or in need for airway protection. Severe spinal cord injuries with lesions around vertebral body C3 and higher lead, almost always, to long-term respiratory failure and in cases of C4–5 lesions to long-term respiratory insufficiency (phrenic nerve arises from spinal nerve roots C3–5).

## THE PATIENT IS WEANED—CAN THE TRACHEA BE SAFELY EXTUBATED?

### Does the Patient Have an Intact Gag and Cough?

Once oxygenation and ventilation have been normalized and the patient is deemed ready to be liberated from the ventilator, the next question is whether the patient has a sufficient gag reflex, and is able to protect his/her airway. Without a gag reflex, extubation is contraindicated (Table 1, step 6). The next important question is whether the patient has a strong enough cough to bring up secretions and clear the airway from obstructing substances. **☞ Only after verifying that the patient has a normal vigorous gag and cough mechanism should the clinician advance to the step of considering ETT removal. ☞**

### Does the Patient Have a Difficult Airway?

**☞ A history of difficult intubation, or an examination that concludes the airway will be difficult to reintubate**

(i.e., presence of a halo), requires a planned extubation sequence usually involving fiberoptic bronchoscopy and or an AEC. If placing an ETT is known to be difficult, helpful tools as described in the ASA Difficult Airway Algorithm (Volume 1, Chapter 9) should be at the bedside and a person comfortable with the application of these tools present. It is prudent to have a surgeon—capable of doing an emergency tracheostomy—aware of a planned “difficult” extubation and standing by. To minimize the chance of serious complications, it is most reasonable to extubate these patients only if successful extubation and discontinuation from mechanical support is highly likely.

### Strategies for Extubating the Difficult Airway

The first step is to keep the patient NPO following the usual NPO guidelines by the American Society of Anesthesiology in order to decrease the risk of aspiration. Please see also the ASA Difficult Airway Algorithm for options to extubate a patient safely. It is not a particular technique but one’s familiarity with the technique that decides safety and success.

A good first choice is the use of a tube exchanger: a long (>50 cm) rigid plastic tubing which is placed through the in situ ETT allowing the ETT to slide over it. Ideally, the patient is appropriately informed, well prepared, and compliant. The ETT is removed carefully: close observation for respiratory sufficiency is obligatory. The tube exchanger is removed if the patient is breathing comfortably.

If later on the patient fails extubation, it is critical to maintain spontaneous ventilation until an ETT can be placed successfully (e.g., via fiberoptic bronchoscopy). If the patient becomes obtunded, he/she might tolerate an LMA through which an ETT can be placed, preferably with fiberoptic guidance (221).

### EYE TO THE FUTURE

Ongoing research will help us to improve outcomes and promote more successful recovery from respiratory failure. One such new approach, by Martinez et al. (62), plots  $\dot{V}_E$  recovery time after a two-hour SBT. In this introductory study,  $\dot{V}_E$  recovery time outperformed RR (cut off = 38 breaths/min) and RSBI (cut off = 105 breaths/min/L) (62). Unfortunately, the number of patients evaluated in the Martinez et al. study was small, as was the number of patients requiring prolonged mechanical ventilation. Although the results are encouraging, the threshold for discrimination between weaning success and failure is not robust enough as a single measure of weaning.

Newer sedative drugs that do not inhibit ventilatory drive (e.g., dexmedetomidine) are proving potent adjuncts to standard practices in the difficult-to-wean patients.

In the future, more sophisticated ventilators will help us to determine the earliest and safest time to discontinue mechanical ventilation by integrating and extrapolating numerous weaning parameters.

Finally, “step-down” weaning units are likely to play a more prominent role in acute patient care. These units would accept chronically ventilator-dependent patients who have recovered from their acute disease processes but have become debilitated and ventilator dependent. Most of these patients would already have had a tracheostomy performed, and failed weaning for a significant period of time.

### SUMMARY

Weaning remains a major challenge for patients recovering from respiratory failure. Employing the seven-step approach reviewed in Table 1 ensures that patients are capable of tolerating weaning (steps 1–5), patients are evaluated for ability to protect their airway once extubated (step 6), and the likelihood that reintubation will be difficult (step 7).

The search continues to find the single weaning parameter that best predicts success, but currently the RSBI provides the best indicator. Nearly all patients with RSBI <50 are capable of breathing on their own, whereas those with RSBI >100 are unlikely to tolerate weaning and require strength training, or further improvement in their overall condition. Patients with RSBI in the middle of these two extremes require additional data to make the correct weaning decision. One newer weaning parameter that may provide such data is the  $\dot{V}_E$  recovery time (62). No particular weaning strategy (SBT, SIMV, PSV, etc.) has proven superior to others. In difficult-to-wean patients, efforts are spent in reviewing each organ system and optimizing these, as the patient recovers from the primary disease. Additionally, strength and endurance training are thought to be beneficial, especially in debilitated patients. The optimum methodology and duration of sprinting regimens are the subject of ongoing research.

### KEY POINTS

- ☞ The weaning sequence should proceed along a logical stepwise evaluation pathway.
- ☞ Clinicians should closely review the contributors to respiratory failure at the moment the patient is intubated, and commence optimization of all anticipated impediments to weaning from the beginning.
- ☞ The patient is not ready to proceed with weaning until he/she can maintain adequate oxygen saturation, both at rest and with modest exertion (i.e., during weaning).
- ☞ When the WOB is excessive (Fig. 1), even young and otherwise healthy patients can develop respiratory failure.
- ☞ Some weaning parameters reflect the WOB that must be performed by the patient (e.g.,  $\dot{V}_E$ ,  $C_L$ ,  $R_{AW}$ ), whereas others reflect the patient’s ability to perform that work (e.g., MIF, VC, RSBI).
- ☞ The RSBI is the most widely used weaning parameter, because it is easy to obtain, predictive, and illustrative; patients failing to wean develop a breathing pattern characterized by small tidal volumes and increased RRs.
- ☞ Resistance created by the ETT, ventilator tubing, and circuit valves can be overcome by the addition of a minimal amount (i.e., 5 cmH<sub>2</sub>O) of pressure support.
- ☞ Most experienced intensivists recognize that no single mode of weaning is best for all patients in all circumstances.
- ☞ The benefits of weaning protocols derived partly from the more frequent evaluations of respiratory status, decreasing delays caused by the false assumption that the patient is not yet weanable.
- ☞ Dysfunction of other (nonpulmonary) organ systems can also prolong weaning. Treating functional organ failures can help to turn a difficult-to-wean patient into one who can be successfully weaned.
- ☞ Only after verifying that the patient has a normal vigorous gag and cough mechanism should the clinician advance to the step of considering ETT removal.

✦ A history of difficult intubation, or an examination that concludes the airway will be difficult to reintubate (i.e., presence of a halo), requires a planned extubation sequence usually involving fiberoptic bronchoscopy and or an AEC.

Michael Berrigan

Department of Anesthesiology and Critical Care Medicine, George Washington University Hospital, Washington, D.C., U.S.A.

### INTRODUCTION

✂ Extubation of a known difficult airway and especially planned endotracheal tube (ETT) change in a critically ill patient should be approached with a similar degree of concern and preparation as that given to initial intubation. ✂ That is, the patient should be evaluated for difficulty of reintubation due to known anatomic or pathologic airway conditions. In addition, the likelihood of difficulty maintaining cardiopulmonary function during the reintubation interval must be incorporated into the airway plan of patients dependent upon high levels of ventilatory support. Similarly, perturbations in intracranial pressure (ICP) in patients with decreased intracranial compliance must be considered in trauma patients requiring ETT change. The basic aphorism “Never take out that which you can not put back in” should be followed when the tube is critical to the patient’s survival.

The incidence of tracheal reintubation in the surgical intensive care unit (SICU) setting has been reported as 4% in a study of 700 consecutive extubations (1). It should be noted that a very low incidence of reintubation may not necessarily be a good thing. It might indicate excessively conservative management and an unnecessarily prolonged course of mechanical ventilation (MV) in many patients. The reintubation rates reported in the postanesthesia care unit are much lower, less than 0.2% (2,3). In the intensive care unit (ICU), self-extubation, either deliberate or accidental, accounts for slightly more than 10% of all extubations (4). After controlling for comorbidities and severity of illness, the need for reintubation has been shown to be an independent predictor of mortality (5). Although this higher mortality was associated with nonairway problems, rather than with complications of the reintubation itself, in a medical ICU (6), numerous airway-related mishaps are involved in the morbidity of reintubation, especially in the SICU where post-extubation stridor can result from numerous complications of resuscitation, primary disease, trauma, or burns.

Practice guidelines for management of the difficult airway developed by the American Society of Anesthesiologists (ASA) in 1993, and updated in 2003, recommend that airway practitioners should have a “Preformed strategy for extubation of the difficult airway” (7,8). The recommended components of the preformed extubation strategy are listed in Table 1 (7).

This chapter reviews the risk factors for difficult extubation in critically ill patients, or ETT change, along with other criteria that should be evaluated prior to extubation. Next the value of airway exchange catheters (AECs) and fiberoptic bronchoscopes (FOBs) during ETT change or removal is surveyed. Guidelines for the use of other adjunct devices and rescue maneuvers are also provided. This chapter should be reviewed along with Volume 1, Chapter 9, and Volume 2, Chapter 28.

### EXTUBATION/REINTUBATION CONSIDERATIONS/ RISK FACTORS

Some extubations in the ICU are inherently more risky than others. For example, patients with a history of difficult intubation, and those who have undergone a procedure or developed a condition that makes reintubation more challenging are considered “difficult intubation” patients. Others with risk factors for surgical-airway difficulty (e.g., radiation therapy or tissue swelling) represent risks in terms of backup procedures. In addition, those with physiologic risk factors [e.g., requirement for high  $F_{I}O_2$ , positive end expiratory pressure (PEEP), inability to do the work of breathing (WOB) or clear secretions] will not likely tolerate ETT removal for long. Likewise, those with unstable ICP or hemodynamic status, and those pharmacological risk factors all require specific preparation and treatment (Table 2).

Although the presence of an indwelling ETT implies previous intubation success, the ease with which the ETT was placed is not necessarily obvious. Consequently, it is important to determine the circumstances (ease or difficulty) with which the previous intubation occurred. The medical record is helpful in this regard if the documentation was well done. However, there are many instances when this information will not be available.

#### Intubation History

Any mention of a difficult intubation during prior airway manipulations requires further investigation and clarification. If the patient came from the operative suite, a record of the intubation should be chronicled in the anesthesia record. When difficult intubation is mentioned, it is

**Table 1** The Preformulated Extubation Strategy

A consideration of the relative merits of awake extubation versus extubation
An evaluation for general clinical factors that may produce an adverse impact on ventilation after the patient has been extubated
The formulation of an airway management plan that can be implemented if the patient is not able to maintain adequate ventilation after extubation
A consideration of the short-term use of an AEC that can serve as a guide for expedited reintubation; this type of device is usually inserted through the lumen of the tracheal tube and into the trachea before the tracheal tube is removed; the device may be rigid to facilitate intubation and/or hollow to facilitate ventilation

Abbreviation: AEC, airway exchange catheter.

important to note the circumstances surrounding the intubation and the technique(s) used. Among the variables to be noted are whether or not the patient was easily ventilated by mask, the position of the patient, the specifics of the equipment used, the number of attempts required, and which member of the health-care team (novice vs. senior airway expert) performed the intubation.

### Physical Examination of the Airway

Physical evaluation techniques for determining the ease or difficulty of intubation are improving in precision. A

**Table 2** Causes of Difficult Extubation/Reintubation

Causes	Mechanism	Examples
Difficult reintubation/ ventilation	Anatomic	I-IG, OPV, MS, H&N ROM
	Pathologic	Trauma, fluid, angioedema
	Mechanical	Halo, fused spine, IMF
Will not tolerate extubation for long (i.e., patients are not weaned, but need an ETT change)	Impaired oxygenation	↑ PEEP, ↑ F <sub>I</sub> O <sub>2</sub>
		↑'d WOB
	↓'d ability to WOB	↑ RSBI, or ↓ MIF
	Other systemic or neurologic conditions	Shock—numerous etiologies (Volume 2, Chapter 18) ↑'d ICP

Abbreviations: CO<sub>2</sub>, carbon dioxide; F<sub>I</sub>O<sub>2</sub>, fraction of inhaled O<sub>2</sub>; H&N, head and neck; ICP, intracranial pressure; I-IG, inter-incisor gap; IMF, intermaxillary fixation; MIF, maximum inspiratory force; MS, mandibular space; OPV, oral-pharyngeal view; PEEP, positive end expiratory pressure; PIPs, peak inspiratory pressure; ↑ R<sub>AW</sub>, airway resistance; ROM, range of motion; RSBI, rapid shallow breathing index; WOB, work of breathing; ↑, high; ↓'d, decreased; ↑'d, increased; V<sub>E</sub>, minute ventilation; V<sub>D</sub>, dead space; ↓, low.

formal 11-step airway evaluation as outlined in Volume 1, Chapter 9 should be performed in all patients prior to intubation, and prior to elective ETT change in the ICU. There is a high predictive value in addressing measurements such as the thyromental distance (TMD), mouth opening, and neck extension (9). The Mallampati test, which involves visual inspection of the pharynx, is less precise in the intubated patient. However, a receding chin (short TMD), a pronounced dental overbite, a short, thick neck, a highly arched palate, and a small mouth can all be appreciated by physical exam. All have been associated with a difficult tracheal intubation. The reader is referred to Volume 1, Chapter 9 for complete guidelines on the 11-step airway examination. In addition, those patients whose neck movement is restricted by pathology or by external restraint such as a cervical collar or rigid halo device represent additional hazards likely due to technical difficulties in intubating the trachea.

### Postsurgical/Trauma Considerations

✎ **A critical airway consideration in the posttrauma or critically ill surgical patient is the likelihood of periglottic swelling or pathology that could lead to postextubation stridor and possible inability to intubate or ventilate the patient.** ✎

Risk factors for postextubation stridor include: airway edema due to massive resuscitation and/or hypoalbuminemia, high levels of circulating inflammatory mediators due to sepsis/systemic inflammatory response syndrome, direct neck trauma, or burns (especially to neck and face). In addition, prolonged intubation can cause ulcers to develop on the vocal cords, or cysts to form, which can obstruct the airway following extubation. Another important consideration is recurrent laryngeal nerve injury, which will cause unopposed adduction of the vocal cord involved, and consequent stridor.

### Techniques for Predicting Postextubation Stridor

✎ **In the case of patients at high risk for postextubation stridor, a formal evaluation for periglottic swelling should be performed prior to attempts at extubation or ETT exchange. Options for evaluation of airway swelling include: (i) cuff-leak test, (ii) FOB evaluation, and (iii) imaging studies.** ✎

### Cuff-Leak Test

The cuff-leak test has been used in a variety of ways over the years, with varying degrees of success. Potgieter and Hammond (10) described a qualitative cuff-leak test performed by deflation of the ETT cuff, digital occlusion of the tube, and an assessment of air movement around the tube. They evaluated this in 10 patients who had previously had required intubation for upper-airway obstruction due to edema. They did not describe the extubation of patients without a cuff-leak or the implications of leaving the tube in place until a cuff-leak develops. The authors also failed to emphasize the difference in evaluation success rates when flow is characterized during exhalation versus inhalation. When clear flow occurs during exhalation only (where there is less propensity for airway closure), but not during inhalation (where collapse is more likely to occur due to dynamic resistive changes), then the predictive power of extubation success is likely to be lower than in situations where clear airflow is heard around the obstructed ETT during both inhalation and exhalation. Kemper et al. (11) confirmed Potgieter's observation in a pediatric burn

and trauma unit, concluding that the absence of a cuff leak was the best predictor of the need for reintubation or tracheostomy.

Fisher and Raper (12) observed that all 60 patients with a cuff leak were successfully extubated, but two patients extubated without a cuff leak required reintubation, and five patients who repeatedly failed the test required tracheostomy. They subsequently studied 10 patients without a cuff leak; only three of whom required reintubation or tracheostomy, whereas the majority tolerated extubation despite “failing” the cuff-leak test.

Owing to the generally poor positive predictive value (true positive tests divided by total positive tests) of the qualitative cuff-leak test (with a “positive test” defined as absent airflow around the obstructed ETT with the cuff down) (12,13), techniques for quantitating the cuff-leak test were developed. Indeed, investigators can now quantify the degree of leak around an indwelling ETT, with the cuff deflated, in mechanically ventilated patients. The leak volume in these studies is quantified by measuring the difference in exhaled tidal volume before and after cuff deflation occurs while patients continue to receive positive pressure ventilation.

In the two largest studies of this type to date, the cuff-leak test was not found to be predictive. Engoren (14) studied 524 patients, defining failure as those with <110 mL leak-volume, the study yielded a positive predictive value of zero. Kriner et al. (15) performed a quantitative cuff test on 464 patients who had been intubated an average of  $5 \pm 4$  days in a medical–surgical ICU, a failed cuff-leak test in this study was defined as  $\leq 110$  mL, or  $\leq 15.5\%$  of exhaled volume before cell deflation. These authors conclude that the cuff-leak test is an unreliable indicator of postextubation stridor. A large part of the variability relates to the many factors (besides the cross-sectional area around the ETT that contributes to the degree of leak, e.g., the respiratory mechanics, the inspiratory flow, pressure, and I:E ratio) (16).

**Figure 1** Fiberoptic bronchoscope (FOB). FOB is integral to the evaluation of periglottic swelling often responsible for post-extubation stridor. The FOB is also useful in facilitating reintubation of the difficult airway.

### Fiberoptic Bronchoscopy Evaluation

☞ In situations where the patient is at high risk for postextubation stridor, additional specific evaluation with FOB (Fig. 1) is warranted. ☞ The FOB can be used to suction debris from the airway and improve the immediate postextubation ventilatory status. It can also be used to evaluate the airway for anatomic and pathologic evidence of airway swelling that will increase the risk of postextubation stridor. The use of the FOB for airway manipulations is fully reviewed in Volume 1, Chapter 9.

The patient should be placed on 100% O<sub>2</sub>, and be topicalized with local anesthetics delivered above the glottis (including in the nasal and oral passages), as well as through the ETT to anesthetize the tracheal and bronchial mucosa. The patient should also receive any necessary systemic analgesia and sedation as required to tolerate the procedure. Besides small doses of opioid titrated to a respiration rate (RR)  $\geq 12$ , sedation can be titrated as needed, but should not be so excessive as to obtund the patient. Sedation choices range from low doses of benzodiazepine or propofol, to dexmedetomidine, a newer  $\alpha_2$  agonist that does not depress respiration, but does decrease opioid requirements. The primary side effect of dexmedetomidine is hypotension due to its activation of the  $\alpha_2$ -adrenergic receptor (17). It is dosed intravenously and maintained via intravenous infusion. Currently, dexmedetomidine is approved for up to 24 hours of use; however, there are several reports of longer use in the ICU without complications (18).

Reassuring findings during airway evaluation by FOB include: (i) ability to clearly visualize the vocal cords around the indwelling ETT, (ii) absence of significant supraglottic swelling (that might progress following removal of the ETT), (iii) visualization of room between the anterior commissure of the vocal cords and the ETT (i.e., should be able to pass the FOB alongside the ETT and enter the trachea), (iv) confirmation that the airway passages (trachea and main bronchi) are patent, without massive retained secretions or bronchial plugs, and (v) verification that the posterior membrane of the trachea stays expanded during inhalation (rather than involuting and causing a subglottic form of postextubation stridor). Although these above mentioned findings are reassuring, their predictive power has yet to be confirmed in prospective, randomized, controlled trials (RCTs).

### Imaging Studies

All available imaging data should be evaluated prior to extubation or elective ETT change in patients with likely anatomic or pathologic airway problems that could contribute to postextubation stridor. Although this recommendation constitutes common wisdom, there have not been any prospective RCTs investigating the predictive power of computed tomography or magnetic resonance imaging findings and the likelihood of postextubation stridor.

A recent development in this area has been the introduction of laryngeal ultrasound (US) (19). Laryngeal US is less invasive than FOB. The laryngeal US probe is placed on the skin of the anterior neck at the level of the cricothyroid membrane. Using this technique, Ding et al. demonstrated that laryngeal US was capable of evaluating the vocal cords, laryngeal morphology, and the ease of airflow through the vocal cords. The air column width during cuff deflation appeared to be a potential predictor of postextubation stridor; however, because it was a pilot study, it was not powered enough to provide definitive data.

### Evaluating Ease of Performing Surgical Airway

✎ In the case where airway management is difficult and both conventional and adjunct procedures (described subsequently) all fail, then a surgical airway should be performed. ✎ In fact, in some patients, a surgical airway will be the best first option for definitive airway exchange in the ICU. For example, converting the ETT to a tracheostomy would be warranted in the patient with respiratory failure who requires an ETT change due to balloon cuff rupture, but is expected to have a very difficult reintubation, or has documented tight-swelling around the indwelling ETT. In these cases, going to the operating room and performing a formal tracheostomy under a controlled setting is a safer choice than risking an ETT change in the ICU.

Regardless of planned surgical airway, or if the surgical option is relegated as a "Plan B," an evaluation of the anatomic structure in the neck should be undertaken to determine the ease of performing a surgical airway. In addition, the ability to flex and extend the neck should be determined. Finally, the cricothyroid membrane should be palpated and marked on the neck (in case of need), and a surgical airway kit should be at the bedside, along with a trained surgeon capable of performing the procedure. In the very highest risk cases of all, the neck should even be prepped and draped and the head extended so that an emergency surgical airway could be more easily conducted if needed.

### Other Factors

There are other conditions associated with the inability to safely exchange an ETT or tolerate extubation which do not directly involve upper-airway swelling, or impairment of pulmonary status. There are numerous physiologic risk factors which predispose a patient toward altered mental status, perhaps respiratory insufficiency and systemic inflammation (Volume 2, Chapter 63). In addition, poor planning or absence of qualified airway experts or assistance can be detrimental. It has been estimated that as much as 62% of reintubations are the result of an error of judgment/problem recognition (20). Other contributing factors included high unit activity, difficult patient habitus, and lack of patient cooperation. ✎ When considering ETT change or extubation, decisions must be made on an individual basis with evaluation of the entire clinical picture considered rather than focusing upon a single event or parameter. ✎ Patient secretions are often overlooked; adequate suctioning of the oropharynx should be performed prior to any attempt at extubation or ETT exchange. An antisialagogue may be useful in this regard.

### EXTUBATION IN THE INTENSIVE CARE UNIT

In preparing a patient for extubation in the ICU, all the points discussed in "Extubation/Reintubation Considerations/Risk Factors" should be considered. Several additional observations and laboratory studies should be considered to determine the patient's overall fitness for weaning, but above all, sound clinical judgment is required. Prior to attempting ETT removal or exchange, the checklist provided in Table 3 should be followed.

In terms of weaning criteria, the seven-step approach to weaning detailed in Table 1 of Volume 2, Chapter 28 should be used. It is required that the patient has adequate affirmative responses to all seven parameters prior to safe extubation

**Table 3** Criteria Checklist Prior to Extubation/Tube Change

Criteria	Examples/comments
Fulfills all weaning criteria	Necessary if extubation is planned (seven-step approach according to Volume 2, Chapter 28)
Successful "cuff-leak test"	No leak = ↑'d risk of stridor
Pre-extubation FOB exam	Evaluate periglottic anatomy when no leak on cuff-leak test, and other high-risk patients
Extubate over appropriately sized AEC	Use whenever in doubt about airway caliber adequacy for extubation, and when reintubation expected to be difficult
Assistance tools available	The following tools are useful: O <sub>2</sub> , suction, RDL, FOB (pre-ensheathed), LMA, Combitube, TTJV, surgeon

*Abbreviations:* AEC, airway exchange catheter; FOB, fiberoptic bronchoscope; LMA, laryngeal mask airway; O<sub>2</sub>, oxygen; RDL, rigid direct laryngoscopy; TTJV, transtracheal jet ventilation; ↑'d, increased.

in the SICU. The seven requirements are: (i) the patient has recovered from or improved sufficiently from the primary disease process that necessitated intubation and MV; (ii) there is no intercurrent condition that will require continued MV (e.g., renal failure, liver failure, neuromuscular weakness, etc.); (iii) the patient is able to maintain adequate oxygenation with reduced FiO<sub>2</sub> (PaO<sub>2</sub> > 90 mmHg on FiO<sub>2</sub> ≤ 0.4 with PEEP ≤ 8); (iv) the WOB is not high (i.e., the  $\dot{V}_E$  is not excessive, the airway resistance is not elevated, and the compliance is not too low); (v) the patient must be able to do the WOB [i.e., the maximum inspiratory force (MIF) and vital capacity are high, and the rapid shallow breathing index (RSBI) is low (<50 is excellent, <100 may be adequate)]; (vi) the patient is awake, cooperative, and has intact airway reflexes (e.g., gag and cough); and (vii) the patient does not have a reason for difficult reintubation if he/she fails extubation. If reintubation is expected to be difficult, the patient should initially be extubated over an AEC.

✎ In terms of weaning parameters, the RSBI is probably the single best indicator for determining the patient's ability to perform the required WOB. ✎ The RSBI is defined as the RR divided by the tidal volume in liters achieved while breathing spontaneously. Those patients with an RSBI >100 generally cannot tolerate extubation (21,22).

No one set of criteria or parameters will be able to predict the success of extubation with certainty. The following criteria are a list of guidelines which may be employed in evaluating the patient for a potential extubation.

### ENDOTRACHEAL TUBE EXCHANGE

Although extubation ultimately remains the goal for every patient on MV, ETT exchange may be required until the patient has improved enough to fulfill the seven criteria for weaning. Indications for ETT exchange include damaged ETT, exchange of a specialized ETT (e.g., double-lumen ETT), and exchange of ETT size to allow for bronchoscopy (Table 4). In addition, if an excessively small ETT is in place, optimal ventilator settings may not be achieved due

**Table 4** Indications for Endotracheal Tube (ETT) Exchange

Damaged ETT
Exchange of a specialized ETT (e.g., double-lumen tube)
ETT exchange to allow for bronchoscopy
Exchange of a small ETT for a larger one to aid in positive pressure ventilation

to the resistance encountered due to the small internal diameter of the ETT.

To determine the feasibility of safe ETT exchange, all elements discussed in “Extubation/Reintubation Considerations/Risk Factors” should be considered. In addition, an FOB examination should be performed and the FOB should be available for the management of the difficult airway (23). The other methods mentioned in Table 5 are used less frequently depending upon experience and familiarity.

### Direct Laryngoscopy—Simple Endotracheal Tube Exchange

☞ **Direct laryngoscopy is the most common and simplest method for establishing airway access and appropriate when reintubation is not expected to be difficult (Fig. 2).**

☞ As with all procedures, experienced personnel should perform direct laryngoscopy. It is the procedure of choice for simple and uncomplicated ETT exchange, as would be anticipated in patients with known easy airway and without swelling which could cause postextubation stridor. However, the critically ill patient is seldom simple and uncomplicated. The postsurgical and physiologic changes in the airway that develop in the ICU patient may make direct laryngoscopy more difficult. Any attempts to perform direct laryngoscopy should be done carefully, and numerous attempts will be harmful to the patient. If the airway structures are in any way obscure, another method of airway access should be considered so that edema and hemorrhage will not complicate the picture further. These alternative methods are considered subsequently.

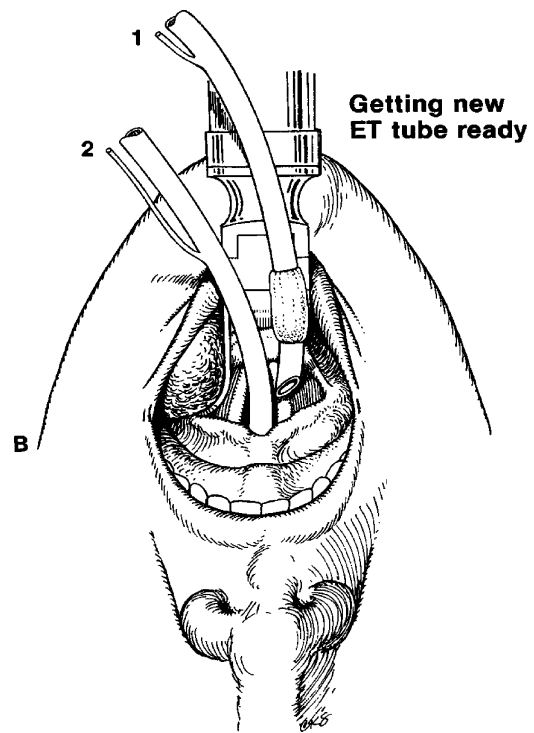

### Airway Exchange Catheters

AECs are devices designed to allow the exchange of one ETT for another without losing access to the airway (Fig. 3). The AEC can also be used to administer O<sub>2</sub> and to detect O<sub>2</sub> (Table 6). These are especially useful when the airway was difficult or is expected to be difficult to reestablish. These AECs have been used safely for the extubation of patients

**Table 5** Commonly Used Devices for Endotracheal Tube Exchange

**Figure 2** Use of direct laryngoscopy for endotracheal tube (ETT) change. Changing an ETT with direct laryngoscopy is appropriate in patients without expected airway difficulty. However, other techniques, involving use of an airway exchange catheter and/or a fiberoptic bronchoscope are recommended for difficult airways. Note: “1” refers to new ETT and “2” refers to malfunctioning ETT.

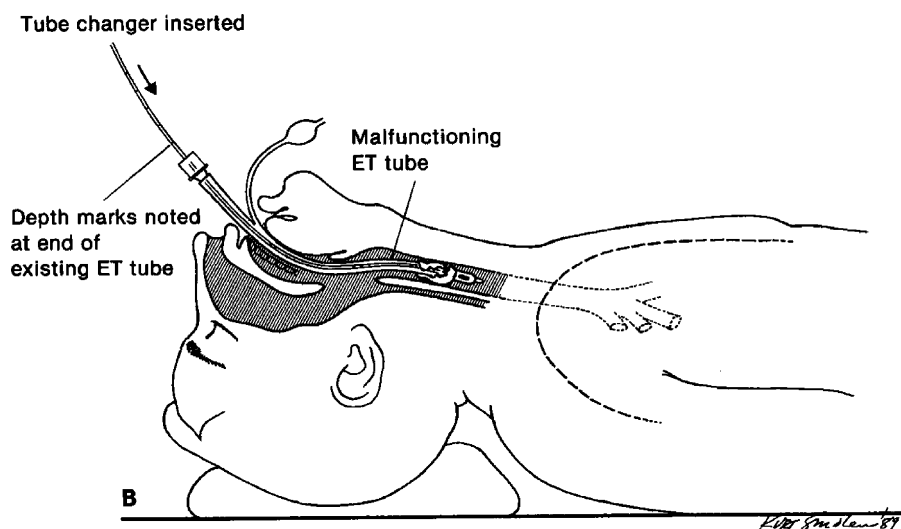

with a known difficult airway for two decades. In a study of 40 patients with a known difficult airway who were extubated using the AEC, four required reintubation; all were accomplished successfully using the AEC (24).

The most frequent indication for the use of an AEC is a damaged ETT, or the need for a different sized or specialized ETT. In addition to use as a stylette, or guide for reintubation, AECs can also be used as a backup, left in the trachea following extubation for minutes to hours. The hollow lumen can be used for insufflating oxygen or to sample CO<sub>2</sub>. These catheters are specially designed to facilitate their use. The features include: (i) measurement markings allowing the determination of the catheter length relative to that of the ETT. (ii) Distal openings and a standard 15-mm adapter which allow for ventilation using a ventilator circuit or ambu bag during the exchange or as a bridge between ETTs. (iii) These are available in different sizes and lengths to accommodate differing ETT inner diameters and lengths (Table 7).

### Risks

☞ **The risks involved in using AECs include loss of the established airway and damage to the airway from the device.** ☞

The loss of the airway may result from kinking or flexing the AEC while withdrawing the damaged ETT. The use of a small amount of water-based lubricant may help protect against this. AEC has a blunt tip, however, there remains the risk of penetrating a bronchus or creating a clinically significant mucosal tear while using this device. It is

**Figure 3** Use of airway exchange catheter (AEC) for endotracheal tube change. An AEC can be used as a stylette to guide reintubation, as well as a conduit for providing O<sub>2</sub> and/or measuring CO<sub>2</sub> during airway manipulations.

recommended that the tip of the AEC remain 2–3 cm above the carina in order to avoid the more sensitive areas of lung architecture.

#### Technique

The process for exchanging an ETT over AEC is relatively intuitive. There are a few points which should be emphasized so that patient safety is maintained throughout the procedure. Whenever possible, the original ETT position should be determined by FOB. If this is not done, the equipment should be immediately available. All standard airway equipment should be immediately on hand as well (laryngoscope with multiple blades, ETT sizes, and stylettes).

**Figure 4** Technique for airway exchange catheter-assisted endotracheal tube (ETT) exchange. (A) The AEC is placed down the indwelling ETT. (B) Removal of the ETT tube over the AEC while keeping position of the AEC unchanged. (C) Placement of the new ETT over the AEC. (D) Removal of the AEC while firmly securing placement of the new ETT.

The method for confirming ETT position should be determined in advance. Capnography, whenever available, should be used. Waiting for an AP chest film is inadequate management.

Even seasoned experts of AEC use should refamiliarize themselves with the AEC and the ventilation adapters. The AEC should be lubricated prior to use. The AEC is placed into the ETT, and the depth is noted against a landmark such as the level of the upper incisors. If possible, the AEC should be confirmed to be in the trachea by capnography. Once confirmed, the cuff balloon is deflated on the ETT and the ETT is removed without moving the AEC. The new ETT is then threaded over the indwelling AEC and advanced into the appropriate depth. The cuff balloon is inflated on the new ETT, and the AEC is removed. Confirmation of proper ETT position (Fig. 5) should be accomplished by capnography and/or by FOB.

✎ If excessive resistance is encountered while removing the ETT, the withdrawal should be halted while the apparatus is reexamined. ✎ Providing the ETT is still within the trachea, the AEC can be removed, and an FOB inserted to investigate. If the AEC and the ETT get stuck together, both may need to be removed completely and an alternative method of airway access may need to be attempted. Having an FOB pre-ensleaved with an ETT for emergency use can be useful at this time. Bag-mask ventilation may need to be employed between the time of ETT removal and the reestablishment of the ETT. If the patient remains hemodynamically stable with good oxygenation and adequate ventilation, several attempts to complete a

smooth transition can be attempted. In less stable patients, use of an airway-intubating mask, or laryngeal mask airway (LMA) can provide ventilation, while intubation is achieved using the FOB (as explained subsequently).

### Fiberoptic Intubation

☞ **FOB-assisted techniques are useful for cases of suspected or confirmed difficult airway and as an adjunct to use of the AEC.** ☞ It is also useful for confirmation of ETT placement. In addition, airway obstructions, particularly those below the vocal cords, can be evaluated and treated with FOB, as can airway blockages due to secretions and plugs.

In patients who have known or suspected pathology involving the airway, extubation using the FOB is indicated. There are several techniques used for ETT exchange using the bronchoscope. The FOB (with pre-ensleaved ETT) can be inserted into the oropharynx alongside the in situ ETT and passed down to the carina if there is sufficient room in the trachea. The ETT can be slid over the FOB into position using it as a stylette guide. Sometimes using concomitant direct laryngoscopy can help facilitate ETT passage in appropriately sedated or anesthetized patients. Alternatively, the old ETT can be removed after the FOB is in

place, and before inserting the new ETT passed over the FOB into position.

Another possibility is passing an AEC down the existing ETT and slowly backing both the old ETT out, then intubating the trachea with a “pre-ensleaved” FOB alongside the AEC. The technique carries a slightly higher risk than using the AEC as a guide for both removal of the old ETT and insertion of the new ETT because the airway is insecure for a short period of time and the field of view through the bronchoscope may change rapidly.

It is recommended that a full bronchoscope examination occurs prior to the planned extubation in high-risk patients. This allows for the adequate sedation of the patient reducing the stress of airway manipulation or loss of the airway in an uncooperative patient. Information obtained from this inspection will better prepare the health-care team to have any emergency equipment or personnel available should the patient deteriorate acutely following extubation.

### Laryngeal Mask Airway and Intubating Laryngeal Mask Airway Devices

The LMA was developed by Dr. Archie Brain in 1981. It became commercially available in Europe in the late 1980s. As its inception, the LMA has gained wide acceptance as a tool for airway management. Its role in the difficult airway algorithm was established in the 1990s, and was incorporated into the emergency limb of the American Society of Anesthesiology Difficult Airway (DA) Algorithm in 1993. The LMA has more recently been inserted into the main limb of the “revised” ASA DA algorithm in 2003. It can be a useful device in the ICU setting as well.

Several types of LMA products are available, although the basic design principle is same throughout. The teardrop shape of the LMA conforms to the oropharynx to create a seal in the soft tissues directly above the airway. When positioned properly, it effectively removes the upper-airway soft-tissue obstruction to the trachea allowing for easy ventilation.

☞ **The LMA can be a life-saving measure, as it can provide ventilation, and serves as a guide to FOB-assisted intubation.** ☞ It does not by itself, however, deliver a definitive airway. Patients with the LMA device are still susceptible to aspiration. In addition, the LMA can become dislodged at any time and these patients must be closely monitored.

There is a specially designed intubating LMA, also known as the Fastrach™, which has a larger aperture facing the vocal cords, which allows for blind passage of the ETT (Fig. 6) (25). This device is not recommended in situations where blind manipulation could convert a partial airway obstruction into a complete airway obstruction. For example, in all cases of stridor or airway injury, a technique using visualization through an FOB is far safer. Whenever intubating patients through a preexisting LMA, a longer ETT is optimal (26).

**Figure 5** Endotracheal tube depth of insertion. The figure shows standard distances from key anatomic landmarks. When using an airway exchange catheter (AEC), it should not be positioned below the carina, especially if used to provide jet ventilation. To protect against barotrauma, place AEC no deeper than 26 cm from upper incisors, and use <25 psi pressure if using jet ventilation.

**Figure 6** The intubating laryngeal mask airway (LMA) or LMA Fastrach™. (A) The ETT with removable 15-mm adapter for passage down the lumen of the LMA device. (B) The stabilizing rod which holds the position of the ETT while the intubating LMA device is withdrawn. (C) The LMA Fastrach™ device.

The LMA is ideally used in a spontaneously breathing patient. MV is possible, although the pressures generated by the ventilator should not exceed 20 mmHg (the pressure at which the lower esophageal sphincter opens) so that insufflation of the stomach can be avoided. Ventilation may be required in this manner as a “bridging” measure while the airway is secured.

One advantage of using a properly placed LMA as a guide for FOB-assisted intubation is the ability to deliver an elevated  $\text{FiO}_2$  in a patient who may be in respiratory failure. Volume 1, Chapter 9 provides additional insight into the uses of the LMA. Briefly, placement of the LMA occurs as follows.

### Lighted Stylette

A lighted stylette may be useful as an emergency backup for intubating patients whose vocal cords may not be visualized under direct laryngoscopy (Fig. 7). The stylette has a light source at the tip which can be appreciated through the soft tissues of the neck and airway. It is very simple to use and one can become rapidly proficient in performing ETT intubation using this technique (27). It is very important to dim the ambient light surrounding the patient while using this device because success is dependent upon visualizing the light source through the soft tissues of the neck and upper

**Figure 7** The lighted stylette. The light at the tip transilluminates the cartilage and soft tissues of the trachea and the neck.

**Figure 8** The Wu scope. This scope has specific positions for placement of the endotracheal tube (ETT) and the fiber-optic scope which is used to guide the suction catheter and ETT past the vocal cords and into the tracheal lumen.

neck, making this tool less useful in emergency trauma situations where lighting can be diminished.

### Wu Scope

The Wu Scope is a specially designed device: a tubular laryngoscope blade. A fiberoptic light source is passed down the tubular blade, illuminating the tip (Fig. 8). An ETT is passed through the Wu Scope and placed under direct visualization. The device requires some practice to become proficient. However, the Wu Scope offers the advantage of allowing laryngoscopy without neck extension and jaw lift while allowing direct visualization of the vocal cords.

ETT exchange using the Wu Scope has been described and may be used as a backup device in a patient with a difficult airway (28). The tubular design of the Wu Scope provides an avenue for the ETT to bypass the soft tissue of the oropharynx. When using the Wu Scope, the vocal cords should be identified, and a soft flexible device such as a flexible suction catheter should be passed down through the ETT and through the vocal cords. This serves as a soft guide over which the ETT is passed into the trachea under direct vision.

### Bullard Scope

The Bullard Scope is another laryngoscope which may be used for ETT exchange in the same manner as the Wu Scope. The laryngoscope blade is flat and the ETT sits over a contoured stylette attached to the blade. The Bullard Scope uses a standard laryngoscopy handle, and when attached it illuminates a light source at the tip of the blade. The eyepiece of the scope is located near the handle, and the lens is located at the tip of the blade adjacent to the light source. Placement of the Bullard Scope should be done carefully to avoid iatrogenic trauma to the mouth and teeth. Once the view of the vocal cords has been obtained, the old ETT should be removed carefully and the

new one passed under visualization through the Bullard Scope.

### Surgical Airway

Both tracheostomy and cricothyroidectomy provide definitive airway options. In elective situations, the tracheostomy is preferred, whereas the cricothyroidectomy is more rapidly established and therefore favored in an emergency. In some patients, converting an existing ETT airway to a tracheostomy is the best first choice for ETT exchange. The cricothyroidectomy is relegated to situations where the airway cannot be established using the above mentioned standard measures. These techniques are described in greater detail in Volume 1, Chapter 9.

### EYE TO THE FUTURE

New advances for facilitating extubation of the difficult airway and ETT exchange in high-risk patients are anticipated to occur in the realms of diagnosis, monitoring, and management. No single laboratory test or imaging study can yet definitively predict airway difficulty, or ability to tolerate extubation. Research advances are anticipated in airway imaging, and in staging airway swelling by FOB exam. Accurate prediction of safe extubation and ETT exchange is facilitated by sound judgment that considers the patient's condition and all of the possible tools available for diagnosis, monitoring, and facilitation of the difficult airway.

### SUMMARY

Extubation and ETT exchange have not received the same emphasis in literature as intubation and definitive airway management. The extubation or ETT exchange of the patient with a difficult airway presents a unique problem affecting critically ill trauma patients with potentially rapid and severe complications. It is important to note that any patient can develop a difficult airway depending upon their physical status and operative care. Extubation and ETT exchange can most safely be performed by physicians with up-to-date knowledge of the tools available, training and experience in their use, and sound clinical judgment in their use, along with preparations, attention to detail, and adequate help when they are employed.

### KEY POINTS

- ✎ Extubation of a known difficult airway and especially planned ETT change in a critically ill patient should be approached with a similar degree of concern and preparation as that given to initial intubation.
- ✎ A critical airway consideration in the posttrauma or critically ill surgical patient is the likelihood of periglottic swelling or pathology that could lead to postextubation stridor and possible inability to intubate or ventilate the patient.
- ✎ In the case of patients at high risk for postextubation stridor, a formal evaluation for periglottic swelling should be performed prior to attempts at extubation or ETT exchange. Options for evaluation of airway

swelling include: (i) cuff-leak test, (ii) FOB evaluation, and (iii) imaging studies.

- ✎ In situations where the patient is at high risk for postextubation stridor, additional specific evaluation with FOB (Fig. 1) is warranted.
- ✎ In the case where airway management is difficult and both conventional and adjunct procedures (described subsequently) all fail, then a surgical airway should be performed.
- ✎ When considering ETT change or extubation, decisions must be made on an individual basis with evaluation of the entire clinical picture considered rather than focusing upon a single event or parameter.
- ✎ In terms of weaning parameters, the RSBI is probably the single best indicator for determining the patient's ability to perform the required WOB.
- ✎ Direct laryngoscopy is the most common and simplest method for establishing airway access and appropriate when reintubation is not expected to be difficult (Fig. 2).
- ✎ The risks involved in using AECs include loss of the established airway and damage to the airway from the device.
- ✎ If excessive resistance is encountered while removing the ETT, the withdrawal should be halted while the apparatus is reexamined.
- ✎ FOB-assisted techniques are useful for cases of suspected or confirmed difficult airway and as an adjunct to use of the AEC.
- ✎ The LMA can be a life-saving measure, as it can provide ventilation, and serves as a guide to FOB-assisted intubation.

### INTRODUCTION: STRESS ULCERS

☞ **Stress ulcers are common in critically ill patients, but clinically important bleeding occurs in only 5% or less of these patients. Mortality in this small group of patients can be as high as 50%. ☞** Stress-induced gastritis and ulcers have been reported to occur in 75% to 100% of patients admitted to critical care units (1). These lesions are associated with major trauma, surgical procedures, shock, sepsis, hemorrhage, coagulopathy, hepatic, renal, and pulmonary failure (2). Stress ulcers occurring in severely burned patients are called Curling's ulcers, while those associated with central nervous system (CNS) diseases are referred to as Cushing's ulcers (3,4). Curling's ulcers are merely a form of stress ulcer, whereas they appear to be a unique entity that behaves more like peptic ulcers. ☞ **Stress ulcers are found in the proximal stomach and are usually multiple, superficial, and diffuse. Deeper lesions can lead to major hemorrhage. ☞**

The pathogenesis of peptic ulcers appears to be different from that of common stress ulcers. For example, common ("non-Cushing") stress ulcers usually occur in the proximal stomach, whereas peptic ulcer lesions usually develop in the gastric antrum and in the duodenum. In addition, common "non-Cushing" stress ulcers are typically superficial and more numerous than peptic ulcer lesions. The shallow, diffuse stress ulcers typically result in clinically occult or mild bleeding. However, deeper ulcerated lesions can occur and lead to significant gross hemorrhage.

Occult bleeding is exemplified by a patient with guaiac positive gastric aspirate or stool sample. Overt bleeding can present as hematemesis, hematochezia, or melena with or without hemodynamic instability. Clinically significant hemorrhage is characterized by overt bleeding with signs and symptoms of hemodynamic instability requiring aggressive resuscitation, often with blood transfusion. Although only a small proportion (1–6%) of patients with stress gastritis develops clinically significant bleeding, the mortality rate among this subset of patients approaches 50% (5–7).

Therefore, the prevention and effective management of these ulcers constitute a major clinical imperative in critically ill patients. Not surprisingly, in recent years, there has been rapid proliferation of a variety of therapeutic agents designed to combat or prevent stress ulcers in critically ill patients. These drugs include: sucralfate, histamine type-2 receptor antagonists (H<sub>2</sub>RAs), proton pump inhibitors

(PPIs), prostaglandins (PGs) (e.g., misoprostol), and antacids among others. Early enteral nutrition (Volume 2, Chapter 32) is another important protective factor against stress ulcer formation.

This chapter reviews the pathogenesis of stress gastritis including the protective role of normal mucosal blood flow and the injurious effects of H<sup>+</sup> ions following ischemia and reperfusion. The protective barriers provided by mucus production and bicarbonate secretion are discussed, along with conditions that disrupt these factors and promote epithelial injury. Endogenous PGs and nitric oxide (NO) are produced by the luminal epithelium and their protective roles are also elaborated upon. The benefits of normal gut motility and nutrition comprise some of the other known, protective factors, and these are identified. This chapter also reviews the pathologic appearance and risk factors for stress ulcer formation. The rationale for various ulcer prophylactic agents and their specific mechanisms of action are then described. Finally, the complications of gastrointestinal prophylaxis and the management principles for gastrointestinal (GI) bleeding are reviewed, along with the patient populations at greatest risk [those with coagulopathies, requiring mechanical ventilation, and severe trauma (especially CNS injury)].

### PATHOPHYSIOLOGY

The pathogenesis of stress gastritis and ulceration is multifactorial; however, splanchnic hypoperfusion, mucosal injury, and low pH are probably the most important risk factors. The presence of amino acids in the stomach stimulates gastrin release by the G cells in the gastric antrum. Gastrin and pituitary adenylate cyclase-activating polypeptide trigger histamine release (8,9). Histamine and calcium in turn promote acid release by the parietal cells. Although acid production plays a central role in the development of gastric mucosal injury, a low pH alone not sufficient to induce stress ulcer formation (10–13). Increased acid production only partially explains why critically ill patients are at risk for gastric mucosal ulceration. In fact, acid production is sometimes diminished in this group of patients (13).

Compromised mucosal barrier function, which is often associated with critical illness (e.g., sepsis, shock, hemorrhage), is also operative. Indeed, relatively small

**Table 1** Pathophysiologic Factors that Are Involved in the Development of Stress Ulcers

Protective	Deleterious
Mucosal blood flow	Acid secretion
Mucus production	Hypotension
CGRP	Reperfusion
Bicarbonate secretion	Reactive oxygen species
Intact epithelia	$\alpha$ - and $\beta$ -adrenoreceptor agonists
Nitric oxide	Nitric oxide
Prostaglandins	Pylori
Intact gastric and intestinal motility	Reflux of bile salts
Adequate nutritional status	
Epidermal growth factor	

Abbreviation: CGRP, calcitonin gene-related peptide.

amounts of acid can lead to significant mucosal injury and the subsequent development of stress gastritis in this setting. The physiological function in the stomach and proximal small intestine are known to be impaired during critical illnesses (14,15). For example, mucosal blood flow is reduced, gastric emptying is impaired, and acid production is deranged (16,17). The small bowel exhibits decreased motility and mucosal perfusion (14,16). The combination of these derangements leads to an unfavorable balance between protective and deleterious factors resulting in mucosal injury (Table 1).

### Mucosal Blood Flow, Ischemia, and Reperfusion Injury

Mucosal blood flow plays an essential role in maintaining mucosal homeostasis and when impaired gastritis and ulceration are common (18). Mucosal blood flow is dependent on total gastric blood flow and microcirculatory perfusion. These are important in maintaining the mucosal barrier. The microcirculation provides epithelial cells with the necessary nutrients and oxygen for generating the ATP that is essential for maintenance of normal homeostasis. In addition, the microcirculation transports deleterious protons and other agents that traverse the epithelial barrier away from the mucosa and brings them into the interstitial fluid. Therefore, gastric and mucosal blood flow prevents epithelial injury by tightly regulating the local pH. In addition, the microcirculation supports the repair of injured epithelium by removing harmful reactive oxygen species from the local microenvironment.

✎ **Decreases in blood flow to the gastric epithelium, whether as a result of globally diminished circulating blood volume or reduced microcirculatory blood flow, leads to impairment of the epithelial defense mechanisms.** ✎

Critically ill patients may have low blood pressure resulting in diminished gastric blood flow. Shock leads to a drop in gastric mucosal blood flow secondary to a decrease in circulating blood volume, vasodilatation or local vasoconstriction (19). Consequently, in shock states the normal oxygen and nutrient supply to the epithelial lining of the stomach is compromised resulting in decreased cellular ATP (18). Experimental animal data suggest that in shock states, gastric blood flow may be intact while the microcirculation is impaired (20). Diminution in microcirculatory blood flow can give rise to shunting in the local environment, thereby reducing the gastric mucosa's ability to counter the damage caused by hydrogen ions. A disruption in blood flow results in anaerobic metabolism and the buildup of oxygen-free radicals, leading to lipid peroxidation and

damage to mucosal cells (21,22). Additional experiments have shown the relationship between blood flow and the development of gastric and duodenal injury (23). Even if adequate blood flow is restored, secondary reperfusion injury may occur as a result of oxidative stress (24–27).

Another mechanism that can lead to gastric mucosal injury is the inhibition of the gastric hyperemic response to acid back diffusion. It is thought that under normal conditions, gastric mucosal blood flow increases when the mucosa is acidified. This defense mechanism is mediated by the release of the vasodilator calcitonin gene-related peptide (CGRP) from capsaicin-sensitive nerve fibers (28). Endogenous and exogenous  $\alpha$ - and  $\beta$ -adrenoreceptor agonists can block the release of the transmitter and suppress the gastric mucosal vasodilator response. Critically ill patients often have increased levels of endogenous catecholamines which can block the release of CGRP. In addition, therapeutic agents such as dobutamine are often used in critically ill patients to improve cardiac output and regional perfusion; the global hemodynamic improvement afforded by such agents may paradoxically result in local gastric mucosal hypoperfusion leading to epithelial damage (29).

### Mucus Production and Bicarbonate Secretion

The gastric mucosa is covered by a tightly adherent thin layer of mucus that functions as the first line of defense against stress-related injury. This physical mucus barrier is composed of a glycoprotein matrix and bicarbonate that prevents the direct contact of pepsin and hydrogen ions with the gastric mucosa. Ischemia, fasting states, and steroids can change the composition of the mucus layer by reducing the level of glycoprotein and allowing hydrogen ions access to the mucosa (30,31). Shock states lead to a diminution of ATP, which in turn leads to reduced secretion of mucus and bicarbonate (32). Additionally, as reperfusion occurs, reactive oxygen species are generated which further destroy the mucus layer disrupting its protective properties (21,33).

### Intact Epithelium

The epithelium of the stomach forms another effective defense mechanism. Any condition that leads to tissue hypoxia such as shock, sepsis, and trauma can disrupt the normal cell turnover and proliferation rate. DNA, RNA, and protein synthesis rates are diminished during periods of stress, starvation, and catabolism. Mucosal injury is further exacerbated by the resultant cellular acidosis, release of proteases, and phospholipases. The normal proliferation/apoptotic balance is altered as mucosal injury progresses with increasing cell necrosis and initiation of the inflammatory cascade. This cascade may exacerbate the inciting event and contribute to the development of multi-organ failure that is seen in critically ill patients.

### Prostaglandins and Nitric Oxide

Prostaglandins normally play a protective role in maintaining an intact gastric mucosal barrier. They increase mucosal blood flow and stimulate the production of mucus and bicarbonate to protect the mucosa against acid-induced injury. Prostaglandins also attenuate the vasoconstrictive effects of angiotensin II in shock states (34). Both prostaglandin E-2 (PGE<sub>2</sub>) and prostaglandin I-2 (PGI<sub>2</sub>) are present in the gastric mucosa and protect against the deleterious effects of substances such as nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, and alcohol (35–37).

NO is a potent local vasodilator that appears to play a protective role in gastric mucosal barrier function. The con-

stitutive isoform of NO synthase is present throughout the gastrointestinal tract. Physiologic levels of NO support the defense mechanisms of the gastric mucosa by maintaining gastric mucosal perfusion. In addition, NO downregulates neutrophil and platelet activation, thus attenuating the inflammatory response. Under hypoxic conditions, the inducible form of NO synthase (iNOS) is upregulated, leading to sustained overproduction of NO. Paradoxically, while physiological (i.e., low) levels of NO contribute to normal mucosal homeostasis, pathological (high) levels of NO can trigger an inflammatory response in the gastric mucosa (related to excess free-radical production) resulting in gastric mucosal damage and cell death (38).

### Gastrointestinal Motility and Nutritional Status

Up to 50% of critically ill patients develop gastrointestinal dysmotility (15). This dysmotility may be a result of local or central factors. The failure of the migrating motor complex, which is responsible for gastroduodenal peristalsis, to originate in the stomach leads not only to local hypokinesia but also to small bowel dysmotility (14). These motility disturbances may be further exacerbated by the use of pharmaceutical agents such as dopamine in the critically ill by reducing antral contractions and increasing duodenal contractions (39). The resulting reluctance to feed these patients may lead to an increased risk of developing stress gastritis.

Nutritionally depleted patients are at risk for stress gastritis. Inadequate protein levels may lead to gastrointestinal mucosal edema, which in turn leads to malabsorption. Protein malabsorption triggers a cycle where absorption of amino acids and peptides is limited resulting in increased mucosal edema (Volume 2, Chapter 32).

### OTHER FACTORS

Other pathophysiologic factors that contribute to stress gastritis include bile reflux, *Helicobacter pylori*, and epidermal growth factor (EGF) deficiency. Bile reflux is a consequence of gastric and proximal small bowel dysmotility. Bile reflux can injure the gastric mucosa and contribute to stress gastritis (40).

While *H. pylori* has been linked to peptic ulcer disease, its role in the pathogenesis of stress gastritis is not clear. Elevated levels of anti-*H. pylori* immunoglobulin A are associated with increased risk of bleeding secondary to stress gastritis in critically ill patients. In contrast, patients with peptic ulcer disease have elevated anti-*H. pylori* IgG levels. In stress gastritis, patients have colonization of both the body and antrum of the stomach, but in peptic ulcer disease the body and antrum have significantly less *H. pylori* infestation. The difference in microbial exposure between the two ulcer conditions may determine the divergence in virulence and inflammatory response observed between the two conditions (41).

EGF is produced by the salivary glands. Evidence suggests that EGF is necessary not only to maintain an intact intestinal epithelial lining, but also for effective repair of the damaged gastric mucosa (42,43). EGF is important for gastric mucosal restitution and for the maintenance of intracellular pH in mucosal epithelia, which is largely regulated by various isoforms of Na<sup>+</sup>/H<sup>+</sup> exchangers (NHEs) throughout the gastrointestinal tract (44). EGF is known to stimulate the expression and function of NHEs (43,45).

### Pathogenesis of CNS-Related Stress Ulcers

The pathogenesis of stress gastritis secondary to CNS injury or illness differs from stress gastritis related to other forms of trauma and critical illnesses. CNS-related ulcers are commonly referred to as Cushing's ulcers. Patients with CNS injuries develop increased gastric acid secretion in response to autonomic dysregulation originating in the hypothalamus (46–48). In experimental conditions, direct vagal nerve stimulation leads to gastric acid hypersecretion (49). Cushing's ulcers are similar to peptic ulcers. They are single and deeper than lesions that are traditionally associated with stress gastritis. Thus, Cushing's ulcers are more prone to perforation.

An important clinical note is that patients on high-dose steroids are also at increased risk. Furthermore, patients with spinal cord injuries may not present with typical signs of peritonitis (due to skeletal muscle paralysis) despite a frank perforated duodenal ulcer. Accordingly, vigilance is required in this patient population.

### Pathophysiology Summary

In summary, hydrogen ions are necessary for the development of stress ulcers. But stress ulcers do not occur without the disruption of basal mucosal defense mechanisms. Acidotic critically ill patients have inadequate mucosal blood flow and an impaired ability to neutralize hydrogen ions. In addition, microcirculatory hypoperfusion diminishes mucus, bicarbonate, and PG production. This impairment in epithelial protective mechanisms allows the mucosa to become damaged. Restitution and regeneration are inhibited in the face of inadequate nutrition, reduced proteins, diminished ATP, PGs, and EGF. The injured mucosa is unable to protect itself against deleterious factors such as hydrogen ions, bile, and oxygen-free radicals. Even when adequate blood flow is reestablished, reperfusion can initially accentuate the mucosal injury by producing reactive oxygen and nitrogen species that exacerbate the inflammatory response. CNS-related stress ulcers (Cushing's ulcers) are related to elevated hydrogen ion levels (like common stress ulcers), but they are usually singular, deep, and prone to perforation.

☞ **Hydrogen ions play a central role in the development of stress ulcers. However, stress ulcers do not develop under normal circumstances because mucosal epithelial damage is limited by protective mechanisms including adequate blood flow, normal mucus production, buffering by bicarbonate secretion, mucosal PGs, and NO, as well as epithelial repair facilitated by EGF.** ☞

### PATHOLOGICAL APPEARANCE

The gross and microscopic appearance of stress gastritis is time dependent. In the first 24 hours, stress gastritis ulcers are diffuse and shallow, and accompanied by focal hemorrhage. Histologically, stress gastritis ulcers have a leukocytic infiltrate. After 24 to 72 hours, tissue reactions occur; the ulcers lose their erythematous appearance and develop coagulation necrosis, cell infiltration, and hemorrhage with extension into the deeper mucosal layers. Extension into the submucosa leads to bleeding. If the patient's clinical condition improves, these ulcers will heal.

☞ **Stress ulcers appear differently at various stages of development, and lesions of dissimilar morphological stages can be seen in the same patient.** ☞

**Table 2** Risk Factors in the Development of Stress Ulcers in Adult and Pediatric Patients

Adult	Pediatric
Mechanical ventilation (>48 hr)	Coagulopathy
Coagulopathy (platelets <50,000; INR >2.5; PT >2 control)	Surgery (>3 hr)
Major surgery	Trauma
Head or multiple trauma	Burns (>13% BSA)
Burn injury (>30% BSA)	Pneumonia
Sepsis	Pediatric Risk of Mortality Score >10
Shock	
Multisystem organ failure	
Steroid therapy	
Solid organ transplantation	
Prolonged intensive care unit stay	
History of ulcer disease or gastrointestinal bleeding	

Abbreviations: BSA, body surface area; INR, international normalized ratio; PT, prothrombin time.

## RISK FACTORS

Several clinical states are associated with the development of stress gastritis (2). Coagulopathy (platelets <50,000; INR >2.5, PT >2 control) and respiratory failure (mechanical ventilation > 48 hr) are the two most important clinical factors related to clinically significant bleeding from stress gastritis (2). Additional high-risk groups include patients who have had recent major surgery, head or multiple trauma, burn injury (>30%), sepsis, shock, multiorgan system failure, steroid therapy, solid organ transplantation, or prolonged intensive care unit stay (50).

Despite physiologic differences between adults and children, pediatric patients are also at risk for the development of stress gastritis (51,52). In the pediatric population, coagulopathy, shock, surgery greater than three hours, burns [>13% body surface area (BSA)], trauma, pneumonia, and Pediatric Risk of Mortality Score greater than 10 are considered important risk factors for the development of stress gastritis ulcers (Table 2) (53–56).

**Respiratory failure and coagulopathy are the two most important factors associated with the development of stress ulcers.**

## CLINICAL SIGNS AND SYMPTOMS

Stress gastritis ulcers are generally asymptomatic in the early stages and do not manifest overt bleeding. As stress

becomes prolonged or more severe, bleeding is often detected. Categorizing ulcer-associated hemorrhages is crucial for patient care and clinical research endeavors. Ulcer-associated bleeding is categorized into three types: (i) hemodynamically stable patients with superficial diffuse ulcers and guaiac-positive gastric aspirate or stool samples have occult bleeding. Occult bleeding is the most common type of stress gastritis-related hemorrhage. Most lesions are not very deep and do not erode into any large vessels; (ii) hemodynamically stable patients with overt bleeding may have hematemesis, hematochezia, or melena but it is generally not clinically significant; gastric aspirates contain gross blood or coffee-ground material; (iii) hemodynamically unstable patients with clinically significant bleeding are those demonstrating cardiovascular and hematological signs associated with overt bleeding. These signs include: (i) >20 mmHg decrease in the resting systolic blood pressure (SBP); (ii) an orthostatic decrease of >10 mmHg in SBP; >20 bpm increase in heart rate; >2 g/dL drop in hemoglobin concentration (2). Bleeding classification assists clinicians and researchers in stratifying patients at risk for bleeding and determining appropriate therapeutic regimens (Table 3).

**Patients with stress ulcers are usually asymptomatic. Those patients who do bleed can have occult or overt bleeding, with or without hemodynamic instability.**

## GI PROPHYLAXIS RATIONALE AND GOALS

The key to stress gastritis prophylaxis is selecting high-risk patients and treating them early. Several risk factors are associated with stress gastritis and due to the identification of these factors and institution of prophylaxis measures, few patients develop clinically significant bleeding now. Improvements in resuscitation, early enteral nutrition, and basic supportive care help sustain “at-risk” patients who are susceptible to stress gastritis. Hydrogen ions play a pivotal role in the pathogenesis of stress gastritis. Therefore, the inhibition of acid secretion is the central target in ulcer prophylaxis. Several drugs reduce gastric pH including antacids, H<sub>2</sub>RAs, and PPIs.

Stress ulcer prophylaxis is an important therapeutic maneuver in the critical care setting. The most significant consequence from stress-induced ulcers is hemorrhage. Mechanical ventilation and coagulopathy are the only independent risk factors connected to clinically relevant bleeding. Gastric acid production is central to the development of stress-induced ulcers; hence, inhibition of acid production is the main goal in preventing stress gastritis. Clinical trials demonstrate that keeping gastric pH above 3.5 can prevent mucosal injury (57). The following section will review the

**Table 3** Bleeding States Associated with Stress Ulcers

Type	Occult bleeding	Overt bleeding	Clinically significant bleeding
Hemodynamic stability	Stable	Stable	Unstable
Type of ulcer	Superficial	Deep	Erosion into vessel
Clinical signs/symptoms	Guaiac-positive gastric aspirate or stool sample	Hematemesis, melena, gross blood in gastric aspirate or coffee-ground material	↓ SBP >20 mmHg; ↑ Heart rate >20 bpm; ↓ orthostatic SBP 20 mmHg; ↓ Hemoglobin 2 g/dL

Abbreviation: SBP, systolic blood pressure.

therapeutic strategies commonly used to prevent the development of stress gastritis.

Ulcer prophylaxis is designed to raise the intragastric pH to  $>4.0$ . A pH  $<4.0$  does not inactivate pepsin and permits fibrinolysis. Once upper gastrointestinal bleeding starts, intragastric pH  $>4.0$ , but  $<6.0$  may be inadequate to prevent recurrent bleeding. During overt bleeding, a pH of  $>6.0$  should be achieved to prevent the breakdown of blood clots and the spread of bleeding (58–60). Under acidic conditions, platelets do not aggregate and gastric mucosa does not heal (58,61). The next section will deal with the options available for stress ulcer prophylaxis.

☞ **As hydrogen ions play a central role in stress ulcer development, raising gastric pH is necessary for prevention of stress gastritis. Maintaining gastric pH  $>4.0$  will prophylax against stress ulcer formation, but once bleeding starts, a pH greater than 6.0 is required to prevent rebleeding.** ☞

## ULCER PROPHYLAXIS OPTIONS

Drugs/treatments used for stress ulcer prophylaxis can be broadly classified into cytoprotective agents (e.g., sucralfate, misoprostol, and enteral nutrition) and acid reducers (e.g., H<sub>2</sub>RAs, PPIs, and antacids). Each of these commonly employed drugs and treatments will be reviewed.

### Sucralfate

#### **Background and Mechanism of Action**

Sucralfate is an orally administered basic aluminum salt of sulfated sucrose. It is a nonabsorbable agent that exerts its cytoprotective effects by binding to the gastric mucosa and forming a gel-like barrier that allows mucosal healing beneath the protective gel-like layer. In acidic environments, the aluminum and sulfate disassociate into ions. The highly polar sulfide anions bind to cations such as mucins and exposed proteins serving to coat mucosal defects.

Although its mechanism of action is not entirely known, some theorize that sucralfate acts as a physical barrier to acid-induced damage or stimulates local PG synthesis (62). Other reports suggest that sucralfate downregulates endothelin 1 expression, binds to bile salts, inhibits pepsin, and increases bicarbonate excretion (62–64).

#### **Efficacy vs. Complication Profile**

Various meta-analyses examined the difference in efficacy between sucralfate and H<sub>2</sub>RAs or antacids and placebo. These analyses revealed disparate conclusions. Messori et al. did not show any difference in efficacy between sucralfate and H<sub>2</sub>RAs as compared to placebo (65). A meta-analysis by Cook et al. suggested that sucralfate and H<sub>2</sub>RAs were comparable in preventing clinically overt bleeding. Interestingly, sucralfate administration correlated with a reduction in mortality (61). A prospective randomized trial revealed that the H<sub>2</sub>RA, ranitidine, was more efficacious than sucralfate in preventing clinically important bleeding, but there was no difference in length of stay or mortality (66). These studies suggest that sucralfate is equivalent to H<sub>2</sub>RAs in preventing overt bleeding from stress gastritis.

The sucralfate complication profile is low. One potential risk is nosocomial pneumonia. As sucralfate is delivered via a nasogastric tube directly into the stomach, the gastroesophageal junction is stented open, thus permitting aspiration of stomach contents into the lung. However, sucralfate does not alter stomach flora, a process that is linked to

nosocomial pneumonia. Nonetheless, controversy persists regarding the role of sucralfate therapy in the development of nosocomial pneumonia when compared to antacids or H<sub>2</sub>RAs.

Additional complications include aluminum absorption (only 3–5% absorbed) in patients with renal failure. Aluminum binds to the phosphate which prevents absorption. Therefore, aluminum absorption can cause hypophosphatemia even in patients with normal renal function. Constipation and drug interactions (fluroquinolones, phentoin, and warfarin) can occur in some patients. Bezoar formation has been reported with the use of sucralfate in pediatric patients (67). Sucralfate is on the Food and Drug Administration (FDA) “Class B” agent (safe to use during pregnancy).

Although readily available, sucralfate is not FDA approved for use as prophylaxis against stress gastritis. Sucralfate is generally underused, partly due to its four-times-a-day dosing compared to once-daily dosing for PPIs. Another problem with sucralfate is its disrupting effect on viewing the gastric mucosa using endoscopy.

☞ **Sucralfate works by binding to the stomach lining and thus has to be introduced directly into the stomach. It is efficacious in preventing stress ulcers, with a low complication profile, but has not been shown to improve outcome.** ☞

### H<sub>2</sub> Receptor Antagonists

#### **Background and Mechanism of Action**

Histamine binds to the histamine receptor-2 on parietal cells and stimulates the production and release of hydrochloric acid. In the late 1970s, cimetidine, a prototypical H<sub>2</sub>RA, was introduced as the treatment for peptic ulcer disease. Since the introduction of H<sub>2</sub>RAs, they have been a mainstay in acid-suppressing treatment.

H<sub>2</sub>RAs block the histamine receptor and subsequently reduce hydrogen ion production levels. H<sub>2</sub>RAs have limitations as global hydrogen ion production regulators as histamine does not completely activate all intramural hydrogen production.

#### **Efficacy vs. Complication Profile**

Approximately 70% to 80% of duodenal ulcers and 55% to 65% of gastric ulcers are healed by H<sub>2</sub>RAs after four to six weeks of therapy. Based on the early successes in preventing the progression of peptic ulcer disease, clinicians began to investigate the efficacy of H<sub>2</sub>RAs in controlling acute upper gastrointestinal bleeding. Little data support the use of H<sub>2</sub>RAs in abrogating bleeding complications of peptic ulcer disease (68,69). In a meta-analysis by Collins et al., they collated and analyzed 27 randomized prospective trials with approximately 2500 total patients who were treated with H<sub>2</sub>RAs. The data suggest that H<sub>2</sub>RAs limited rebleeding in patients after endoscopic control of upper GI bleeding. Walt et al. tested this hypothesis by examining the ability of famotidine to limit upper GI bleeding in patients with peptic ulcer disease; however, they found no improvement over placebo controls (69).

Complications and side effects related to H<sub>2</sub>RA are significant. In some cases, raising intraluminal pH makes gastric mucosa susceptible to injury by lowering the intracellular pH. Some investigators propose that stress ulceration may be related to intramural pH and not to intraluminal pH (70). H<sub>2</sub>RAs are associated with tachyphylaxis, diarrhea, headache, mental status changes, hyperprolactinemia (cimetidine), rashes, vomiting, and

drowsiness. In pediatric patients, there is a higher incidence of thrombocytopenia as compared to adults with the use of cimetidine (71).

Other medications that rely on an acidic environment for absorption must be used with caution in all drugs that increase gastric pH. Ampicillin and ketoconazole both have lower serum concentrations and bioavailability in this setting. Additionally, some H<sub>2</sub>RAs (cimetidine more than ranitidine) inhibit the cytochrome P450 (CYP450) system. Famotidine and nizatidine do not affect the CYP450 enzyme.

Furthermore, H<sub>2</sub>RA use is associated with nosocomial infection for several reasons: (i) H<sub>2</sub>RAs alter the composition of the gastric microbial flora and lead to selection of more virulent microbes; (ii) critically ill patients are at higher risk of aspiration; and (iii) aspiration is followed by the onset of nosocomial pneumonia (72). But some believe that the role of H<sub>2</sub>RAs in nosocomial infection is overstated. The risk of nosocomial pneumonia has not been validated in the meta-analysis by Messori et al. or by the randomized control study by Cook et al. (65,66). Some evidence suggests that H<sub>2</sub>RAs lose their inhibitory effect on acid secretion over time (73,74). H<sub>2</sub>RA tachyphylaxis and the association with nosocomial pneumonia have led to a reduction in H<sub>2</sub>RA use as the mainstay in controlling stress-related gastritis and its most significant consequence, upper GI bleeding.

Cimetidine, ranitidine, famotidine, and nizatidine are widely available in the United States. Only cimetidine is FDA approved for the prevention of bleeding in critically ill patients as a continuous intravenous infusion. The oral H<sub>2</sub>RAs are limited by malabsorption.

☞ **H<sub>2</sub>RAs work by blocking histamine receptors on parietal cells. They are efficacious in raising pH, but they are associated with nosocomial pneumonia and tachyphylaxis. Survival benefit has not been demonstrated with H<sub>2</sub>RAs.** ☞

## Proton Pump Inhibitors

### Background and Mechanism of Action

The goal of PPIs is to provide substantial, long-lasting elevation in gastric pH. PPIs are the most potent acid-suppressing agents available. The first PPI, omeprazole, was made clinically available in an oral formulation in 1989. Recently, intravenous PPIs were introduced and added to the therapeutic armamentarium for the prevention of stress ulcers. Pantoprazole, introduced in 2001 in the U.S. market, is the first intravenous PPI used in the United States.

The hydrogen (H<sup>+</sup>)/potassium (K<sup>+</sup>) ATPase pump exchanges H<sup>+</sup> ions for K<sup>+</sup> ions in parietal cells leading to the production of extracellular hydrochloric acid. PPIs directly block the H<sup>+</sup>/K<sup>+</sup> ATPase proton pump in parietal cells. PPIs bind to cysteine residues in the transmembrane domains of the adenosine triphosphatase enzyme. The bound enzyme is unable to produce acid. Most PPIs are delivered enterally, absorbed beyond the pylorus and then transported in the blood stream to the parietal cells. PPIs are activated in an acidic environment and therefore only inhibit actively secreting proton pumps. PPIs bind irreversibly to the proton pump enzyme; and the inhibitory effects can only be overcome by the de novo production of a new proton pump enzyme. New proton pumps are synthesized every 72 hours.

### Efficacy vs. Complication Profile

PPIs maintain higher gastric pH than H<sub>2</sub>RAs (74). PPIs decrease the rate of duodenal ulcers by 80% to 100%, and the formation of gastric ulcers by 70%. However, no study

has definitively demonstrated the efficacy of PPIs in stress ulceration protection (75–77).

PPIs are metabolized through the CYP450 system and sulfate conjugation in the liver. PPIs appear to have minimal interactions with other medications, which make them particularly useful in the critical care setting. Nonspecific adverse events associated with the use of PPIs include vomiting, diarrhea, constipation, and rashes. Tachyphylaxis has not been documented with PPIs.

Originally PPIs were only available as enteral agents. PPIs are acid labile and therefore they are enteric coated to protect against gastric inactivation. The use of oral PPIs in the critical care setting is limited because many patients do not have postpyloric feeding tubes. The introduction of intravenous PPIs in the United States has permitted their use in critically ill patients at the highest risk of developing stress ulcers.

☞ **PPIs work by irreversibly binding the proton pump, thereby preventing release of hydrogen ions. Efficacious in raising gastric pH, their role in preventing stress ulcers is not defined. Most PPIs are available in oral form, although intravenous agents are now available.** ☞

## Antacids

Antacids are no longer considered the mainstay in stress gastritis prophylaxis. Antacids are efficacious in preventing stress-related mucosal damage. But frequent enteral dosing and side effects limit their use in most settings. Side effects include hypermagnesemia, hypophosphatemia, intestinal distension, diarrhea, constipation, bezoar formation, and nosocomial pneumonia (78–90). Antacids are FDA approved for the prevention of stress-related mucosal disease.

☞ **Antacids are efficacious but difficult to use in critically ill patients.** ☞

## Misoprostol

Misoprostol is a PG analog that inhibits gastric acid secretion, and may improve mucosal blood flow. The anti-secretory activity is less potent than that provided by the H<sub>2</sub>RAs or PPIs. Misoprostol is the only FDA-approved PG analog that has shown benefit in the prevention of peptic ulcer disease. Although PGs are important in preventing acid-related mucosal injury under physiological conditions, and peptic ulcers due to NSAIDs, the use of synthetic PG analogues has not yet been shown to be efficacious in preventing stress gastritis or stress-related bleeding.

## Enteral Nutrition

Enteral nutrition is ineffective in preventing stress gastritis. The inconsistency attributed to enteral feeding may be due to the inability of enteral feeds to consistently raise gastric pH (81). In addition, the mode of delivering enteral feedings is not resolved. Some clinicians prefer prepyloric feedings while others favor postpyloric feeding. Enteral feeds may play an important role in reducing the incidence of stress gastritis by helping to maintain positive nitrogen balance.

## COMPLICATIONS OF GASTROINTESTINAL PROPHYLAXIS

Specific complications related to the different agents have been discussed in detail in the aforementioned section. Interactions between prophylactic agents and other

medications are not uncommon and should be monitored. Agents that increase gastric pH promote bacterial overgrowth in the stomach and nosocomial pneumonia. Studies are discordant in their results. Some studies find an increase in nosocomial pneumonia in antacid- or H<sub>2</sub>RAs-treated patients compared to sucralfate-treated patients (82,83), while other studies find no difference among these agents (60,84,85). In a randomized trial involving 1200 patients comparing sucralfate and ranitidine no statistical difference between the groups was seen with regard to the development of nosocomial pneumonia, although there was an overall lower incidence in the sucralfate group (66). Environmental factors such as the use of nasogastric tubes that stent open the lower esophageal sphincter and allow reflux of gastric contents into the upper airway complicate the analyses. The issue of increased nosocomial pneumonia associated with prophylactic agents is unresolved but with current data the differences between medications seems small.

✎ **Nosocomial pneumonia is a theoretic complication with all agents that raise gastric pH; however, the incidence of this complication is very low.** ✎

### MANAGEMENT OF ACUTE BLEEDING ASSOCIATED WITH STRESS GASTRITIS

Critically ill patients who bleed from stress ulcers are initially managed with standard resuscitation ATLS protocols. The principles involve the ABCs of resuscitation including airway protection and hemodynamic stabilization. Intravenous PPIs should be started promptly. A nasogastric tube is placed into the stomach and the stomach is lavaged until clear. Serial hematocrit measurements are monitored. Endoscopy is performed as necessary, and all high-risk lesions in the stomach should be treated with injection of epinephrine and thermocoagulation.

Gastric pH measurements should be monitored, and a pH >6 is targeted in order to prevent rebleeding (57). PPIs have been shown to be effective in preventing recurrent bleeding after successful endoscopic therapy (86,87).

### OVERALL STRATEGY FOR GI PROPHYLAXIS

Based on the pathophysiology of stress ulcer formation, one of the most important maneuvers in preventing the development of stress gastritis in critically ill patients is to increase mucosal blood flow and subsequent oxygen delivery. Therapies directed at achieving this objective reduce the overall progression of stress gastritis and its major sequelae, clinically overt bleeding.

Stress gastritis prophylaxis is strongly recommended in coagulopathic patients, and all those who are anticipated to require mechanical ventilation for greater than 48 hours. Ulcer prophylaxis is also recommended in patients with at least two of the following risk factors: anticipated ICU stay more than one week; occult bleeding of any duration; sepsis; and steroids use (250 mg/day hydrocortisone or equivalent). In addition, patients with CNS injury, >10% BSA burn or a history of ulcer disease or gastrointestinal bleeding should be placed on prophylactic medication (88).

The best agent for prophylaxis is not clear. Sucralfate and H<sub>2</sub>RAs have similar efficacy but H<sub>2</sub>RAs are easier to use and a reasonable first-line therapy. If famotadine has been used in the past without success, sucralfate may be used. Although PPIs are more effective than H<sub>2</sub>RAs in raising intragastric pH, their efficacy in preventing stress gastritis is not markedly different. However, PPIs may be most beneficial when the prevention of recurrent bleeding is necessary after endoscopic therapy; monitoring gastric pH has not been documented to be beneficial in stress ulcer prophylaxis. However, pH monitoring (to maintain pH >6.0) is likely valuable after successful endoscopic management of stress gastritis-related bleeding. Figure 1 outlines the prophylaxis algorithm and management of stress ulcer bleeding.

### EYE TO THE FUTURE

It has not been clearly demonstrated which agent is most efficacious in the prevention of stress ulcers. Current options include sucralfate, misoprostol, H<sub>2</sub>RAs, or PPIs. As only one intravenous PPI is currently approved for use in the United States, experience is limited and comparisons with H<sub>2</sub>RAs are continuing. Furthermore, whether any of these agents will actually prevent clinically important bleeding and reduce mortality may be ultimately more relevant.

Investigation into the etiology, prevention and treatment of stress ulcers continues to progress. The subsequent discussion reviews some of these new investigations in the clinical management of stress gastritis, including diagnostic technologies and novel mediator manipulation.

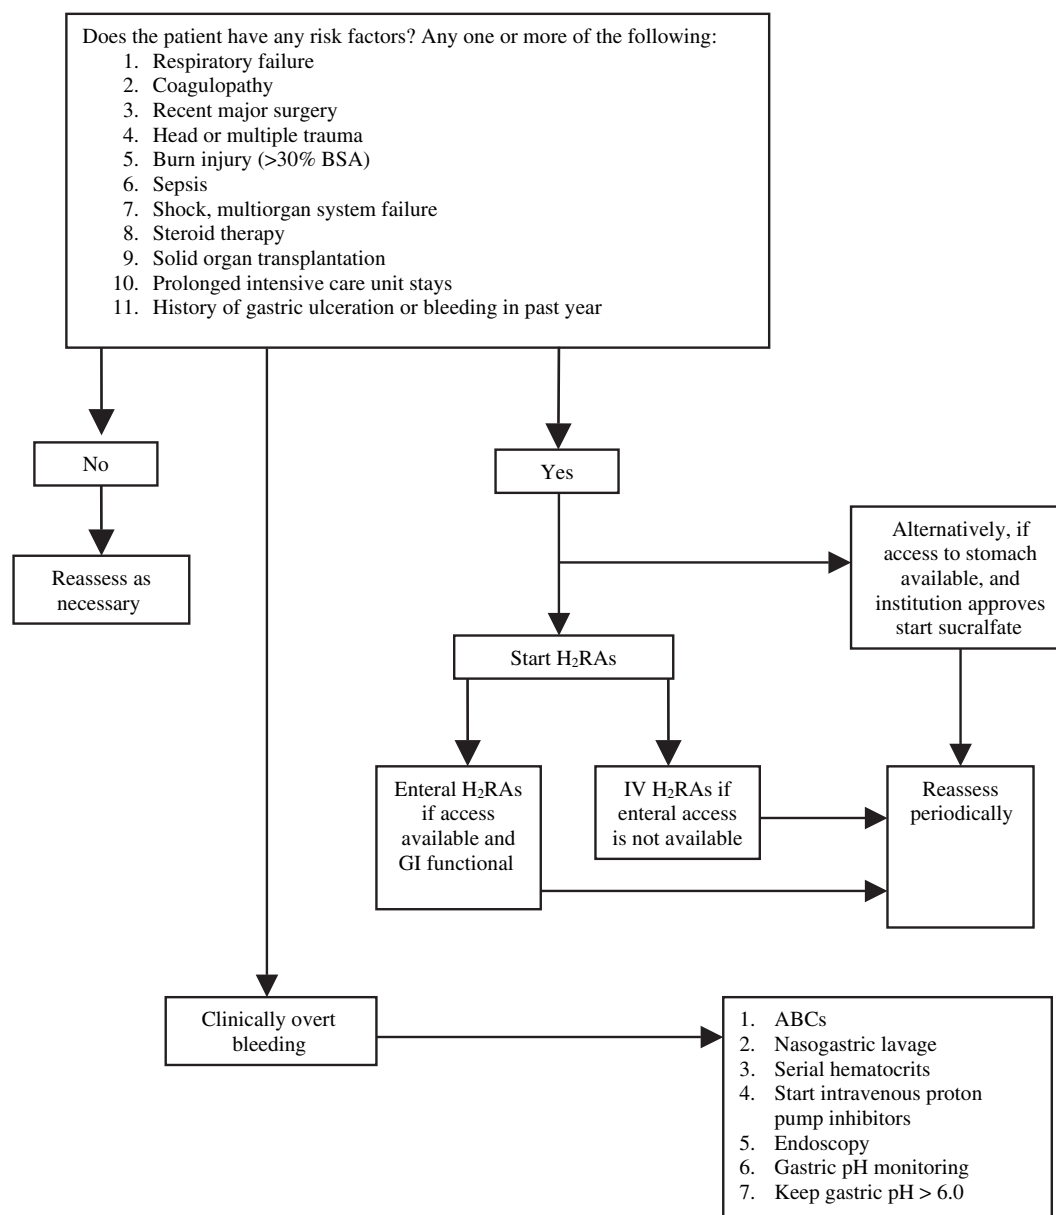

### Diagnostic Screening for High-Risk Patients

The identification of patients at risk for developing stress gastritis continues to be an elusive target. Although several risk factors (burns, trauma, CNS catastrophes) have been identified and analyzed as outlined in the section "Risk Factors," modern pharmacogenetic-based strategies may offer customized patient-specific data that pinpoint the risk in other populations, and may influence appropriate drug and dosage targets for previously identified high-risk patients. For example, gene microarray and proteomic analyses may reveal the pertinent gene and protein variations in critically ill patients most likely to suffer from stress gastritis. Furthermore, these approaches may identify a set of genes or proteins that predict positive therapeutic responses or the potential for deleterious drug side effects. This knowledge would provide the clinician and pharmacist with a detailed report of what drug or drug combination may be most efficacious.

### Novel Candidate Mediators

Some postulate that the increasing levels of proapoptotic proteins lead to gastric injury and therefore, antiapoptosis therapy could potentially attenuate the development of stress gastritis. For instance, apoptosis-modulating proteins (e.g., Bcl-2 family members or Fas/FasL) may play a role in stress ulcer pathogenesis. Zhonghua et al. studied bcl-2 (an antiapoptotic protein), Bax (a proapoptotic protein), and Fas/Fas ligand (proapoptotic proteins) in a rat model of stress-induced ulceration (89–95). They found that in rats immersed in water and restrained, decreased bcl-2 and increased Bax levels correlated with apoptosis but Fas/FasL protein levels did not correlate with stress ulcer injury.

**Figure 1** Prophylaxis and management of stress ulcers bleeding. *Abbreviations:* BSA, body surface area; H<sub>2</sub>RAs, histamine type-2 receptor antagonists; ABCs, airway, breathing, and circulation.

Therefore, increasing bcl-2 and decreasing Bax expression may play a crucial role in abrogating stress ulcer pathogenesis. Another protein that could reduce the development of stress gastritis is heat shock protein 70 (hsp70). Shichijo et al. have shown that spontaneously hypertensive rats with increased levels of hsp70 are protected against water stress and restraint-induced gastritis (96). The authors propose that hsp70 protects against ulceration by increasing mucosal blood flow. Therapies directed at increasing hsp70 levels could also lead to decreases in stress gastritis.

### Novel Therapeutics Nearing Clinical Trials

Several modalities are on the horizon that hold promise for reducing the formation of stress-induced gastritis by blocking the effects of reactive oxygen species. Ohta et al. determined that injecting stressed rats with superoxide

dismutase and catalase attenuated the formation of stress-related gastric ulcers (97). In addition, Bulbulla et al. demonstrated that intragastric L-tryptophan reduces the mucosal damage in immobilized rats as compared to controls by an alternative antioxidant mechanism (90). Hormonal strategies have been tested in a number of laboratories and these approaches may also augment our current armamentarium of antiulcer therapy. Bombesin and candesartan, the angiotensin II AT<sub>1</sub> receptor antagonist, prevent hemorrhagic and cold-induced stress ulcers in rats. Bombesin is thought to work via a cholecystokinin receptor mechanism while candesartan works by a combination of gastric blood flow protection, decreased sympathoadrenal activation, and anti-inflammatory effects while maintaining the protective glucocorticoid effects and PGE-2 release (89,98). All of these therapeutic measures remain largely experimental and human testing is still required.

Nontraditional antiulcer therapeutics may also provide clues to the pathogenesis and treatment. Recently, two studies report the use of herbal remedies for the treatment of gastric ulcers. Shirwaikar et al. examined the effects of the ethanol extract of *Ageratum conyzoides* in preventing cold restraint stress ulcer in rats and found that it reduces the ulcer size and number mediated possibly by its antioxidant activity,  $\text{Ca}^{2+}$  channel blocking and antiserotogenic properties (99). In another report, Sairam et al. demonstrated the protective activity of *Asparagus racemosus* against cold restraint stress-induced gastric ulcers (100). They showed significant protection against acute gastric ulcer formation and an increase in mucosal defensive factors such as mucus secretion, cellular mucus, and the life span of cells. *A. racemosus* had little or no effect on the production of offensive factors like acid and pepsin.

## SUMMARY

All critically ill patients are at risk to develop stress-related gastric mucosal disease. A small number of patients go on to develop clinically significant bleeding. The need for prophylactic therapy in these patients is particularly important in the group of patients who are at highest risk: those with coagulopathy and/or in respiratory failure requiring mechanical ventilation. Current data demonstrate that sucralfate and  $\text{H}_2$ RAs are comparable in preventing stress gastritis, but the impact that this has on stress gastritis-related bleeding and mortality is less clear. Maximizing hemodynamic management combined with PPIs may be the best method to reduce mortality and bleeding (and rebleeding) from stress gastritis in the highest-risk patients.

Finally, while future work in stress gastritis is necessary, it is also very critical to determine the most efficacious management algorithm in patients at risk for stress gastritis. Current options include  $\text{H}_2$ RAs, PPIs, sucralfate, misoprostol, and antacid therapy. The least manpower is used on  $\text{H}_2$ RAs, PPIs, however, the side effects of increased gram-negative organisms and other side effects must be weighed against the use of other agents. The ability of  $\text{H}_2$ RAs or PPIs to prevent clinically important bleeding and reduce mortality may be ultimately more relevant but this comparison remains untested. Additionally studies designed to compare the efficacies of the  $\text{H}_2$ RAs and PPIs in various high-risk populations are also required. Finally, several new and novel modulators may be on the horizon of stress ulcer prophylaxis and treatment following trauma and critically illness.

## KEY POINTS

- ✎ Stress ulcers are common in critically ill patients, but clinically important bleeding occurs in only 5% or less of these patients. Mortality in this small group of patients can be as high as 50%.
- ✎ Stress ulcers are found in the proximal stomach and are usually multiple, superficial, and diffuse. Deeper lesions can lead to major hemorrhage.
- ✎ Decreases in blood flow to the gastric epithelium, whether as a result of globally diminished circulating blood volume or reduced microcirculatory blood

flow, leads to impairment of the epithelial defense mechanisms.

- ✎ Hydrogen ions play a central role in the development of stress ulcers. However, stress ulcers do not develop under normal circumstances because mucosal epithelial damage is limited by protective mechanisms including adequate blood flow, normal mucus production, buffering by bicarbonate secretion, mucosal PGs, and NO, as well as epithelial repair facilitated by EGF.
- ✎ Stress ulcers appear differently at various stages of development and lesions of dissimilar morphological stages can be seen in the same patient.
- ✎ Respiratory failure and coagulopathy are the two most important factors associated with the development of stress ulcers.
- ✎ Patients with stress ulcers are usually asymptomatic. Those patients who do bleed can have occult or overt bleeding, with or without hemodynamic instability.
- ✎ As hydrogen ions play a central role in stress ulcer development, raising gastric pH is necessary for prevention of stress gastritis. Maintaining gastric pH  $>4.0$  will prophylax against stress ulcer formation, but once bleeding starts, a pH  $>6.0$  is required to prevent rebleeding.
- ✎ Sucralfate works by binding to the stomach lining and thus has to be introduced directly into the stomach. It is efficacious in preventing stress ulcers, with a low complication profile, but has not been shown to improve outcome.
- ✎  $\text{H}_2$ RAs work by blocking histamine receptors on parietal cells. They are efficacious in raising pH, but they are associated with nosocomial pneumonia and tachyphylaxis. Survival benefit has not been demonstrated with  $\text{H}_2$ RAs.
- ✎ PPIs work by irreversibly binding the proton pump, thereby preventing release of hydrogen ions. Efficacious in raising gastric pH, their role in preventing stress ulcers is not defined. Most PPIs are available in oral form, although intravenous agents are now available.
- ✎ Antacids are efficacious but difficult to use in critically ill patients.
- ✎ Nosocomial pneumonia is a theoretic complication with all agents that raise gastric pH; however, the incidence of this complication is very low.

## INTRODUCTION

The administration of enteral or parenteral nutrition constitutes one of the pillars of modern critical care, as nutritional status directly affects morbidity and mortality (1,2). Nutritional needs vary in response to metabolic changes, age, sex, growth periods, stress (i.e., trauma, disease, pregnancy, etc.), and physical condition. During critical illness, retention of sodium and water, along with loss of lean body mass from immobility and hypermetabolism, is related with the risk of multiorgan dysfunction syndrome, infection, and healing difficulties. Furthermore, these inflammatory changes can confound the monitoring of factors usually used in nutritional assessment.

The phenomenon of hypermetabolism was first described over 70 years ago in a landmark paper by Cuthbertson (3). More recently, hypermetabolism is recognized to occur in most critically ill patients, when in the catabolic state due to inflammatory mediators from severe trauma, burns, and disease states such as sepsis or the systemic inflammatory response syndrome (SIRS). This results in a rapid loss of total body mass, mainly from muscles. Early identification of high-risk patients and efficacious monitoring of nutritional support can reduce postoperative complications and decrease surgical intensive care unit (SICU) length of stay.

Nutritional assessment tools should be easy to use, reliable, reproducible, and inexpensive. Furthermore, these tools should be continuously available, and minimally perturbed by conditions associated with the underlying illness. ⚡ **No gold standard in nutritional assessment currently exists.** ⚡ All the tools mentioned in this chapter fulfill certain criteria but are lacking in other aspects.

This chapter reviews the nutritional and metabolic assessment tools commonly employed in critically ill trauma and burn patients. The nutritional assessment parameters that should be initially evaluated are first reviewed in the chapter, including pertinent information that should be sought in a carefully taken history and physical (H&P).

In addition, the anthropometric measurements commonly determined by registered dietitians, are surveyed along with laboratory values, predictive equations, and indirect calorimetry. The principal determinants of nitrogen balance and the continuous measurement of caloric expenditures are also provided. The chapter finishes with a survey of the pitfalls of nutritional assessment and the eye to the future.

## INITIAL ASSESSMENT

### History and Physical

The initial nutritional assessment is focused on determining the baseline nutritional state through information gleaned in the H&P exam, including a review of the patient's medical, surgical, social, and drug history, along with the review of systems.

The history as related to nutritional assessment should at minimum include the following: age, sex, and history of present illness (including duration of the disease process and of the state of malnutrition prior to seeking medical care). Any history of gastrointestinal (GI) symptoms should be elucidated, including changes in appetite, eating, or bowel patterns that would suggest alteration in the patient's absorption and/or metabolism (e.g., diarrhea, constipation, and steatorrhea).

Patients who have been vomiting for days with or without gastric outlet obstruction will have struggled with maintaining adequate caloric intake and electrolyte balance. Patients with drug addiction, alcoholism, or psychiatric disorders or malignancy often have anorexia and rarely meet their bodies' metabolic demands. Patients should also be screened for the presence of systemic diseases (e.g., liver, renal, congestive heart failure, or diabetes), and metabolic disorders. Similarly, patients with pretrauma symptoms of malabsorption (i.e., symptomatic Crohn's disease with progressive weight loss) are likely to be malnourished despite reporting seemingly adequate caloric intake.

Use of appropriate nutrition supplementation and providing adequate macro- and micronutrients will help maintain or improve nutritional status during hospitalization.

Previously hospitalized patients, those who are institutionalized, or transferred from another facility will need to provide a list of current medications.

Diuretics decrease the amount of body water and therefore affect body composition studies. Some medications such as propofol are lipid based, and their administration in itself provides patients with caloric intake that needs to be included into evaluations and later calculations of total caloric intake. Steroid use induces hyperglycemia which requires close monitoring and control via carbohydrate controlled diets and effective insulin therapy. Calories from dextrose-containing intravenous fluid and alcohol drips should also be accounted for.

The review of systems relevant to nutritional status includes: (i) history of recent weight change (particularly involuntary weight loss of 20% over two to six months or 10% over one month), (ii) difficulty in chewing/swallowing (dependence on thickened liquids and mechanically altered diets), (iii) emesis, nausea, and change in appetite, and (iv) bowel habits (presence of diarrhea or constipation for more than three days).

The nutritional history should be aimed at screening for individuals who are at risk of having protein-calorie malnutrition as well as identifying individuals with potential macro- and micronutrient deficiencies (Table 1). Hence, a nutrition support care plan should be established with

**Table 1** Physical Examination Findings Consistent with Malnutrition

Physical examination	Deficiency/interpretation
<i>General appearance</i>	
Weight loss, decreased muscle mass, decreased subcutaneous fat	Protein/calorie malnutrition (<90% IBW), severe malnutrition (<70% IBW)
<i>Skin</i>	
Xerosis (dryness)	Essential fatty acids
Dermatitis	Vitamin C
Easy bruising	Vitamin K
Perifollicular hemorrhages	Vitamin C
Poor wound healing	Protein and zinc
<i>Nails</i>	
Koilonychia	Iron
Spoon-shaped, transverse ridging	Protein
Head, eyes, ears, nose, throat (HEENT)	
<i>Hair</i>	
Pigment changes, alopecia, easily pluckable without pain, flag spin (transverse depigmentation of hair)	Protein
<i>Eyes</i>	
Conjunctival pallor	Iron
Bitot's spot (triangular, shiny, gray spots on conjunctiva)	Vitamin A
Ophthalmoplegia	Thiamine, phosphorus
Impaired night vision	Vitamin A
<i>Nose</i>	
Nasolabial seborrhea	Vitamin A, zinc, fatty acids, riboflavin, pyridoxine
<i>Mouth/throat</i>	
Glossitis	Riboflavin, niacin, vitamin B12
Cheilosis	Pyridoxine, folate
Angular stomatitis	
Swollen, bleeding, retracted gums	Vitamin C
<i>GI</i>	
Diarrhea	Zinc, niacin
Extremities	
Edema	Protein
Muscle wasting	Protein
Osteoporosis/osteomalacia	Calcium, vitamin D
<i>Neurologic system</i>	
Disorientation, confabulation	Niacin, phosphorus
Impaired cerebellar functioning	Thiamine
Peripheral neuropathy	Thiamine, pyridoxine, vitamin E
Impaired vibratory/position sense	Vitamin B12

Abbreviation: IBW, ideal body weight.

goals to prevent starvation-induced complications, to improve clinical outcomes, and to correct existing metabolic or nutritional deficiencies that arise from a disease or treatment. For example, trauma patients admitted with alcohol dependence develop water-soluble vitamin (e.g., thiamine) deficiencies, and those on prolonged courses of broad-spectrum antibiotics will develop vitamin K malabsorption and depletion of healthy gut flora.

The most important element of the careful nutritional history is the presence or absence of recent weight change. This parameter has been evaluated extensively and is linked to mortality in several trials (4–6). Blackburn et al. (7) provide the clinician with the guidelines for the determination of the severity of the weight change (Table 2).

Part of the history includes the patient's current injuries. In particular, injuries or burns to the arms or bilateral upper extremity fractures should be noted. These patients can easily become malnourished because physical limitations prevent them from cutting their food and/or transferring it to their mouth. The nutrition support care plan should include an order that an individual is directed to assist them with eating. Another source of malnutrition is repeated periods of fasting prior to anesthesia for surgical procedures. Again, a review of all injuries will predict how many surgeries may be required. Thus, in addition to planning practical measures such as ensuring that the time of surgery is predictable so that the fasting period is minimized, caloric intake can be calculated to compensate for these periods.

The physical characteristics reflecting nutritional status include the baseline muscle mass, body fat, and subjectively the quality of hair and skin. Presence of stomatitis, friable gingival mucosa, easily pluckable hair, dermatological changes, and poor dentition may be associated with nutritional and vitamin deficiencies.

The abbreviated H&P performed during the primary and secondary surveys as per the Advanced Trauma Life Support® (ATLS®) paradigm should be supplemented with a complete H&P as part of the tertiary survey (Volume 1, Chapter 42).

### Subjective Global Assessment Method

Several formal assessment tools have been designed to help organize nutrition-oriented H&P data into a format that facilitates the analysis. Among these, the Subjective Global Assessment (SGA) is the most widely used (Fig. 1) (8,9). The SGA summarizes weight change, dietary intake, GI symptoms, functional impairment, and physical examination. Both long- and short-term weight changes are assessed, and the severity of the weight change in the last six months is expressed as the percentages (A = <5%; B = 5–10%; C = >10%).

Symptoms of nausea, emesis, diarrhea, and anorexia are noted. These GI symptoms should be present almost daily for one to two weeks preceding the assessment to be considered significant. The degree and duration of the functional impairment related to nutritional intake is recorded. Finally, four observations derived from the physical examination are evaluated (loss of subcutaneous fat, muscle wasting, edema, and ascites). Once the assessment is complete, the patient is graded as well nourished, mildly or severely malnourished.

In general, the patient with significant weight loss, poor intake, severe nausea, emesis or anorexia, is bedridden, and has evidence of fat and muscle wasting would be considered severely malnourished. In contrast, the patient with no weight loss, no decrease in dietary intake, no nausea or anorexia, appropriate functional status, and no signs of muscle or fat wasting would be deemed well nourished. The method is only semiquantitative, and absolute numbers are not used. Rather, the tool serves more as a score card where trends are revealed. For example, even significant weight loss over the last six months is not a strong indicator of severe malnutrition, when offset by the recent (previous two weeks) trend toward weight gain in the setting of minimal or no stress (10).

The SGA has been found to be an inexpensive, quick, and reliable tool for the initial screening of patients who are malnourished (11,12). In the recent evaluation of 100 surgical patients, SGA was found to be a highly sensitive (100%) and specific (69%) tool for the identification of malnutrition (13). Despite its partly subjective and semiquantitative nature, it possesses good interobserver correlation (9,14). The SGA has also been found to be a sensitive and specific assessment tool in the pediatric surgical subgroup of patients (15). As such, **SGA is a valuable tool in the initial screening for malnutrition in the majority of the situations where the information regarding the status of the patient prior to admission is readily available.**

### Anthropometric Measurements

Anthropometry describes quantitative measurements in patients that assist in the evaluation of nutritional status. Anthropometrics were first used in the nineteenth century as an element of forensic science. Anthropometric measurements are the oldest and most studied ways to assess the nutritional status of patients. These are generally rapid, inexpensive, and noninvasive methods for assessing nutritional status. Although operator- and technique-related errors do occur, when performed consistently with adherence to the stringent set of rules, anthropometric measurements provide a solid basis not only for the initial assessment, but also allow for the ongoing monitoring nutritional status.

The most basic anthropometric measurements are the height and weight, which are obtained on admission. Weight should be measured daily to facilitate detection of changes in fluid status and to globally monitor nutritional trends. Both absolute weight and weight change over time could be used as predictors of outcome for the patients.

**Weight loss is expected during hospitalization, and nutrition therapy goal should include maintaining ≥90% admit or usual weight.** Losses of 40% or more of admit weight is often fatal due to the substantial loss of lean body mass (16). Clinicians should be aware that weight loss, although occurring, may not be apparent in critically ill patients who develop tissue edema secondary to SIRS. Only when the edema resolves, will true weight loss

Risk Factor	Subcategories	SGA SCORE		
		A	B	C
<b>Weight Change</b>	Total weight loss over last 6 months: ____ kg.			
Over the past 6 Months	A. No weight gain, no change, or mild (<5%) weight loss			
	B. Moderate weight loss (5- 10 %)			
	C. Severe weight loss (> 10%)			
In the past 2 weeks	A. Weight is increasing			
	B. No change in weight			
	C. Weight is decreasing			
<b>Dietary Intake</b>				
Change in Dietary Intake	A. No change or slight change for short duration			
	B. Intake borderline and decreasing; intake poor and increasing; intake poor, no change based on prior intake			
	C. Intake poor and decreasing			
Duration and degree of change	A. Less than 2 weeks, little or no change			
	B. More than 2 weeks, mild to moderate suboptimal diet			
	C. Unable to eat or starvation			
<b>Presence of GI Symptoms</b>				
	A. Few or no symptoms intermittently			
	B. Some symptoms for >2 weeks; severe symptoms that are improving			
	C. Symptoms daily or frequently >2 weeks			
<b>Functional Status</b>				
	A. No impairment in strength, stamina and full functional capacity; mild-moderate loss and improving			
	B. Mild to moderate loss of strength, stamina / some loss of daily activity or severe loss but now improving			
	C. Severe loss of function, stamina and strength			
<b>Metabolic Demand</b>				
	A. No stress			
	B. Low or moderate stress			
	C. High stress			
<b>Physical Examination</b>				
Subcutaneous loss of fat	A. Little or no loss			
	B. Mild-moderate in all areas; severe loss in some areas			
	C. Severe loss in most areas			
Muscle wasting	A. Little or no loss			
	B. Mild to moderate in all areas; severe loss in some areas			
	C. Severe loss in most areas			
Edema	A. Little or no edema			
	B. Mild to moderate edema			
	C. Severe edema			
Ascites	A. No ascites or only on imaging			
	B. Mild to moderate ascites or improving clinically			
	C. Severe ascites or progressive ascites Overall SGA score A or B or C			

**Figure 1** SGA scoring sheet. SGA is a mainly subjective means of assessing the nutritional status. SGA classifies the patient as: A—well-nourished, B—moderately malnourished, and C—severely malnourished. The clinician rates each parameter as A, B, or C. If there are no more B or C ratings, the patient is more likely to be malnourished. If the ratings are on the left-hand side, the patient is likely to be well nourished. *Abbreviation:* SGA, subjective global assessment. *Source:* From Ref. 10.

become apparent by which time protein losses may be significant.

The pioneering paper by Studley (16) published in 1936 was the first to link outcome to the weight loss in patients undergoing surgery for peptic ulcer disease. He noticed that those with the most rapid weight loss had worse outcomes than the patients whose weight remained stable. Hill and Jonathan (17) have categorized the degree of weight loss with functional abnormalities. Weight loss of <10% of body weight is not associated with functional abnormalities, whereas weight loss of 10% to 20% is accompanied by functional abnormalities, with weight loss of >20% being most indicative of malnutrition, and multiple

functional abnormalities are detectable in virtually all patients (17).

Patient's admission weight can be used as a determinant of nutritional status. The Hamwi "rule of thumb" calculation is one of the most commonly used methods to determine ideal body weight (IBW):

Men: 106 lb for the first 5 ft, then 6 lb for every inch over 5 ft.  
Women: 100 lb for the first 5 ft, then 5 lb for every inch over 5 ft.

An acceptable body weight is  $\pm 10\%$  of their ideal weight for all frame sizes.

Another standard available for estimation of IBW is the 1983 Metropolitan Life Height and Weight Table and the NHANES I (1971–1974)/NHANES II (1976–1980)

**Table 3** Ideal Body Weight Ranges

IBW (%)	Classification
<70	Severely underweight
70–80	Moderately underweight
80–90	Mildly underweight
90–119	Healthy
120–134	Overweight
135–149	Obese
>150	Morbidly obese

Abbreviation: IBW, ideal body weight.

nutrition surveys (18,19). The tables provide clinicians one of the earliest examples of the anthropometric measurements used as the predictors of life expectancy and mortality (Table 3), however, it is not commonly used in the clinical setting.

It is important to note that comparing the patient's current weight to usual body weight is usually more useful than comparing current weight to an ideal weight. Body mass index (BMI) has been used as the measurement that correctly captures the relationship between the height and the weight, and is somewhat independent of height. BMI of 14 to 15 kg/m<sup>2</sup> is associated with significant mortality (20,21). BMI of less than 20 was found to be highly sensitive in elderly patients, or patients with cancer, but not in cirrhotic patients with tense ascites, cardiovascular, and neurological patients (22).

A study of lung transplant patients from the University of Toronto demonstrated that BMI <17 kg/m<sup>2</sup> or >25 kg/m<sup>2</sup> increased the risk of dying within 90 days posttransplant (23). However, not all literature supports the use of BMI as a sensitive indicator of malnutrition. In a prospective study of 640 hospitalized patients, four different widely available and locally accepted nutritional assessment methods were compared. BMI was shown to be the least sensitive method of the four (refer Table 4 for BMI classifications) (24).

Anthropometric measurements of fat stores are inexpensive, simple, and effective means of estimating the size of the largest energy-rich component of the human body. These measurements require only the skin fold caliper and measuring tape to perform. However, the amount of fat in the healthy subjects varies widely. For example, very little fat is sufficient in an athlete who is able to maintain his energy intake from food and has large muscle mass. The same amount of fat is insufficient in the critically ill patient who struggles with infection and stress from major abdominal surgery or trauma with little or no energy intake.

**Table 4** Interpretation of Body Mass Index for Males and Females

BMI interpretation	Males	Females
Lean	<18.5	<19.5
Normal	18.5–23.5	19.5–24.5
Excess weight	>23.5–29.5	>24.5–29.5
Obese	>29.5	>29.5

Abbreviation: BMI, body mass index.

In order to assess total body fat stores, both skin fold thickness and the estimation of the limb fat area are the methods focused on the single measurement. Skin fold thickness can be measured over the biceps, triceps, thigh, or calf. Alternatively, subscapular or suprailiac skin folds can be used. Skin fold measurements are preferably done in the standing position (which partially limits their use for critically ill trauma patients).

In a study of 1561 patients admitted to the hospital emergently, mid-upper arm circumference was found to be a better predictor of the poor outcome than BMI (25). Similarly, mid-thigh circumference was found to be a statistically significant predictor of mortality in 142 patients with chronic obstructive pulmonary disease (COPD) (26). Not all studies, however, fall on the side of anthropometric measurements being reliable in the clinical settings. In the study of 158 consecutive medical admissions, mid-arm circumference was found to have poor validity in evaluation of malnutrition (27). Therefore, care should be exercised in using these measurements as the stand-alone methods for the evaluation of nutritional status.

## Laboratory Values

### Nitrogen Balance

Evaluation of the nitrogen balance is one of the oldest methods to estimate protein needs and adequacy of nutritional status. This method is based on the fact that protein is the only constituent in the human body composed of nitrogen. Therefore, by comparing protein intake and nitrogen waste, conclusions can be made regarding the nutritional balance of nitrogen and hence overall nutrition. Proper evaluation of the nitrogen balance involves total urea nitrogen (TUN) measurement of all the waste including urine, feces, nails, hair lost, etc. over the course of several days. Many facilities, however, do not have the equipment to determine TUN. Instead, they obtain a urinary urea nitrogen (UUN) value and estimate the other losses. It has been proposed that up to seven days are required to reflect the adaptation to the dietary change (28). However, the most dramatic drop in the urinary nitrogen excretion occurs in response to the deficiency in protein intake occurring in the first three days (29).

From the clinically relevant standpoint, it is acceptable to approximate the losses by measuring the UUN content over the course of 24 hours and compare it to the protein/nitrogen intake over the same period. The most common conversion factor for dietary protein is 6.25 g protein for every gram of nitrogen. Heymsfield et al. (30), for example, consider that total daily nitrogen excretion is urea nitrogen plus 1.5–2.0 g for most hospitalized patients. Other estimates, however, place the amount of nonurinary nitrogen losses at approximately 4 g/day.

Nitrogen balance = nitrogen intake – nitrogen losses.

Nitrogen intake = protein intake/6.25 (or appropriate conversion factor for nutrition regimen).

Nitrogen losses equal to 4 g is a commonly used factor to estimate nitrogen losses from the GI tract, in addition to UUN.

The goal is to be in +2 nitrogen balance. To estimate protein requirements based on a UUN value:

Estimated protein needs = [UUN+4 (insensible loss)+2 (for positive N balance)] × 6.25.

It should be pointed out that the 4 g/day allowance for the nonurinary nitrogen losses from fecal matter and skin is

**Table 5** Approximate Values of Nitrogen Loss in Normal and Catabolic States

24 hrs urinary nitrogen loss (g)	24 hrs nonurinary nitrogen losses (g)	Level of metabolism
<6	4	Normal
6–12	4	Mild catabolism
12–18	4	Moderate catabolism
>18	4	Severe catabolism

only applicable in the situations when the patient's major source of excretion is urine. In the cases of renal failure (BUN >50 mg/dL or urine output <500 mL/day), severe diarrhea, lymphatic leak, or exudative drainage from the body (i.e., burns, high-volume fistula output, multiple decubitus ulcers, surgical drains, chylothorax, etc.) nitrogen losses can be very substantially higher, and should be considered in any calculations of the nitrogen balance. In 1987, Waxman et al. (31) attempted to quantify protein losses through severe burns by deriving the formula: (g) =  $1.2 \times \text{body surface area (m}^2) \times \% \text{ burn}$ .

Critically ill patients are usually in a heightened state of catabolism. In this condition, patients often lose 16–20 g of nitrogen per day (up to 24 g/day in some cases) as opposed to nonstressed individuals who lose only 10–12 g/day. The classification of the degree of catabolism based on the nitrogen excretion in the urine is summarized in Table 5.

The degree of catabolism following trauma, burns, and critical illness is notoriously difficult to control. Nutritional supplementation by any route may blunt, but will never completely reverse the catabolic state of the patient (32,33). **✎ The goal for nutritional support is to minimize the degree of catabolism and to maintain the patient in the normal to only mildly catabolic state throughout the acute phase of illness.** **✎** The protein intake for the critically ill patient should be tailored to this goal.

### Hepatic Transport Proteins

Several proteins produced by the liver have been used to estimate the nutritional status of the patient. The most commonly used proteins are albumin, prealbumin, transferrin, and retinol-binding protein (RBP) (Table 6). Of these, albumin has been studied most extensively. Serum albumin concentration represents the balance between the hepatic synthesis and albumin degradation and clearance from the body. Approximately two-thirds of the albumin reside in the extravascular compartment (34). The half-life of albumin is approximately 21 days. Several well-designed studies demonstrated the correlation of low serum albumin and increased rate of complications (35–37).

For example, a study of 54,215 patients undergoing major noncardiac surgery in the VA system demonstrated that compared with the patients whose albumin levels was 46 g/L, the patients with the albumin levels of 21 g/L and above had increase in mortality from less than 1% to 29% and increase in morbidity rates from 10% to 65% (38). The levels of albumin drop in response to malnutrition. The drop, however, is offset by the shift of the albumin from the extravascular pool and by decreased degradation. Fol-

lowing trauma, sepsis, or after major surgery, the levels of albumin usually decrease precipitously. The mechanisms responsible are decreased hepatic synthesis, increased degradation, and hemodilution due to fluid resuscitation (39–41). Despite above mentioned confounding factors, albumin remains one of the easiest and most well studied parameters for the long-term assessment of the nutritional status of the patients.

However, due to its relatively long half-life (21 days), albumin is not a good indicator of the acute changes in the nutritional status. Accordingly, other proteins are used for the assessment of nutritional status and monitoring of nutritional progress in critical care. Transferrin has a half-life of approximately eight days. It therefore would seem to be better suited for the evaluation of acute changes in metabolism and nutritional status. However, transferrin concentration varies widely in healthy subjects. Furthermore, as this protein is part of the hepatic acute-phase response (APR), its concentration is elevated in both anemia and infection.

The preferred protein parameter for assessing nutritional status in critically ill patients is prealbumin. This protein has rapid turnover with a half-life of approximately 72 hours. As such, its levels fall and rise as nutrition status deteriorates and improves, respectively (42). In burn patients, the initial drop in prealbumin reaches maximum decline on postburn days six to eight (42). In a study of more than 1600 patients on maintenance hemodialysis therapy, prealbumin was inversely related to mortality, with a relative risk reduction of 6% per 1 mg/dL increase in prealbumin (43). Prealbumin levels are elevated in renal failure due to decreased excretion and long-term steroid therapy and lowered in liver failure due to decreased synthesis. Acceptable prealbumin levels for patients with renal failure, receiving hemodialysis, and on steroids are  $\geq 30$  mg/dL (44). The presence of these conditions as well as the acute response phase should be considered when making interpretations of prealbumin level.

### Acute-Phase Proteins

Despite adequate nutritional support, prealbumin levels may not rise at goal improvement rate of 0.5–1 mg/dL/day. Drawing a C-reactive protein (CRP) level may be helpful to confirm decreased constitutive protein (i.e., albumin, prealbumin, RBP, and transferrin) synthesis. **✎ During critical illness, the liver reprioritizes protein synthesis to acute-phase proteins (i.e., CRP, alpha<sub>1</sub>-acid glycoprotein, alpha<sub>1</sub>-protease inhibitor, fibrinogen, and haptoglobin) instead of constitutive proteins (i.e., albumin, prealbumin, and RBP) (45), hence an inverse relationship between CRP and prealbumin levels develops.** **✎**

A prompt increase in prealbumin may be seen when CRP levels fall below 10–15 mg/dL. If prealbumin levels do not rise, the nutrition support regimen should be reevaluated (refer to Table 7 for more information). The body's response to physical and psychological stress is called the APR and occurs during strenuous exercise, childbirth, burn, trauma, tissue ischemia, surgical operation, and allergic reactions. Clinical symptoms of APR include increased heart rate, fever, hemodynamic instability, altered level of consciousness and/or anorexia in addition to changes in body mineral stores, hormone levels, coagulation factors, blood cellular components, and plasma proteins. During APR, 30% of total body protein synthesis is dedi-

**Table 6** Hepatic Transport Proteins

Serum protein	Clinical significance	Half-life (days)	Function	Causes of increased values	Causes of decreased values
Albumin	2.8–3.5 g/dL (mild depletion)  2.1–2.7 g/dL (moderate depletion) <2.1 g/dL (severe depletion)	14–20	Carrier protein, maintenance of plasma oncotic pressure	Dehydration	Blood loss associated with trauma and surgery, fluid repletion during resuscitation, liver disease, infection, nephrotic syndrome, overhydration, malabsorption
Transferrin	150–200 mg/dL (mild depletion) 100–150 mg/dL (moderate depletion) <100 mg/dL (severe depletion)	8–10	Carrier protein for iron	Pregnancy, hepatitis, iron deficiency, dehydration, chronic blood loss	Chronic infection, acute catabolic states, nephritic syndrome, increased iron stores, liver damage, overhydration, malnutrition
Prealbumin	10–15 mg/dL (mild depletion)  5–10 mg/dL (moderate depletion) <5 mg/dL (severe depletion)	2–3	Carrier protein for RBP, transport protein for thyroxine	Chronic renal failure, steroid use	Acute catabolic states, past surgery, altered energy and nitrogen balance, liver disease, infection, dialysis
RBP	Neglects acute changes in protein malnutrition; normal range of 2.7–7.60 mg/dL	0.5	Transports retinol	Renal failure, pregnancy	Vitamin A deficiency, acute catabolic states, past surgery, liver disease

Abbreviation: RBP, retinol binding protein.

Source: From Ref. 106.

cated to the production of acute-phase proteins—mainly CRP with a half-life of approximately 48 to 72 hours (Table 7) (46).

RBP has a small body pool and very short half-life (<12 hours). Like prealbumin, its concentration responds rapidly to variations in the energy intake and protein intake. Both prealbumin and RBP are therefore suited for the evaluation of the changes in the nutritional status with the limitations aforementioned.

### Triglyceride Levels

Another important nutrition laboratory marker is serum triglyceride levels. Patients who are receiving propofol (Diprivan®) for sedation are receiving approximately 1.1 kcal/mL, which may add up to a significant source of fat calories. When greater than 1 g/kg/day or 0.1 g/kg/hr of lipid are infused, hepatic fat clearance may be compromised leading to elevated triglycerides. It is recommended to check triglyceride levels weekly for a goal of  $\leq 400$  mg/dL.

If elevated triglyceride levels continue, changing to a fat-free sedative (i.e., dexmetomidine), is recommended. If elevated triglycerides continue after the halt of parenteral intralipid infusion or propofol, an evaluation for carnitine deficiency should be initiated.

Patients receiving parenteral intralipids with elevated triglycerides (>400 mg/dL) should have intralipids checked five hours after the lipid infusion is stopped. If levels continue to be elevated, approximately 500 mL of 10% intralipids or 250 mL of 20% intralipids should be provided over 8 to 10 hours, three times a week (47). Five hundred milliliters of 20% intralipid may also be given once per week. ⚡ **Essential fatty acid deficiency arises one to three weeks after fat-free parenteral nutrition is initiated.** ⚡ Propofol and parenteral intralipids should be used with caution because they are mainly composed of soybean oil or omega-six fatty acids, which have been shown to be immunosuppressive.

In a study done by Mayer et al. (48) on 10 critically ill patients with septic shock randomly receiving either n-6

**Table 7** Nutritional Assessment Parameters

Parameters	Significance	Goals
Prealbumin	Half-life 2–3 days Synthesized by: liver Filtered by: kidneys  Mild depletion: 10–18 Elevated values: steroid use and renal failure Decreased values: stress, infection, and critical illness or elevated CRP	When nutrition support initiated, goal improvement is 1 mg/dL/day  Normal: >18 Moderate: 5–10  Severe: <5 Renal failure or steroids: ≥30 (44)
APP	Opsonins: CRP, protein protease inhibitors: alpha <sub>1</sub> -protease inhibitor, hemostatic agents: fibrinogen, transporters: haptoglobin Alpha <sub>1</sub> -acid glycoprotein (45) Levels ≤48–72 hr postinjury When APP levels elevated, prealbumin levels decrease	CRP levels goal Baseline normal: <3 CRP level during bacterial infection: 30–35 Viral infection: <20 Posttrauma: 20–35 (107)
24 hr—UUN	Formula to estimate protein needed to achieve 0 N balance: (24 hr UUN + four for skin and fecal losses) = Y Y × 6.25 g protein/1 g N = g protein Waxman formula: (g) = 1.2 × BSA (m <sup>2</sup> ) × % burn	Positive N balance 2–4 g Values inaccurate when: BUN >50 mg/dL urine output <500 mL/dL, multiple wounds/burns/large fistula and surgical output, dialysis
Triglycerides	To assess tolerance of TPN intralipids or fat containing sedative (i.e., propofol); to determine if hepatic fat clearance is optimal	Acceptable level: <400 mg/dL; if levels are higher, hold fats for 5 hrs and recheck; if levels remain elevated, infuse 250 mL TPN intralipids weekly to prevent EFAD; if levels are elevated, check for carnitine deficiency
Dry weight	To monitor losses of lean body mass; however, values may fluctuate with fluids, different scale use, dialysis, and burns; used to calculate calorie, protein, and fluid needs	Prevent loss of ≥10% admit or dry weight Losing ≥40% admit or dry weight is generally fatal (due to loss of substantial lean body mass)
Visual assessment, GI losses	Monitoring for symptoms of macro- and micronutrient deficiency, lean body mass wasting, edema, etc. GI losses may cause electrolyte imbalances (i.e., NG/OG fluids, ileostomy/rectal output, surgical drains)	Provide adequate MVI and mineral supplementation and electrolyte repletion to prevent deficiencies which may arise from long-term nutrition support or present illness
Indirect calorimetry	Gold standard to determine energy expenditure RQ: $\dot{V} \text{CO}_2 / \dot{V} \text{O}_2$ Requires skilled personnel to interpret data Patient must be in the supine position either with continuous nutrition support or measurement taken 2 hrs postmeal	Caution when interpreting data RQ <0.7 oxidation of alcohol, ketones, carbohydrate synthesis, measurement problem 0.70–0.75 mostly lipid oxidation, possible starvation >1.00 lipogenesis, primarily carbohydrate oxidation, hyperventilation, measurement problem

*Abbreviations:* APP, acute-phase proteins; BSA, body surface area; BUN, blood urea nitrogen;  $\dot{V} \text{CO}_2$ , CO<sub>2</sub> production;  $\dot{V} \text{O}_2$ , O<sub>2</sub> consumption; EFAD, essential fatty acid deficiency; MVI, multivitamins; N, nitrogen; NG, nasogastric; RQ, respiratory quotient; TPN, total parenteral nutrition; UUN, urine urea nitrogen.

or n-3 lipid emulsion as parenteral nutrition for 10 days, CRP concentration and leukocyte count were increased in the n-6 group and decreased in the n-3 group—but the difference was not statistically significant. The same authors showed that n-3-enriched parenteral lipid emulsions may improve immunocompetence and inflammation in critically ill patients with sepsis (49). The FDA has not approved the use of omega-3 parenteral emulsions till now despite wide use in Europe.

Despite the reasonable biochemical basis for the use of protein levels for the evaluation of the nutritional status and multiple studies which validated this approach, some have found a discrepancy between anthropometry and use of nutritional markers for the assessment of nutritional status (50). **Clinicians, therefore, are advised to exercise some degree of caution while using the biochemical markers exclusively for the nutritional assessment.**

### Predictive Equations for Determining Caloric Requirements

The accurate estimation of the energy requirements allows intensivists to avoid the dangers of overfeeding critically ill patients while providing enough calories to combat malnutrition. Adequate nutrition is used to reduce the rate of complications and to decrease the hospital stay (51,52). It is also important in attenuating APR in critical illness (53,54).

The energy requirements of the individual are composed of resting metabolic rate, thermogenic response to food, and physical activity. Of these, the resting energy expenditure (REE) is the largest contributor to the total energy expenditure (TEE).

In 1919, Harris and Benedict (55) published their landmark study on the prediction of the basal metabolic rate in healthy individuals.

#### Box 1. Harris–Benedict Equations

Male:  $REE = 66 + 13.7 (\text{weight in kg}) + 5 (\text{height in cm}) - 6.8 (\text{age in years})$

Female:  $REE = 665 + 9.6 (\text{weight in kg}) + 1.8 (\text{height in cm}) - 4.7 (\text{age in years})$

Since then, the Harris–Benedict equations have been used to predict energy requirements in diverse groups of patients. These equations, however, were derived from the measurements of healthy subjects. Together with the realization that nutrition plays a crucial role in the care of critically ill patients came the attempts to use the equations to estimate the energy requirements of the critically ill patients. Through decades, these equations remained the standard for the assessment of the energy requirements. Their validity has been challenged recently (56,57). Multiple coefficients have been used to adjust the equations to evaluate the patients under various degrees of stress (Table 8) (58).

Other equations have been developed to improve accuracy over these original ones. Of these, the equations designed by Owen et al. (59) and the World Health Organization (WHO) have been shown to be more accurate.

#### Box 2. Owen et al. (60) Estimation of Caloric Requirements

Men  $EE = [879 + 10.20 \times \text{weight (kg)}] \times 4.184$

Women  $EE = [795 + 7.18 \times \text{weight (kg)}] \times 4.184$

**Table 8** Injury Correction Factors for Different Surgical Insults

Injury correction factor	Clinical situation
1.3	Nonstressed, nutritionally sound patient
1.4	For minimal stress (elective surgery, cancer, minimal trauma)
1.5	Moderate stress (orthopedic surgery, major musculoskeletal trauma)
1.6	Severe stress (major trauma, sepsis)
1.7	Extreme stress (severe closed head injury, ARDS, sepsis)
2.1	Major burn

Abbreviation: ARDS, acute respiratory distress syndrome.

Source: From Ref. 50.

#### Box 3. WHO Estimation of Caloric Requirements (61)

Men 18 to 30 years old  $EE = 64.4 \times \text{weight (kg)} - 113.0 \times \text{height (m)} + 3000$

30 to 60 years old  $EE = 19.2 \times \text{weight (kg)} + 66.9 \times \text{height (m)} + 3769$

Women 18 to 30 years old  $EE = 55.6$

$\times \text{weight (kg)} + 1397.4 \times \text{height (m)} + 146$

30 to 60 years old  $EE = 36.4 \times \text{weight (kg)} - 104.6$

$\times \text{height (m)} + 3619$

Another useful set of equations was developed by Ireton-Jones et al. (63). Unlike the other sets, these equations are designed to be used specifically for critically ill patients from the outset without the need for the correction factors.

#### Box 4. Ireton–Jones Equations

Spontaneously breathing patients:  $EEE = 629 - 11A + 25W - 609O$

Ventilator-dependent patients:  $EEE = 1784 - 11A + 5W + 244G + 239T + 804B$

EEE = estimated energy expenditure, A = age (years),

W = weight (kg), O = presence of obesity (>30% IBW;

0 = absent, 1 = present), G = gender (1—male,

0—female), T = diagnosis of trauma (0—absent,

1—present), B = diagnosis of burn (0—absent,

1—present)

These equations have been validated in several studies (64,65).

Lastly, a simple but commonly used energy expenditure equation is to calculate calorie and protein range based on weight in kilograms. Ranges of 20–35 kcal/kg would be appropriate for trauma, critical illness, and mild to severe stress. Estimating energy needs for obese patients (>135% IBW) brings a challenge. The use of the Ireton-Jones et al. (62) equation has closely estimated indirect calorimetry results. However, 11–14 kcal/kg of actual body weight per day and 1.5–2.1 g protein/kg IBW per day would be an appropriate initial range to meet energy needs of the critically ill obese patient (66). For trauma and critical care patients, providing protein of at least 1–1.2 g protein/kg initially for one to two weeks is adequate (67). Providing greater than 1.5 g protein/kg does not further reduce nitrogen losses (68). Azotemia may result when protein of more than 2 g protein/kg is provided (69) (refer to Table 9 for kcal, protein, and fluid guidelines).

Determination of kcal, fluid, and protein needs weight should be adjusted for patients with multiple amputations to prevent overfeeding or underfeeding. Table 10 provides adjustment information. For example, when calculating the IBW of a 5 ft 5 in. tall, 70-kg male with a below-knee amputation (BKA), using the Hamwi method IBW is 62 kg but when adjusted for BKA the patient's IBW would be: 62 kg—62 (7.1% for BKA) = 57.5 kg. Therefore, the patient would be 122% of IBW—slightly overweight.

✎ **The Harris–Benedict equations remain the standard, and most widely used equation for the estimation of the energy expenditures.** ✎ It is worth noting that the equipment used by Harris and Benedict consisted of the humidified breathing circuit in which  $\dot{V} \text{CO}_2$  was trapped and weighted. The  $\dot{V} \text{O}_2$  was determined by the amount of  $\text{O}_2$  injected into the circuit (70). The formulas, therefore, have been designed on the same principle as indirect calorimetry.

**Table 9** General Guidelines for Estimating Calorie, Protein, and Fluid Needs

Degree of metabolic stress	Total kcal/kg/day	Grams protein/kg/day	Fluid
Mild to moderate stress	25–30	0.8–1.5	1–1.5 mL/kcal for maintenance unless
Severe stress	30–35	1.5–2	restricted; additional free water indicated
Standard ICU	20–25	1.2–2	in absence of IVF in all tube fed patients
Obese (BMI > 27)	11–14 of actual weight	1.5–2.1 IBW	unless restricted
Burn	BEE × 1.2–1.5	2–2.5	
Trauma	20–35	1.2–2	

*Abbreviations:* BMI, body mass index, BEE, basal energy expenditure; ICU, intensive care unit; IBW, ideal body weight; IVF, intravenous fluids.

### Indirect Calorimetry

Two types of calorimetry have been employed for the calculation of the energy expenditure. Direct calorimetry measures heat produced by the subject, as a direct measure of energy expenditure. This method is plagued by high cost and complicated engineering. Alternatively, indirect calorimetry has emerged as the viable method for the estimation of the REE. It is based on the measurements of  $\dot{V} O_2$  and the  $\dot{V} CO_2$  by the subjects. From these data, the energy expenditure is estimated. The equation used for the calculation of the energy expenditure is called the Weir equation:

$EE = [\dot{V} O_2 (3.941) + \dot{V} CO_2 (1.11)] \times 1440 \text{ min/day}$  (71). In more general terms, the Weir equation assumes the following form:

$$EE = [(K_1 \times VO_2) + (K_2 \times VCO_2) \times 1.44 - (K_3 \times UN)] \quad (1)$$

where  $K_1$ ,  $K_2$ , and  $K_3$  are the constants. Various sources report different numbers for the  $K_{1-3}$  with the range for  $K_1$  being 3.58 to 5.5,  $K_2$  1.10 to 1.7, and  $K_3$  1.44 to 3.44 (72–74). For the sake of simplicity, the urinary nitrogen measure can be omitted, as its contribution to the overall caloric expenditure is minimal. As a matter of fact, it has been shown that 100% error in the calculation of the nitrogen contribution would result in less than 4% error in the overall energy expenditure calculation (75).

Metabolic monitoring using indirect calorimetry has the advantage over formulas to account for variables that are difficult to measure such as energy expended from pain, physical therapy, sepsis, or respiratory complications. To perform the measurements, the equipment should be capable of measuring basic spirometry as well as performing the measurements of the partial pressures of gases in the inhaled and exhaled gas mixtures (76). The machines currently available measure and calculate the REE (intermittent

monitor), which is slightly higher than the basic energy expenditure and lower than the TEE (continuous monitor). Nonetheless, indirect calorimetry has been shown to accurately approximate the caloric requirements (56,73,77–78). As defined in the review written by Brandi et al. (73), indirect calorimetry plays the role in the assessment of the patients who fail to respond adequately to traditional nutritional therapy. It is currently considered by many that **indirect calorimetry is the standard technique in the clinical armamentarium against which all other methods of nutritional assessment should be measured.** Some of the limitations of using a metabolic monitor include chest tubes with pulmonary air leaks, air leak past the tracheal cuff, or requirement of >80% FiO<sub>2</sub> (79,80)

Respiratory quotient (RQ) is defined as the ratio of  $\dot{V} CO_2$  produced to  $\dot{V} O_2$  consumed ( $\dot{V} CO_2/\dot{V} O_2$ ). RQ above 1.0 is suggestive of overfeeding and of lipogenesis. Likewise the values of RQ below 0.85 suggest underfeeding and continued use of endogenous fat stores (Table 10). In the study of 263 patients from 30 kindred (long-term ventilator weaning) hospitals demonstrated the RQ measurement of more than 1.0 to be 85.1% specific but only 38.5% sensitive in detecting patients being overfed. Likewise, an RQ measurement of less than 0.85 was shown to be 72.2% specific and 55.8% sensitive for the detection of underfeeding. **Based on these numbers, it is hard to use the RQ as the monitoring tool or as assessment tool for the determination of the adequacy of nutritional regimen (81).**

RQ, however, can be used for the validation of the indirect calorimetry measurements with RQ values outside the physiologic range resulting from problems with the quantity or quality of nutritional intake, as well as from problems with the testing process.

### MONITORING METABOLIC DEMANDS/NUTRITIONAL SUPPLY

#### Nitrogen Balance

Nitrogen balance, which requires 24-hour urine collection, is necessary to assess the net protein delivery. The goal of nutritional support is to achieve the positive nitrogen balance of 2–4 g/day in critically ill patients (as described earlier).

The context in which nitrogen balance is discussed here is as a measure of metabolic demand. The 2–4 g/day goal might not be obtainable in the patients in the acute phase of the critical illness (82–84). In the study of eight patients in septic shock, Streat et al. (84) found a significant degree of loss of the lean body mass despite aggressive nutritional regimen. In another study of the 20 medical patients in multiorgan system failure, the researchers have found that neither hypercaloric nor isocaloric nutritional support pre-

**Table 10** Adjusting Weight for Amputation

Body parts	Adjustment (%)

Above knee	11
Entire leg	16

*Source:* From Ref. 107.

vented protein catabolism; in contrast, they enhanced the metabolic burden (83).

Nonetheless, continuous monitoring of the nitrogen balance allows clinicians to tailor the diet regimens to offset the effects of the catabolic state of the acute illness (85). Nitrogen balance should be calculated weekly for critically ill patients and others at risk for malnutrition by the screening methods described elsewhere in this chapter.

### Measurement of Continuous Caloric Expenditure

As discussed previously, indirect calorimetry has emerged as the robust tool for the management of the challenging patients with severe trauma and sepsis. The continuous metabolic measurements during the 24-hour period eliminate the theoretical problems with the errors in assessment of the metabolic needs caused by circadian rhythms, intermittent feedings, and stress of the treatments. Continuous indirect calorimetry is laborious and expensive as it ties the machine to the particular patient for the duration of the measurement. In the past, metabolic cart or a tent was used for the determination of the energy expenditure. This technique implied intermittent assessment, or, in other words, the “snapshot” picture of the energy expenditure. Recently, research has focused on the accuracy of intermittent indirect calorimetry as a tool for the determination of the energy expenditure (86–90). In the study by Smyrniotis et al. (86), 30-minute indirect calorimetry measurements between 11 P.M. and 3 P.M. were found to predict energy expenditure acceptably well for clinical use. Similarly, van Lanschot et al. (89) concluded that acceptable accuracy can be achieved with two 15-minute measurements in a 24-hour period. It appears that there is sufficient evidence to recommend short-period measurements as a viable way to estimate 24-hour energy expenditure.

### PITFALLS IN NUTRITIONAL SYSTEMS EVALUATION

The acute response to injury alters metabolism dramatically (91). Most of the baseline tables need modifications for critical illness. In patients with multiple trauma or severe sepsis, there is less correlation between the levels of IGF-1, prealbumin, and transferrin and the change in the total body protein, making these markers less useful for following changes in protein stores early in the course of critical illness (91). Anthropometrics are easy to perform on the patients in the upright position. However, trauma patients, especially in the critical care settings, usually have major limitations in mobility rendering anthropometric measurements difficult to perform and sometimes unreliable.

Nutritional history preceding the accident or onset of critical illness is sometimes unobtainable by the changes in the patient’s mental status. SGA discussed earlier in this chapter has been used fairly extensively to recognize nutritional problems in patients (9,14,92,93). It has been shown to be the accurate predictor of malnutrition in the geriatric population (14,93) and in acute renal failure patients (94) specifically.

The SGA depends on careful collection of the information by trained observers. In at least one study, SGA failed to distinguish between the levels of malnutrition in the dialysis patients. In comparison with the total body nitrogen, the authors concluded that SGA is not a reliable predictor of degree of malnutrition (95).

Indirect calorimetry use is best reserved for the monitoring of the change in metabolic demands of severely injured or sickest patients when other methods fail to help in achievement of adequate nutritional status.

### EYE TO THE FUTURE

Several body composition testing techniques have been suggested to be more accurate than currently employed methods. Among these are nuclear magnetic resonance, dual-energy X-ray absorptiometry (96,97), whole body conductance/impedance (98–101), neutron activation (102), air displacement plethysmograph (103), and hydrodensitometry (99,104). These methods are currently very expensive and difficult to implement on a broad scale. However, if the current trends in the search for a more precise tool continue, some of these new techniques might gain more popularity and, therefore, would become more suitable for the bedside applications.

### SUMMARY

This chapter provides an overview of the armamentarium readily available to the interested clinicians in the majority of large trauma centers and SICU. The tools described have all been successfully employed in the nutritional assessment of the critically ill and injured patients. However, as it has been pointed out previously, all of the methods described here possess certain limitations. Despite great advances in the field of nutrition over the recent decades, the search for the cheap, easy to use, and reliable nutrition assessment tool continues. **At present there remains no viable substitution to the continuous and relentless attention to multiple small details of the patient’s progress for the accurate assessment and monitoring of the nutritional status.**

### KEY POINTS

- ☞ No gold standard in nutritional assessment currently exists.
- ☞ SGA is a valuable tool in the initial screening for malnutrition in the majority of the situations where the information regarding the status of the patient prior to admission is readily available.
- ☞ Weight loss is expected during hospitalization, and nutrition therapy goal should include maintaining  $\geq 90\%$  admit or usual weight.
- ☞ The goal for nutritional support is to minimize the degree of catabolism and to maintain the patient in the normal to only mildly catabolic state throughout the acute phase of illness.
- ☞ During critical illness, the liver reprioritizes protein synthesis to acute-phase proteins (i.e., CRP,  $\alpha_1$ -acid glycoprotein,  $\alpha_1$ -protease inhibitor, fibrinogen, and haptoglobin) instead of constitutive proteins (i.e., albumin, prealbumin, and RBP) (45), hence an inverse relationship between CRP and prealbumin levels develops.
- ☞ Essential fatty acid deficiency arises one to three weeks after fat-free parenteral nutrition is initiated.
- ☞ Clinicians, therefore, are advised to exercise some degree of caution while using the biochemical markers exclusively for the nutritional assessment.

- ✦ The Harris–Benedict equations remain the standard, and most widely used equations for the estimation of the energy expenditures.
- ✦ Indirect calorimetry is the standard technique in the clinical armamentarium against which all other methods of nutritional assessment should be measured.
- ✦ Based on these numbers, it is hard to use the RQ as the monitoring tool or as assessment tool for the determination of the adequacy of nutritional regimen (81).
- ✦ At present, there remains no viable substitution to the continuous and relentless attention to multiple small details of the patient's progress for the accurate assessment and monitoring of the nutritional status.

### INTRODUCTION

Nutritional depletion is associated with malnutrition, increased morbidity—including delayed wound healing—increased lengths of hospital stay, and increased mortality (1). Malnutrition is common in hospitalized trauma patients with an incidence of 30% to 55% (2). Nutrition provides vital cell substrates, antioxidants, vitamins, and minerals required for recovery from illness (3). The two current mainstays of nutritional therapy are enteral and parenteral, with most investigators agreeing that the enteral route should be utilized when at all feasible (2–6).

Anatomically, enteral nutritional support requires a functional gut, a minimum of 100 cm of jejunum and 150 cm of ileum, and some colon, preferably with an intact ileocecal valve (7). Physiologically, the gut must receive adequate splanchnic blood flow and be free of obstruction, infection, ileus, or major mucosal injury. The earlier feeding resumes after resuscitation from trauma or burns, the more likely these conditions will be met.

The benefits of enteral nutrition include the maintenance of gut microflora and decreased bacterial translocation leading to enhanced immune function (2). Increasing gastric blood flow protects the gastric mucosa (4) and assists in maintaining mucosal barrier integrity (2), which results in decreased stress ulceration in critically ill and ventilated patients. Enteral nutrition is associated with decreased catabolic response to injury and improved wound healing (4). Utilization of enteral nutrition is associated with lower cost and fewer major complications than that of parenteral feeding (2). Also, it appears to improve survival in patients with severe injuries, acute pancreatitis, inflammatory bowel disease, and posthepatic transplantation (5). An outcome study by Adams et al. (2) demonstrated a significant reduction in septic morbidity in patients receiving enteral feeds against those on total parenteral nutrition (TPN).

It has become increasingly established that enteral feeding is generally well tolerated in critical illness, including following trauma and surgery. **In situations where full enteral nutrition is not tolerated, as little as 20% of overall nutrient calories administered to the gut can be sufficient to show benefits as opposed to TPN alone (5).**

### TRAUMA AND CRITICAL ILLNESS CONSIDERATIONS

Body stores will be adequate to provide nutrients during short periods of moderate stress without compromising physiologic functions or altering resistance to infection, or impairing wound healing. However, the greater the physiologic stress and the worse the baseline nutritional status, the shorter the duration of starvation tolerated before these complications begin to occur. **Patients most likely to benefit from nutritional support are those with baseline malnutrition in whom a protracted period of starvation would otherwise occur (8).** By definition, patients categorized as malnourished have lost greater than 10% of their ideal body weight (9). Enteral nutrition should be considered in healthy uninjured patients who have been without nutrition for three to five days and whose disease process is anticipated to last more than ten days (10). In previously well-nourished persons with short (<1 week) anticipated duration of fasting, it is difficult to demonstrate improvement in outcome with nutrition support (8). The Eastern Association for the Surgery of Trauma (EAST) practice management guidelines for nutritional support provide helpful recommendations on when, what, and where to feed various types of trauma injuries, which include head injury, spinal cord injury, postgastrointestinal surgery, and pancreatitis, based on 28 clinical studies between 1976 and 2000 (Table 1).

#### Post-Trauma

Multisystem trauma results in a hypermetabolic state resulting in an energy expenditure of 120% to 140% of basal levels (11). Generally speaking, the higher the injury severity score (ISS), the greater the hypermetabolic state. Without provision of exogenous substrates, amino acids are leached from endogenous protein stores including skeletal muscle and visceral structural elements. The resultant acute protein malnutrition is associated with cardiac, pulmonary, hepatic, gastrointestinal (GI), and immunologic dysfunctions. Late infectious complications can prolong the hypermetabolic or hypercatabolic state, eventually resulting in multiple-organ failure (12). **Early enteral feeding should be instituted in all severely injured trauma patients (ISS > 17) without contraindications.**

**Table 1** EAST Practice Nutrition Support Management Guidelines<sup>a</sup>

Diagnosis	Head injury	Abdominal injury	Spinal cord injury	Post-GI surgery	Pancreatitis
When to feed	As soon as possible	Immediately after patient is resuscitated	Within 72 hr of admission	Within hours after surgery if feasible	Immediately
What to feed	Immune-enhanced or high-protein formulas	Immune-enhanced or high-protein formulas	Immune-enhanced or high-protein formulas	Immune-enhanced or high-protein formulas	High nitrogen elemental formula
Where to feed	Stomach if feasible, if not tolerated in 48 hrs feed distally	Stomach if feasible, distally if undergoing laparotomy for injury	Stomach if feasible	Stomach if feasible, distally if not	Distally, preferably past the ligament of Treitz
Calorie needs	30 kcal/kg; 25 kcal/kg if pharmacologically paralyzed	25–30 kcal/kg	20–22 kcal/kg for quadriplegia; 22–24 kcal/kg for paraplegia	25–30 kcal/kg	25–35 kcal/kg
Protein needs	1.5–2 g/kg	1.5–2 g/kg	1–1.5 g/kg	1–1.5 g/kg	1–1.5 g/kg

<sup>a</sup>EAST = Eastern Association for the Surgery of Trauma.

Though trauma victims are generally young, well nourished, and free of pre-existing comorbid diseases, long-term catabolism can have detrimental effects. Biffl et al. (12) evaluated the effect of early nutritional support on patients with major torso trauma. They found early feeding to be feasible in this population, and that enteral nutrition resulted in higher total lymphocyte counts, cumulative positive nitrogen balance, and a lower rate of septic complications versus patients receiving TPN (12). Intensive study has been performed to determine the optimal route of nutrition to prevent the breakdown of lean muscle. In 1986, Moore and Jones compared enteral and parenteral feeding in patients who underwent laparotomy for severe abdominal trauma. Though nutritional parameters and overall complications were not different between groups, septic morbidity was higher in the parenteral group (11).

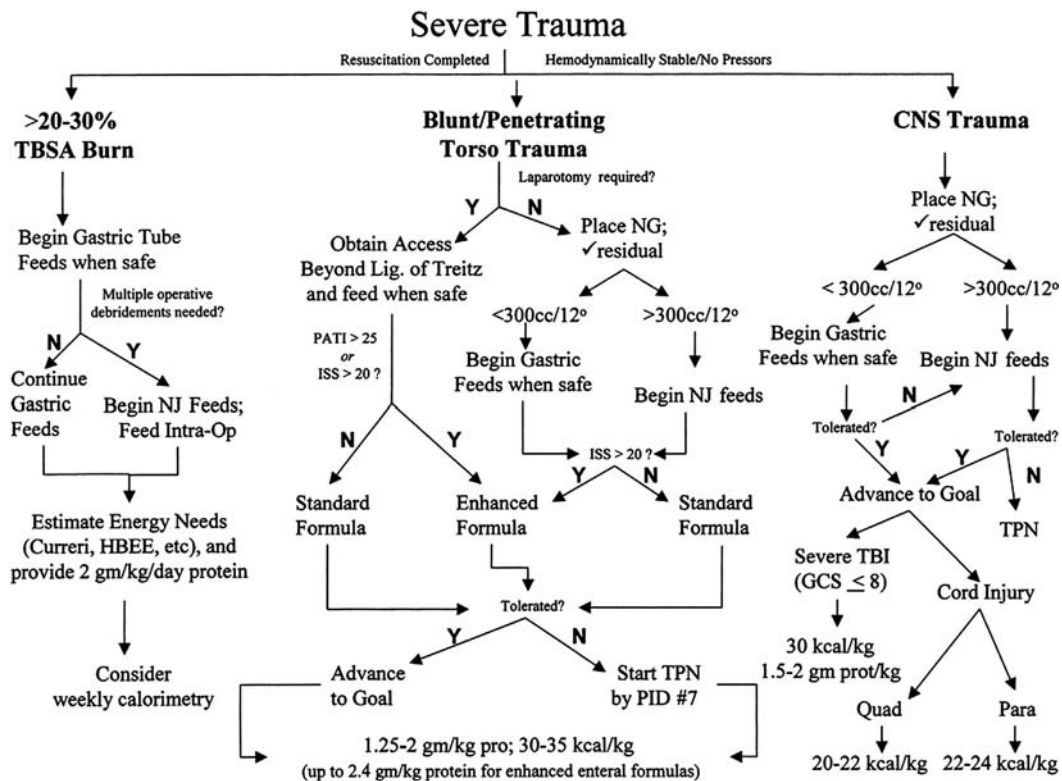

Kudsk et al. (13) also reported a decreased rate of septic complications including pneumonia, intra-abdominal abscess, and line sepsis in enterally fed patients with severe abdominal trauma. Furthermore, the sicker patients' abdominal trauma index [(ATI)  $\geq$  24, ISS  $\geq$  20, transfusions = 20 units, and reoperation] had significantly fewer infections when enterally fed (13). In addition, enteral feeding produced greater increases in constitutive proteins and greater decreases in acute-phase proteins after severe trauma (13).

☞ **The current EAST guidelines (Fig. 1) recommend that patients with blunt and penetrating abdominal injuries be fed enterally because of the lower incidence of septic complications compared with parenterally fed patients (11).** ☞ As trauma patients are hypermetabolic, depletion of nutrient stores proceeds more rapidly in the case of total starvation than it does in healthy patients. So, the consequences of starvation evolve more rapidly in stressed, catabolic patients than in healthy individuals. Because of this, nutritional support in a severely injured patient should be achieved no later than the seventh day, whether by enteral or parenteral means, or by a combination of the two (Fig. 1). Over time, the dose of parenteral nutrition can be incrementally decreased as GI function returns (11).

### Burn Injury

☞ **The goal in burn patients is to initiate enteral nutrition within six hours of presentation to prevent body weight loss of more than 10% of their baseline status (14).** ☞ When a person sustains a burn, healing of the wound consumes large quantities of energy (14), resulting in elevation of the basal metabolic rate and doubling of the resting energy expenditure (REE) (15). The burn-related hypermetabolism results from elevation in catabolic hormones, cortisol, and catecholamines as well as from a decrease in the normal endogenous activity of the anabolic agents (14). This intense metabolic demand causes loss of body fat stores as well as loss of visceral and structural protein mass. In addition, burn injury predisposes to immunosuppression, delayed wound healing, and generalized muscle weakness, all of which prolong rehabilitation (15). In severely malnourished states, lean body mass loss of more than 40% correlates with imminent mortality, whereas limiting weight loss to less than 10% of baseline state is associated with better outcomes (14). Finally, the length of time and severity of the hypermetabolic and catabolic responses persist for over a year following the initial burn injury (14).

Severely burned children receiving a protein supplemented enteral diet demonstrated a higher survival rate

**Figure 1** One proposed algorithm for feeding trauma and burn patients. *Abbreviations:* NJ, naso-jejunal; PID, post-injury day. *Source:* From Ref. 11.

and lower sepsis rate than those on a normal enteral diet (13). Based on studies such as these, it is not surprising that the American Society of Parenteral and Enteral Nutrition (ASPEN) Guidelines of 2002 recommend administering adequate amounts of calories and increased protein following burns (16).

The ASPEN Guidelines of 2002 also recommend enteral over parenteral nutrition (16). Studies in burn patients have shown that enteral nutrition provides superior nutritional support through maintenance of gut mucosal integrity, prevention of increased secretion of catabolic hormones (14), and higher survival rates (13). Though there is concern over inadequate splanchnic blood flow to support the use of the gut in the early postburn period, the immediate use of high calorie enteral feeding during the postburn shock phase has a positive effect on splanchnic perfusion. Conversely, the use of supplemental parenteral nutrition in burned patients leads to a significantly decreased survival rate (14). Intraoperative enteral feeding not only is well tolerated in burn patients but also leads to more successful attainment of calorie and protein goals in those requiring frequent burn wound debridements (11).

Critically ill, anuric ventilated patients on continuous renal replacement therapy (CRRT) have also been shown to have better outcomes with enteral compound to parenteral nutrition ( $P = Q 04$ ) (17). The REE tended to be higher than predicted, and the use of a metabolic cart was found to be particularly useful in ensuring adequate energy provision (17), as is common in many burn patients (13–15).

### Traumatic Brain Injury

Patients with traumatic brain injury (TBI) are hypermetabolic and catabolic similar to trauma patients. Numerous studies

have been performed to investigate the effect of TBI on nutritional need. On average, caloric expenditure following TBI averages 140% of normal REE (18). The increased REE is due to elevated oxygen consumption ( $\dot{V}O_2$ ) caused by increased elaboration of stress hormone. Other factors increasing the metabolic demand include hyperventilation, fever, seizures, and posturing when present. Patients with decerebrate or decorticate posturing have demonstrated elevations in energy expenditure of 200% to 250% of the predicted value. TBI patients with elevated intracranial pressures (ICPs) refractory to standard therapy benefit from pharmacologic manipulation. High-dose barbiturates used to induce pharmacologic coma can decrease REE by as much as 40% below predicted levels. Other common pharmacologic interventions, such as neuromuscular blockade, reduce energy expenditure by 42% below predicted energy expenditure (11). So, patients requiring pharmacologic sedation or coma have a lower caloric expenditure of 100% to 120% of the predicted value (18).

♣ **To prevent devastating losses of nutrient stores and improve patient outcome, nutritional supplementation should begin no later than 72 hours following TBI (18).** ♣ Nitrogen loss of 0.2 g/kg/day occurs in TBI patients, which is two to three times higher than normal fasting nitrogen loss. After seven days without nutritional supplementation this rate of nitrogen loss can decrease lean body mass by 10% (18). During the first two weeks after injury, REE rises regardless of the patient's clinical course. Undernutrition during this two-week interval can result in up to 30% weight loss and increased mortality rate. Although steroids are a contributing factor for hyperglycemia in the TBI patient, no difference has been observed in the nutritional status of these patients who do or do not receive these drugs (19).

## Spinal Cord Injury

Nutritional supplementation is associated with decreased mortality and disability in patients who have sustained a spinal cord injury (SCI) (20). Though there is no study showing a benefit of enteral versus parenteral nutrition in SCI patients, enteral nutrition is preferred due to decreased cost and lower rate of complications (11).

After the initial period of increased REE, SCI patients exhibit a decrease in energy expenditure. During this acute period, nitrogen excretion is increased, which may be due to muscle denervation and atrophy in the muscle segments distal to the injury. Within four weeks of an SCI, patients can lose up to 10% to 20% of their body weight, 85% of which is from loss of lean body mass. This loss is extremely difficult to correct even with aggressive nutritional replacement. Finally, the enforced immobility and nutritional compromise increase the patient's risk of infections, respiratory, wound, and urinary, thereby increasing ventilatory time, antibiotic administration, hospital length of stay, and recovery (20).

☞ **After the acute SCI phase, there is a period of reduced REE in proportion to the amount of paralyzed muscle mass.** ☞ So, the higher the lesion, the lower the REE measurement; for example quadriplegics require 55% to 90% of predicted REE and paraplegic patients require 80% to 90% (11). Although it is imperative to recognize the hypometabolic response in SCI patients to avoid the adverse effects of overfeeding, the precise time window when the hypermetabolic response gives way to the hypometabolic state is often complicated by intercurrent medical problems (e.g., pneumonia), which themselves increase the REE. Accordingly a metabolic cart is useful in these patients when their caloric needs are not obvious on the basis of normal nutritional markers (e.g., prealbumin levels) (Volume 2, Chapter 31).

## Pancreatitis

Acute pancreatitis begins with a localized inflammatory process within the pancreas. However, with severe forms of the disease, extensive surrounding tissue destruction can occur. This results in profound systemic, metabolic derangements due to release of hydrolytic enzymes, toxins, and cytokines (21). The resulting condition is one characterized as hypermetabolic, hyperdynamic, systemic inflammatory response syndrome (SIRS), which leads to a highly catabolic stress state (22). The consequent rapid consumption of nutrient stores is characterized as a negative nitrogen balance condition. The REE increases by 77% to 139% of predicted value due to the hypermetabolic state. Catabolism and proteolysis of skeletal muscle increases by as much as 80% and nitrogen loss increases as much as 20–40 g/day. Gluconeogenesis increases, and glucose clearance and oxidation diminish, leading to glucose intolerance. Finally, development of hypocalcemia is common due to saponification, hypoalbuminemia, hypomagnesemia, increased calcitonin release, and decreased parathyroid hormone secretion (21).

Historically, the standard of care has involved gut rest and utilization of TPN for nutritional supplementation (22). Recent studies have shown that enteral feeding is safe and well tolerated in severe acute pancreatitis (23), with the caveat that pancreatic stimulation be avoided (24). Animal studies have shown that the site of GI feeding determines whether the pancreas is stimulated (22). With this in mind, current recommendations include placement of an enteral feeding tube distal to the ligament of Treitz (24) as jejunal

feeding results in a negligible increase in pancreatic exocrine secretion of enzymes and bicarbonate, and volume (22).

A recent meta-analysis by Marik and Zaloga (22) showed that patients who received enteral nutrition had lower rates of pneumonia, pancreatic and abdominal abscess, as well as wound and blood stream infections, than those receiving parenteral nutrition. In addition, enterally fed patients had a lower requirement for surgical intervention and shorter length of hospital stay (23,24).

Severe ileus preventing enteral feeding is common in the early stages of disease; most patients tolerate continuous low-volume nasojejunal (N-J) infusion. ☞ **Enteral feeding by an N-J tube or percutaneous jejunostomy has largely replaced TPN in the management of patients with pancreatitis (24).** ☞

More recently, a randomized study by Eatock et al. (25) compared elemental tube feeds administered via nasogastric (N-G) and N-J routes in patients with severe acute pancreatitis. The results indicated that N-G feeding was safe when an elemental diet formula was used with little difference in pain, analgesic requirements, serum C-reactive protein (CRP) concentrations, and clinical outcome (25). So, patients with severe acute pancreatitis without ileus may tolerate N-G administration of semielemental low-fat feeding. This would be favored, as the placement of N-G tubes is far easier and more cost-effective (23). Thus, patients with moderate to severe pancreatitis (Ranson's score >3) should be considered for enteral nutrition. Patients with mild pancreatitis normally resume oral intake within 48 hours, thereby negating the benefit of enteral nutrition.

## Systemic Inflammatory Response Syndrome

SIRS, as well as sepsis and multiple organ dysfunction syndrome (MODS) (Volume 2, Chapter 63), are all associated with an increased REE and nutritional stress. These conditions represent a spectrum of illnesses with increasing severity of catabolism and increasing associated mortalities (26).

☞ **Patients with SIRS with or without MODS have elevated total caloric requirements, increased net protein catabolism, and increased micronutrient requirements (27).** ☞ The REE increases to at least 55% above predicted levels (28), so caloric requirements may need to be increased by 10% to 20%. The increased net protein catabolism necessitates an increase in protein administration. In general, nitrogen retention is promoted with 1.5–2.0 g/kg/day of protein (amino acids). In addition, hyperglycemia and triglyceride intolerance are common. Hyperglycemia, even in the absence of diabetes mellitus, is frequently present and requires tight control (27).

## Surgery/Peritonitis

Patients undergoing surgery face many metabolic and physiologic challenges that compromise nutrition. Postoperative nausea, emesis, pain, anorexia, catabolism, infection, and wound healing tax the patient's nutritional reserves. Poor nutritional status in postoperative patients compromises organ and immune function, as well as muscle strength, and puts the patients at an increased risk for the development of infectious complications. In addition, delayed wound healing leads to prolonged recovery time. All of these factors contribute to increased length of hospital stay, readmission rates, and health-care costs (Fig. 2) (29).

Patients with peritonitis were historically treated with bowel rest and gastric decompression until return of normal GI function. Recent studies of surgical patients including those with peritonitis refute this early thinking (30). In an

**Figure 2** Variability of the metabolic rate depending on the level of injury. *Source:* From Ref. 77.

analysis of patients with generalized peritonitis, the GI tract recovers its tone and function within 48 hours (30). Early enteral nutrition not only is tolerated in these patients but also results in improved weight gain, nitrogen balance, and serum albumin (30). ⚡ **Gut perforation after repair generally remains secure and is not necessarily put at risk of leakage by enteral nutrition started at 48 hours after surgery (30).** ⚡

### Malignancy

There is no evidence to support routine use of preoperative enteral nutrition in well-nourished patients undergoing chemotherapy or surgery for cancer; but it is indicated in malnourished patients with a functional GI tract who are unable to ingest sufficient nutrients orally (31). By virtue of their location, upper aero digestive tract tumors can profoundly impair swallowing and cause dysphagia (32). Patients with cancer of the head and neck are predisposed to malnutrition due to pre-existing alcohol and tobacco use. It is estimated that up to 57% of patients with cancer of the head and neck have significant weight loss prior to beginning treatment (31). In addition, therapies to treat these tumors, including surgery, radiation, and chemotherapy, will adversely affect nutritional status (31) and even when successful may further impair swallowing function (33). So, most patients with advanced malignancies will have compromised nutritional status at the initial medical evaluation (32).

Though the complications from the tumor or therapies prevent oral intake, the remaining GI tract is usually functional and enteral nutrition can be administered via a feeding tube. In addition, numerous studies have shown the importance of maintaining the patient's nutritional status during the treatment of these tumors (33). In a prospective study of patients with esophageal cancer undergoing chemoradiation, enteral nutrition effectively prevented weight loss during therapy. Patients who are better nourished have been found to have fewer complications and improved survival (33). ⚡ **For malnourished patients undergoing resection of their tumor, 7 to 10 days of preoperative enteral nutrition support is associated with a 10% reduction in morbidity and improved quality of life (31).** ⚡

Finally, when a severe, acute insult is superimposed on the underlying debilitating effects of cancer, malnutrition is almost unavoidable. It is no surprise that malnutrition is

almost universally present in cancer patients requiring admission to a surgical intensive care unit (SICU). Enteral feeding is superior to TPN and can prevent or reverse host tissue wasting, broaden the spectrum of clinical options, and possibly improve clinical outcome (31).

### Contraindications

The only absolute contraindication to enteral nutrition associates with intestinal obstruction, perforation, ischemia, and major ileus. Other contraindications include patients with intractable vomiting, severe diarrhea, circulatory shock, and GI hemorrhage. Large-volume (500 mL/day) enterocutaneous fistulas represent relative contraindications that can sometimes tolerate elemental diets and/or tubes that both administer nutrients and control fistula drainage.

Finally, though a patient may qualify for nutritional supplementation, it is imperative both to consider the patient's wishes (29) and to determine whether enteral nutrition is appropriate for patients whose prognosis does not warrant aggressive nutritional support due to futility of the disease process (8) (Volume 2, Chapter 67).

## INITIATION AND ADVANCEMENT OF ENTERAL NUTRITION

### Early vs. Late

Historically, delayed institution of feeding was preferred due to the prevalence of gastroparesis and lack of bowel sounds in critically ill, injured, and postoperative patients, both of which were thought to indicate an increased risk of tube feeding intolerance. However, it is now known that small-bowel function, including the ability to absorb nutrients, remains intact despite critical illness, gastroparesis, and lack of bowel sounds. Finally, it has been popularly propagated that patients can easily tolerate five to seven days of starvation without clinical detriment. However, it is now recognized that critically ill trauma and burn patients (as aforementioned) are hypermetabolic following injury and are at increased risk of secondary complications (including infections and wound breakdown) if nutrition is withheld even for a couple of days following injury (11–16).

### Tube Feed Advancement

Tolerance of enteral nutrition advancement is partly dependent upon the formula administered and the route of administration. When feeding gastrically, the osmolality can be higher than when feeding into the jejunum. But because of gastric atony in numerous situations, advancement may be slower than when fed distally. Gastric tube feeding should be initiated at a rate of 10–20 mL/hr of volume via a pump in critically ill patients. After four hours of feeding, enteral administration is temporarily held and the gastric contents aspirated to evaluate the residual gastric volume (RGV). If the RGV is less than 400–500 mL, the tube feeding should be considered to be tolerated and can be advanced after readministering the aspirated volume. Advancement occurs with 10–20 mL increments every two to four hours until the goal rate is attained. The implementation of tube feed advancement can be successfully increased more rapidly in many patients to more rapidly attain the goal rate (5).

When small-bowel feeding occurs, the volume should be increased first using a hypo-osmotic solution followed by advancement of the osmolality. Administration of solutions composed of greater than 300–400 mOsm is not tolerated

and can result in diarrhea. The authors have found that the jejunum can tolerate up to 110 mL/hr of iso-osmotic enteral formula with minimal GI distress. As previously discussed, the presence of bowel sounds and the passage of flatus or stool are not necessary for initiation of tube feeding (27).

Though full feeding can usually be achieved within one to three days, many patients remain underfed despite receiving enteral feeding (1). Reasons include slow tube feed advancement, feeding interruption due to surgery, procedures, and patient transport. When patients have tolerated enteral nutrition well for several days, intermittent bolus supplementation can often be tolerated to make up for the lost nutrition due to procedural interruptions.

### Continuous vs. Bolus Feeding

Continuous feeding involves administering the total daily nutritional volume in equal hourly increments. Proponents note less abdominal distention and regurgitation due to the lower total stomach volume, and is generally the optimal method to initiate tube feedings.

Bolus or intermittent feeding involves dividing the total volume for 24 hours into equal portions to be administered as four to six separate feedings given over approximately an hour each. Adequate free water flushes should also be provided to meet hydration needs and prevent clogging of feeding tube. The benefits of this approach include increased patient mobility and freedom. As such, bolus feeding is more appropriate for ambulatory (rather than critically ill) patients. Some patients may note early satiety, nausea, or emesis, which can be resolved by administering the bolus over a longer duration (32). Intermittent feeding is also believed to decrease gastric pH between feedings, causing bacterial destruction and a decreased risk of pneumonia after aspiration of regurgitated gastric contents.

A prospective, randomized study of 41 mechanically ventilated patients was performed to compare intermittent gastric feeding, continuous gastric feeding, continuous jejunal feedings, and the risk of aspiration by Metheny et al. (34). Though they noted some variability in gastric pH, there was no difference in the rate of aspiration (34). The most important factor in determining which patients best qualify for intermittent versus continuous feeding is the route of administration. As noted earlier, the small bowel will not tolerate large volumes, so bolus feeds are not recommended and continuous feeding is preferred. If the patient is receiving intragastric feeds then it is possible to achieve nutritional goals with either intermittent or continuous feeding (32). However, bolus feeding should only be considered in patients that have already demonstrated the ability to tolerate continuous feeds for several days.

### Transitional Feeding

When patients are transitioning from parenteral to enteral nutrition the physician should provide clear weaning procedures to the nurses. There is no set formula on how to wean parenteral nutrition and increase enteral goal rate. However, with parenteral nutrition, trophic feeding of 10–20 mL/hr should be initiated when GI function is stable. If the patient is able to tolerate trophic feeding based on presence of residuals (<400 mL), discontinuing parenteral intralipids would be the first action. Precise weaning would be achieved if nutrient calculation is conducted by the physician or the clinical dietitian; however, as this is a time-consuming process, equations such as increasing

enteral rate and decreasing TPN rate every two to four hours to sum the enteral goal rate have been helpful. When patients are ready for oral intake, a swallowing evaluation should be ordered to assess for thin liquid tolerance.

## ROUTES OF ADMINISTRATION

✎ The route of enteral nutrition administration is influenced by the patient's clinical prognosis, anticipated duration of feeding, gut patency, motility and anatomy, and risk of aspiration (32). ✎ Though there are many forms of access for enteral feeding, they all result in placement of the nutrient load into either the stomach or small bowel.

### Normal Physiology of the Stomach and the Small Intestine

When selecting the appropriate route for feeding, it is necessary to consider the normal function of the location selected. The stomach neutralizes and dilutes osmotic loads. So, when a hyperosmotic fluid enters the stomach, gastric motility is inhibited to allow time for gastric secretion to convert the hyperosmotic fluid to an iso-osmotic fluid. Once the fluid is adequately diluted, it can be transferred via the pylorus into the duodenum.

The small bowel, unlike the stomach, is unable to tolerate large osmotic loads. The small intestine is the primary area for nutrient absorption. Products of protein digestion, such as dipeptides, oligopeptides, and single amino acids, are completely absorbed in the first 120 cm of jejunum. Carbohydrates are absorbed high in the jejunum. Though simple sugars are preferred, more complex carbohydrates are absorbed after additional enzymatic cleavage. Fat is the most difficult nutrient to absorb, as it is dependent upon proper release and mixing of bile and pancreatic enzymes (5).

### Short-Term Access

Options for short-term access involve placement of a tube via either the nose or the mouth with location of the distal tip into the stomach for gastric feeds or into the duodenum or jejunum for postpyloric feeding (2). Regardless of the location chosen, it should be utilized for short-term access of no more than two to four weeks, after which placement of a long-term device [e.g., percutaneous endoscopic gastrostomy (PEG)] should be considered (1).

Larger, 16- or 18-French diameter N-G tubes are satisfactory for short-term use as they are less likely to clog and allow for assessment of GI tolerance via checking gastric residuals (5). Unfortunately, these tubes have been known to increase the risk of sinusitis, nasopharyngeal ulceration, nasal septum necrosis, nasal ala necrosis, otitis, hoarseness, and vocal cord paralysis (1), and can be uncomfortable for the conscious patient (2).

Smaller-diameter (Dobhoff® and Kaofeed®) feeding tubes are constructed with a weighted tip and an insertion stylet to facilitate placement (32). These tubes allow short-term access but due to the small diameter more easily clog and do not easily allow evaluation of gastric residuals as they collapse when aspirating through them. The primary benefit is greater patient satisfaction and decreased risk of sinusitis (5). It is appropriate to initiate tube feeding with the larger-bore feeding tube and convert to a smaller-bore N-G tube once it has been proven that the patient will

tolerate gastric feeding. In addition, once the GI tract becomes functional, it is possible to attempt feeding orally with an N-G/N-J tube in place (35). Oroenteric tubes, unlike nasoenteric tubes, involve tube insertion via the mouth. These tubes are useful in sedated and intubated patients, but commonly stimulate the gag reflex in conscious patients (2).

Naso/oroenteric feeding requires tube passage via the nose or mouth with placement distal to the pylorus. Standard-length feeding tubes (e.g., Dobhoff and Kaofeed) are placed with the distal tip in the duodenum, whereas the longer (Stayput<sup>®</sup>) tubes allow placement of the distal tip into the jejunum (5). Methods to assist placement include use of weighted tubes, administration of prokinetic agents (i.e., metoclopramide, erythromycin salts) before inserting the tube, and finally fluoroscopic or endoscopic placement (1). Some studies have demonstrated that small-bowel feeding allows the goal rate to be obtained more rapidly, although these results have not been consistent (36).

If an aggressive advancement protocol is utilized, naso/orogastrically fed patients receive equivalent amounts of enteral nutrition as those fed in the duodenum. The only groups with potential benefit from postpyloric feeding are those with gastroparesis and gastric atony (35), gastric outlet obstruction, and possibly those with pancreatitis (21–25) and those at high risk of pulmonary aspiration due to elevated gastric residuals (e.g., TBI patients) (37). Although some investigators have found that jejunal feeding leads to earlier achievement of daily caloric goal compared with patients fed intragastrically, overall rates are similar in those who can tolerate gastric feeds (38).

The primary drawback is the difficulty in positioning the feeding tube postpylorically and frequent proximal tube migration. Therefore, these tubes must be monitored radiographically to avoid gastric feeding, aspiration, and possible pneumonia in high-risk patients. Other disadvantages of these small-bowel feeding tubes include increased cost and risk of occlusion (36). To decrease the risk of complication, tube position should be confirmed by air insufflation and auscultation of the epigastrium, or aspiration of gastric contents. Radiologic confirmation is the most accurate test to assess feeding tube placement (35).

All of the above tubes are associated with potential complications. Esophageal and gastric erosions (5), esophageal stricture, and esophagitis occur due to mucosal irritation by repetitive contact with the feeding tube. Pneumothorax and intrapulmonary feeding (35) can occur when the tip of a metal-weighted feeding tube enters the trachea and punctures the lung. Patients at the highest risk have a depressed cough reflex due to sedation or coma. Some feeding tubes, e.g., Stayput, contain an indwelling, removable metal stylet to facilitate tube placement. Malposition of the tube and stylet can cause esophageal perforation and pneumothorax (5).

Tube occlusion occurs frequently due to inspissated feedings, pulverized medications (7), and inadequate flushing (35). This is prevented by flushing the tube with 15–20 mL of fluid (13) every six hours (35) before and after the instillation of medications (13), avoiding administration of pill fragments or thick medications, and conversion of medications to a liquid form when possible (7). Once a tube is clogged, flushing with warm water, carbonated beverages, acidic juices, proteolytic enzymes, and meat tenderizer may clear the obstruction. Although cleaning the tube with a guidewire is often mentioned, it should be avoided as there is a risk of tube perforation (13). Finally, the most

common complication is the removal of the feeding tube by the patient (35).

Intragastric feeding tubes are associated with gastroesophageal reflux and pulmonary aspiration. Possible causes include high residual gastric volumes (RGVs) (5) and incomplete closure of the lower esophageal sphincter due to stenting by the feeding tube (2). Occurrence of aspiration and subsequent pulmonary infection can be minimized by elevating the head of the bed ( $>30^\circ$ ), radiographic confirmation of feeding tube placement, utilization of feeding protocols, and monitoring RGVs. Generally, RGVs less than or equal to 500 mL are tolerated in adults, whereas larger residual volumes are correlated with increased risk of reflux into the esophagus. The use of RGVs is not a reliable marker to predict aspiration in the critically ill patient (39). As aforementioned, occlusion of the nasal passages with large-bore tubes increases the risk of sinusitis (Fig. 5).

### Long-Term Access

☞ Patients who require long-term, that is, more than two to four weeks, enteral nutrition require permanent access for feeding. ☞ Options include gastrostomy, jejunostomy, or a combination of both, which can be placed via percutaneous or transabdominal approaches (35).

#### Gastrostomy

The first option is intragastric feeding with a gastrostomy. This can be performed surgically or percutaneously (i.e., PEG). For this route to be successful, the patient must tolerate gastric feeding. Patients with gastroparesis, multiple episodes of aspiration, esophageal obstruction, wired jaw, multiple previous laparotomies, and gastric malignancy are not candidates for this procedure (40). Due to the risk of aspiration with intragastric feeding, it is recommended that feeds be discontinued one to two hours preoperatively with low continuous naso- or orogastric suction (2).

#### Jejunostomy

An alternative to gastrostomy is jejunostomy placement, which is appropriate for patients at high risk of aspiration or with abnormal gastric function (35). A jejunostomy requires formation of a stoma between a loop of proximal jejunum and the skin, which can be accomplished surgically or percutaneously. Thus, nutrients are administered directly into the upper small intestine while bypassing or resting the proximal GI tract. Indications for jejunostomy placement include gastric outlet obstruction, gastroparesis, nonfunctioning gastrojejunostomy, anastomotic leak or stricture after esophagectomy, and aspiration (31). Regardless of the approach, jejunostomy placement allows prompt attainment of caloric goals. Though the complications of jejunostomy placement are very few, they include intraperitoneal leak, bowel obstruction, wound infection, fistula formation, and aspiration pneumonitis (41).

#### Combined Gastrojejunostomy Tube Placement

The final option is placement of a gastrojejunostomy (G-J) tube. This can be performed surgically or percutaneously. A G-J tube provides access for concomitant continuous jejunal feeding as well as gastric decompression with the gastrostomy. This route allows feeding tolerance in patients with gastric paresis and does not need to be discontinued for operative intervention. A disadvantage of these tubes is tube migration proximally into the stomach, which then requires

endoscopic repositioning. This tube was proposed to reduce reflux and aspiration; however, studies have found a higher rate of tube dysfunction, 50% to 85%, and no reduction in the risk of aspiration (32).

## TECHNIQUES FOR PLACING PERCUTANEOUS FEEDING TUBES

### Open Surgical Technique

The open surgical gastrostomy was first performed in 1876, by Vernueuil with later modifications in technique by Witzel, Janway, and Stamm. Although rarely done following trauma surgery, it can be performed during laparotomy or as a separate procedure. Open surgical gastrostomies are mostly indicated in patients with esophageal disease including atresia, stricture, or malignancy, as well as cancer and neuromuscular dysphagia. Relative contraindications include primary gastric disease, abnormal gastric or duodenal emptying, and significant esophageal reflux (35).

The Stamm gastrostomy is the most common surgical gastrostomy performed. It involves creating two incisions in the anterior abdominal wall. One is placed midline to access the intra-abdominal contents, and the other is placed over the stomach for the gastrostomy tube (Fig. 3A). The gastrostomy is passed through the anterior abdominal wall and inserted into the stomach via a gastrotomy, an incision in the stomach (Fig. 3B). The feeding tube is secured by balloon inflation and an inner purse-string suture (Fig. 3C). After the feeding tube is passed through the anterior abdominal wall (Fig. 3D), a second purse-string suture is utilized to reinforce the gastric opening and anchor the anterior gastric wall to the anterior abdominal wall (42) (Fig. 3E).

An alternative to surgical gastrostomy is a surgical jejunostomy. Contraindications include Crohn's disease and ascites (35). A jejunostomy can be created by performing

a subserosal, "Witzel" tunnel, or with a needle catheter jejunostomy. In the Witzel procedure, an opening is created in the jejunum for feeding tube insertion. The bowel is then pliated to cover the feeding tube with the external surface of the jejunum and attached to the undersurface of the anterior abdominal wall.

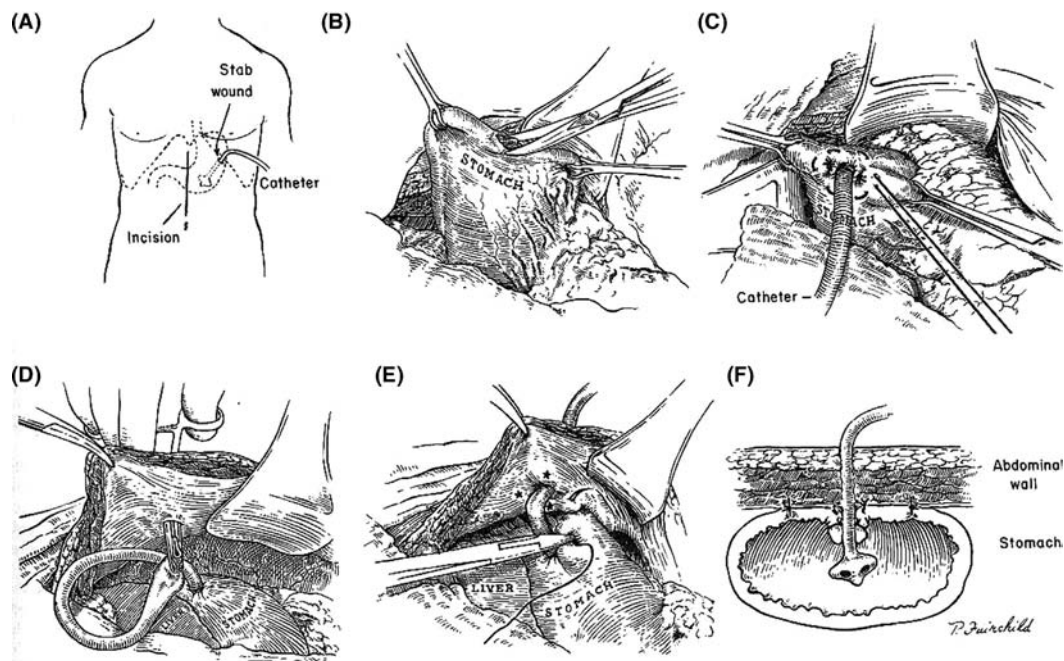

The needle catheter jejunostomy is performed by passing a 16-gauge polyvinyl catheter through the antimesenteric border of the jejunum, 15 cm distal to the ligament of Trietz (32). The opposite end of the jejunal feeding tube is passed through the abdominal wall distant from the laparotomy incision (35). A rare complication of needle jejunostomy feeding is bowel necrosis, occurring with an incidence of 0.15% to 0.29% (41).

Complications for both the surgical gastrostomy and jejunostomy include local irritation, hemorrhage, skin excoriations, wound infection, wound dehiscence, and intraperitoneal leakage (35).

### Laparoscopic Feeding Tube Placement

General anesthesia is not necessarily required for this procedure. A prospective randomized study by Duh et al. (43) compared the use of general anesthesia versus local anesthesia for the placement of laparoscopic feeding tube placement, demonstrating that the use of intravenous sedation and local injection at the trocar sites allowed adequate relaxation of the abdominal musculature and adequate pain and anxiety control to safely accomplish the procedure. In these cases, pneumoperitoneum is typically decreased to 6–8 mmHg from the standard 15 mmHg, thus decreasing patient discomfort without compromising intra-abdominal visualization (43).

This procedure is most useful in patients with total or incomplete obstruction of the hypopharynx or esophagus.

**Figure 3** (A) Small incision is made in the midline. (B) Grasp midanterior gastric wall with babcock forceps and a small incision made in the stomach wall. (C) Gastrostomy tube inserted into the stomach and held in place with a purse-string suture. A second purse-string suture is placed around the gastrostomy tube. (D) Stab wound made in left midrectus region over the stomach for passage of the gastrostomy tube. (E) Stomach wall is anchored to the peritoneum with the second purse-string suture. (F) Side view after gastrostomy procedure is complete. *Source:* From Ref. 78.

The procedure utilizes port placement and insufflation of the abdomen to visualize the intra-abdominal contents. A site for gastrostomy placement is chosen and must easily reach the abdominal wall without tension. The stomach is fixed in four sites with sutures to both elevate and stabilize the organ (Fig. 4A). A needle with a catheter is inserted into the stomach and the needle removed. The Seldinger technique is utilized to insert the feeding tube (Fig. 4B). The gastrostomy is inserted and held in place with T-fasteners (Fig. 4C) (44).

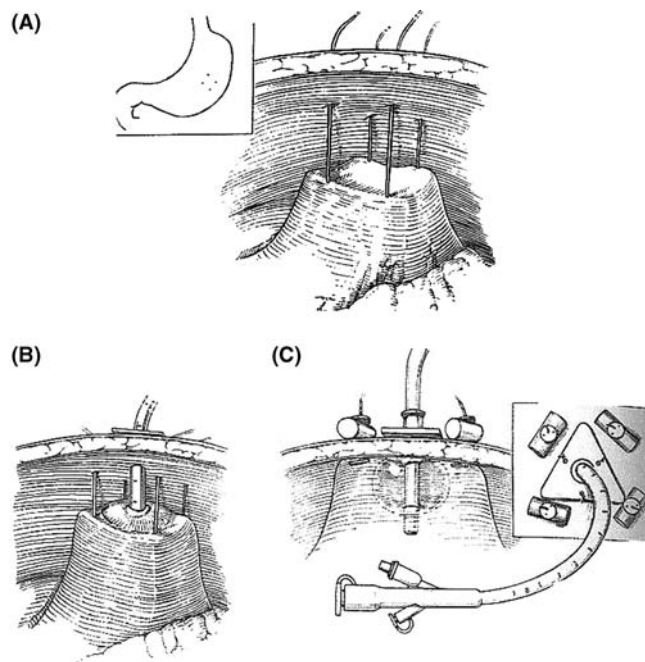

### Percutaneous Techniques

The percutaneous approach was first described in 1979 by Gauderer (38) and has widely replaced surgical gastrostomies due to the inherent safety and rapidity of the procedure (2). This procedure can be performed by multiple specialists in the GI suite, or at the bedside in the SICU or a step-down unit. A percutaneous gastrostomy utilizes a single exit wound and can be performed with local anesthesia and light sedation or general anesthesia. Combined, these differences result in a significantly lower cost than that of surgical gastrostomy. Enteral feeds can be instituted within 24 hours after gastrostomy placement as opposed to waiting for bowel sounds two to three days postsurgical gastrostomy (38). Both percutaneous gastrostomy and jejunostomy placement can be performed with an endoscope or laparoscope, or radiologically.

However, true percutaneous jejunostomies carry a high rate of complications including dislodgement, occlusion, bowel obstruction, and small-bowel ischemia (5).

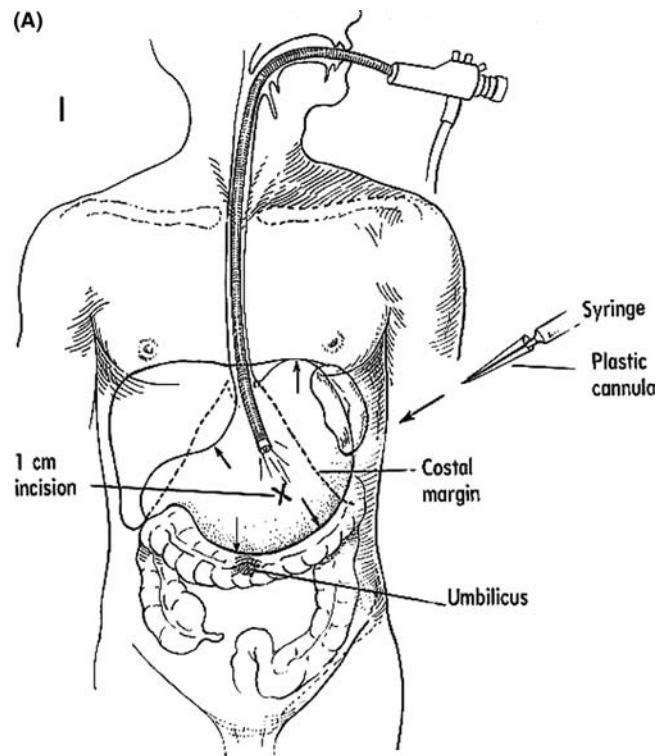

### Endoscopic

PEG is preferred to surgical gastrostomy due to increased safety, increased cost-effectiveness, decreased procedure-related mortality (2%), and complication rate (35). Endoscopic

**Figure 4** (A) Four sutures are placed to elevate and stabilize the anterior gastric wall. (B) The needle catheter complex is inserted into the anterior gastric wall. (C) The feeding tube has been inserted and the balloon inflated. Finally, the sutures are tightened with T-fasteners to maintain approximation of the gastric wall and the peritoneum. *Source:* From Ref. 44.

gastrostomy involves placing an endoscope through the mouth into the stomach (Fig. 5A). Once the stomach is insufflated, the endoscope is manipulated to view the anterior wall of the stomach. An assistant locates the area of endoscopic illumination on the abdominal wall (Fig. 5B) and inserts a needle with catheter at this site. Once the needle is removed, a guidewire is passed into the stomach via the catheter and grasped by the endoscopic snare (Fig. 5C). The guidewire and endoscope are removed to allow the PEG tube to be attached to the guidewire. The assistant pulls the extra-abdominal portion of the guidewire to move the gastrostomy through the mouth into the stomach until the tube portion of the gastrostomy passes through the abdominal wall (Fig. 5D). The extra-abdominal portion of the gastrostomy is cut to attach to a feeding port. Movement of the gastrostomy is inhibited by a plastic bolster on the extra-abdominal side, along with a bell or diaphragm placed against the gastric mucosa (Fig. 5E). This causes the stomach to become adherent to the inner wall of the abdomen. A variation of endoscopic gastrostomy placement includes the push. This procedure is relatively contraindicated in morbidly obese patients, as gastric transillumination

**Figure 5** (Continued on next page) (A) The endoscope is placed into the stomach and the stomach insufflated. (B) Once the endoscope is in the stomach, the stomach is insufflated with air and the endoscope positioned to transilluminate through the stomach. (C) The needle and catheter are passed through the abdominal wall into the stomach. The needle is removed and the guidewire inserted into the stomach via the catheter. The guidewire is grasped by the endoscopic snare. (D) The endoscope, snare, and guidewire are pulled out via the mouth. The guidewire is attached to the PEG tube and pulled back through the mouth into the stomach by putting traction on the guidewire. (E) The PEG is pulled through the stomach and anterior abdominal wall. Figure 5 (Continued from previous page)

is often not possible. So, there is an increased risk of inappropriate placement and injury to intra-abdominal structures (32). Other contraindications include occluding pharyngeal or esophageal tumors, ascites, peritoneal dialysis, and coagulopathy (35). Endoscopic percutaneous jejunostomy requires placement of an extension through an existing gastrostomy tube creating a G-J tube (5). These have limited usefulness due to the difficulty with insertion and common proximal migration into the stomach (35).

### **Interventional Radiologic**

Interventional radiologically placed feeding tubes are becoming increasingly used in patients who are difficult to treat endoscopically. Patients who benefit most from this approach are morbidly obese, require gastric decompression (5), have ascites, require peritoneal dialysis (35), or have an esophageal obstruction or other anatomic features inhibiting oral endoscopic entry (32).

Radiographic placement can be performed using one of two methods. In the first, the stomach is inflated with air via the N-G tube to allow fluoroscopic visualization of the gas-filled viscous (45). The stomach is then stabilized with two or three gastropexy T-fasteners placed around the intended puncture site. A small incision is then made in the center of the gastropexy fasteners (46) and the stomach punctured with an 18-gauge needle aimed at the greater curvature. A stiff guidewire is passed through the needle and looped into the stomach. The percutaneous tract is serially dilated and a locking loop pigtail catheter or an inflatable balloon catheter (12–28 French) is inserted. A T-fastener is utilized to anchor the gastric wall to the anterior abdominal wall, thereby promoting adherence and preventing leakage of gastric contents into the peritoneal cavity. Once the tube is secured to the abdominal wall with either an in-built fixation device or suture (45), the tube may be used after 24 hours. The sutures and T-fasteners can be removed after two weeks.

The second option mimics the procedure for PEG placement. After the stomach is insufflated, a small incision is created in the skin and the stomach punctured with a single T-fastener. Once the stomach is stabilized, the stomach is punctured and a guidewire inserted and advanced toward the G-E junction. The guidewire exits via the mouth and attached to the gastrostomy mushroom catheter. The gastropexy fastener is cut and the mushroom catheter pulled through the mouth to exit via the stomach and anterior abdominal wall. It should be noted that the pigtail catheter has shorter patency rates and a higher likelihood of dislodgement, peritonitis, and wound infection. So, if the esophagus is patent, the mushroom catheter appears to be the superior method (46).

Radiographic jejunostomy placement with fluoroscopic guidance involves opacification of the small bowel with iodinated contrast medium. A loop of jejunum near the anterior abdominal wall is visualized fluoroscopically and punctured with a fine needle (20–22 gauge) for passage of a stiff guidewire into the distal jejunum. The jejunum is affixed to the abdominal wall by T-fasteners and a locking pigtail catheter is inserted into the distal jejunum. Problems of this technique include difficulty in puncturing the jejunum, because it tends to be pushed away from an approaching needle. Jejunal puncture can be facilitated by the use of a target such as a snare or a catheter which has been passed perorally into the jejunum to the site of puncture. The target is easily visualized

fluoroscopically to aid percutaneous jejunal catheterization. A second problem is the difficulty of obtaining appropriate antegrade positioning in the distal jejunum if the guidewire is passed retrogradely in the jejunum after the initial puncture (47).

Radiographic G-J placement requires insufflation and puncture of the stomach. Next, an angled-tip catheter is manipulated through the pylorus into the duodenum and jejunum. An extra stiff guidewire is passed through the catheter into the jejunum and the tract through the abdominal wall dilated. Finally, a percutaneous G-J tube is inserted so that the tip is in the proximal jejunum (47).

The technical success of radiographically placed gastrostomies and G-J tubes is close to 100% in most series. This procedure may not be possible in patients with previous partial gastrectomy and large left lobe of the liver and in patients in whom it is unable to separate the stomach and transverse colon (47). In addition, extreme caution must be exercised in patients with portal hypertension, as puncture of gastric varices can result in hemorrhage (45). Major complications such as peritonitis from leakage into the abdomen, puncture of the transverse colon, and puncture of the transverse colon occur in 1% to 6% of cases. Minor complications occur in 3% to 12% of cases and are due to tube occlusion or dislodgement (47).

### **Complications**

Major complications of gastrostomy placement include gastric perforation, bleeding, peritonitis, subcutaneous abscess, necrotizing fasciitis, ileus, and aspiration. Hemorrhage is due to injury to an abdominal wall blood vessel, erosion caused by pressure from the gastrostomy bolster on the anterior wall of the stomach, ulcers caused by balloon gastrostomy placement in the posterior gastric wall, and duodenal ulcer (48).

Minor complications include wound infection, tube removal, and pneumoperitoneum. A recent meta-analysis of seven published studies established that a single intravenous dose of a broad-spectrum antibiotic was effective in reducing the incidence of peristomal wound infections (32). Inadvertent tube removal by the patient is a frequent occurrence. Though prevention is not always possible, attempts can be made by covering the gastrostomy with a dressing or abdominal binder and covering the hands of an agitated patient with mitts or restraints (48). Minor complications are usually not life threatening and merely require tube replacement or exit site care and do not require surgical intervention (47).

Tube-related complications include small-bowel obstruction, obstruction of bile flow at the ampulla of Vater, cologastric and colocolic fistulas, acute gastric dilation, and retrograde migration of the gastrostomy tube into the abdominal wall or sinus tract. Perforation of the colon or cologastric fistula is a rare but potentially catastrophic complication. If the colon lies between the stomach and the anterior abdominal wall, gastrostomy placement perforates the colon. Initially patients may be asymptomatic. Once symptoms develop, they range in severity from perigastrostomy drainage to sepsis with fever, hemodynamic instability, abdominal tenderness, rebound, and leukocytosis.

In addition, peritonitis and intra-abdominal abscess can develop from enteral feeds leaking into the abdomen. Diagnosis is especially difficult in an unconscious patient in whom symptoms may be masked. So, it is imperative to have a high index of suspicion (48).

An alternate presentation occurs when the gastrostomy tube migrates into the colon via the gastrocolic fistula. Huang described a patient who within minutes of PEG feeding developed sudden, transient diarrhea composed of undigested tube feed formula. Patients may deposit fecal material in the PEG tube or may present with foul-smelling eructations or feculent vomiting resulting from retrograde passage of fecal material from the colon into the stomach via the gastrocolic fistula.

Diagnosis necessitates performance of a contrast study by either the gastrostomy tube or per rectum. Urgent operative repair is indicated in patients with peritonitis (49). In patients with peritonitis, correction methods include exploratory laparotomy, resection of the through-and-through colonic injury, irrigation of the abdomen, and closure with a colostomy or primary anastomosis (48). As most patients do not have peritonitis, the gastrostomy can be removed without the need for operative intervention. The residual tract to the skin closes within several days. If a new feeding tube is required, another gastrostomy can be placed. These complications can be minimized by ensuring a well-defined transillumination site before insertion of the needle (35,49).

## ENTERAL FORMULA OPTIONS

Nutritional requirements are affected by size, age, and energy expenditure of the patient. Nutritional requirement can be calculated using the Harris-Benedict formulas (see Volume 2, Chapter 31). In a healthy patient, protein requirement is 0.8 g/kg/day, but due to the hypermetabolism associated with critical illness, protein requirements are increased to 1.5–2 g/kg/day. The goal is to provide adequate amounts of protein to maintain a positive nitrogen balance (10). However, protein delivery of more than 2.5 g/kg is not recommended as it can cause azotemia and exacerbate metabolic acidosis in critically ill patients. Carbohydrates provide 50% to 80% of nonprotein calories (50). Carbohydrates act to prevent protein gluconeogenesis for glucose-dependent tissues, such as bone marrow, erythrocytes, and brain tissue, as well as prevent ketogenesis (29). The remaining nonprotein calories are derived from fat. A minimum of 2% to 4% of calories from linoleic acid is necessary to prevent essential fatty acid deficiency. Multivitamins, such as vitamins A, B, C, and E, and trace elements, such as zinc, chromium, and selenium, are provided as well (50).

Obesity is the most common chronic disease in the United States and the incidence is continuing to increase. Over 50% of adults are overweight [body mass index (BMI)] 25 to 29; 15% are obese (BMI 30–34); 5% are seriously obese (BMI 35–40); and 3% are morbidly obese (BMI >40). As with any other patient, for a patient who suffers from a catabolic illness such as trauma, burn, or sepsis, nutritional support must be instituted expeditiously. Starvation is not an appropriate strategy as it results in loss of lean body mass (1). When determining the calorie needs of an obese patient it is imperative to utilize ideal body weight and not actual body weight (10). Some institutions have begun to implement hypocaloric regimens for critically ill obese patients. Hypocaloric nutritional supplementation has allowed a positive nitrogen balance to be obtained. This may occur due to utilization of endogenous fat stores for energy. In a recent study of obese patients admitted to surgical or trauma ICUs, patients receiving hypocaloric

nutrition had shorter ICU stay, fewer days with antibiotic therapy, and fewer ventilator days (29).

When selecting a formula, one must consider the patient's nutrient intake, GI function, existence of comorbid diseases, as well as organ function. Appropriate selection can be daunting as there are over 100 varieties and brands of tube feeds available for use (51). The types and use of tube feeds can be divided into general categories, which include standard, elemental, immune modulating, and disease-specific formulas.

## Standard Formulas

☞ **Standard formulas are the most widely utilized form of enteral nutrition. They are designed for patients with normal or near-normal GI function.** ☞ Due to adequate GI function, the nitrogen source can be provided by whole protein. The carbohydrates are composed of partial enzyme hydrolysates of starch. Due to the number of lactose-intolerant patients and the prevalence of transient acquired lactase deficiency in critically ill patients, most formulas do not include lactose as a carbohydrate source (5). The lipid source is either composed of long-chain triacylglycerols or medium-chain triacylglycerols. These formulas provide an energy source as well as fluid, fiber, trace elements, and vitamins (51).

## Elemental Formulas

☞ **Elemental formulas were created to provide a complete set of nutrients in a form that required little or no digestion; thus, it could be utilized in patients with a dysfunctional GI tract (52).** ☞ For example, patients with short bowel syndrome or diseased bowel have difficulty tolerating complex diets. When presented with complex nutrients, inadequate luminal hydrolysis and brush border membrane hydrolysis lead to decreased ability to break down the nutrients to their most basic form (51). The few nutrients that are successfully processed are inadequately absorbed due to the markedly decreased area for absorption. In short, the inadequate amalgamation leads to malnutrition (5).

To facilitate maximal absorption, the nutrients are provided in their most basic form. Proteins consist of small peptides of two to three amino acid residues in chains. The carbohydrates consist of maltodextrins, a heterogenous mixture of glucose polymers with more than 10 glucose molecules. As many of these patients suffer from steatorrhea, the lipids in elemental formulas consist of either long-chain fatty acids or medium-length fatty acids. Formulas with long-chain fatty acids use linoleic acid in the hope of preventing essential fatty acid deficiency. Unlike long-chain fatty acids, medium-chain fatty acids are less complex, allowing increased absorption (51).

Of great concern are the fluid and electrolyte losses in patients with diseases of malabsorption. Patients with end jejunostomies and/or resection of the ileum and large intestine are at the highest risk for loss of large quantities of sodium, potassium, magnesium, and zinc. Though sodium absorption is promoted by luminal carbohydrate, bicarbonate, and amino acids, passive secretion down a concentration gradient overwhelms the active transcellular absorption. Ingestion of low-sodium products results in net sodium losses. So it is recommended that these formulas contain sodium concentrations between 80 and 90 mmol/L (51).

### Immune Modulating Formulas

Immune-modulating formulas were created in an attempt to modify the impaired immune status of critically ill patients, which increases the risk of the development of infectious complications (53), SIRS, and MODS (54). Nutritional deficits produce atrophy and impaired function of lymphoid organs, leading to an increased risk of infection. Excessive nutrition, especially large quantities of fat intake (especially  $\omega$ -6 fatty acids), can cause immunosuppression as well (9). For this reason, extensive research has been invested to determine formula components which would facilitate modification of the disease-induced immune dysfunction. To date supplements studied include arginine, glutamine, nucleotides, and  $\omega$ -3-fatty acids (5).

#### Arginine

Arginine is a nonessential amino acid which modulates the immune system by promoting normal T-cell proliferation and function (53), enhancing delayed type hypersensitivity and lymphocyte blastogenesis as well as stimulating macrophages and natural killer cell function (9). In addition, it is a substrate for several enzymes and is the sole precursor for the production of nitric oxide (NO). Under normal conditions, arginine is not required for normal growth and development. In humans, *de novo* synthesis from citrulline provides adequate levels of arginine. In periods of stress induced by trauma or severe sepsis, arginine is depleted from the plasma and may become essential. A potential drawback of supplementation with arginine is increased production of NO, which has been hypothesized to have a potentially detrimental vasodilatory effect in septic shock. A decreased level of NO metabolites has been found in the plasma of trauma patients (53). So it has been hypothesized that arginine-mediated NO production might lead to an exacerbation of vasodilation in septic patients (53). Other studies indicate arginine supplementation can improve nitrogen balance (29) and aid in wound healing (5).

#### Glutamine

Glutamine is an oxidative fuel for rapidly replicating cells, including GI mucosal cells, hepatocytes, lymphocytes, and macrophages. It also serves as a nitrogen shuttle among organs (9), and as a substrate for gluconeogenesis (29). It is also a precursor of the antioxidant glutathione (9), nucleic acids, nucleotides, amino acids, and protein (55). Though glutamine is typically considered nonessential, during stressed states glutamine levels decline as consumption exceeds synthesis (29). An exogenous source of glutamine is necessary to avoid catabolism and muscle glutamine depletion (9). Human studies have shown that glutamine attenuates gut atrophy in the fasting state, maintains ATP levels in oxidant injured cells, and preserves immune cellularity of the gut in prolonged parenteral feeding. In addition, a systematic review of randomized controlled trials in adult surgical or critically ill patients suggests that glutamine supplementation may reduce infectious complications, duration of hospital stay, and possibly mortality (55). However, glutamine supplementation has also been associated with elevated levels of liver enzymes (29).

#### Nucleotides

The purine (adenine, guanine) and pyrimidine (thymidine, uracil) nucleotides are precursors for DNA and RNA (11). Purines and pyrimidines are synthesized by the liver from amino acids. Reduction in dietary nucleotides results in

suppression of cellular immune responses via inability of T cells to undergo blastogenesis (10). Administration of nucleotides appears to be essential for cell energetics (adenosine triphosphate) and may also play a role as physiologic mediators (cyclic adenosine monophosphate). Administration of these agents promotes natural killer cell cytotoxicity and enhances resistance to infection (11). Finally, they may also increase the disease-free duration of cancer patients undergoing treatment (56).

#### Fatty Acids

Dietary lipids are essential components of all living cells and aid formation of the bilipid structure of cell membranes, are sources of energy, and are precursors to numerous biologically active compounds (57). Linoleic acid,  $\omega$ -6 fatty acid, is metabolized to arachidonic acid. This is further metabolized to eicosanoid prostanoids responsible for inflammation and increased immunosuppression and leukotrienes. Whereas,  $\alpha$ -linoleic acid,  $\omega$ -3 fatty acid, is a precursor of eicosapentaenoic acid which leads to prostanoids and leukotrienes, which have anti-inflammatory and immune-enhancing properties. In addition,  $\omega$ -3 fatty acids have been shown to inhibit the formation of  $\omega$ -6 fatty acid products, thereby blocking their immunosuppressive effects (51). The eicosanoids alter cytokine production and intracellular signaling. As an example, prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) significantly increases intracellular cAMP levels and prevents the increase in intracellular calcium that is an early event in T-cell activation. Both PGE<sub>1</sub> and PGE<sub>2</sub> are potent inhibitors of interleukin-2 (IL-2) and IL-2 receptor production, and they modulate protein kinase C (PKC) activation. In contrast, leukotriene (LT) B<sub>4</sub> enhances the generation of IFN $\gamma$  and IL-2 (57).

Humans can synthesize all the lipids necessary for health except  $\omega$ -3 and  $\omega$ -6 long-chain fatty acids. Both of these essential fatty acids are found in common dietary substances, such as canola oil, soybean oil, and fish oil (57). For this reason,  $\omega$ -3 fatty acids are being studied in immunonutrition to evaluate their ability to act as substrate for the synthesis of immune-modulating prostanoids and leukotrienes (9). To date,  $\omega$ -3 fatty acid supplementation has been shown to improve survival after burn injury, reduce postinjury infectious complications, and diminish immunosuppression secondary to transfusion.

Initial results indicated that immune-modulating formulas could decrease infection rates and length of stay. A multicenter prospective randomized clinical trial with administration of immune-modulating formula for 7 to 10 days showed reduced rates of infection and wound complications and shorter hospital stays for critically ill patients. Another multicenter trial with trauma patients revealed significantly fewer intra-abdominal abscesses and less multiple organ failure (8). More recent studies dispute these findings.

Nonetheless, the immune-enhancing diet summit of 2000 recommended administration of immune-enhancing diets to patients with blunt and penetrating torso trauma especially when the ISS is greater than or equal to 18, or the ATI is greater than or equal to 20. In addition, administration of immune-enhancing diets was also recommended for patients with Glasgow coma score less than 8, patients with 30% or greater third-degree burns, and ventilator-dependent nonseptic patients. It is not recommended in septic patients, as two studies demonstrated increased mortality in septic patients receiving immune-modulating diets (16).

### Disease-Specific Formulas

When a patient presents to the intensive care unit critically ill, pre-existing diseases must be accounted for, as they can affect the care of the patient and may worsen during the course of illness. In cases where there were no pre-existing diseases, patients may develop pulmonary, hepatic, and renal dysfunction due to their disease process. For this reason, research has been performed to determine the effects, if any, of disease-specific enteral formulas.

### Pulmonary Formulas

Most patients with isolated respiratory failure will receive adequate nutrition with the application of standard enteral formulas. Overfeeding (with a high ratio of calories from carbohydrates or a total excess of calories) results in excessive CO<sub>2</sub> production and an increased work of breathing which results in difficulty weaning. This should be considered in patients receiving nutritional support with difficulty weaning from the mechanical ventilator, and a metabolic cart evaluation can be helpful (Volume 2, Chapter 31) (27).

Pulmonary formulas are composed of high fat (50%) and diminished levels of carbohydrates to reduce CO<sub>2</sub> production. In preclinical studies, tailored pulmonary formulas reduced pulmonary neutrophil accumulation and inflammatory cytokines and improved cardiopulmonary hemodynamics and gas exchange. This disease-specific pulmonary formulation contains eicosapentaenoic acid,  $\alpha$ -linolenic acid (which modify production of proinflammatory cytokines), and antioxidants (vitamin E, vitamin C, and beta-carotene), and is a calorically dense formula, suitable, in particular, for fluid-restricted patients with ARDS (8).

### Hepatic Formulas

The normal functioning liver has many complex functions. Hepatic Kupfer cells engulf and detoxify intestinal bacteria and endotoxins. It also clears activated inflammatory mediators such as leukotrienes and cytokines. When liver function is impaired, inflammatory mediators are incompletely filtered, contributing to increased caloric expenditure, protein catabolism, hyperinsulinemia, hyperglucagonemia, and ultimately malnutrition. Depending on disease severity, patients present with hyperbilirubinemia, coagulopathy, vasodilation, and alterations in mental status (58). In addition, patients with liver failure have increased losses of potassium, magnesium, and zinc (27). As long as the patient is not at risk of developing encephalopathy, a standard or elemental formula is appropriate.

Hepatic encephalopathy can occur in both patients with and without pre-existing liver disease. Acute hepatic encephalopathy most commonly occurs in patients without pre-existing hepatic disease due to fulminant viral or toxic hepatitis. Patients with pre-existing liver disease can develop acute episodic hepatic encephalopathy due to excessive intake of proteins, from an upper GI bleed, or from other precipitating conditions, such as spontaneous bacterial peritonitis (or other form of sepsis). Possible theories to explain the occurrence of encephalopathy include inability of the liver to clear gut-derived substances, such as ammonia and gamma-aminobutyric acid, due to portosystemic shunting or severe hepatocellular failure, as well as altered amino acid metabolism, which results in creation of false neurotransmitters.

Normally aromatic amino acids (AAAs), such as phenylalanine, tyrosine, and tryptophan, are produced in the gut during digestion and cleared by the liver. With

hepatic dysfunction, branch chain amino acid (BCAA) levels decrease while AAA levels increase. The reduction in the plasma BCAA/AAA ratio favors brain uptake of aromatics because they compete for transport across the blood-brain barrier leading to an influx of false neurotransmitters (58). So patients with liver failure and risk of encephalopathy should receive formulas containing high concentrations of BCAAs (27), and low concentrations of methionine, AAA, phenylalanine, tyrosine, and tryptophan are indicated (51). BCAA, leucine, isoleucine, and valine are essential amino acids required for protein synthesis (27). Infusion of BCAAs corrects the imbalance between AAAs and BCAAs in plasma and the central nervous system that contribute to mental disturbances (8). These modified formulas permit greater protein intake without inducing encephalopathy unlike standard protein formulas (58), which lead to improved nitrogen balance (8).

Regardless of the risk of encephalopathy, the nonprotein energy content is predominantly carbohydrate rather than lipid, as many patients have cholestatic jaundice and are unable to assimilate long-chain triacylglycerols. In elemental formulas, 5% of the energy content is linoleic acid to prevent central fatty acid deficiency. The sodium content is low as most patients have high total body sodium content due to underlying hyperaldosteronism (51). In addition, patients with ascites benefit from fluid restriction (27).

### Renal Formulas

Renal failure is characterized as fluid intolerance and elevated plasma levels of potassium, magnesium, and phosphate. Frequent monitoring of these electrolytes is required and the amounts administered reduced to maintain appropriate plasma levels. In the ICU, patients may require continuous renal replacement therapy (CRRT) (which tends to decrease phosphate levels), and the use of high-protein or standard formula to provide up to 2.5 g/kg/day is recommended, as a large percentage of protein is lost through the filtration process (59).

Patients with end-stage renal disease commonly have malnutrition and muscle catabolism, resulting in muscle wasting and fatigue. Blood levels of essential amino acids, especially BCAAs, are lower in patients than in control subjects with the same protein intake (56). In chronic renal failure, large protein and volume loads must be avoided. For this reason, enteral formulas have been created which consist of higher total calories (1.5–2 cal/mL) in a smaller total volume. These formulas provide the calories with increased proportions of fat and less protein (e.g., Nepro, Nutrirenal, Novasource Renal) (5). The protein dose of 0.5–0.8 g/kg/day is associated with preservation of renal function (27). Finally, maintaining an arterial blood pH of 7.35 is associated with reduced net catabolism.

Acute renal failure (ARF) occurs most commonly in the setting of shock, trauma, sepsis, or multiple organ failure. It is characterized by excessive protein catabolism and negative nitrogen balance. This is most likely due to the toxic effects of high metabolic byproduct concentration, altered levels of catabolic hormones, circulating cytokines and serum proteases, insulin resistance, metabolic acidosis, and inadequate supply of nutritional substrates.

Mitigation of the hypermetabolic state can be accomplished by controlling infection, optimizing oxygen transport, and providing adequate metabolic and nutritional support. If unsuccessful, the generalized nutritional deficiency can progress to MODS (60).

Similar to patients with chronic renal failure, those with ARF have a high prevalence of malnutrition which increases the likelihood of in-hospital complications and death (61). Unlike patients with chronic renal failure, there is no demonstrable advantage to limitation of protein load in patients with acute renal insufficiency (27), in fact, prolonged delivery of protein-restricted diets can lead to increased skeletal muscle protein breakdown (13). Protein intake should be between 1.2 and 1.5 g/kg/day in patients with ARF to maintain a neutral nitrogen balance (61).

For patients with both chronic and acute renal failure, dialysis therapy further complicates nutritional supplementation. Adjustment of glucose administration is often needed in patients receiving peritoneal dialysis, which contains a significant amount of glucose, thereby increasing the risk of hyperglycemia. In addition, peritoneal dialysis, hemodialysis, and hemodilution remove considerable amounts of amino acids (27). The study by Scheinkestel et al. (17) evaluated the effect of improved nitrogen balance on the outcome in critically ill patients on CRRT. They found that nitrogen balance was inversely proportional to REE, that is, higher levels of stress cause an increase in REE, which results in decreased nitrogen balance. In addition, nitrogen balance correlates with both hospital and intensive care unit outcomes. So, patients with positive nitrogen balance were more likely to survive, and every 1-g/day increase in nitrogen balance correlated with a 21% increased probability of survival (17).

The Kidney Disease Outcome Quality Initiative recommends protein intake in maintenance dialysis patients who are acutely ill to be at least 1.2 g/kg/day for hemodialysis and 1.3 g/kg/day for peritoneal dialysis. Due to the highly catabolic state associated with critical illness, patients with sepsis or CRRT may have greater protein requirements. This is supported by the fact that during CRRT 10% to 15% of amino acids are lost in the dialysate (60). In the critically ill patients, a positive nitrogen balance is attained with a protein ingestion of 2 g/kg/day or more (17).

### Oral Dietary Supplements

Canned liquid meal replacement beverages are widely available commercially. ⚡ **The oral dietary supplements are true supplements, that is, they are not nutritionally complete. The use of these products is as an additional, highly concentrated nutritional source for individuals who are unable to ingest adequate nutrients with a standard oral diet (1).** ⚡ Unlike tube feed formulas, these products must be palatable for patient tolerance. In general, they are packaged in 200–250 mL containers as a liquid, and a few are produced in semisolid or solid form. The products are composed of whole proteins, and nonprotein calories are derived from carbohydrates and long-chain triacylglycerols. They usually lack fiber, lactose, and gluten, making them safe for those who are lactose intolerant and have celiac sprue (51).

### Use of Probiotics and Functional Fibers

Probiotics are live microorganisms (e.g., *Lactobacillus* species, *Bifidobacterium* species, and normal GI yeasts) that can be administered with enteral nutrition to restore the intestinal microflora balance, which is often disturbed in critically ill trauma patients. Some desirable properties resulting from probiotic strains when they colonize the human intestine include resistance to acid and bile, production of antimicrobial substances, and antagonism against pathogenic bacteria. Probiotics also produce nutrients and antioxidants,

participate in growth regulation, reduce endotoxins, and activate mucosa-associated lymphoid tissues (MALT) (62).

Probiotic effects on humoral processes include stimulating IgA and NO, inhibiting IgE, and modulating cytokines (62). On the cellular level, probiotics stimulate macrophage function, natural killer cell activity, growth, regeneration, and apoptosis (62). Putative clinical effects include decreased incidence and severity of sepsis in ICU and major surgery patients, decreased duration or prevention of diarrhea, *Clostridium difficile* infections, and decreased septic manifestations in pancreatitis.

Prebiotics or dietary fibers (i.e., fructooligosaccharides, glycomannans, insulin, algal fibers, and pectin) have been supplemented into a variety of enteral nutrition solutions to help control diarrhea and maintain fluid absorption in the colon. A recent prospective multicenter study evaluated the effects of a high-protein formula enriched with artinine, fiber, and antioxidants compared with a standard high-protein formula for early enteral nutrition in 200 critically ill patients. The supplemented group had a lower incidence of catheter-related sepsis than the control group (63).

The combined use of probiotics with prebiotics has been recently coined “synbiotics.” The beneficial effects of synbiotics have been studied in arteriosclerosis, Crohn’s disease, chronic liver disease, acute pancreatitis, abdominal surgery, liver transplantation, the ICU, and ulcerative colitis (64).

For the critically ill patients, the stress, extensive medication treatment, antibiotic variety, all contribute to the depletion of invaluable gut flora and the overabundance of pathogenic harmful bacteria. Synbiotics in the twenty-first century may become the main foundation for the nutrition therapy of the sickest patients.

Though these specialty products are available, they are markedly more expensive than standard formulas. Therefore, clinicians should be challenged to evaluate both the appropriate macronutrients and micronutrients as well as to justify the additional cost in relation to the patient’s outcome (29).

### TUBE FEED INTOLERANCE

The enteric nervous system consists of GI neurons that can function independently of the central nervous system to control motility, exocrine and endocrine secretion, and gut microcirculation. The enteric nervous system communicates with the CNS via sympathetic and parasympathetic afferent and efferent neurons. Normally when a food bolus enters the small intestine, serotonin is released due to mucosal stimulation or mechanical distention of the gut lumen, which triggers activity of intrinsic afferent neurons. Above the site of intraluminal stimulus, ascending cholinergic interneurons relay the signal to excitatory motor neurons that contain acetylcholine and substance P. This results in contraction of the circular muscle layer above the stimulus. At the same time, descending cholinergic interneurons activate inhibitory motor neurons that contain NO, vasoactive intestinal polypeptide, and adenosine triphosphate, causing relaxation below the stimulus. The resultant forces propel the bolus in an antegrade direction also called peristalsis (65).

Disruption of this complex process (i.e., inadequate mucosal stimulation, altered neurotransmitter production, inhibitors to neurotransmission) can result in diminished gut motility. Acute gastric and intestinal ileus can also

result from selective suppression of excitatory motor reflexes via sympathetic nerves or sustained intrinsic inhibitory neural overactivity. Dopamine-2 receptors in the gut decrease gastric emptying and intestinal motility. Increased production of NO due to activation of the nonneuronal inducible NO synthase or decreased production of motilin may result in ileus. Other putative causes include use of continuous liquid enteral feeding (which decreases mucosal stimulation) and decreased production of adenosine triphosphate, or substance P (65).

Though many critically ill patients suffer from tube feed intolerance (5), or gastroparesis, the exact cause is often unknown. Numerous etiological agents have been shown to depress gastric motor activity, including pain, anxiety, recent abdominal surgery, peritonitis, sepsis, pancreatitis, diabetes mellitus/hyperglycemia, head injury, increased intracranial pressure, burn injury, and medications (beta agonists, anticholinergic agents, dopamine, and opioids). Gastroparesis leads to increased gastric residuals and predisposes the patient to gastroesophageal reflux, emesis, and aspiration. Also, it impairs absorption of drugs and nutrients administered into the stomach (66). So, the required nutritional demands of the patient cannot be met, leading to inadequate protein and calorie administration (5).

It is important to note that although gastric residuals are measured to determine tube feed tolerance, this correlation has yet to be validated. It is thought that high gastric residuals (>500 mL) correlate with tube feed intolerance and increased risk of aspiration. Low residuals of less than 100 mL should indicate a low risk of aspiration. Though GRVs are frequently associated with comorbidities such as vasopressor use, sedation, sepsis, and emesis, GRVs alone have little independent clinical utility. A prospective study by McClave and associates showed no relationship between GRVs and risk of aspiration or regurgitation as well as no association between aspiration or regurgitation and pneumonia. Of note, there was no difference in regurgitation or aspiration and pneumonia in patients with gastric residual cutoffs of 200 or 400 mL (39). As there is no consensus on the safe or normal GRV utilized, the higher value (400–500 mL) to determine tube feed tolerance can be used safely.

The least labor-intensive adjustments to promote GI motility include control of pain, anxiety, and blood sugar levels (66), and adjusting the level of the head of the bed (67). In the management of the polytrauma or postoperation surgical patient, opioid administration is often required. If opioids are thought to impair gastric motility, the use of dilaudid (less gastroparesis) should be considered with supplemental sedation using dexmedetomidine (on  $\alpha$ -2 agonist with opioid sparing properties). **When these adjustments fail to alleviate gastroparesis, institution of promotility agents, metoclopramide and erythromycin, can be utilized.**

### Promotility Drugs

Metoclopramide is a well-known prokinetic medication with an unclear mechanism of action. Studies have shown that it facilitates the release of acetylcholine from gut cholinergic neurons, antagonizes the inhibitory effects of dopamine on GI motility, and has a direct effect on lower esophageal smooth muscle. In high concentrations, it blocks 5-hydroxytryptamine (5-HT) receptors in the upper GI tract. Finally, it enhances antropyloroduodenal coordination and propagation of duodenal contractions (66). Through these physiologic effects, metoclopramide facilitates peristalsis and

gastric emptying (68), as well as esophageal and small intestine promotility (13). It has been proven effective in diabetic patients with gastroparesis as well as critically ill patients (65). Metoclopramide is administered IV, as a tablet, or syrup (13).

In a normal patient, the enterochromaffin cells of the proximal small intestine produce a 22-amino acid peptide called motilin. Motilin binds motilin receptors found on cholinergic nerves. Motilin receptor activation causes release of acetylcholine, which acts on cholinergic pathways in the enteric nervous system to mediate motility.

In the esophagus, motilin increases lower esophageal sphincter tone and esophageal peristalsis to assist propulsion and avoid reflux. It is thought that motilin release is inhibited in critically ill patients and results in gastroparesis. Erythromycin, a macrolide antibiotic, affects gastric motility by activating the motilin receptors in the gut. Erythromycin has been found to improve gastric emptying in patients with diabetic gastroparesis, vagotomy, chronic intestinal pseudo-obstruction, and denervated whole stomach after esophageal resection.

Chapman and colleagues investigated the effect of erythromycin in critically ill patients with depressed gastric emptying. They assessed gastric residuals to determine the effect of erythromycin on gastric emptying in 20 mechanically ventilated patients being given enteral nutrition.

Erythromycin significantly diminished gastric residuals, presumably by increasing gastric emptying. Enteral feeding was subsequently successful in 90% of the erythromycin patients versus 50% of the control patients (65). Erythromycin can be administered IV, IM, or orally. The optimum dose has not been clearly established, but 250 mg IV every six hours is commonly utilized (36). Patients in the ICU will occasionally have large gastric residuals regardless of receiving metoclopramide. The addition of erythromycin frequently improves gastric emptying in these patients (65). Though there are no studies supporting it, there is concern that erythromycin therapy in critically ill patients may alter native bacterial flora, increase the risk of infection, and promote antibiotic resistance, especially to *Streptococcus pneumoniae* (69). Also, there is concern that erythromycin may increase the risk of cardiac dysrhythmias (36).

### Postpyloric Feeding

A final option involves institution of postpyloric feeding. Spontaneous duodenal passage of weighted feeding tubes occurs in approximately 95% of general ward surgical patients, but only in 61% of critically ill patients (68). Manipulation of the tube into the duodenum or jejunum can be enhanced in some patients with metoclopramide, but predicting which patients will be assisted is difficult (68). Erythromycin is a second option for pharmacologic manipulation of feeding tubes. Three adult studies have shown that erythromycin facilitates passage of feeding tubes in both healthy and critically ill patients (65). The highest success rates for feeding tube placement involve the use of endoscopy, which is an expensive solution. Another option utilizes feeding tube manipulation with fluoroscopic guidance (also expensive). Recent modifications in tube feed catheters involve the addition of flaps to facilitate placement into the jejunum by allowing peristalsis to gently drag the catheter into the small bowel. This tube is promoted as allowing rapid bedside placement by clinicians without the additional cost of endoscopy or fluoroscopy (36).

Although distal tubes allow feeding in the small bowel in patients who do not tolerate gastric feeding, studies do not show a reduction in the incidence of aspiration between those fed postpylorically and those fed intragastrically (68).

In a recent study comparing the efficacy of gastric feeding supplemented with prokinetic agents to distal small-bowel feeding tubes, it has been demonstrated that gastric feeding with erythromycin (200 mg intravenously every eight hours) was equivalent to distal feeding both in terms of meeting nutritional goals and in overall clinical outcomes (36).

### Prone Positioning Considerations

Some critically ill patients with ARDS will require prone positioning during mechanical ventilation. There is an increased risk of regurgitation in this position compared with the supine position with 30° of head of bed elevation. Enteral nutrition should be stopped at least two hours before proning to prevent aspiration pneumonia, vomiting, and GI distress. According to a 71-patient, prospective, comparative study, enteral nutrition during the prone position was poorly tolerated, and postpyloric feeding tube placement with promotility agents was recommended for optimal enteral feeding tolerance (70). Tube feeding goal rate adjustments should be made in order to provide adequate calories and protein for patients during the nonprone portion of the SICU care.

## COMPLICATIONS OF ENTERAL NUTRITION

### Aspiration and Pneumonia

All critically ill tube-fed patients are at risk of tube feed aspiration due to altered level of consciousness, abnormal gastric motility, emesis, and reflux. Decreased level of consciousness is due to patient sedation from iatrogenically administered medications, alcohol, and drug ingestion. In addition, a GCS less than 9 is a significant risk factor for aspiration and pneumonia. Patients with decreased level of consciousness have a depression of upper airway reflexes (cough and gag) and a reduction of lower esophageal sphincter pressure. Absence of these safeguards for airway protection allows accumulated oropharyngeal secretions and regurgitated gastric contents to be aspirated into the lungs. For critically ill patients requiring mechanical ventilation, cuffed endotracheal tubes were designed to seal the lower airway and prevent the entry of materials from the upper airway. Unfortunately they often fail to provide a consistent barrier against aspirated materials (34).

Decreased gastric motility is a frequent problem in critically ill patients because of underlying disease or injury. Dive et al. utilized manometry to compare gastroduodenal motility in 12 critically ill, mechanically ventilated patients with that in 12 healthy control volunteers. The frequency of contractions was significantly decreased in the critically ill group, and more importantly the loss of peristaltic activity was greater in the stomach than in the duodenum. Factors that decrease GI motility include neurologic impairment with elevated ICP and medications.

For example, propofol is a visceral smooth muscle relaxant. In healthy persons the effect is insignificant, but it may contribute to delayed gastric emptying in patients receiving other medications that slow gastric motility. Low-dose dopamine slows gastroduodenal motility in mechanically ventilated, critically ill patients. Opioids can delay gastric emptying, through both central and peripheral

mechanisms. The enteral administration of opioid antagonists has been suggested as a possible method to improve gastric emptying and decrease the frequency of aspiration in mechanically ventilated patients receiving opioid analgesia.

When gastric motility is moderately or seriously impaired, feedings accumulate in the stomach along with gastric secretions and predispose patients to reflux and aspiration. Another risk factor is recurrent episodes of emesis; in these patients tube feedings should be held or reduced and antiemetic medications administered (34). Aspiration can result from refluxed tube feedings or oropharyngeal secretions that are unrelated to feedings (32). Pulmonary aspiration of tube feed can result in hypoxia and/or pneumonia (67).

To determine whether tube feeds are contaminating the lungs, the color of respiratory secretions can be assessed after adding several drops of blue food coloring to the feeding formula. However, one study showed that the sensitivity of blue dye for the detection of aspiration was only 15%, and a study in animals determined that the sensitivity of blue dye detection of aspiration decreased after multiple aspiration events. However, the FDA in a public health bulletin in 2003 noted an association between the use of blue dye in enteral feedings and discoloration of body fluids and skin as well as serious metabolic complications including death. The FDA suggested that patients at risk for increased intestinal permeability, including those with sepsis, burns, trauma, shock, surgical interventions, renal failure, celiac sprue, and inflammatory bowel disease, appear to have an increased risk of absorbing blue dye from tinted enteral feedings.

An alternative for detecting tube feed aspiration is the use of glucose oxidase reagent strips. Proponents believe glucose strips are safer and more accurate than blue dye. Drawbacks of glucose strips include the possibility of false positives in the presence of blood in tracheobronchial aspirates and the possibility of false negatives in patients receiving low-glucose enteral feeding. In addition, glucose reagent strips were not designed to test for pulmonary aspirate, cost more than blue dye, and may require certification before clinicians can integrate them into care (71).

When trauma or surgery causes significantly delayed GI motility, small-bowel function usually returns before gastric or colonic activity. Also, small-bowel activity may be less adversely affected than either gastric or colonic function in acute medical conditions such as pancreatitis. So if gastric motility is significantly slowed, small-bowel feedings are preferred (34). Though small-bowel feeding is thought to decrease the risk of aspiration, it has not been proven in studies (32). Studies have revealed that feeding the duodenum or jejunum results in stimulation of gastric secretions and duodenogastric reflux. So utilizing a postpyloric feeding tube to insert feeds and a separate nasogastric tube (NGT) to aspirate gastric contents or a combination gastrojejunostomy tube may be the safest option. Finally, if bolus or intermittent gastric feedings are not tolerated, continuous feedings may be better tolerated. There are no studies that demonstrate a reduced rate of aspiration with administration of continuous feeding, yet this is more commonly used in critically ill patients.

Continuous subglottic suction appears to help prevent or delay the development of nosocomial pneumonia in mechanically ventilated patients by removing pooled secretions that may leak around the endotracheal tube cuff. A sleep study suggested that continuous aspiration of subglottic secretions could decrease bacterial colonization of

the respiratory tract, but may also result in mucosal damage at the level of the suction port (34).

### Bacterial Contamination

Microbial contamination of enteral feeds is associated with pneumonia (35), diarrhea (72), and sepsis. Anderson et al. compared locally prepared, manipulated, and nonmanipulated formulas and the development of diarrhea. As would be expected, the locally prepared and manipulated formulas contained a significantly higher number of organisms than the nonmanipulated formulas. The risk of contamination in manipulated or reconstituted tube feeding has been supported in numerous studies. Manipulated formulas have a 30% to 60% risk of preadministration contamination, whereas Okuma et al. (72) found sterile ready-to-use formulas have a 2% risk. Okuma et al. (72) studied liquid ready-to-use enteral feeds and found 10 of 48 postadministration samples were contaminated. Though there were a high number of contaminated samples, only two patients developed diarrhea (72).

Due to the high morbidity and mortality due to infection in the critically ill, recommendations have been created to decrease the risk of bacterial contamination in tube feeds. Use of a closed enteral nutrition delivery system, where the tube feed is prepackaged with a tube for administration, may carry the lowest risk of contamination (72).

### Diarrhea

GI side effects of tube feeding include nausea and vomiting, abdominal pain, and diarrhea (32). Diarrhea is the most common complication, with a rate of 30% to 50% of critically ill patients receiving tube feedings being affected (72). As diarrhea results in ongoing GI protein, electrolyte, fluid losses, and malabsorption, control is mandatory. Numerous causes of diarrhea exist and include medications (promotility agents, antibiotics, sorbitol-containing elixirs/suspensions), hyperosmolar formulas, prolonged bowel rest, severe hypoproteinemia, infection, and increased dietary fat (10). Additional causes include infected diets, lactose intolerance, ingestion of laxatives, and hypoalbuminemia (51).

The most rapid intervention involves a review of medications, and all prokinetic agents should be discontinued (73). A common pharmacologic cause of diarrhea in tube-fed patients is administration of large doses of nonabsorbable carbohydrate such as sorbitol (32). Sorbitol is a component of common medicinal elixirs, such as acetaminophen, theophylline, and cimetidine, to improve palatability and results in osmotic shifts and diarrhea (7). Finally, the combination of antibiotics and infection is responsible for three-quarters of the cases of diarrhea (13). Antibiotic use can lead to proliferation of *C. difficile* and development of pseudomembranous colitis. In a normal patient, short-chained fatty acids (SCFAs) have multiple functions. In the colon, they enhance water and electrolyte absorption, increase colonocyte proliferation and metabolic energy production, enhance blood flow, stimulate the autonomic nervous system, and increase GI hormone production (51). When *C. difficile* occurs, it blocks the conversion of carbohydrates to SCFAs, causing diarrhea development (32). **It is mandatory that clostridial infection as the cause of diarrhea be eliminated, as pharmacologic manipulation of gut motility in an infected patient can result in severe toxicity.**

Once infectious causes of diarrhea have been eliminated, enteral formula, concentration, and rate of administration can be altered. If the diarrhea persists, trials of

antidiarrheal agents such as diphenoxylate or loperamide are justified in an effort to maintain adequate delivery of nutrients (32). In some cases, administration of opiates may be necessary. They act by slowing intestinal motility, but are contraindicated in patients with infectious diarrhea, or they may lead to prolonged retention of the toxins. Only in the most severe cases will discontinuation of enteral feeding and temporary administration of parenteral nutrition be necessary (10).

### Overfeeding/Hyperglycemia

Though catabolic patients require higher levels of nutritional supplementation, care must be taken to avoid overfeeding. When this occurs, the high-carbohydrate diet leads to accumulation of increased fat mass without changes in lean body mass. In addition, the overfed patient commonly suffers from hyperglycemia, which leads to an increased insulin requirement. Hyperglycemia has also been associated with a negative influence on the outcome of septic and critically ill patients. Detrimental effects of hyperglycemia include a predisposition to severe infections, MODS, and death. In addition, the elevated plasma levels of glucose impair immune function by altering macrophage cytokine productions, diminishing lymphocyte proliferation, and depressing intracellular bactericidal activity of leucocytes. So, preventing hyperglycemia results in improved immune response and wound healing (14). In addition, recent studies have revealed reduction in mortality rate of critically ill patients treated aggressively with insulin (Volume 2, Chapter 60) (10).

It is important to note that overfeeding is associated with inability to wean patients from mechanical ventilation. Administration of excessive carbohydrate loads (>500 g/day or >50% total calories from carbohydrate) results in overproduction of CO<sub>2</sub>. When ability to excrete CO<sub>2</sub> by the lungs is overwhelmed, hypercapnia results (10). Therefore, ensuring adequate but not excessive feeding is mandatory.

### Small-Bowel Necrosis

A dreaded yet rare complication of both gastric and small bowel feedings is nonocclusive small-bowel necrosis (34). To date, nonocclusive bowel necrosis has been reported in 0.3% of critically ill patients who are given tube feedings. Bowel necrosis is hypothesized to be due to a combination of factors which cause ischemia, or compromised blood flow to the bowel. Factors include hypotension and the use of vasoconstrictive medications. The body responds by shunting the blood flow from the small intestine to maintain cerebral and cardiac perfusion. In general, the remaining blood flow to the bowel is adequate to maintain perfusion in the resting state (32). Addition of an iatrogenic stressor, which increases the metabolic demand of the intestine, increases the flow necessary to provide adequate bowel perfusion. Ischemia is induced which, if uncorrected with fluid resuscitation and discontinuation of tube feeding, may result in necrosis (41).

Patients with ischemia commonly have abdominal pain and tenderness, but it is difficult to detect as many of the patients at risk are typically sedated and mechanically ventilated. Furthermore, both enteral feed intolerance and paralytic ileus are common in this group of patients (74). So, any critically ill patient who experiences abdominal distention, pain (34), tachycardia, temperature elevation (13), and possibly increasing GRVs while receiving either

continuous gastric or small-bowel feedings must be evaluated for tube feed necrosis. The use of gastric tonometry may be useful for detecting nonocclusive small-bowel necrosis; for example, low mucosal pH (<7.30) measurements were detected in three patients who demonstrated this condition during enteral feeding advancement. If there is concern of tube feed necrosis, enteral feeding should be immediately discontinued. If the ischemia progresses, the patient may continue to deteriorate and show signs of hypotension and septic shock with fever, tachycardia, and abnormal white blood cell count. Emergent surgical intervention often is mandated (34).

A study by Desai et al. found ischemic intestinal pathology to be a common autopsy finding in patients with large burns, being present in more than 50% of those patients who succumb to their injury, although it was clinically identified in less than 1%. In addition, the mortality rate associated with ischemic enterocolitis is extremely high (60–69%) (74). So, a high index of suspicion is mandatory for this unusual complication.

### Refeeding Syndrome

Refeeding syndrome is a common condition in previously malnourished patients, where aggressive nutritional supplementation increases the basal metabolic rate with the use of glucose as the primary energy source. As minerals shift intracellularly, the serum levels fall precipitously (35). The resulting hypophosphatemia, hypokalemia, thiamine deficiency, and hypomagnesemia (50) lead to cardiorespiratory and neurologic dysfunction. Patients develop congestive heart failure, respiratory failure, lethargy, confusion, coma, convulsions, and death (35). Patients most at risk have a history of anorexia, chronic alcoholism (50), chronic malnutrition, prolonged fast, or intravenous hydration only (35). In addition, increased insulin levels result in an antidiuretic effect and fluid retention. The sudden expansion of extracellular fluid leads to cardiac decompensation. On the other hand, the dextrose load can result in hyperglycemia, osmotic diuresis, and dehydration (1). So, it is imperative to closely monitor electrolyte and glucose serum levels so as to diagnose and treat refeeding syndrome rapidly.

### NUTRITIONAL MONITORING

Once nutritional supplementation is instituted, it is mandatory to evaluate the adequacy of the supplementation. Many of the common markers of nutritional deficiency such as weight loss and anthropometric measurements are not useful in trauma patients due to massive fluid shifts.

Of the laboratory values currently available clinically to assess nutritional status, albumin, transferrin, and prealbumin are the most common. In addition, collecting a 24-hour urine urea nitrogen, indirect calorimetry, estimating nutritional needs via energy formulas, and monitoring overall improvement in medical condition help determine if the nutritional care plan is appropriate and effective (refer to Volume 2, Chapter 31 for additional information on nutritional monitoring).

### EYE TO THE FUTURE

Though the ideal enteral feeding formula has yet to be identified, it is clear from research over the last 20 years that the gut is the preferred method with which to restore nutritional integrity in both trauma and critically ill patients. The importance of various strains of fibers and beneficial bacteria or synbiotics continues to peak interest in hopes to help fight infection and nutrient absorption. Astaxanthin, a reddish-orange carotenoid pigment, has been studied in animal models and shown to have antioxidative and anti-inflammatory effects, bringing promise to human health (75).

Increased interest in polyphenol and its antioxidant capacity, especially Curcumin, has brought promise to the treatment of atherosclerosis, cancer, diabetes, respiratory, liver, pancreatic, gastric, and intestinal diseases when supplemented in the oral diet (76). Synbiotic therapy also brings promise to improving nutrient absorption for the critically ill patients.

Future research will concentrate on improved modes of delivery and attempts at identifying immune-enhancing substances that can prevent the deleterious effects of nutritional depletion and starvation.

### SUMMARY

Due to the prevalence of pre-existing malnutrition and the risk of developing malnutrition in critically ill patients, it is imperative to consider early nutritional supplementation. When the patient's GI tract is functional, the enteral route is preferred. Again, the route of administration and the formula used should take into account the patient's clinical state, anticipated duration of feeding, gut patency, and risk of aspiration. Care must be taken to minimize the interruption of nutritional administration, and efficacy of nutritional supplementation should be determined with weekly measurements of metabolic parameters.

### KEY POINTS

- ☞ In situations where full enteral nutrition is not tolerated, as little as 20% of overall nutrient calories administered to the gut can be sufficient to show benefits as opposed to TPN alone (5).
- ☞ Patients most likely to benefit from nutritional support are those with baseline malnutrition in whom a protracted period of starvation would otherwise occur (8).
- ☞ Early enteral feeding should be instituted in all severely injured trauma patients (ISS > 17) without contraindications.
- ☞ The current EAST guidelines (Fig. 1) recommend that patients with blunt and penetrating abdominal injuries be fed enterally because of the lower incidence of septic complications compared with parenterally fed patients (11).
- ☞ The goal in burn patients is to initiate enteral nutrition within six hours of presentation to prevent body weight loss of more than 10% of their baseline status (14).
- ☞ To prevent devastating losses of nutrient stores and improve patient outcome, nutritional supplementation should begin no later than 72 hours following TBI (18).

- ✂ After the acute SCI phase, there is a period of reduced REE in proportion to the amount of paralyzed muscle mass.
- ✂ Enteral feeding by an N-J tube or percutaneous jejunostomy has largely replaced TPN in the management of patients with pancreatitis (24).
- ✂ Patients with SIRS with or without MODS have elevated total caloric requirements, increased net protein catabolism, and increased micronutrient requirements (27).
- ✂ Gut perforation after repair generally remains secure and is not necessarily put at risk of leakage by enteral nutrition started at 48 hours after surgery (30).
- ✂ For malnourished patients undergoing resection of their tumor, 7 to 10 days of preoperative enteral nutrition support is associated with a 10% reduction in morbidity and improved quality of life (31).
- ✂ The route of enteral nutrition administration is influenced by the patient's clinical prognosis, anticipated duration of feeding, gut patency, motility and anatomy, and risk of aspiration (32).
- ✂ Patients who require long-term, that is, more than two to four weeks, enteral nutrition require permanent access for feeding.
- ✂ Standard formulas are the most widely utilized form of enteral nutrition. They are designed for patients with normal or near-normal GI function.
- ✂ Elemental formulas were created to provide a complete set of nutrients in a form that required little or no digestion; thus, it could be utilized in patients with a dysfunctional GI tract (52).
- ✂ The oral dietary supplements are true supplements, that is, they are not nutritionally complete. The use of these products is as an additional, highly concentrated nutritional source for individuals who are unable to ingest adequate nutrients with a standard oral diet (1).
- ✂ When these adjustments fail to alleviate gastroparesis, institution of promotility agents, metoclopramide and erythromycin, can be utilized.
- ✂ It is mandatory that clostridial infection, as the cause of diarrhea be eliminated, as pharmacologic manipulation of gut motility in an infected patient can result in severe toxicity.

## Parenteral Nutrition

Grant V. Bochicchio and Shelley Nehman

Department of Surgery, University of Maryland School of Medicine, Baltimore, Maryland, U.S.A.

Jua Choi

Department of Nutrition, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

The concept and implementation of parenteral nutrition (PN) began nearly a century ago. In 1912, Fohn and Denis (1) reported that protein hydrolysis led to gut absorption. These findings fostered the idea that the gut could be bypassed to provide nutrition, and inspired Henriques and Anderson (2), in 1913, to administer hydrolyzed protein intravenously in an animal study. PN was actively investigated following that study. A significant breakthrough occurred in 1925 when Seibert (3) discovered that pyrogens, elicited from bacteria, were responsible for the fever and chills associated with the infusion of intravenous (IV) substances. In 1939, Elman and Weiner (4) reported on the first successful use of total parenteral nutrition (TPN) in man. However, TPN did not become widely accepted until 1967 when Dudrick et al. (5) at the University of Pennsylvania demonstrated that normal growth and development could occur solely with the administration of TPN [without any enteral nutrition (EN) at all].

TPN became the predominant route of nutrition administration in the 1970s, because it was widely available, and could be used regardless of the patient's gastrointestinal (GI) function. In the 1980s, however, several unique advantages of EN became more apparent, including the benefit of direct nourishment of the gut endothelium by enteral amino acids such as glutamine, the first-pass effect of EN through the liver, decreased nitrogen losses compared to TPN, less glucose intolerance, and so on. Furthermore, data began to emerge demonstrating a survival advantage with EN in certain trauma conditions (especially the burn patient; see Volume 1, Chapter 34), as well as a decrease in complication rates (e.g., line sepsis; see Volume 2, Chapter 49). According to a meta-analysis of prospective, randomized clinical trials among 27 studies, TPN is associated with a higher rate of infection than EN in both malnourished and nonmalnourished patients (6). PN is expensive because of cost of admixture, placing venous access, laboratory monitoring, and costs to treat complications (7). Protection against gut atrophy, preservation of gut flora, and improved immunocompetence became even greater positive attributes of EN, and in the early 1990s the trend had reverted back toward using EN whenever possible (Volume 2, Chapter 32).

Although the enteral route remains the favored portal for nutritional administration to critically ill patients, TPN is still required for patients who cannot be fed enterally. This chapter reviews the indications for PN, the routes of

administration, and nutritional requirements in terms of macronutrients (protein, carbohydrate, and fat) and micronutrients (vitamins, trace elements, and electrolytes). Next, the clinical applications of PN are discussed in terms of initiation, maintenance, and withdrawal. The complications of PN are then reviewed, followed by a brief summary of nutrient monitoring considerations for patients receiving PN (Volume 2, Chapter 31). Special disease states that are common in critical illness (e.g., diabetes, renal failure, and liver failure) are also reviewed in terms of their effect on TPN. In the section "Eye to the Future," current areas of research are discussed.

### INDICATIONS

EN (Volume 2, Chapter 32) represents the preferred route of nutrition administration when the gut is functional and can be used, whereas TPN remains the mainstay of nutritional support whenever EN is contraindicated (Table 1), or gut function is impaired either due to injury or ileus (from surgical manipulation, infection, or medications, especially opiates) (Table 2). In these settings, TPN should be considered after three to four days of starvation in previously healthy critically ill patients. In previously ill, malnourished, or severely injured patients with a nonfunctioning GI tract or no enteral feeding access, TPN should be considered earlier in their care, that is, immediately postresuscitation when prolonged critical care is anticipated. For example, patients who suffer from small-bowel obstruction or malabsorptive capacity such as inflammatory bowel disease or short gut syndrome, and are expected to be nil per os (NPO) for greater than seven days should be considered for TPN as soon as possible.

In a large study, TPN was only shown to benefit severely malnourished patients, whereas TPN was associated with a worse risk benefit ratio in previously healthy patients (i.e., complications including infections were greater than nutritional benefits) (8). Thus, the risks of TPN (line-related infections, hyperglycemia, refeeding syndrome, hepatic dysfunction) must be weighed against the presumed harm of a short-term (three to seven days) fasting.

### ROUTES OF ADMINISTRATION

Vein location, macronutrient concentration, and volume capacity of the patient need to be carefully reviewed before

**Table 1** Indications for Total Parenteral Nutrition

TPN indication	Issue and relative importance	Exceptions—recommendations
SBO Ischemic colon	Distended bowel May not tolerate feeding	Rest gut—no exception Rest gut—until POD#1 surgical revision or with improvement
Pancreatitis	Feeding causes pancreatic enzymes to be elaborated	Recent data support trophic enteral feeding, some believe full EN is indicated providing the tube is in the jejunum
Short gut syndrome	Inability to absorb nutrients	Need jejunum to absorb water, need distal ileum to absorb vitamin B12, lack of colon, not as devastating as lack of small bowel?
Pancreatitis (now controversial)	Feeding causes pancreatic enzymes to be elaborated	Recent data supports trophic enteral feeding, some believe full EN is indicated providing the tube is in the jejunum

The authors believe that the above total parenteral nutrition (TPN) indications encompass the major clinical situations where enteral nutrition is contraindicated. Whenever the gut can be used, the authors recommend providing enteral nutrition (EN) rather than administering TPN.

*Abbreviations:* EN, enteral nutrition; POD, postoperative day; SBO, small bowel obstruction.

the initiation of PN. Central vessels are able to handle higher macronutrient concentrations compared with peripheral vessels without the risk of thrombophlebitis or

**Table 2** Reasons Why Physicians May Halt Enteral Nutrition

Reason to halt Enteral Nutrition	Cause	Treatment
High residuals 7 cm <sup>3</sup> /kg (after 4–5 hr of tube feeding)	Gastric atony, small bowel obstruction, ileus, rate of feeding too fast	Rule out obstruction (rectal exam, KUB and lateral decub or upright abdominal film); if no obstruction, resume feeding, at slower rate; if high residuals occur second time, provide a brief period of bowel rest (4–24 hr), then resume enteral feeding; also, attempt to reduce opiates, and add or increase reglan or cisapride
Vomiting	All above, plus hypotension, improper tube placement, TF osmolality too high, medications coadministered, critical illness	Same as above, except rest till patient no longer vomiting; also, consider antiemetics, including ondansatran
Diarrhea	Sorbitol elixirs, intolerance of medications (e.g., antibiotics), bacterial infection (e.g., <i>Clostridium difficile</i> )	Omit offending agents, provide bulk, treat infection (e.g., <i>C. difficile</i> Rx with Flagyl or oral vancomycin)
Constipation	Opiates, dehydration, lack of fiber	Limit opiates (e.g., switch to nonsteroidal antiinflammatory drugs), hydrate, suppositories, fiber

*Abbreviations:* KUB, kidneys, ureter, bladder; TF, tube feeds.

vessel damage (9). True peripheral veins can tolerate no more than 900 mOsm/L. Concentrations of calcium  $\leq 5$  mEq/L and potassium  $\leq 40$  mEq/L should be used whenever possible, and the infusion of lipids to decrease osmolality (10). ⚡ **As TPN solutions are hyperosmolar, a large-diameter vein with adequate flow rate is required to allow for rapid dilution of TPN products within the vessel.** ⚡ Common peripheral PN (PPN) solutions contain no more than 10% dextrose and 4% amino acids for safe administration. Full calorie and protein needs can only be met when a patient is able to tolerate larger volumes of dilute (compared with centrally administered) PN. Peripheral veins can be used to administer isotonic fat emulsions and hypocaloric dextrose solutions (i.e.,  $<10\%$  dextrose). However, their use is limited to merely preventing starvation adaptation and minimizing nitrogen loss, because they cannot accommodate the high osmolar load needed to provide calories and nutrients required for TPN. Accordingly, the authors recommend that TPN be administered through either a standard central line or a peripherally inserted central catheter line.

Owing to the anatomical location of the large veins where central lines are placed, complications such as pneumothorax, arterial cannulation, and air embolism can occur. In addition, catheter-associated sepsis can be a potentially lethal complication of this procedure in combination with TPN use. Therefore, experienced personnel utilizing proper sterile technique are recommended for placement of central lines for PN.

### Practical Considerations Regarding IV Site Selection

The technical details of central vein insertion are reviewed in Volume 1, Chapter 10 and infectious considerations are provided in Volume 2, Chapter 49; these topics are beyond the scope of this chapter, but certain practical considerations warrant inclusion here.

⚡ **The preferred site of central venous catheter placement for PN is the subclavian vein.** ⚡ This route is most comfortable for the patient, following insertion, and is less easily

dislodged as compared with the internal jugular route. Furthermore, the subclavian site has the lowest infection rate of the common central line access locations (Volume 2, Chapter 49). When the subclavian site is unavailable, the internal jugular (uncomfortable) or the femoral vein (increased risk of lower extremity deep vein thrombosis and limitation of mobility) may be used.

If a pulmonary artery (PA) catheter is placed, some recommend against infusing through the distal PA port, with the concern that this may lead to pulmonary infiltrates. However, there are no published data to support this assertion. Consequently, PN can be instilled through any of the ports not being used for other drugs (typically the right atrium or right ventricle infusion ports, but even the PA distal port can be used for short durations when needed).

### Skin Site Preparation and Maintenance

The skin site should be scrubbed with a chlorhexidine preparation and permitted to dry for at least 30 seconds prior to catheter insertion. Surgical caps, mask, sterile gown, and gloves are mandatory. In addition to the site drape provided in the kit, a sterile full body sheet should be draped across the patient in order to minimize contamination.

After the catheter is inserted and sutured in place, the skin should be thoroughly washed with a saline-soaked gauze and dried with a clean sterile gauze to eliminate any residual blood—which can become a nidus for infection. Next, a clear adhesive dressing should be placed over the venepuncture and catheter suture sites, in order to further decrease the infection rate (11). A postprocedure chest radiograph is obtained to confirm placement and assure proper anatomical location. Dressings should be sterilely changed daily.

The catheter should be used solely for PN, to minimize the possibility of contaminating an entry port to the catheter. The catheter should be routinely changed per standard protocols (Volume 2, Chapter 49).

## ENERGY, FLUID, AND MACRONUTRIENT REQUIREMENTS

### Energy Requirements

There are several methods that can be used to determine energy expenditure (Volume 2, Chapter 31). **Indirect calorimetry is considered as the golden standard for the measurement of metabolic rate and substrate utilization.**

The measurement of inspired oxygen ( $O_2$ ) and expired carbon dioxide ( $CO_2$ ) are used to calculate resting energy expenditure and respiratory quotient (RQ). The RQ is the ratio of  $CO_2$  production ( $\dot{V}CO_2$ ) and  $O_2$  consumption ( $\dot{V}O_2$ ), and reflects the net substrate utilization of carbohydrate, protein, and fat. The goal of normal RQ in parenteral nutrition and TPN is to obtain mixed fuel utilization, which is demonstrated by an RQ of approximately 0.8, within the range 0.85–0.95 (7). A low RQ  $\leq 0.7$  indicates fat oxidation, and a high RQ ( $>1.0$ ) indicates lipogenesis, which occurs with excess total calorie or carbohydrate administration (12). However, the low specificity and sensitivity of RQ may be an unreliable tool in the assessment of under- or overfeeding the critically ill patient (13).

Limitations to indirect calorimetry include inaccuracies in the measurement of gas exchange, cost, and availability of the apparatus. When indirect calorimetry is not available, the use of predictive equations is necessary to determine energy requirements.

The Harris–Benedict equation is commonly used to estimate basal energy expenditure (BEE) (14). Developed in

1919, the equation was derived from indirect calorimetry measurement of healthy men and women:

$$\text{Men: BEE} = 66 + 13.8(\text{wt in kg}) + 5(\text{ht in cm}) - 6.8(\text{age})$$

$$\text{Women: BEE} = 655 + 9.6(\text{wt in kg}) + 1.8(\text{ht in cm}) - 4.7(\text{age})$$

Activity and stress factors, which add to the BEE, have also been studied (15). The overaddition of these factors may cause an overestimation of energy requirements and overfeeding (16). Therefore, hypermetabolism and nutrition requirements in critically ill patients should be carefully scrutinized, with the goal of providing adequate calories, but not overfeeding.

In general, the increases observed in metabolic rate are reported to be 110% to 120% in elective surgery and medical patients, 135% to 150% in trauma, and 150% to 170% in burns and sepsis (17–22). Comparisons between the Harris–Benedict equation and measured energy expenditure have demonstrated that these formulas only provide a good first approximation, and that actual measurements (e.g., indirect calorimetry) are required to provide conclusive caloric requirements and expenditure data. Other methods may be used to determine the adequacy of nutrition (see subsequently, and Volume 2, Chapter 31).

General recommendations for most acutely ill patients are to provide a range of 25 to 30 nonprotein calories per kilogram per day (23,24), and 1.25–2 g protein per kilogram per day (25). The caloric requirements should be individualized with respect to the degree of stress and/or sepsis, organ failure, percentage of ideal body weight (IBW) or BMI, age, pharmacological therapy, and presence of quadri- or paraplegia. IBW may be derived by using the Hamwi method. For men: 106 lb (for first 5 ft) + 6 lb (for each additional inch past 5 ft). For women: 100 lb (for first 5 ft) + 5 lb (for each additional inch past 5 ft). For example, the IBW for a 6-ft 1-in male would be 106 lb + 6(13 in) = 178 lb. IBW  $<90\%$  is considered underweight,  $>125\%$  overweight,  $>130\%$  obese, and  $>150\%$  morbidly obese. The calories should be provided in the form of protein, carbohydrate, and fat as described subsequently.

### Fluid Requirements

The fluid management in PN depends upon the hydration status of the patient. Solutions may be concentrated or volume expanded as necessary. In the acute care setting, supplemental IV fluids can be provided in case of dehydration or resuscitation. In terms of baseline fluid requirements, administering the equivalent milliliter of fluid as the patient's calculated basal caloric requirements generally provides the appropriate hydration (e.g., approximately 30 mL/kg/day in a 70-kg patient equals about 2.1 L of TPN solution per day).

Generally TPN orders should be written twice daily, so that changes in electrolytes or acid base status can be addressed on an every 12-hour basis, without wasting too much of the costly TPN solution. Additional fluid requirements are supplemented via additional IV fluid. In the hemodynamically stable patient, this is administered as one-half normal saline. In hemodynamically unstable patients, larger fluid volumes with higher sodium-containing formulations are utilized.

## Macronutrients

### Protein

**The provision of adequate protein as an energy source is necessary for proper utilization of amino acids.**

**Table 3** Water and Nutrient Requirements for Total Parenteral Nutrition

Water/nutrient	Per kg basis	Average amount for 70-kg patient over 24 hr
Water	4 cm <sup>3</sup> /kg/hr (first 10 kg)	960 cm <sup>3</sup>
	2 cm <sup>3</sup> /kg/hr (second 10 kg)	480 cm <sup>3</sup>
	1 cm <sup>3</sup> /kg/hr (subsequent kg)	1200 cm <sup>3</sup> 2640 mL/24 hr
Carbohydrate (D <sub>20</sub> )	4–6 g/kg/min (GIR); D <sub>20</sub> = 200 g glucose L	2 mg/kg/min GIR
Protein	0.8–1 g/kg/day—healthy	56–70 g/day
	1–1.2 g/kg/day—mild stress	70–84 g/day
	1.2–1.5 g/kg/day—moderate stress (i.e., dialysis, trauma)	84–105 g/day
	1.5–2 g/kg/day—severe stress (i.e., CVVHD/HDF, burns)	105–140 g/day
Fat (240 mL/day, 20% intralipid)	<1 g/kg/day or <0.1 g/kg/hr	0.8 g/kg/day or 0.03 g/kg/hr

*Abbreviations:* CVVHD, continuous veno-venous hemodiafiltration; GIR, glucose infusion rate; HDF, hemodialysis filtration.

### Healthy adults require 0.8–1.0 g of protein per kilogram per day (26). ♂

The role of protein administration in critical illness is to decrease muscle catabolism, aid wound healing, and support/enhance immune function. Recommendations for hospitalized patients vary with disease state (Table 3). Critically ill patients without renal or hepatic dysfunction generally require ~1.5 g of protein per kilogram per day (27–29). Patients with protein-losing medical conditions such as burns, large wounds, or high, output GI fistulas may require additional protein of up to 2.0 g of protein per kilogram per day.

Patients with chronic renal failure should have their protein restricted to 0.6–0.8 g/kg/day (30). In patients who are dependent on hemodialysis or peritoneal dialysis, protein requirement may be increased from 1.2 to 1.3 g/kg/day (31,32). Patients who receive renal replacement therapy (CRRT, CVVHD, or CVVHDF) have daily protein requirements of up to 2.5 g/kg/day in order to achieve nitrogen balance due to the hypercatabolic nature of acute renal failure and protein losses during filtration (33).

In hepatic disease, protein restriction is not recommended (in the absence of encephalopathy) due to the prevalence of catabolism and malnutrition. ♂ **In acute hepatic encephalopathy, a temporary restriction of protein to 0.8 g/kg/day may be warranted (34,35).** ♂ Furthermore, patients with hepatic encephalopathy have an impaired ability to metabolize aromatic amino acids (AAAs) and may have a depressed concentration of branched chain amino acids (BCAAs). Accordingly, BCAAs should be used rather than AAAs in the case of chronic hepatic encephalopathy unresponsive to protein restriction and pharmacotherapy. BCAAs by themselves, as a specific treatment for hepatic encephalopathy, have not been shown to decrease mortality (36–39).

Currently, parenteral protein is provided as crystalline amino acids. This formulation does not promote microbial growth and has improved nitrogen balance when compared to previously used casein solutions (40). The amino acid profile is based on the recommendations of the World Health Organization (WHO) for adequate essential amino acid (EAA) proportions (41). The concentration of the solutions ranges from 2.25% to 15%. Generally, 1 g of protein provides four calories in PN solutions.

There are several modified amino acid profiles that are available for certain diseases or conditions. In renal failure, it was hypothesized that if only EAAs were provided it would

result in improved urea recycling and conversion to nonessential amino acids. Studies have challenged the theory of urea recycling and have demonstrated that synthesis of all amino acids is not accomplished (42–44). Several studies have not shown improvement in renal function, catabolism, or mortality when parenteral EAAs are provided (44–47).

In sepsis and injury, exogenous BCAAs may improve protein synthesis as they are used preferentially by skeletal muscles when plasma levels are depressed. Several studies on parenteral BCAAs in critical illness have yielded varying results. Some have shown improved protein synthesis, however, mortality was not improved (48–51). The use of parenteral BCAAs is therefore controversial.

♂ **Glutamine is a conditional EAA during hypercatabolic states, such as stress, trauma, or burns (52,53).** ♂ Glutamine is involved in protein synthesis, transport, and supports rapidly dividing cells such as lymphocytes and enterocytes. Glutamine is absent from commercially available parenteral feeding formulas because it is unstable, and is degraded to the toxic pyroglutamic acid when stored in aqueous solution. In experimental protocols, glutamine has been added successfully to the PN solution, and is available for parenteral use in Europe as a dipeptide. In parenteral solutions, glutamine has recently been shown to be stable, and dipeptides have been included in PN (54,55). Glutamine in EN has been shown to stimulate the gut luminal mucosa, however, in the parenteral form this has not been shown.

Several recent studies regarding parenteral supplementation of L-glutamine or L-alanyl-L-glutamine in critical illness have shown improved nitrogen balance, decreased length of stay, decreased infection, and in some studies, reduced mortality (56–63). However, not all studies have been able to replicate these results (64). The level of glutamine supplementation varied and thus the role of parenteral glutamine remains controversial.

Glutamine is absent from commercially available parenteral formulas because of its aforementioned instability and degradation to pyroglutamic acid (toxic in aqueous solution). However, parenteral glutamine is mainly useful for gut luminal nutrition when administered enterally; hence, its absence from parenteral formulas is not considered problematic. In protocol settings, glutamine may be added to parenteral solutions. Further research and development is required to consider glutamine as part of a commercially mandatory supplement in PN solution.

### Carbohydrate

Within 24 hours of metabolic stress, glycogen stores in the liver and skeletal muscle are depleted. The body converts skeletal muscle protein (primarily glutamine and alanine) to glucose via gluconeogenesis to meet basal metabolic demand. The minimum requirement of glucose is 100–150 g/day to fuel the brain, renal medulla, and white and red blood cells (65). The maximum glucose utilization rate in critical illness is 5–7 mg/kg/min (66,67). ⚡ **Providing carbohydrate in excess can lead to hyperglycemia, hypertriglyceridemia, and an increased RQ (>1.0).** ⚡

The primary purpose of parenteral carbohydrate is to provide an energy source. The parenteral carbohydrate approved and commonly used in the United States is glucose. Parenteral glucose solutions are in the form of dextrose monohydrate, which is available in concentrations of 2.5% to 70%. A 5% dextrose solution contains 5 g/100 cm<sup>3</sup> or 50 g/L. ⚡ **Most TPN regimens utilize ≤25% dextrose (D<sub>25</sub>) and most PPN regimens utilize ≤10% dextrose (D<sub>10</sub>) for safe osmolarity infusion.** ⚡ One gram of dextrose provides 3.4 calories. Thus, 1 L of D<sub>25</sub> provides 250 g or 850 calories, and most 70-kg patients would receive about 2 L of this solution at a glucose infusion rate of 2.5 mg/kg/min (Table 3). Owing to the high osmolarity of parenteral dextrose, concentrations >10% require infusion through a central line. Other forms of carbohydrate have been studied, including fructose (68), sorbitol (which is converted to fructose), xylitol (69,70), and glycerol in traumatized patients (71,72). Alternate carbohydrate sources are not available in the United States.

### Fat

Lipids in parenteral solutions provide calories and prevent essential fatty acid deficiency (EFAD). EFAD can develop in three weeks of fat-free PN. ⚡ **Providing approximately 2% to 4% of total calories as linoleic acid can prevent the occurrence of EFAD (73,74).** ⚡ The use of topical vegetable oils to prevent EFAD is controversial (75–78). Additional topics relating to EFAD are discussed subsequently.

The type of parenteral lipid available in the United States is composed of long-chain triglycerides (LCTs). There have been studies suggesting LCTs impair the immune system, specifically the reticuloendothelial system (RES) (79). Current recommendations are to limit lipids to 1 g/kg/day or <0.1 g/kg/hr (Table 3). Alternatively, patients can receive 25% to 30% total calories as lipids as a result of concern over the impact of immune suppression in hospitalized patients (80,81).

In the United States, parenteral lipids contain soybean and/or safflower oil, egg yolk phospholipid, and glycerol emulsifiers. The concentrations available are 10%, 20%, and 30%, with the latter available only in total nutrient admixtures. The 10% emulsion contains 1.1 calories per mL, the 20% contains 2 calories per mL, and the 30% contains 3 calories per mL.

Owing to the impairment of the RES with LCTs, investigations into alternative lipid sources are ongoing. The “structured lipids” commonly studied are a mix of LCT and medium-chain triglycerides (82,83). Structured lipids are not commercially available in the United States. The outcomes reported are improved liver function tests, no increase in low-density lipoprotein:high-density lipoprotein cholesterol ratio, and correction of fatty acid pattern imbalance. Additional alternatives to LCTs are omega-3 fatty acids (84) and short-chain fatty acids (85).

The maximum infusion time of intralipids for 2-in-1 PN solutions should be limited to less than 12 hours as recommended by the Centers for Disease Control, due to reports of gram-negative sepsis associated with IV fat emulsions infusing for periods >12 hours (86). However, intralipids composed in TNA or 3-in-1 mixtures have decreased the risk of bacterial growth because of the low pH environment (87).

## MICRONUTRIENT REQUIREMENTS

### Electrolytes

Electrolytes are added to PN for maintenance or repletion. The quantity will vary depending on the clinical condition of the patient and prescribed medications. Electrolytes provided in PN are sodium, potassium, magnesium, chloride, lactate, and phosphorus. Sodium and potassium can be provided as acetate or chloride if an acid–base imbalance exists. In situations where the patient is noted to have a hyperchloremic metabolic acidosis (e.g., large diarrhea output, fistulas, or renal tubular acidosis, or iatrogenic), then acetate should be provided in larger quantity than chloride. Typically, calcium is provided as gluconate, and magnesium is provided as sulfate due to improved solubility and compatibility (88). Phosphorus may be provided as the sodium or potassium salt.

Guidelines for the quantity of electrolytes to be provided in parenteral solutions vary (Table 4). Generally, the following range of electrolytes are recommended per liter: sodium 100–150 mEq, potassium 60–120 mEq, magnesium 8–24 mEq, calcium 9–22 mEq, and phosphorus 15–30 mEq (89). A sum of less than 40 mEq/L should be used for calcium and phosphorus to prevent precipitation. Management of electrolytes should be assessed with clinical judgment. Medical situations such as renal failure, cardiac issues, hydration status, and intestinal losses should be considered.

### Vitamins

The current recommendation for the vitamin solutions for PN is from the Nutrition Advisory Group of the American Medical Association (AMA) in 1975 (Table 5) (90). The recommendations were created to prevent clinically significant deficiency or toxicity. Most multivitamin preparations are formulated to meet the recommendations. The multivitamin preparation (MVI-12) was studied and found to provide adequate amounts of vitamins except for ascorbic acid in a few of the subjects (91). There has been concern over the possibility of increased vitamin requirements in critically ill or injured patients. Individual vitamin preparations are available, if needed. Parenteral multivitamin preparations are being reformulated to include vitamin K; however, currently vitamin K should be added to the parenteral solution weekly.

### Trace Elements

The most commonly supplemented trace elements are zinc, chromium, manganese, selenium, and copper, based in part on 1977 AMA recommendations (Table 6) (92). Other elements may be additionally supplemented, if needed. There are commercially available trace element preparations for PN. Molybdenum is not routinely supplemented; however, there is one single case of deficiency in a patient on long-term PN (93).

**Table 4** Electrolyte and Mineral Requirements for Total Parenteral Nutrition

Electrolyte	Recommended daily intake (adults)	Effects of serum deficiency	Effects of serum excess
Sodium	100–150 meq	Generalized edema, confusion, hypotension, irritability, lethargy, seizures	Decreased skin turgor, mild irritability in some cases, elevated BUN and hematocrit
Potassium	60–120 meq	Cardiac dysrhythmias (U-waves), multiple irritable dysrhythmias	Cardiac dysrhythmias (peaked T-waves), may not be able to resuscitate without calcium chloride
Chloride/acetate	100–150 meq to maintain acid/base balance	Seen in contraction alkalosis	Non-gap metabolic acidosis
Bicarbonate	Not added to PN: precipitates with calcium and magnesium; changes pH with solution	Metabolic acidosis	Metabolic alkalosis
Calcium	10–15 meq	Paresthesias, irritability, tetany, ventricular arrhythmias	Confusion, dehydration, muscle weakness, nausea, vomiting, coma
Phosphorus	400–900 mg	Muscle weakness, (muscle injury when severe), red blood cell rigidity, leftward shift in the Oxy-Hbg curve (increased O <sub>2</sub> affinity for oxygen and decreased release at tissues)	Paresthesias, flaccid paralysis, mental confusion, hypertension, cardiac arrhythmias, soft-tissue calcification with prolonged elevated levels
Magnesium	120–240 mg	Cardiac dysrhythmias, neurological irritability (including seizures), neuromuscular irritability (including tetany)	Respiratory paralysis, hypotension, premature ventricular contractions, lethargy, cardiac arrest, coma, liver dysfunction

*Abbreviations:* BUN, blood urea nitrogen; Hbg, hemoglobin; PN, parenteral nutrition.

In patients with hepatic dysfunction, withholding manganese and copper may be warranted as they are excreted in bile (94–99). Iron has not been included in trace element preparations due to the potential for anaphylactic reaction. If a patient is on long-term PN and NPO, small amounts of iron dextran may be added to parenteral solutions containing amino acids and dextrose (100). There are conflicting reports on the compatibility of iron with lipid-containing parenteral solutions (101,102).

## IMPLEMENTATION OF PARENTERAL NUTRITION

### Initiation

Before initiation of PN, abnormal electrolytes must be corrected. Once electrolytes are within normal limits, there are a variety of ways to initiate PN. Important factors to consider are the patient's ability to tolerate fluid volume, glucose intolerance, and renal function (i.e., electrolyte status). If fluid tolerance is not known, initiation of PN with 1000 mL of fluid may be prudent. For patients without known diabetes or glucose intolerance, dextrose may be started at 200 g. If diabetes or glucose intolerance is a concern, dextrose may be restricted to 100–150 g and sliding scale regular insulin ordered with blood glucose monitored every four to six hours (67,103). ⚡ **Regular insulin may then be added to the parenteral solution at one-half to two-thirds the previous day's total sliding scale insulin coverage.** ⚡ As the dextrose is increased to goal, the insulin requirements will increase. If a patient is unstable, septic or otherwise physiologically stressed [common in the surgical intensive care unit (SICU) setting], a separate insulin infusion line will better

control glucose due to fluctuations from changes in clinical status. The goal range of blood glucose in the hospital setting has been recently studied (Volume 2, Chapter 60), and tighter glucose control has been observed to improve outcomes, and shown decreased rates of infection, ventilator days, renal failure, length of stay, and mortality (104–106). Current recommended goals in critically ill patients are glucose levels between 80 and 110 mg/dL (Volume 2, Chapter 60).

Amino acids may be given at goal on the first day of PN if renal function is normal, and the patient is hemodynamically stable. Lipids may also be given on the first day if serum triglycerides are less than 400 mg/dL and remain at this level after lipids are infused (107).

### Advancement and Maintenance

The limits to advancing PN are hyperglycemia and fluid tolerance. If these factors are controlled, PN may be advanced on the second day. If hyperglycemia persists, the dextrose content may be increased to goal in increments as insulin is increased.

### Cyclic Feeding Strategies

Cycling PN may be beneficial in stable patients on long-term support. In addition to allowing a patient time-off of an infusion pump at home, cycling can also decrease hepatic complications (108). The potential benefit is derived from mimicking the physiologic fast and feed states. Cycling usually occurs gradually over a two- to three-day period to monitor tolerance to fluid volume and glucose load (109). Patients with impaired renal, cardiac, or hepatic function may not tolerate the rapid volume infusion. Depending

**Table 5** Vitamin Requirements for Total Parenteral Nutrition

Vitamin	Recommended daily Intake	Effects of serum deficiency
A	4500 IU	Infections/sepsis
Thiamine (B1)	5 mg	Wernicke's encephalopathy and Korsakoff's psychosis acidosis, inability to metabolize nutrients via Krebs cycle
Pyridoxine (B6)	6 mg	Neuropathy, dermatitis, irritability
B12	3 µg	Megaloblastic anemia, glossitis
C	50 mg	Scurvy
D	400 IU	Ricketts but exposure to sunlight recommended rather than IV vitamin D which causes bone pain and fractures
E	15 IU	Increased oxidants, and dermatitis
K	Up to 10 mg/day	Decreased vitamin K-dependent coagulation factors: II, VII, IX, X, and decreased anticoagulation factors: protein C, protein S
Folic acid	400 µg	Neuropathy, glossitis
Niacin	15 mg	Delirium, confusion, dermatitis pelagra: dark red erythema of exposed skin, cracked skin, stomatitis, diarrhea
Riboflavin	1.8 mg	Glossitis, cheilosis, pruritis, anogenital inflammation
Pantothenic acid	15 mg	Listlessness, fatigue, irritability, restlessness, malaise, sleep disturbances, nausea, abdominal cramps, vomiting, diarrhea, neuromuscular disturbances, hypoglycemia, increased insulin sensitivity
Biotin	60 µg	Anorexia, pallor, glossitis, nausea, vomiting, depression, lethargy, muscle pain, hair loss, erythematous seborrheic dermatitis, elevated bile pigments/cholesterol

Abbreviation: IV, intravenous.

on patient tolerance, PN can be cycled down to 12 hours, a one-hour taper up and down with either 50 mL or one-half of the goal infusion rate is recommended. Patients with diabetes or glucose intolerance will require slow down (at least a two-hour taper) to prevent hypoglycemia.

## COMPLICATIONS

### Refeeding Syndrome

Refeeding syndrome may occur in malnourished or underfed patients. Hospitalized patients at risk of refeeding syndrome are those who have sustained significant recent weight loss, been kept NPO for greater than 7 to 10 days, as well as those with chronic medical conditions, or alcoholism (110,111). ⚡ **Refeeding syndrome is characterized by hypophosphatemia, hypomagnesemia, hypokalemia, and hyperinsulinemia.** ⚡ Hypophosphatemia is the most frequently observed. Refeeding syndrome is the result of the body shifting from utilizing stored fat to

**Table 6** Trace Element Requirements for Total Parenteral Nutrition

Trace element	Recommended daily intake	Effects of deficiency
Zinc	2–4 mg/L (catabolic)	Dermatitis, alopecia, impaired wound healing, impaired immune function, psychiatric disturbances, gonadal atrophy
Copper	12.2 mg/L (small bowel losses) 300–500 µg	17.7 mg/L (ileostomy or rectal losses) Anemia, demineralization of bone, vascular aneurysms
Iron	0.5–1.5 mg/day in fat-free PN in the form of iron dextran	Anemia
Selenium	50–100 µg	Cardiomyopathy, myositis, arthritis, hair, and nail changes
Chromium	10–15 µg	Glucose intolerance, peripheral neuropathy, hyperlipidemia
Manganese	2–5 mg	Bleeding disorders, impaired wound healing
Molybdenum	10–50 µg	Amino acid intolerance

Abbreviation: PN, parenteral nutrition.

carbohydrate as the primary energy source. As a result, insulin levels increase and as the body shifts to anabolism, electrolytes are consumed via intracellular pathways (112). Thiamine deficiency may contribute to the effects of refeeding syndrome. Fluid retention occurs due to hypoalbuminemia, elevated sodium levels, and carbohydrate metabolism (113,114). Signs and symptoms of refeeding syndrome may include lethargy, weakness, edema, respiratory depression, and cardiac dysrhythmias.

Reducing the occurrence of refeeding syndrome should be considered in patients at risk of developing symptoms. It is ideal to correct electrolyte imbalances prior to initiating nutritional support. Patients with a history of alcoholism should receive vitamin repletion including supplemental thiamine (115). The patient's actual weight should be used in determining calorie and protein requirements. In addition, energy goals for PN should be achieved over the course of several days. When PN is initiated, additional phosphorus, magnesium, and potassium may be added to the solution. During advancement of PN, electrolytes, fluid volume status, and the general condition of the patient should be monitored closely.

### Glycemic Control

Difficulty in managing glucose levels is frequently encountered during PN. Critical illness and stress may compound the problem. Hypoglycemia and, more frequently, hyperglycemia can occur.

Hyperglycemia is a common complication of PN. The causes include stress, insulin resistance or diabetes, steroids, infection, organ failure, and high dextrose concentrations.

♣ **Morbidity and mortality are affected by untreated or poorly treated hyperglycemia (Volume 2, Chapter 60), therefore controlling glucose is a priority (104–106).** ♣ If a patient is a known diabetic, or has elevated glucose values prior to initiation of PN, sliding scale regular insulin and blood glucose monitoring should be started. If a patient has normal glucose values, monitoring blood glucose changes for the first three days of PN may be prudent. The use of insulin drips in the ICU or monitored setting may be beneficial in achieving tight control.

Hypoglycemia is a complication of PN when exogenous insulin is provided in excess of need. Symptoms include dizziness, impaired vision, diaphoresis, headache, and confusion. If a patient has labile glucose values, an insulin drip may improve glucose control. When insulin is added to the parenteral solution, caution should be used in determining the quantity. Insulin adsorbs to glass bottles, polyvinyl chloride bags, and tubing used for PN infusion and therefore, insulin requirements may be increased and bring a challenge to excellent blood sugar control (116). Insulin availability may be increased when a combination of MVIs and trace elements are present in the PN solution (117). Changes in medical condition or medications, such as resolution of an infection or tapering of steroids, should be monitored. Whenever PN is discontinued or cycled, insulin infusion should be likewise turned down. Tapering the PN solution for one to two hours may prevent rebound hypoglycemia. When unplanned interruptions in PN infusion occur, administering a dextrose-containing IV fluid such as dextrose 10% at the same rate for up to four hours may prevent hypoglycemia from abrupt termination of the high dextrose infusion.

### Essential Fatty Acid Deficiency

The occurrence of EFAD with PN in the United States is primarily the result of allergic reactions to IV lipids, or in patients with a contraindication for lipids for several weeks both resulting in lipid-free solutions. In hospitalized, stressed patients, reports of EFAD occurred in one to three weeks (75,76). In stable patients, EFAD may occur within one month (78). The symptoms include dermatitis, alopecia, poor wound healing, increased platelet aggregation, increased capillary fragility, and hepatic dysfunction (118).

Providing 2% to 4% total calories as fat prevents EFAD. There are reports of using topical vegetable oils to correct EFAD, however the results varied (75–78). If EFAD is suspected as a result of lipid-free PN for >1 month, assessing fatty acid status should be completed. A sensitive diagnostic indicator is the triene:tetraene ratio (119). A ratio above 0.4 indicates EFAD.

### Hepatic Dysfunction

The hepatic dysfunction that develops during PN is multifactorial, contributes to morbidity, and it is not well understood. With long-term PN, in particular, there exists a pattern of hepatic dysfunction and potentially hepatic failure. Laboratory abnormalities develop in succession, initially with aspartate aminotransferase, then alkaline phosphatase (AP), and finally with bilirubin (120). Malnourished patients reveal an early rise in AP in addition to cholestasis (121). The incidence of laboratory abnormalities varies from 25% to 100% (122). Both intrahepatic and extrahepatic

abnormalities and complications may occur. Generally, the pathophysiology is reversible after the discontinuation of PN. When long-term PN is given with a modest amount of macronutrients and a minimal amount of fat emulsions, abnormal liver enzymes are common, but severe liver dysfunction is unusual (123).

The most common and earliest intrahepatic complication from PN in adults is steatosis (124). Steatosis can occur as early as five to seven days after the initiation of PN with elevation of liver enzymes within the first three weeks. The causes may include EFAD, choline deficiency, carnitine deficiency, glutamine deficiency, bacterial translocation, and excessive caloric or carbohydrate provision.

The development of cholestasis is more common in infants than adults. Cholestasis generally follows steatosis if PN is not discontinued. Other risk factors for cholestasis include sepsis, EFAD, particular amino acid deficiencies, and length of time on PN. The pathogenesis in adults is unknown.

Although treatment for hepatic dysfunction remains under investigation, there are proposed options for reducing the risk and potentially reversing steatosis and cholestasis. Cycling PN may improve laboratory values and resolve hepatomegaly (108). Providing PN over a shorter duration of time allows for the conversion to fat oxidation, which promotes lipid mobilization and transport (125–127). The addition of a lipid emulsion to PN in place of carbohydrates has decreased the incidence of hepatic dysfunction (128), and it allows one to avoid excessive caloric or dextrose loads. Modifying the amino acid content to include taurine may be beneficial, especially in pediatric PN (129–131). Supplementing PN with choline (132,133), glutamine (134,135), and/or carnitine (136) have been proposed as treatment options for hepatic steatosis. Choline may be mandatory for the synthesis of lipoproteins used in triglyceride transport from the liver to peripheral locations (137). Glutamine may minimize hepatic fat uptake and increase alanine flow through the portal route, thereby promoting ideal hepatic metabolism. Carnitine supplementation (1 g/day for home PN patients) has not shown improvement in steatosis although carnitine deficiency has been proposed as a possible cause of steatosis (136). Of course any amount of enteral feeding, if possible, may decrease hepatic dysfunction (138).

### Micronutrient Deficiencies

Once PN tolerance of macronutrients is established, the daily focus of management shifts to electrolyte balance, and potential deficiencies of electrolytes, vitamins, and minerals. In critical illness, deficiencies may occur due to GI losses, organ dysfunction, surgery, injury, and certain medications. Increased need for zinc due to GI losses should be considered (Table 6) (12). In long-term PN, there have been reports of vitamin and mineral deficiencies. This became apparent during the nationwide multivitamin shortage when several cases of thiamine deficiency and death were reported (139,140). In addition, reports of selenium deficiency due to long-term, selenium-free PN were documented (141,142). Clinical judgment and laboratory values should be used to prevent or treat potential deficiencies in patients who are at risk.

### NUTRITION MONITORING

When initiating PN support, the patient's baseline nutritional status should be evaluated, and the ongoing nutritional

adequacy must be monitored and assured. Volume 2, Chapter 31 covers this topic in greater detail, but it will be briefly discussed here in general terms. A simple and relatively inexpensive way to evaluate nutritional status is to measure serum proteins. The most common proteins that are measured include albumin (half-life = 21 days), transferrin (half-life = 8–9 days), and prealbumin (half-life = 2–3 days) (143).

The most accurate reflection of a critically ill patient's current nutritional state is obtained from the prealbumin level. Of course, multiple factors can impact on the concentration of these proteins including resuscitation, hemoglobin level, and degree of liver failure. Accordingly, following the trend of these proteins in addition to the absolute value is most beneficial. It is optimal to institute standard protocols for obtaining monitoring of nutritional status; for example, every Monday and Thursday, so that the level of progress can be assessed. If the albumin, transferrin, and prealbumin levels have increased, this represents a positive trend and the nutritional plan should be maintained. If the trend is negative or improvement continues at a slow rate, one must reassess the nutritional needs in order to determine an alternative plan to reverse the negative trend. In addition to prealbumin levels, triglyceride levels and liver function enzymes should be monitored on a weekly basis. Triglyceride levels of <250 mg/dL after four hours and <400 mg/dL after continuous infusion are acceptable (144). If levels remain elevated, providing intralipids of 250 mL two to three times weekly to prevent EFAD is appropriate. An increased trend of liver function enzymes may suggest the need for cycling PN, decreasing macronutrient concentrations, and minimizing trace elements to zinc, chromium, and selenium (see subsequently for more information).

## SPECIAL DISEASE STATES AND PARENTERAL NUTRITION

Disease processes such as diabetes, renal failure, and hepatic failure present special concerns and considerations for PN. Tailoring the parenteral prescription for each individual is vital when meeting nutrient needs.

### Diabetes Mellitus

Diabetes mellitus (DM), one of the most common but devastating metabolic diseases, affects more than 16 million Americans. Diabetes is marked by abnormal glucose metabolism, insulin deficiency, and/or irregular insulin response which cause short- and long-term consequences that include hyperglycemia, hyperlipidemia, obesity, heart disease, retinopathy, nephropathy, and vascular damage. Appropriate glucose control is imperative for patients with DM due to risk for catheter infection, wound healing, and mortality. Conservative action may be taken when formulating macronutrient composition. ⚡ **Maximum glucose infusion rate for nondiabetic patients may be 4–6 mg/kg/min.** ⚡ This rate allows peripheral glucose uptake to be maximized and hepatic glucose production to be minimized (66). As mentioned earlier, dextrose in the initial PN infusion may be limited to 100–150 g (103). Once glucose levels are stable and less than 200 mg/dL, dextrose content may be increased by 50–75 g/day. Close attention and adjustments should also be made for outside sources of dextrose (i.e., dextrose intravenous piggybacks and dextrose absorbed from dialysate). In addition, lipid infusion of less than or equal to 30% of nonprotein calories is safe and may decrease exogenous insulin requirements.

Sliding scale insulin is adequate for stable floor patients on PN if blood glucose levels are >140 mg/dL, and one-third to one-half of the previous day's sliding scale insulin dose may be subsequently added to the parenteral bag. For critically ill DM patients, intensive insulin therapy managed with an insulin drip is usually the best choice to achieve glucose between 80 and 110 mg/dL, hence decreasing risk of sepsis, condensing antibiotic therapy, decreasing mechanical ventilation dependence, reducing endogenous glucose production, and further preventing lean body catabolism (106,145). Improved glucose tolerance has been reported in populations with chromium deficiency receiving chromium-supplemented PN solutions. Thus, strong clinical suspicion should accompany any decision to supplement above currently recommended levels (146).

### Renal Failure

Renal failure rapidly causes nutritional imbalances, thereby shifting a patient to a hypercatabolic state. Hypercatabolism in patients with renal failure may be due to inadequate use of nutrients, increased production of catabolic factors, drug therapy, protein losses via dialysis membrane, and toxic-related symptoms such as nausea, vomiting, and anorexia. Renal failure patients in the ICU challenge the entire health team because these patients are in negative nitrogen balance, and the presence of infection intensifies their underlying malnutrition (147,148). PN may be indicated for the renal failure patients who do not tolerate enteral support. Nutrition therapy varies with both the presence of dialysis and type of dialysis [i.e., hemodialysis (HD), CVVHD, peritoneal dialysis (PD)]. Benefits of commercially available renal parenteral formulations have been controversial because patients with renal failure are highly variable based on their renal function, hypermetabolism, and hypercatabolism (45,47,149). ⚡ **Despite the increased need for macro- and micronutrients, supplementing trace minerals in the parenteral solution for patients with renal failure must be carefully evaluated.** ⚡ Moreover, trace mineral excretion is minimal in CVVHD (150).

### Hepatic Failure

Hepatic failure results in a number of different metabolic dysfunctions, such as the ability to metabolize ammonia into urea thereby triggering hepatic encephalopathy. The specific etiological factors related to HD that result in hepatic failure have not been clearly identified; however, they may be associated with increased dietary protein intake, GI bleeding, infections, electrolyte imbalances, surgical procedures, and drugs (151,152). PN support is appropriate for hepatic failure patients who cannot receive enteral support due to active GI hemorrhage or small-bowel obstruction. Central PN is preferred over peripheral because less volume is required to provide adequate calories and protein. According to Plauth et al. (153), parenteral amino acids are less likely to precipitate encephalopathy, however, most patients will accept standard tube-feeding formulas (refer to Volume 2, Chapter 32). Abnormal amino acid profiles have been present under conditions of hepatic encephalopathy: AAA (i.e., tyrosine, tryptophan, and phenylalanine) levels are elevated, whereas BCAA (i.e., isoleucine, valine, and leucine) levels are depressed. Significant liver dysfunction may be seen in patients with a molar ratio of BCAA: AAA of 1.4:2.0 and those encephalopathic patients with a ratio  $\leq 1.0$  (144). Five of the nine randomized controlled studies reviewed in a meta-analysis by Naylor et al.

(39) showed significant improvement in mental recovery from acute encephalopathy with parenteral BCAA formulation and a significant decrease in mortality. However, due to mortality differences and short-term follow-up time among trials, the authors concluded that using parenteral BCAA over standard therapy is not suggested. 🐉 **Most hepatic encephalopathy patients suffer from protein-calorie malnutrition and have been supported with standard solutions under careful awareness of protein intake.** 🐉 HepatAmine® (B. Braun, Irvine, California, U.S.A.) is the only modified amino acid solution that contains high amounts of BCAA versus AAA and should be reserved for patients who have refractory HE. Strict criteria should be implemented to prevent the inappropriate use of hepatic parenteral formula which is more costly than standard solutions. As with renal failure, trace element supplementation (especially copper and manganese) should be minimized to prevent hepatic toxicity.

## EYE TO THE FUTURE

In future research, two areas of focus that are particularly interesting include the use of PN as an enteral growth stimulant and as a cancer-inhibitory factor. Glucagon-like peptide-2 (GLP-2) is an intestinal trophic enteroendocrine peptide that is associated with intestinal adaptation following resection. Martin et al. (154) demonstrated that GLP-2 alone in PN, without enteral feeding, stimulated indices of intestinal adaptation in an animal study. Further studies are warranted to establish the mechanisms of action and therapeutic potential of GLP-2 in animal studies prior to the initiation of human studies.

Jordan et al. examined the effects of a fish oil (FO)-based lipid emulsion rich in omega-3 fatty acids, which is used in humans as a component of PN, on the growth of the colon cancer cell line Caco-2. The authors concluded that FO has a potent antiproliferative effect on Caco-2 cells, at least in part due to a decrease in the progression of the cell cycle and the induction of apoptosis. The combination of FO with 5-fluorouracil resulted in an additive growth inhibitory effect (155).

Dipeptide glutamine and alanyl-glutamine parenteral supplementation helped improve nutrition status (weight, plasma proteins, urinary accumulated creatinine, and nitrogen retention) in rats and may be a helpful supplementation in critically ill patients with moderate or severe stress (156). PN support has been shown to preserve body protein composition for patients with severe acute pancreatitis who are unable to meet nutritional needs solely on EN (157). Patients suffering from severe GI diseases and with irreversible intestinal failure have been supported with long-term PN. Small-bowel transplantation, in addition to development of immunosuppressant medication, has been a life-saving procedure for those who can no longer be maintained on PN.

The growth of digestive disease and intestinal rehabilitation centers in collaboration with new techniques and phenomena such as gut trophic factors, natural additives, small-bowel transplantation, restorative surgery, and PN have helped the specific patient population receive the safest and physiologically appropriate treatment while improving quality of life.

## SUMMARY

Over the past 100 years, there has been significant advancement in the field of nutrition, in which PN has clearly been

one of the most significant. Indirect calorimetry has become the golden standard for energy assessment and nutritional requirements. However, serum proteins still play a major role in the daily clinical practice of nutrition providers. Although there are complications of PN, the benefits clearly outweigh them for patients that cannot tolerate enteral feeds.

Continuing nutrition assessment and monitoring should be practiced in order to potentially wean patients from PN support and begin trophic enteral or oral feeds (Volume 2, Chapters 31 and 32). The three macronutrients of PN, such as carbohydrates, proteins, and fats, should be individualized based on the patient's medical condition and adjusted regularly. Vitamins and minerals should be supplemented and reviewed for appropriateness in order to prevent deficiency, toxicity, and help meet metabolic needs. Lastly, the best PN prescription may be accomplished by proactive efforts made by each health-care team player.

## KEY POINTS

- 🐉 As TPN solutions are hyperosmolar, a large-diameter vein with adequate flow rate is required to allow for rapid dilution of TPN products within the vessel.
- 🐉 The preferred site of central venous catheter placement for PN is the subclavian vein.
- 🐉 Indirect calorimetry is considered as the golden standard for the measurement of metabolic rate and substrate utilization.
- 🐉 The provision of adequate protein as an energy source is necessary for proper utilization of amino acids. Healthy adults require 0.8–1.0 g of protein per kilogram per day (26).
- 🐉 In acute hepatic encephalopathy, a temporary restriction of protein to 0.8 g/kg/day may be warranted (34,35).
- 🐉 Glutamine is a conditional EAA during hypercatabolic states, such as stress, trauma, or burns (52,53).
- 🐉 Providing carbohydrate in excess can lead to hyperglycemia, hypertriglyceridemia, and an increased RQ (>1.0).
- 🐉 Most TPN regimens utilize ≤25% dextrose (D<sub>25</sub>), and most PPN regimens utilize ≤10% dextrose (D<sub>10</sub>) for safe osmolarity infusion.
- 🐉 Providing approximately 2% to 4% of total calories as linoleic acid can prevent the occurrence of EFAD (73,74).
- 🐉 Regular insulin may then be added to the parenteral solution at one-half to two-thirds the previous day's total sliding scale insulin coverage.
- 🐉 Refeeding syndrome is characterized by hypophosphatemia, hypomagnesemia, hypokalemia, and hyperinsulinemia.
- 🐉 Morbidity and mortality are affected by untreated or poorly treated hyperglycemia (Volume 2, Chapter 60), therefore controlling glucose is a priority (104–106).
- 🐉 Maximum glucose infusion rate for nondiabetic patients may be 4–6 mg/kg/min.
- 🐉 Despite the increased need for macro- and micronutrients, supplementing trace minerals in the parenteral solution for patients with renal failure must be carefully evaluated.
- 🐉 Most hepatic encephalopathy patients suffer from protein-calorie malnutrition and have been supported with standard solutions under careful awareness of protein intake.

## Abdominal Compartment Syndrome

Devashish J. Anjaria

Division of Trauma, Burns, and Critical Care, Department of Surgery, UC San Diego Medical Center, San Diego, California, U.S.A.

David B. Hoyt

Department of Surgery, UC Irvine Medical Center, Irvine, California, U.S.A.

### HISTORY AND INTRODUCTION

Compartment syndrome is defined as a “condition in which increased pressure in a confined anatomical space adversely affects the circulation and threatens the function and viability of the tissues therein” (1). Compartment syndromes have been traditionally described to occur within the closed fascial spaces of the extremities. However, in the past 20 years the term has been appropriately extended to include the abdomen. Although the term abdominal compartment syndrome (ACS) was first used by Kron et al. (2) in 1984, the pathophysiology of elevated intra-abdominal pressure (IAP) has been recognized for nearly a century. This review of ACS represents an organizational summation of the factors that have been recognized over that duration to cause critically elevated IAP causing morbidity and mortality.

In 1876, Wendt (3) described the reduction of urinary blood flow which occurs in response to elevated IAP (4). Emerson (5) was the first to describe the cardiovascular derangements associated with elevated IAP in 1911. Although intra-abdominal hypertension (IAH) was shown to increase mortality in animal models by the late nineteenth century, it was the fashioning of a rudimentary ventilatory support device that allowed Emerson to do his work (6). Since that time, the effects of elevated IAP on nearly every organ system have been described. The classic presentation remains the “high-risk” patient with decreasing urinary output and increasing peak inspiratory pressures.

In the late 1940s and early 1950s, pediatric surgeons attempting to repair omphaloceles and gastroschisis discovered that although primary repair was possible, there was a high mortality rate, and these neonates usually died of acute respiratory failure (7,8). These were the first descriptions of ACS in children. By the late 1960s, the need for a staged reduction of abdominal contents was described by Allen and Wrenn (9) with the creation of plastic silos or chimneys, which allowed for temporary abdominal closure (TAC) until the loss of abdominal domain could be overcome. This is the basis for modern decompressive laparotomies with TAC.

With the evolution of laparoscopy in the 1970s, the cardiovascular effects of elevated IAP on patients was increasingly recognized, observed, and further characterized in animal models (10–12). In 1984, with this foundation already laid, Kron coined the term, ACS. In addition, he described an easy, reproducible method for measurement of IAP, and the successful treatment of ACS with decompressive laparotomy (2). After this report, there has been a

plethora of literature describing and characterizing the etiology, diagnosis, and pathophysiology of ACS.

### ETIOLOGY

With improved understanding and recognition of ACS, the reported etiologies have become increasingly varied (Table 1). **Because of the numerous etiologies, a high index of suspicion is required to consider the diagnosis of ACS.** Despite the disparate etiologies, a simple unifying classification scheme has been developed. The initial classifier is the rapidity with which the process develops (acute or chronic). In the acute setting, IAH/ACS is further subclassified as a primary abdominal process (1° ACS), or secondary to accumulation of “third space” fluid; as occurs with massive resuscitation secondary to capillary leak without a primary abdominal process (2° ACS). Regardless of the etiology, if the diagnosis of acute ACS is made, prompt treatment must be undertaken to minimize the morbidity and mortality associated with this condition. Because of this, the recognition and increasing incidence of acute ACS have paralleled the evolution of damage control surgery (Volume 1, Chapter 21) first described in 1983 by Stone et al. (13). Individuals with chronic IAH have had time for the abdomen to accommodate and therefore are usually compensated; however, this baseline IAH may become exacerbated in the setting of acute illness.

### Acute Intra-abdominal Hypertension

A rapid rise in IAP, over hours, which does not allow for accommodation by the abdominal wall results in acute IAH. With progressively increasing IAP, patients have the physiological consequences of IAH which cause progression to ACS. A grading system has been proposed and prospectively evaluated by Meldrum et al. (14) as shown in Table 2. Although this is useful in considering IAH as mild, moderate, or severe, the absolute cutoffs used in creation of the grading scale are somewhat arbitrary. The transition from IAH to ACS is a continuum which is dependent upon many factors including the etiology of the IAH, medical condition of the patient, and the physiological response to the IAH. The exact incidence of ACS in all patients is not known given the wide variety of etiologies. A prospective study reviewing all trauma patients admitted to the intensive care unit (ICU) at the University of Miami

**Table 1** Etiologies of Intra-abdominal Hypertension

Timing and categorization	Etiology
<i>Acute primary</i>	
Intraperitoneal origin	Intraperitoneal hemorrhage (137) Blunt hepatic trauma (127) Bowel obstruction (138) Ileus (139) Acute gastric dilation (46) Pneumoperitoneum (38) Abdominal packing (140) Abscess (141) Ascites (125) Visceral edema (137) Mesenteric revascularization (142) Transplant kidney (143)
Retroperitoneal origin	Pancreatitis (133) Pelvic or retroperitoneal hemorrhage (134) Contained abdominal aortic aneurysm rupture (107,135) Abscess (136)
Abdominal wall	Rectus sheath hematoma (144,145) Burn eschar (146) MAST trousers (147) Repair of large hernia with loss of domain (140) Repair of gastroschisis or omphalocele (148) Laparotomy closure under extreme tension
<i>Acute secondary</i>	Burns (19) Significant nonabdominal trauma (20,149)
<i>Chronic</i>	Obesity (29,150) Ascites (122) Pregnancy (151) Large abdominal tumors (121) Peritoneal dialysis (152)

Abbreviation: MAST, military anti-shock trousers.

found that of 706 patients, 15 (2%) developed IAH. Of these 15, six patients (40%) progressed to ACS with derangement of physiologic parameters, reversed by abdominal decompression (15). A patient with initially mild IAH (grade I) can rapidly progress into severe (grades III and IV) ACS; therefore, in the high-risk patient frequent re-evaluation is indicated. Given the morbid consequences of IAH and ACS, it is better to treat more aggressively if in doubt.

**Table 2** Treatment of Intra-abdominal Hypertension/Abdominal Compartment Syndrome Based on Grade

Grade	Bladder pressure (mmHg)	Recommended treatment
I	10–15	Maintain normovolemia
II	16–25	Hypervolemic resuscitation
III	26–35	Decompression
IV	>35	Decompression and re-exploration

Source: From Ref. 14.

### Primary

As the name suggests, primary ACS is an acute process with an intra-abdominal etiology. The majority of patients seen with ACS will fall into this category. In the trauma setting, hemorrhage (intra-abdominal, retroperitoneal, or pelvic) is the most common etiology. In the severely injured, this sets the stage for shock with massive resuscitation of crystalloid and blood products, which in turn leads to acidosis, hypothermia, and coagulopathy, also known as the “triarchy of death.” This is the setting in which trauma surgeons developed the concept of damage control surgery, as these patients are at very high risk of developing ACS. The abdomens of these patients are often edematous and unable to be closed without developing IAH; in this setting TAC should be employed. Indeed, every patient requiring an abbreviated or damage control laparotomy must be considered at increased risk of developing ACS. In a study examining patients who underwent damage control surgery, 37% subsequently developed ACS requiring decompression (16). This is significantly greater than the 2% incidence in all trauma patients admitted to the University of Miami ICU (15). This disparity underscores the reason why many consider the need for damage control surgery and the likelihood of developing of ACS linked. A prospective study examining the risk factors for developing ACS following trauma found that shock requiring significant crystalloid resuscitation, acidosis, hypothermia, and anemia were all independent predictors of primary ACS (Table 3) (17). Similarly, another study found that a protocol for supranormal resuscitation which required administration of larger quantities of crystalloid and blood products resulted in a higher than conventional resuscitation, and an increased incidence of IAH and ACS (18).

In the general surgery patient, a multitude of etiologies can lead to the development of ACS. Devastating intra-abdominal catastrophes are the most common cause (e.g., ruptured aortic aneurysm, significant intra-abdominal infection/peritonitis, severe pancreatitis, bowel obstruction). Similar to the trauma patient, many of these can be predicted at the primary laparotomy with the observation of visceral edema, and an abdomen that would be difficult to close, necessitating TAC. As in the trauma patient, when initial closure in a high-risk patient is possible, diligent re-evaluation is required to avoid missing the development of ACS.

### Secondary

Although occurring less frequently, ACS is also seen in the absence of abdominal trauma or pathology and is referred to as secondary ACS. A very common setting is the patient with significant extra-abdominal trauma or burns, requiring significant volumes of crystalloid and blood resuscitation, resulting in visceral and retroperitoneal edema and ascites (19,20). Studies examining this subgroup of acute ACS patients reveal that treatment with decompression reversed the immediate physiological consequences of IAH (21). However, Maxwell et al. (22) found the overall incidence of secondary ACS was 0.5% (6 in 1216 surgical ICU patients) with an overall mortality of 67%. While examined for mortality based on etiology, there was 38% mortality for trauma patients and 100% mortality for nontrauma patients with the development of secondary ACS (21). However, centers which use supranormal resuscitation [goal to maintain oxygen delivery index ( $\dot{D}O_2I$ )  $\geq 600$  mL/min m<sup>2</sup>] have shown that this results in a significantly increased incidence of IAH and ACS (18,23). This is because to achieve supranormal

**Table 3** Independent Predictors of Abdominal Compartment Syndrome in Trauma Patients During Initial Emergency Department Resuscitation and Subsequent 24 Hours in the Intensive Care Unit

ACS category	Emergency department		Intensive care unit	
	Independent predictor	Odds ratio	Independent predictor	Odds ratio
All ACS	Crystalloid $\geq 3$ L	23	GAP <sub>CO<sub>2</sub></sub> $\geq 16$	>999.9
	SBP < 86	4.9	Crystalloid $\geq 7.5$ L	166.2
			UO $\leq 150$ mL	89.8
1° ACS			Hb $\leq 8$ g/dL	252.5
	To OR $\leq 75$ min	102.7	CI $\leq 2.6$ L/min/m <sup>2</sup>	12.5
	Crystalloid $\geq 3$ L	69.8	GAP <sub>CO<sub>2</sub></sub> $\geq 16$	54.3
			Temperature $\leq 34^\circ\text{C}$	22.9
			Hb $\leq 8$ g/dL	206.1
2° ACS			BD $\geq 12$ meq/L	3.5
	Crystalloid $\geq 3$ L	15.8	GAP <sub>CO<sub>2</sub></sub> $\geq 16$	>999.9
	No urgent surgery	0.3	Crystalloid $\geq 7.5$ L	38.7
	PRBC $\geq 3$ units	5.6	UO $\leq 150$ mL	64.1

resuscitation, significantly greater volumes of crystalloid and blood resuscitation are required. In another study, independent predictors of secondary ACS were found to include significant crystalloid or blood requirement and shock, as measured by gastric tonometry (Table 3) (17).

### Chronic

With the increasing awareness of the effects and multifactorial prevalence of IAH, it was recognized that chronic conditions could produce IAH and in the proper setting ACS. Examples of conditions that can cause chronic IAH include morbid obesity, ascites, large abdominal tumors, peritoneal dialysis, and pregnancy. Chronic conditions result in slow increases in IAP which are compensated by increasing compliance of the abdominal wall (24). Therefore, these patients usually do not experience the acute deterioration seen with ACS. Despite this, chronic IAH is not benign, as some of the morbidity associated with these conditions is secondary to IAH. For example, some of the ventilatory dysfunction as well as pseudotumor cerebri seen in patients with morbid obesity have been linked to chronic elevation of IAP (25–27). Most importantly, some of these morbidities can be ameliorated by successful therapy (e.g., surgical treatment of morbid obesity, delivery of fetus) (6,28,29).

## DIAGNOSIS

### Clinical Features

Depending on the clinical scenario, the onset and presentation of IAH and ACS can range from insidious to expected. This means that diagnosis of ACS often requires a high index of suspicion, because if missed, the consequences can be disastrous, priming the patient for multiple organ failure or even death. Therefore, it would be beneficial to predict which patient is at a higher risk for the development of ACS. McNelis et al. (30) looked at a cohort of surgical ICU patients who developed ACS and found that using multivariate analysis only 24-hour fluid balance and an elevated peak airway pressure were correlated with the development of ACS. The elevated peak airway pressure is usually a side

effect and not the primary cause of ACS. However, a high peak airway pressure can contribute to IAH. A predictive equation was created to estimate the risk of ACS based upon the 24-hour fluid balance,  $P = 1/(1 + e^{-z})$ , where  $z = -6.7291 + 0.005$  (net 24-hr fluid balance). Looking at trauma patients, as they are at the highest risk of developing ACS, factors as early as three hours postinjury can predict the development of ACS (17). Independent predictors of ACS are listed in Table 3. Markers indicating a need for significant crystalloid resuscitation, hypoperfusion, and need for urgent/emergent surgery (more likely to be damage control) are seen as independent risk factors for the development of ACS.

In a patient with IAH progressing to ACS, the first signs are decreasing urinary output, respiratory failure, and decreased lung compliance, reflected as an elevation in peak airway pressure. However, even with this clinical suspicion, physical examination has a minimal role in the diagnosis of IAP or ACS, as studies looking at physical examination have shown poor sensitivities and specificities. Looking prospectively at abdominal girth, there is a poor correlation ( $R^2 = 0.12$ ) between abdominal girth and IAP (31). This is because there can be significant increase in IAP without significant changes in girth. Palpation of the abdomen has also been shown to have a sensitivity of 40% in diagnosing ACS (32,33). Therefore, when the possibility of IAH or ACS exists, “if you don’t measure IAP you cannot make a diagnosis of IAH or ACS” (34).

### Measurement of Intra-abdominal Pressure

✎ Because of the limitations of clinical examination in diagnosing ACS, measurement of IAP is essential to making the diagnosis. ✎ The abdomen is normally a compliant cavity with minimal pressure. Although overdistended, the compliance decreases and the abdomen becomes a fixed compartment which is relatively noncompressible. The contents of the abdomen can be considered fluid and therefore is subject to Pascal’s law (34). Therefore, IAP can be measured in almost every part of the abdomen, resulting in the myriad of techniques described for IAP measurement. Normally, IAP is equal to atmospheric or subatmospheric pressure with

spontaneous respiration (6,35). In a study examining hospitalized patients with indwelling bladder catheters, the mean IAP was 6.5 mmHg, with a range of 0.2–16.2 mmHg (35). With positive pressure ventilation, IAP is nearly equal to end expiratory pressure with positive end expiratory pressure (PEEP) (36).

### **Direct Intra-abdominal Catheter Placement**

Earlier experiments used either a metal cannula/wide-bore needle or catheter directly inserted into the peritoneal cavity connected to a pressure transducer for measurement of IAP (12,37). The only modern application of direct IAP measurement is that of real-time IAP measurement during laparoscopic surgery (38). The direct measures of IAP were largely abandoned in the mid-1980s, and replaced by indirect techniques once IAP measurements began to be obtained frequently for clinical purposes and used as a criterion for abdominal decompression (2).

### **Inferior Vena Cava Pressure**

A central venous catheter placed via the femoral route can be used to measure pressure in the inferior vena cava. This pressure has good correlation with IAP measured either by direct measurement or urinary bladder pressure (39,40). This method carries the risks of central venous catheters including thrombosis and infection. However to date, no human studies have validated its use prospectively in the setting of ACS.

### **Gastric Pressure**

Intragastric pressure can be used as a measure of IAP. A nasogastric or gastrostomy tube is placed and the stomach instilled with 50–100 mL of water. The proximal end is held perpendicular to the floor or attached to a pressure transducer with the mid-axillary line being used as the zero point (41). Alternatively, a balloon catheter can be placed on the tip of a nasogastric tube with measurement of the balloon pressure as a surrogate to IAP still using the mid-axillary line as a zero point (42). Human studies show correlation between gastric pressure and urinary bladder pressure. No large series have validated the use of this technique in the setting of a patient with suspected ACS. However, this may be a valid alternative for measurement of IAP in patients with bladder trauma in whom bladder distension may be contraindicated.

### **Urinary Bladder Pressure**

Despite the variety of methods described for measurement of IAP, the gold standard continues to be urinary bladder pressure. Originally described by Kron et al. (2), the urinary bladder pressure technique requires a supine patient with an indwelling Foley catheter (Fig. 1). After complete drainage of urine, the bladder is instilled with 50–100 mL of sterile saline to form a continuous column of fluid (without distending the bladder which might cause detrusor spasm). The tubing of the drainage bag is clamped and a 16-gauge needle is inserted through the aspiration port while connected to a pressure transducer or water manometer. The zero reference for the transducer is the pubis symphysis. Many variations on this original technique have been described to eliminate the need for a needle or repeated breaks of the sterile urinary drainage system; however, the basic principle of using a column of fluid to conduct intravesicular pressure which correlates to IAP

**Figure 1** Setup for measurement of urinary bladder pressure.

has not changed (43–46). Critics of this method cite the potential errors from using a fluid-filled transduction system, loss of accurate urinary output measurement, and the risks of infection by breaking a sterile system (34). Despite this, urinary bladder pressure has become the gold standard due to its relative ease of measurement, minimal invasiveness, reproducibility, and the wealth of literature validating its use.

### **Other Measurements of Intra-abdominal Pressure**

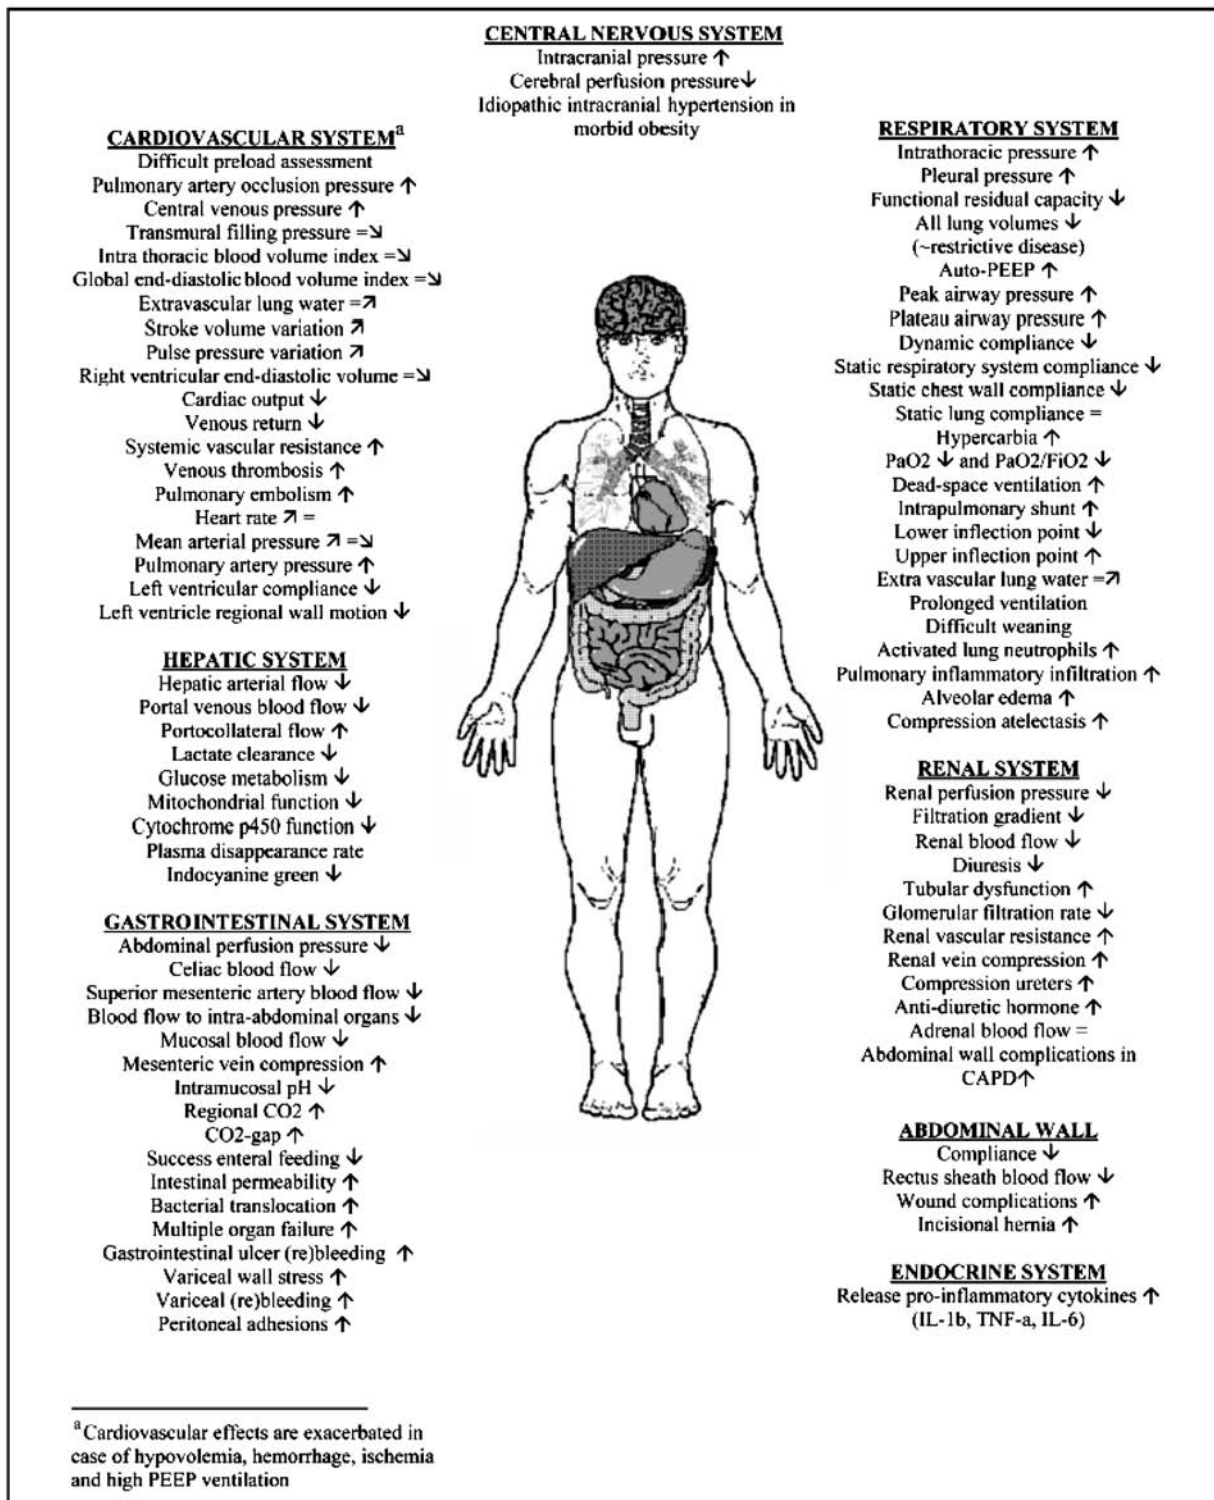

Literature describes the use of fluid balloons or open catheters with slow continuous flow for transduction of rectal or uterine pressures as a surrogate for measuring IAP (34,40,47,48). These are more difficult with no validation in the ICU setting and therefore have no clinical implications at this time. Work has also been done to evaluate microchip-tipped catheters as a source of continuous real-time IAP measurement which could be introduced by any of the above mentioned routes (49). Although this may be promising in the future, currently these catheters are expensive, not readily available, and have not been validated for use in the clinical arena.

## **PATHOPHYSIOLOGY**

The physiological consequences of IAH and ACS are almost as numerous as the etiologies which cause it. Renal dysfunction is the most common presentation, however the morbidity of ACS is not limited to intra-abdominal organs, and has the potential to effect nearly every major system. The pathophysiological implications of IAH/ACS on the most commonly impaired organ systems are summarized in Figure 2 (50). Most of the pathophysiological effects of ACS are reversible, making early diagnosis and prompt treatment imperative.

### **Renal**

The classical effect of IAH/ACS on the renal system is oliguria progressing to anuria with increasing IAP (39,51,52). An IAP of 15–20 mmHg may result in oliguria, while IAP greater than 30 mmHg can lead to anuria. The mechanism of renal dysfunction is multifactorial. ACS results in cardiovascular derangements including decreased cardiac output (Q) (as discussed subsequently), decreased renal arterial

**Figure 2** Pathophysiology of end-organ dysfunction secondary to intra-abdominal hypertension. *Abbreviations:* CAPD, long term ambulatory peritoneal dialysis; IL, interleukin; PEEP, positive end-expiratory pressure; TNF- $\alpha$ , tumor necrosis factor  $\alpha$ . *Source:* From Ref. 50.

flow, increased renal vascular resistance, decreased glomerular filtration, and compression of the renal vein (51,53,54). All these factors contribute to the pathophysiology because maintenance of a normal or supranormal  $\dot{Q}$  with resuscitation in the face of IAH, renal dysfunction persists, and

only corrects after abdominal decompression (39). In addition, the decreased glomerular filtration secondary to arterial, venous, and direct parenchymal compression results in the elaboration of antidiuretic hormone, rennin, and aldosterone. This compensatory endocrine response

further contributes to the clinical renal dysfunction in ACS (55). Compression of the ureter has been ruled out as a potential etiology as stenting of the ureters has not improved renal function (39,56).

### Pulmonary

☞ **The pulmonary dysfunction resulting from IAH is secondary to elevation of bilateral hemidiaphragms in response to the pressure (57).** ☞ This results in secondary compression atelectasis, creating a potential for pulmonary infections and barotrauma. However, more importantly, this results in a reduction in the pulmonary compliance with increasing peak inspiratory pressures seen in patients with volume control ventilation (58). This also results in a reduction of the functional residual capacity, total lung capacity, and residual volume (25,59). Similarly, patients receiving pressure control ventilation will have smaller tidal volumes generated by the same driving pressure. Studies have shown that the overall decreased compliance of the respiratory system is due primarily to decreased compliance of the thoracic cavity and not due to a change in the compliance of the lung itself (60). These changes manifest as hypoventilation, ventilation-perfusion mismatch, and eventual hypercarbia hypoxia (43,57,59). This also causes increased vascular resistance (61).

The elevated IAP results in a direct elevation of intrathoracic pressure (62). To counteract the effects, increased ventilatory pressures and specifically increased PEEP are required, exacerbating the increased intrathoracic pressures caused by the IAH (63). This can result in falsely elevated central venous pressure (CVP) and pulmonary capillary wedge pressures (PCWPs), parameters used for patient management, including determination of the onset of acute respiratory distress syndrome (ARDS). This pathophysiology complicates the standard treatment of ARDS which requires lung-protective strategies including decreased tidal volumes, and limiting peak and plateau inspiratory pressures (64). In patients with elevated intrathoracic pressures secondary to IAH, accurate determination of central pressures becomes increasingly difficult and therefore some have suggested subtracting the IAP from the inspiratory pressure as a better judge of therapy (50). All these effects are effectively treated with abdominal decompression.

### Cardiovascular

☞ **The primary cardiovascular derangement seen secondary to IAH is reduction of CO (36,39,59,62,65–67).** ☞ Multiple etiologies factor into this end result (including decreased preload and contractility with concomitant increased systemic and pulmonary vascular resistance). First, increased IAP causes decreased blood flow in the inferior vena cava and retroperitoneal veins (68,69). This decrease in flow can be seen with IAP of 15 mmHg but continues to decrease with increasing IAP. The area of maximal resistance to caval flow is at the IVC just below the diaphragm. It has been hypothesized that this is secondary to the transition between the high-pressure abdomen and the low-pressure thoracic cavity, as well as possible mechanical stretching of the diaphragmatic crura with protrusion secondary to IAH (68). This is attenuated by decreased venous return from the lower extremities secondary to IAH (70). This decreased venous outflow from the lower extremities can be overcome with the use of intermittent pneumatic compression devices during laparoscopic cholecystectomy (71). In addition, the secondarily increased intrathoracic pressure (i.e., elevated

diaphragms as described aforementioned) result in decreased flow in both the inferior and superior vena cava, thereby causing decreased cardiac preload.

The elevated intrathoracic pressures also result in decreasing ventricular compliance and stroke volume (59,72). At mild elevations of IAP, the heart is able to compensate with increasing rate (73). However, with increasing pressures, there is a concomitant increase in pulmonary vascular resistance (as discussed previously) as well as systemic vascular resistance (69). The exact etiology for the increased systemic vascular resistance is unclear, but it is likely the result of sympathetic stimulation resulting from the relatively low effective circulating blood volume. However, others have also postulated that it is secondary to direct arterial compression (as well as compression of many of the capillary beds) resulting from the increased intra-abdominal and intrathoracic pressures. In addition, IAH results in increased intracranial pressures (ICPs) (see subsequently), which cause the release of vasoconstricting agents such as vasopressin and catecholamines from the central nervous system in order to maintain cerebral perfusion pressure (CPP) by increasing systemic vascular resistance (74). The net result of this decreased preload, decreased cardiac compliance, and increased afterload is a marked reduction in  $\dot{Q}$  seen with increasing IAP, eventually leading to cardiovascular collapse as described by Emerson almost a century ago (4).

In the face of significantly increased IAP, false elevation of CVP and PCWP measurements are seen (57,59,62). When this is taken in context with decreased stroke volume and  $\dot{Q}$ , the clinical picture can resemble cardiac failure. However, the setting of increased inspiratory pressures and increased IAP measurements, the diagnosis of ACS can be surmised. Confirmation of intraventricular volume status and contractility is easily achieved with the use of transesophageal echocardiography.

In the early stages of IAH/ACS, the cardiovascular derangements can be overcome with fluid resuscitation, in contrast to congestive heart failure which can be exacerbated by this therapy (6). In a porcine model of IAH, intravascular volume depletion was seen secondary to prolonged (24-hour) IAH despite elevated CVP (75). Some authors have suggested using volumetric Swan-Ganz catheters to help guide resuscitation in this setting, as all pressure measurements are altered (76). All of these derangements are reversed with treatment of the elevated IAP.

### Hepatic

☞ **Diminished hepatic arterial, portal venous, and microcirculatory blood flow have all been associated with IAH (77).** ☞ When anesthetized pigs had IAP increased to 20 mmHg, despite constant  $\dot{Q}$  and mean arterial pressure, hepatic arterial flow was decreased by 55%, portal vein flow was decreased by 35%, and hepatic microcirculatory flow was decreased 29% compared to controls. Similar decreases in hepatic microcirculatory flow have been seen in patients undergoing laparoscopic cholecystectomy (78). Trauma patients may be at increased risk secondary to the alterations in visceral and portal blood flow occurring during shock (4). Although it is theorized that this in addition to the ischemia-reperfusion injury seen in treated ACS, results in a secondary decrease in hepatic function, commonly referred to as “shock” liver, detailed studies on the effects of ACS on hepatic dysfunction have not been published.

### Splanchnic

Similar to effects seen on the liver, kidney, and the inferior vena cava, the predominant effect of elevated IAP is that of decreased splanchnic perfusion. Splanchnic hypoperfusion can be seen with IAP as low as 15 mmHg, with case reports of intestinal ischemia requiring operative intervention after elective laparoscopy maintaining 15 mmHg pneumoperitoneum (79). This is a rare occurrence and has been hypothesized to require pre-existing vascular compromise to have this outcome. However, mesenteric arterial, intestinal mucosal, and portal venous blood flows have shown to be decreased with elevation of IAP. This can be measured in the clinical setting with gastric tonometry indicating decreased perfusion to the stomach, which has been described by many authors (80–83). One study showed that the decrease in gastric perfusion as inferred by gastric pHi was decreased earlier than the traditional signs of ACS (oliguria, increased peak inspiratory pressures) (84). This decreased gastrointestinal perfusion occurs independent of a decreased  $\dot{Q}$  as it can be shown to occur even when  $\dot{Q}$  is held constant (85). This is a factor to be considered in deliberating the creation of gastrointestinal anastomoses in patients at high risk of developing IAH and secondary complications of the anastomosis.

Elevated IAP has also been shown to increase portal venous pressure (77). This may be a contributing factor in the pathophysiology of esophageal varices in patients with liver failure. Increasing IAP by 10 mmHg resulted in an increase in variceal pressure, radius, volume, and wall tension. Therefore, the elevated IAP that many cirrhotics have secondary to ascites may be a causative factor in the development of variceal hemorrhage (86).

In animal models, there has been suggestion of increased incidence of bacterial translocation in rats as a result of IAH (87). However, this finding has not been reproduced in a larger porcine model (88). In addition, the decreased splanchnic perfusion and reperfusion injury has been shown to result in the production of cytokines from the gut (89). These may play a role in the development of septic complications and or subsequent systemic inflammatory response syndrome (SIRS) and multiple organ failure (Volume 2, Chapter 63).

### Central Nervous System

Although ACS does not cause central nervous system failure, there is a strong relationship between IAH and increased ICP with secondary reduction in CPP shown both in animal models (90–93) as well as humans (92,94). The proposed mechanism for this is the elevated intrathoracic pressures, which result from the IAH, mediated elevation of the diaphragms. The increased intrathoracic pressures, in turn, increase the jugular venous pressure and ICP. This is demonstrated in a porcine model when the effects of IAH on ICP are completely ameliorated by a sternotomy, thereby releasing increased intrathoracic pressure (91).

In humans, Citerio et al. (92) showed that inducing IAH by placing 15-L water bags on the abdomen of patients with moderate-to-severe head injury, a significant increase in intracranial and internal jugular pressures resulted. Patients with clinical ACS and elevated ICP have had correction of ICP with decompressive laparotomy (94). Therefore, monitoring of IAP is recommended in patients with neurotrauma and abdominal injury or reason to suspect IAH, with consideration to decompression in refractory elevation of ICP

(95). In addition, chronic IAH associated with morbid obesity has been implicated in intracranial hypertension and even the development of pseudotumor cerebri (28,94,96). In these cases, weight loss by bariatric surgery results in improvement in the chronic intracranial hypertension (28,94,96).

### Abdominal Wall

Increased IAP causes hypoperfusion of the abdominal wall secondary to a direct compressive effect. In a porcine model, Diebel et al. (97) showed decreased abdominal wall perfusion at all levels of IAH despite maintenance of constant  $\dot{Q}$  and blood pressure. This results in localized ischemia and reperfusion. This has been implied in the high rate of abdominal wound complications (infection, hernia, and dehiscence) in this population. In addition, similar increase in abdominal wall complications have been seen in patients with stable peritoneal dialysis with increased rates of leaks and hernias with increased IAP being an independent risk factor (98).

### Multiple Organ Dysfunction Syndrome

Studies have shown that ACS is an independent predictor for multiple organ dysfunction syndrome (MODS) and that prevention of ACS can decrease the incidence of MODS (17,99,100). In addition to the direct pressure-related effects of IAH on these organs, the process of ACS has been shown to prime the immune system as a result of activating neutrophils and increasing the elaboration of cytokines (89,101). This can set the stage for SIRS and subsequent MODS (Volume 2, Chapter 63) (100,101). In a porcine model, a modest elevation of IAP to 15 mmHg for only 24 hours has been shown to result in MODS (102). **☛ The priming of the immune system and the resultant enhanced inflammatory response may predispose patients with ACS to MODS even after abdominal decompression.** ☛ This may relate to ACS being one of the hits in the two-hit theory of multiple organ failure (99). Because of this, prevention of ACS is paramount in the treatment of the high-risk patient.

## TREATMENT

These diverse affects of ACS, although potentially life-threatening, can be abrogated with early recognition and appropriate treatment. Depending on the clinical scenario, the appropriate treatment strategy may entail resuscitation, minimally invasive decompression, surgical decompression, and the use of TAC as an initial potential preventative measure.

### Prevention

An ounce of prevention is worth a pound of cure. This is as true for ACS as it is for a compartment syndrome of the extremity. Similar to the patient with a significant vascular injury or long-bone fracture who should receive a prophylactic fasciotomy, a patient at high risk of developing IAH or ACS at the time of laparotomy, as is often seen in trauma patients requiring damage control surgery, it is best not to close the abdomen, but instead to treat with a prophylactic “open abdomen,” or TAC. This is the cornerstone of “damage control” trauma surgery. The classic presentation is the patient with severe injuries who is becoming hypothermic, coagulopathic, and acidotic, and requiring massive

resuscitation. Paradoxically, the fluid repletion needed to bring the patient back from the so-called “death spiral,” is the very thing that makes these patients at greatest risk for developing ACS (99,103). Therefore, damage control (Volume 1, Chapter 21) aims to abbreviate definitive control and usually incorporates a TAC both as prophylaxis for ACS as well as lessening operative time and allowing for more prompt return to the ICU for resuscitation.

Numerous TAC techniques have been described in the literature including towel clip closure, Bogota bag, mesh closure, and vacuum packs (104,105). The specific TAC used is less important than to understand and feel comfortable with at least one of these methods for surgeons who may potentially treat patients at risk for or with ACS. ✎ **When used in appropriately selected patients, the use of TAC can be effective in preventing the development of ACS (106).** ✎ Although level I data for improved survival is not available, case-control studies have shown that patients treated at initial laparotomy for potential ACS have a lower incidence of multiple organ failure and lower mortality as compared to those who develop ACS and require a second decompressive laparotomy (107,108). ✎ **When abdominal swelling continues following TAC, it is still possible to develop ACS despite the theoretical “open abdomen”;** therefore, in the setting of a patient with significant risk for developing ACS, regular IAP measurements should still be obtained (109). ✎

### Resuscitation

Although decompressive laparotomy is the gold standard for the treatment of patients with ACS, the exact IAP at which that is indicated is less clear. A grading system for IAH/ACS was proposed and prospectively evaluated by Meldrum et al. (14), and this is shown in Table 2. Grade I IAH usually requires no intervention and has subsequently been shown to be within the upper range of IAPs measured in “normal” hospitalized patients. Patients with grade II IAH may respond to hypervolemic resuscitation. Depending on the etiology in a given patient, this may be sufficient with careful observation and repeated measurement to track the trends of the IAP. However, as previously discussed, supranormal resuscitation can lead to visceral and retroperitoneal edema, thereby worsening IAH. In a study of trauma patients matched for severity of illness, the patients who progressed toward ACS did not respond to fluid loading and did not demonstrate a significant increase in  $\dot{Q}$  to crystalloid/colloid boluses (110). The conclusion of this study was that fluid resuscitation could not overcome impending ACS, much as fluid resuscitation, by itself, will not overcome cardiac tamponade. Other authors have argued that given the poor sensitivity of IAP to predict ACS, that a surrogate marker of abdominal perfusion pressure (APP), which is equal to IAP minus mean arterial pressure, be used to drive resuscitation. The argument being that APP is a measure of overall abdominal perfusion and therefore a better indicator of the end effects of IAH. They recommend that APP be maintained greater than 50 mmHg and that if this is not possible, decompressive laparotomy be performed (111). However, although this may be a useful guide, APP has not been validated in multiple trials. Therefore, the overall clinical picture (oliguria, increased peak inspiratory pressure, worsening of acidosis) and trends in the IAP should guide therapy rather than relying upon any single absolute number. There is a suggestion that abdominal muscular tone may play a role in elevating IAP, and therefore case report exists of the treatment of ACS with

neuromuscular blockade with resulting decreased IAP preventing the need in that patient for decompressive laparotomy (112). If in doubt, err toward decompressive laparotomy as it is the only therapy for all of the pathological consequences of elevated IAP.

## Abdominal Decompression

### Considerations Prior to Laparotomy

✎ **The mainstay of treatment of suspected or confirmed ACS is laparotomy with abdominal decompression and TAC.** ✎ Realizing that this may result in an initial drop in systemic and pulmonary vascular resistance as well as venous pooling prior to decompressing the abdomen, the patient’s intravascular volume should be restored and metabolic perturbations corrected (acidosis, hypothermia, coagulopathy) prior to decompression if at all possible. However, decompression should not be delayed if this is not easily achieved (65). Fluid resuscitation should be continued after decompression as an ischemia-reperfusion washout syndrome can occur with the possibility of instability, dysrhythmias, or cardiac arrest. Cases of asystole have been reported with an incidence as high as 12% in some series (113). Because of this, the authors recommend having a cardiac arrest cart at the bedside prior to undertaking decompression in patients with advanced (grade IV) ACS.

✎ **During mesenteric reperfusion immediately following abdominal decompression, a washout of the products of anaerobic metabolism occurs, and can lead to significant hypotension (113).** ✎ Because of this, preparation for abdominal decompression involves maneuvers similar to those taken immediately prior to aortic cross-clamp removal after aneurysm repair: (i) large-bore intravenous access; (ii) warm intravenous fluids infusing prior to decompression with availability of a rapid infuser; (iii) dopamine or other vasopressors prepared and in line (only to be used when intravascular volume replacement is inadequate to treat the hypotension resulting from reperfusion product-mediated venous pooling and decreased vascular resistance); (iv) prepare to compensate for the washout of lactate (and  $\text{CO}_2$ ) from the gut and lower extremities by temporarily increasing the overall minute ventilation; (v) because acidosis is anticipated, sodium bicarbonate should be immediately available if needed; (vi) calcium chloride 250–500 mg should be prophylactically administered immediately following decompression to protect against myocardial irritability from potassium washout during reperfusion, as well as to bolster the transient hypocalcemia associated with sodium bicarbonate administration. Morris et al. (114) recommend 2 L of normal saline, with 50 g mannitol and 50 meq sodium bicarbonate per liter intravenous fluids prior to decompression.

Fortunately, with abdominal decompression there is a sudden increase in pulmonary compliance with a resultant increase in tidal volume delivered to the patient. Although beneficial to blow-off  $\text{CO}_2$  in the severely debilitated patients with anticipated acid washout, this can eventually result in respiratory alkalosis after the acute decompression, and should be adjusted as needed, after stabilization.

The other consideration prior to decompression is whether the ACS is secondary to or associated with significant hemorrhage. The importance of this is determining the ideal location for abdominal decompression. Patients with full ACS are difficult to ventilate and unstable, making bedside ICU decompression an attractive option. However, recognizing that a significant portion of these patients will have significant hemorrhage especially in the

trauma setting, if the patient is stable for transport, decompression should be undertaken in the operating room. If the patient is unstable, bedside decompression can be performed, with operating room standby. If significant hemorrhage is encountered, temporary hemostasis is achieved with packing and following stability the patient is transported to the operating theater for definitive surgical hemostasis.

### Temporary Abdominal Closure

Once a decompressive laparotomy is performed, the question as to the ideal TAC arises. There is a wide variety of TAC described in the literature and a complete review of these is beyond the scope of this discussion. In brief, the goal is to open the fascia, releasing pressure, and allowing the intra-abdominal volume to expand into the new space, while still providing coverage of the bowel and abdominal contents preventing desiccation. The original TAC was the towel clip closure of the skin, however, this still limits the amount that the intra-abdominal compartment can expand and is therefore rarely used in cases of ACS (Fig. 3) today (115). **One of the easiest methods of achieving TAC is using the Bogota bag technique, a variation of the silos created by pediatric surgeons in the treatment of gastroschisis and omphaloceles.** First described by Londoni while he was a chief resident in Bogota, Colombia, this involves suturing a sterile plastic 3-L urologic irrigation bag to either the fascia or skin to allow visualization of the bowel as well as ample volume for the intra-abdominal contents to expand (Fig. 4) (116).

Recently, the vacuum pack closure has also gained popularity in which a polypropylene sheet is tucked into the abdomen on top of which a towel is tucked into the

**Figure 3** Towel clip closure of the abdomen. As the skin is still approximated, the increase in abdominal domain is modest.

**Figure 4** The “Bogota bag” method of temporary abdominal closure. A urological irrigation fluid bag is sutured to the skin and external drains are placed for control and quantification of leaking fluid or hemorrhage.

abdomen. This is covered with drains and sealed with plastic adhesive drape. The drains are then placed to continuous suction, allowing for an easily created TAC (117). A variety of commercial TAC devices are now available, including Velcro, zippers, vacuum-assisted devices, and others, but availability and experience with these are still institution dependent (118,119). The important point is that the surgeon is to be familiar and experienced with at least one of these techniques if the need for TAC arises. In the case of a patient with a TAC who develops ACS, abdominal reexploration with a wider/looser TAC is required (109).

Once a TAC or “open abdomen” is created, the goal is to correct the factors causing the ACS and closure of the abdomen. This requires correction of the initial disease process (coagulopathy, acidosis, etc.), and usually mobilization of visceral and abdominal wall edema to facilitate closure. Of note, all the open abdomen techniques result in colonization of the skin and open wound, and therefore if fascial closure is possible, the skin should be left open because of the high rate of wound complications if closed. If this is not possible in a single operation, staged procedures may be needed with gradual approximation of the abdominal fascia. In some patients, fascial closure is impossible, necessitating closure with absorbable mesh with eventual skin graft to create a controlled ventral hernia (Figs. 5 and 6). These patients will eventually require abdominal wall reconstruction six months to a year after all the inflammation has resolved and the intra-abdominal adhesions are remodeling (120).

### Percutaneous/Laparoscopy

Although the gold standard for the treatment of ACS is decompressive laparotomy, in selected circumstances a less invasive method may be adequate. The most common circumstance in which a percutaneous approach may be a viable option is that of ACS secondary to ascites or a large loculated fluid collection (121,122). In cases of ascites secondary to hepatic failure, this is the preferred method as a laparotomy carries a risk of a persistent ascites leak. In addition, there are reports of using percutaneous decompression in cases of 2° ACS with significant ascites in burn patients and trauma patients, although there is some data to suggest that this is less effective in patients with >80% total body surface area

**Figure 5** In cases where primary closure of the fascia is not possible at reoperation, temporary abdominal closure is accomplished using an absorbable mesh fascial closure. This allows coverage and the formation of granulation tissue to occur over the bowel and omentum.

(TBSA) burns (123–125). Even in the setting of secondary ACS secondary to burn, the frequency of being able to treat with percutaneous techniques is limited. In a retrospective review of 1014 consecutive burn patients, 10 developed ACS requiring surgical interventions, only two cases (both with isolated ascites) were amenable to percutaneous drainage (19). Case reports also exist of the use of laparoscopy or percutaneous drainage for the treatment of ACS secondary to blunt hepatic trauma (126,127). This should only be used in cases of isolated injury where ACS is secondary to hemoperitoneum

**Figure 6** Once adequate granulation has occurred with an absorbable mesh closure, the mesh is removed and the abdomen is “closed” with a split thickness skin graft to create a controlled ventral hernia.

without edematous bowel from resuscitation; and therefore application of this technique is limited. If one of these minimally invasive methods fails to correct the IAH, then decompressive laparotomy should naturally be performed.

## EYE TO THE FUTURE

In the future, real-time IAP measurement may be possible using microchip-tipped catheters allowing earlier diagnosis and treatment of IAH or impending ACS in high-risk patients rather than intermittent bladder pressure (34). The future of ACS therapy will be in prevention rather than treatment. Once ACS has occurred, significant mortality results, and therefore the optimal goal will be prevention by better predictive models and prophylactic decompressive celiotomy before the onset. In addition, improved resuscitative techniques and modalities (i.e., synthetic blood substitutes) may reduce the amount of crystalloid needed and therefore the incidence of ACS (128,129). Once ACS has set in, work in animal models using pharmacological therapy with either octreotide or vasopressin is showing potential for being able to attenuate the effects of the ischemia/reperfusion after abdominal decompression, and therefore potentially decreasing the incidence of MODS and mortality (130,131). Finally, improvements in the management of open abdomens may result in fewer patients requiring a planned ventral hernia and delayed abdominal reconstructions (132).

## SUMMARY

IAH and ACS are relatively common phenomena with a wide range of etiologies. Given the often subtle and insidious onset, and the potentially grave consequence when the diagnosis/treatment is delayed or missed, a high index of suspicion is required. If the possibility of IAH is entertained, IAP must be measured, as objective measurement is the only method to diagnose or rule out ACS. The result of IAH is seen most readily in the renal and respiratory systems, however, almost every organ system can be affected. In trauma or other patients at high risk for developing ACS on the basis of perioperative findings, the best treatment is the use of a TAC to decrease the incidence (if not completely prevent) the development of ACS. If ACS develops, prompt treatment with decompression will afford the best therapy with resolution of cardiovascular, pulmonary, and renal derangements, although the stage may be set for subsequent multiple organ failure.

## KEY POINTS

- 🐍 Because of the numerous etiologies, a high index of suspicion is required to consider the diagnosis of ACS.
- 🐍 Because of the limitations of clinical examination in diagnosing ACS, measurement of IAP is essential to making the diagnosis.
- 🐍 Despite the variety of methods described for measurement of IAP, the gold standard continues to be urinary bladder pressure.
- 🐍 Renal dysfunction is the most common presentation, however, the morbidity of ACS is not limited to intra-abdominal organs, and has the potential to effect nearly every major system.

- ✂ Most of the pathophysiologic effects of ACS are reversible, making early diagnosis and prompt treatment imperative.
- ✂ An IAP of 15–20 mmHg may result in oliguria, while IAP greater than 30 mmHg can lead to anuria.
- ✂ The pulmonary dysfunction resulting from IAH is secondary to elevation of bilateral hemidiaphragms in response to the pressure (57).
- ✂ The primary cardiovascular derangement seen secondary to IAH is reduction of Q.
- ✂ Diminished hepatic arterial, portal venous, and microcirculatory blood flow have all been associated with IAH.
- ✂ The priming of the immune system and the resultant enhanced inflammatory response may predispose patients with ACS to MODS even after abdominal decompression.
- ✂ When used in appropriately selected patients, the use of TAC can be effective in preventing the development of ACS.
- ✂ When abdominal swelling continues following TAC, it is still possible to develop ACS despite the theoretical “open abdomen”; therefore, in the setting of a patient with significant risk for developing ACS, regular IAP measurements should still be obtained.
- ✂ The mainstay of treatment of suspected or confirmed ACS is laparotomy with abdominal decompression and TAC.
- ✂ During mesenteric reperfusion immediately following abdominal decompression, a washout of the products of anaerobic metabolism occurs, and can lead to significant hypotension (113).
- ✂ One of the easiest methods of achieving TAC is using the Bogota bag technique, a variation of the silos created by pediatric surgeons in the treatment of gastroschisis and omphaloceles.

## Liver Dysfunction in the Previously Well Patient

Joel R. Peerless

Department of Surgical Critical Care, MetroHealth Medical Center, Case Western Reserve University, Cleveland, Ohio, U.S.A.

### INTRODUCTION

The hepatobiliary system plays a major role in energy metabolism, bilirubin metabolism, coagulation, digestion, and the immune response. The liver receives a large portion of the cardiac output and, as such, critically ill patients with any combination of trauma, hemodynamic instability, and sepsis are subject to hepatic dysfunction. Most critically ill patients are administered multiple medications which may affect hepatic function, and hepatic dysfunction may require alterations in drug dosing. Knowledge of the etiologies of hepatic dysfunction, hepatic function in disease states, and alterations in drug metabolism in the critically ill patient will aid the clinician in the generalized support of the critically ill patient with hepatic dysfunction.

### OVERVIEW OF NORMAL HEPATIC ANATOMY

#### Hepatic Anatomy and Blood Supply

The liver weighs approximately 1500 g, is enclosed within a fibrous sheath (Glisson's capsule), and is located in the right upper quadrant of the abdomen. The upper border of the liver lies approximately at the level of the nipples. The lower border corresponds to the costal cartilage of the right ninth and left eighth ribs.

The liver receives approximately 25% of the total cardiac output. The blood supply to the liver is situated to process, modify, and detoxify nutrients and metabolic fuels from the intestinal lumen (1). Blood supply to the liver is derived from two sources, the portal vein and the hepatic artery. Blood in the portal vein drains blood from the digestive tract between the proximal stomach to the upper rectum, spleen, pancreas, and gall bladder (2,3). The portal vein accounts for 75% of the total hepatic blood flow (1–4).

The common hepatic artery is one of three major branches of the celiac axis, and provides branches to the gall bladder via the cystic arteries (2,3). Although the hepatic artery accounts for only 25% of hepatic blood flow, it provides 50% of the oxygen requirements to the hepatocytes, and hepatic arterial flow may become predominant in a cirrhotic liver with decreased portal vein perfusion (2,3). Hepatic collateral circulation can be dilated in cases of cirrhosis or thrombosis of portal or hepatic veins. The most common sites of increased collateral portal circulation are the submucosal vessels of the esophagus and stomach (Fig. 1).

#### Hepatic Microcirculation

Hepatocytes are polyhedral cells with a central spherical nucleus, arranged in plates one cell in thickness with blood-filled sinusoids on each side of the plates (2,3). Hepatocytes comprise 65% of the cells in the liver, have specialized oxidative activities, and are spatially arranged to achieve these functions (2,3).

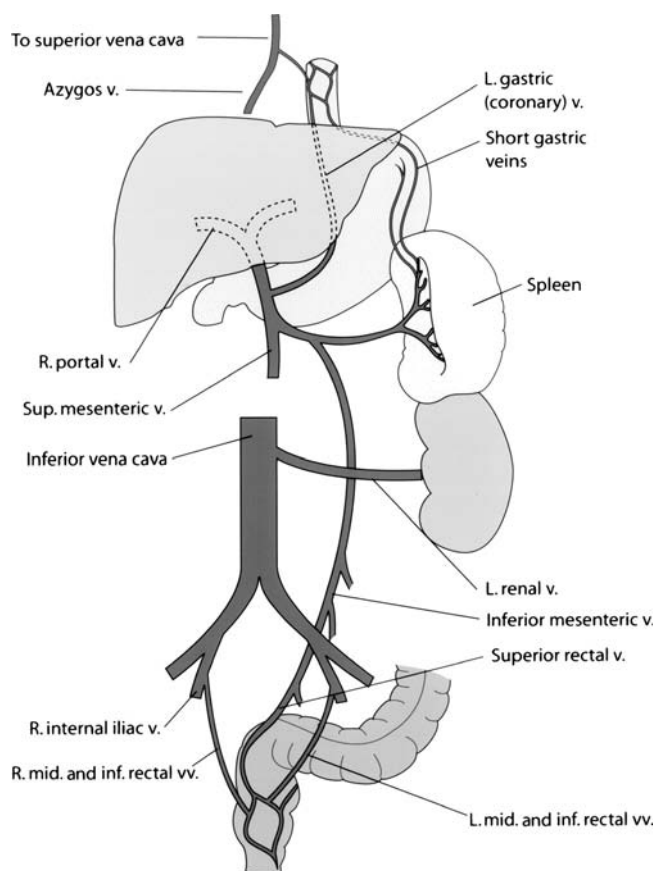

The liver is classically divided into lobules (1–2 mm hexagons) oriented around a central vein (the terminal hepatic vein) which drains into the hepatic vein. At every other apex of the hexagonal lobule is a portal triad, which includes a bile duct, a branch of the hepatic artery, and a branch of the portal vein. The portal venous blood and the hepatic arterial blood mix and bathe the hepatocytes via sinusoids.

Sinusoids are the major site for blood-flow regulation, hepatic capacitance, and solute exchange between blood and hepatocyte (4). The flow of mixed portal vein blood and hepatic arterial blood is in the opposite direction of the bile formation. The hepatic sinusoids eventually empty into the terminal hepatic venule. Hepatic sinusoids are fenestrated with scanty subendothelial stromal material, permitting passage of large macromolecules (2,3). Sinusoids bridge the gap between terminal portal venules (inflow) and hepatic venules (outflow) (2–4). This low-pressure system results in a constant, sluggish blood flow through the sinusoids (2,3).

The three-dimensional organization of the functional liver anatomy can be further described by the Acinar model, in which hepatocytes surround a terminal central hepatic vein which forms the pericentral zone (Fig. 2) (2,3). Pericentral hepatocytes differ from the hepatocytes that surround the central vein in synthetic capabilities, enzymes, and susceptibility to liver injury (Fig. 3) (2,3). Hepatocytes that are further away from the portal blood supply are more prone to hypoxic effects of ischemia and react differently to toxin exposure. ⚡ **The geographic position of hepatocytes and their exposure to gradients of nutrients and waste products leads to location-related variations in susceptibility to ischemia and drug toxicity (2).** ⚡

#### Biliary System

Bile drains from each hepatic segment through bile canaliculi, to small hepatic ducts, to right and left hepatic ducts, which eventually form a common hepatic duct (Fig. 4). The common hepatic duct joins with the cystic duct to form the common bile duct (CBD) emptying into the duodenum via the ampulla of Vater. The function of the gall bladder is to concentrate and store bile during fasting; and

**Figure 1** Diagram of the portal circulation. The most important sites for the potential development of portosystemic collateral vessels involve the areas where systemic veins join the portal system. (i) Esophageal submucosal veins, supplied by the left gastric vein and draining into the superior vena cava through the azygos vein. (ii) Paraumbilical veins, supplied by the umbilical portion of the left portal vein and draining into abdominal wall veins near the umbilicus (not shown). These veins may form a caput medusa at the umbilicus. (iii) Rectal submucosal veins, supplied by the inferior mesenteric vein through the superior rectal vein and draining into the internal iliac veins through the middle rectal veins. (iv) Splenorenal shunts: created spontaneously or surgically. (v) Short gastric veins communicate with the esophageal plexus. *Source:* From Ref. 84.

having a volume of 30–70 mL may add this stored bile following a large fatty meal (1).

## NORMAL HEPATIC FUNCTION

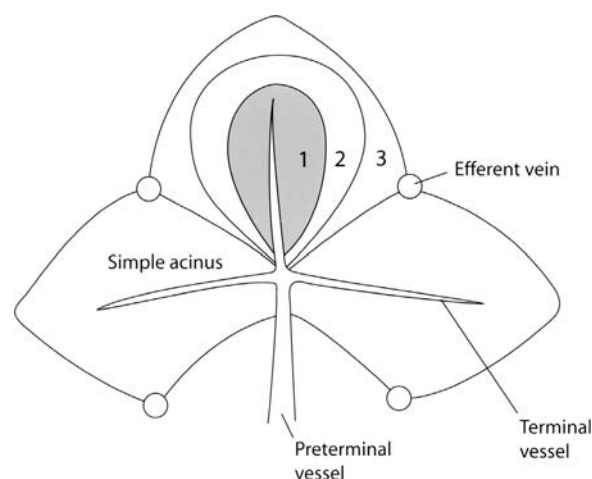

### Energy Metabolism

#### Carbohydrate Metabolism

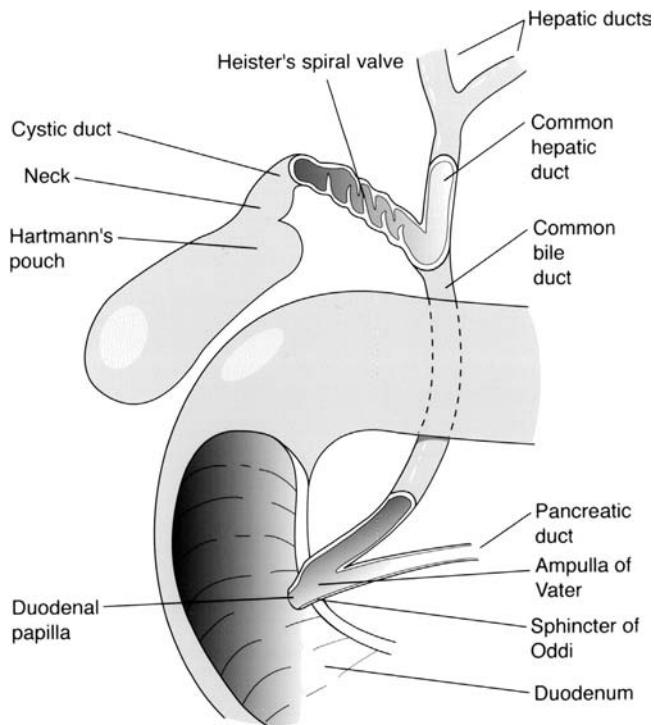

The liver is responsible for maintenance of normal glucose levels through regulation of glycogenolysis and gluconeogenesis (5). In the fed state, glucose is stored as glycogen or converted to fatty acids that are then stored in adipose tissue (5). Hepatic glycogen is the main storage site for glucose-dependent organs [brain, red blood cells (RBCs), retina, and renal medulla] (1). The normal liver has a 24- to 48-hour supply of glycogen. Alcoholics and malnourished patients have little or no stored glycogen and are more

**Figure 2** Three-dimensional architectural drawing of the normal human liver. The major components of the portal tract (or canal) include a branch of the portal vein, a hepatic arteriole, a bile duct, and some lymphatics (not shown). Also shown in the figure are cholangioles that carry bile from the canaliculi to the bile duct (listed as lymphatic). The hepatic arterial blood empties into the interlobular sinusoids mixing with the portal venous blood which enters the sinusoids via inlet venules. This nutrient-rich blood eventually empties into the central hepatic veins. The perisinusoidal space of Disse separates the sinusoidal blood from the hepatocytes. The hepatocytes empty their bile on the opposite side of their cells into the bile canaliculi. *Source:* From Ref. 85.

**Figure 3** The complex acinar structure as conceived by Rappaport. The preterminal vessel is the proximal portion of the mixed hepatic arterial and portal venous sinusoidal blood, and the terminal portion is the distal end. The terminal hepatic venule is labeled as efferent vein. The margins of the shaded zones represent planes of equal blood pressure (isobars), oxygen content, or other characteristics. Periportal tissue (zone 1) receives blood that is higher in oxygen content than perivenular (zone 3) tissue. The acinus is bulb shaped, and the classic lobule is composed of several wedge-shaped portions, (called primary lobule, not indicated). The hepatic microcirculatory subunit is the smallest functional unit in which there is the potential for countercurrent flow. *Source:* From Ref. 85.

**Figure 4** Gallbladder and biliary system. The right and left hepatic ducts coalesce to form the common hepatic duct which can empty into the CBD or into the cystic duct for storage in the gallbladder for later use. The CBD joins the pancreatic duct at the ampulla of Vater and empties into the duodenum via the duodenal papilla. This anatomy explains why the passage of gall stones can either cause obstruction of the CBD and result in dilation of intrahepatic ducts (causing cholestatic jaundice), or obstruct pancreatic exocrine function resulting in gall stone pancreatitis. When the stone is only obstructing the cystic duct (simple cholelithiasis), the patient may complain of pain, and could later develop secondary infection related to the obstruction, but will not necessarily have an elevation of either bilirubin levels or pancreatic enzymes. *Abbreviation:* CBD, common bile duct. *Source:* From Ref. 85.

prone to hypoglycemia. Insulin stimulates the formation of glycogen and inhibits gluconeogenesis (5). Glycogenolysis and gluconeogenesis are stimulated by glucagon and epinephrine. Precursors for glucose formation are lactate, pyruvate, and amino acids (1,2).

### Lipid Metabolism

The liver plays a central role in fatty acid metabolism (1). Oxidation of fatty acids to carbon dioxide and water yields the highest production of adenosine triphosphate (1). In the fed state, the liver esterifies fatty acids to triglycerides and other esters, which provide energy for the liver. In the fasting state, fatty acid synthesis is inhibited. Obesity, diabetes mellitus, corticosteroid therapy, and ethanol ingestion can result in fatty liver, an excess accumulation of triglyceride. Alcoholic ketosis occurs secondary to ethanol or acetaldehyde-mediated impairment of fatty acid oxidation (5).

### Amino Acid and Protein Metabolism

The liver is the major site for the synthesis of proteins involved in coagulation, transport, and acute phase reactants. Plasma protein synthesis accounts for 80% of all

hepatic protein synthesis, and is regulated by multiple factors, including availability of nutritional components, genetic determinants, drugs, toxins, as well as the presence of inflammatory or catabolic states (5). ⚡ **Acute hepatic disease will have a greater effect on proteins with rapid turnover (i.e., coagulation factors) than those that turn over more slowly, such as albumin (5).** ⚡

### Bilirubin Metabolism

Almost 70% of bilirubin is derived from the heme moiety of hemoglobin from erythrocytes sequestered in the spleen, liver, and bone marrow. The remaining bilirubin results from the breakdown of nonhemoglobin protein, cytochrome P-450, in the liver. Unconjugated bilirubin is water insoluble, highly bound to albumin, and not excreted in the urine. Following transport to the liver, carrier proteins mediate passage through large fenestrations in the cells of the sinusoidal lining and contact the hepatocyte plasma membrane. Bilirubin is conjugated with glucuronic acid, becoming water soluble, and secreted into the bile canaliculus. Serum bilirubin is normally at least 70% conjugated (Fig. 5) (4–8).

### Bile Formation

Bile is composed of conjugated bile acids, cholesterol, phospholipids, and protein. In the initial formation of bile, bile acids and bilirubin are taken up at the sinusoidal membrane (4). Bile is formed at a rate of 0.42 mL/min (4). Eighty percent of bile is secreted by hepatocytes and 20% by the bile duct epithelial cells (4). Inhibition of the sphincter of Oddi by cholecystikinin stimulates expulsion of preformed bile into the duodenum (1,4).

The formation of bile is a high-energy expenditure process. To conserve energy and maintain the large stores of bile required for digestive purposes, an enterohepatic circulation recirculates bile 6 to 15 times per day (4). Active secretion of bile salts across the canalicular membrane is the primary metabolic pump of the enterohepatic circulation (4). Malfunction of the enterohepatic circulation leads to a decreased bile acid pool, which predisposes to gall stone formation (4).

### Vitamin Metabolism

The liver is vital to the uptake, storage, and mobilization of many vitamins. Bile salts are required for absorption of the fat-soluble vitamins A, D, E, and K. Vitamin D conversion to 25-hydroxycalciferol, the first step of vitamin D activation, occurs in the liver (4). Vitamin K is essential for the activation of the coagulation factors II, VII, IX, and X (4).

## BIOCHEMICAL EVALUATION OF HEPATIC DYSFUNCTION

The liver is one of the most frequently damaged organs in the body, but also has one of the greatest regenerative capacities, and has enormous functional reserve. Only 10% of hepatic parenchyma is required for normal liver function. Thus, evidence of liver injury does not necessarily mean that hepatic dysfunction is occurring.

The most common method of assessing hepatic health is to obtain a measure of liver function tests (LFTs). The common LFTs include hepatic enzymes called bilirubin. When liver injury occurs, hepatic enzymes leak into the circulation, and bilirubin levels increase. An additional

**Figure 5** Schematic diagram summarizing the structural and biochemical pathways involved in bilirubin metabolism. During its carriage in the plasma, bilirubin is strongly, but reversibly bound to albumin. In hepatic sinusoids, this complex comes in direct contact with the basolateral domain of the hepatocyte plasma membrane through fenestrae of the specialized hepatic endothelial cells. At the hepatocyte surface, dissociation of the albumin-bilirubin complex occurs, and bilirubin enters hepatocytes by a specific uptake mechanism. A fraction of the bilirubin is also derived from catabolism of hepatocellular heme proteins. Storage within the hepatocyte is accomplished by binding of bilirubin to a group of cytosolic proteins, glutathione-S-transferases (GSTs) (also termed ligandin or Y-protein). Binding to these proteins keeps bilirubin in solution and inhibits its efflux from the cell, thereby increasing the net uptake. Conjugation of bilirubin in the endoplasmic reticulum is catalyzed by bilirubin-UDP-glucuronosyltransferase, forming bilirubin monoglucuronide and diglucuronide. Both conjugates may bind to GSTs in the cytosol. Conjugation is obligatory for efficient transport across the bile canaliculus. This process is normally rate-limiting in bilirubin throughput, and is shared by other organic anions, but not bile salts. *Source:* From Ref. 85.

measure of liver function is provided by assessing the synthetic function of the liver (e.g., albumin, prealbumin, and coagulation factors). These various methods of evaluating liver injury and viability with biochemical measurements will be reviewed in the following sections.

## Hepatic Enzymes

### Aminotransferases

The aminotransferases, aspartate aminotransferase (AST, formerly serum glutamic oxaloacetic transaminase), and alanine aminotransferase (ALT, formerly serum glutamic pyruvic transaminase) measure liver injury (Table 1). While ALT is relatively specific to the liver, AST is found in the liver as well as skeletal and cardiac muscle, kidney, brain, pancreas, and blood (7). Absolute elevations of AST and ALT reflect leakage from damaged liver cells (7), as well as the early phase of acute biliary obstruction (8).

The level of elevation of aminotransferases may be an indication of the etiology of hepatic dysfunction. ALT and AST levels less than 300 IU/L are seen in alcoholic hepatitis and biliary obstruction. Patients with advanced cirrhosis may have normal or near normal levels of aminotransferases (7).

Mild to moderate elevations of aminotransferases (250–1000 IU/L) are seen with viral infection, drug-induced hepatitis, nonsteroidal antiinflammatory agents, cocaine, modest hepatic inflammation, steatosis, drugs, alcohol, chronic viral hepatitis, and cirrhosis (7). **Aminotransferase levels of greater than 1000 IU/L are almost always due to hepatocellular injury, and can be seen with drug- and or toxin-induced hepatic injury, and acute viral hepatitis (7).**

The level of elevation of aminotransferases correlates poorly with the extent of necrosis, and is not predictive of outcome (7,8). Aminotransferase levels may fall during the course of massive hepatic necrosis, and a rapid fall in enzyme levels in combination with a rising bilirubin and prolonged prothrombin time may portend a poor prognosis (7,8).

**In most hepatic injuries, the ratio of AST to ALT is usually 1:1; however, ratios of 2:1 or greater are common in alcoholic hepatitis.** A high AST to ALT ratio in the absence of alcohol abuse may represent cirrhosis (7).

### Alkaline Phosphatase

Alkaline phosphatase (AP) is present mostly in liver and bone. Hepatic AP is present in the hepatocyte plasma membrane and the lumen of the bile duct epithelium (7). Elevations of AP are secondary to increased synthesis and release of enzyme into the circulation (7). Hepatocyte plasma membranes are solubilized by bile acids, which are retained in settings of cholestasis. The retention of bile acids facilitates the release of AP, thus the rise of AP after acute biliary obstruction (7). Because elevations of AP require synthesis of new enzymes, AP may not increase for one to two days after biliary obstruction (7). The half-life of AP is approximately one week, thus levels may remain elevated for days to weeks after resolution of biliary obstruction (8).

Levels of AP of 3 to 10 times normal are seen in both intrahepatic and extrahepatic obstruction of bile flow. Slight to moderate increases in AP may be seen in hepatitis and cirrhosis. Higher levels may be seen with infiltrative hepatic disorders secondary to intrahepatic bile duct compression (7,8). Severe bacterial infection is also associated with an isolated rise in AP (7).

### Lactate Dehydrogenase

Elevations of lactate dehydrogenase (LDH) are seen in many different tissue injuries, including skeletal and cardiac muscle, hemolysis, stroke, and renal infarct. LDH is especially high in ischemic hepatitis. A sustained elevation of LDH with AP is indicative of malignant infiltration of the liver (7).

### Gamma-Glutamyl Transpeptidase

Gamma-glutamyl transpeptidase (GGTP) is present in many tissues, but not in bone, and thus may be useful in confirming hepatic elevations of AP (7,8). GGTP is inducible by alcohol, and thus may be useful in detecting alcohol abuse. GGTP is also elevated in biliary obstruction, but is not as sensitive for obstruction as 5'-nucleotidase (NT).

**Table 1** Biochemical Liver Function Tests

Test/basis of abnormality	Normal range	Level of elevation	Extrahepatic sources
Aminotransferases/leakage from damaged tissue	AST 10–40 U/L	Modest—many types of hepatic disease	ALT—relatively specific for hepatocellular necrosis AST—skeletal and cardiac muscle; kidney, brain, pancreas, RBCs
	ALT 10–55 U/L	Marked—hepatitis (ischemic, viral, toxic)	
AP/Overproduction and leakage into serum	45–115 U/L	Levels <300 U/L with AST:ALT ratio >2:1—alcoholic hepatitis, cirrhosis	Bone growth or disease (tumor, fracture, Paget’s disease); placenta, intestine, tumors
		Modest—many types of hepatic disease Marked—extra and intrahepatic cholestasis, diffuse infiltrating disease (tumor); occasional alcoholic hepatitis	
Gammaglutamyl transpeptidase/overproduction and leakage into serum	0–30 U/L	Same as AP Induced by ethanol, drugs GGTP:AP ratio >2.5 suggestive of alcoholic liver disease	Kidney, spleen, pancreas, heart, lung, brain
5’NT/overproduction and leakage into serum	0–11 U/L	Same as AP	Relatively specific for liver disease
Bilirubin/decreased hepatic clearance	0–1.0 mg/dL	Modest—many types of hepatic disease	Increased breakdown of hemoglobin
	0–17 μmol/L	Marked—extra and intrahepatic cholestasis; alcoholic, drug-induced or viral hepatitis	
Prothrombin time/decreased synthetic activity	10.9–12.5 sec	Acute or chronic liver failure (unresponsive to vitamin K) Biliary obstruction (responsive to vitamin K)	Vitamin K deficiency (malabsorption, malnutrition, antibiotics); consumptive coagulopathy
Albumin/decreased synthetic activity; increased catabolism	4.0–6.0 g/dL	Chronic liver failure	Decreased in nephrotic syndrome, protein losing enteropathy, vascular leak, malnutrition, malignancy, inflammatory states

*Abbreviations:* AST, aspartate aminotransferase; ALT, alanine aminotransferase; RBC, red blood cells; GGTP, gamma-glutamyl transpeptidase; AP, alkaline phosphatase; 5’NT, 5’-nucleotidase.

*Source:* From Ref. 1, p. 1127.

### 5’-Nucleotidase

5’-NT is present in small quantities in numerous organs, but is only present in high concentrations in liver tissue (7,8). The enzyme is located in the hepatocyte sinusoidal and canalicular bile membranes and may reflect bile obstruction (7,8). Because 5’-NT is predominantly located in or near the bile canalicular membrane, its elevation is more specific for biliary obstruction than either AP or GGTP, both of which are diffusely distributed throughout the liver.

### Bilirubin

#### Normal Serum Bilirubin Levels (in Health)

Bilirubin results from the metabolism of the porphyrin ring component of heme-containing proteins (chiefly hemoglobin and myoglobin). Bilirubin exists in the blood in

two forms, conjugated (water soluble) and unconjugated (water insoluble, bound to albumin). Most clinical labs use the Van den Bergh assay to determine the conjugated “direct” reacting component (reacts prior to addition of alcohol) and the total bilirubin (the amount that reacts after the addition of alcohol). The indirect amount is the total minus the direct, and correlates with the unconjugated portion. ⚡ **Normally, the total bilirubin is less than 1 mg/dL, and at least 70% is conjugated (direct reacting).** ⚡ The rate-limiting step in bilirubin metabolism is not conjugation (a property which remains intact even with severe liver disease). Rather, transport of conjugated bilirubin into the bile canaliculi is the rate limiting step, explaining why elevated bilirubin is seen in all forms of acute liver disease including that due to ischemia and shock liver.

## **Causes of Hyperbilirubinemia (Jaundice)**

### **Overproduction of Bilirubin**

In the trauma patient, the administration of multiple blood transfusions may result in a bilirubin load that overwhelms the conjugation and excretory capacity of the liver (9,10). In an effort to rotate stocks of packed RBCs, those first released from the blood bank are usually the oldest ones on the shelf. These older, more fragile RBCs lyse quickly within the reticuloendothelial system, and the resultant increase in unconjugated bilirubin is analogous to any other source of hemolytic anemia. The normal rate of bilirubin production is approximately 250–300 mg/day, an amount equal to a 500 mL transfusion of RBCs.

Resorption of hematomas is another common cause of unconjugated hyperbilirubinemia, in patients with major trauma or those undergoing major aortic procedures (7,10). Drug-induced or immune-mediated hemolysis, mechanical damage to RBCs (mechanical heart valves), or hemoglobinopathies (sickle cell anemia) may also result in overproduction of bilirubin (7,9,10). The inability to respond to an increased bilirubin load is accentuated with underlying liver disease or acute ischemic injury (9).

### **Acute Hepatocellular Injury**

Acute hepatocellular injury may occur secondary to hypoperfusion, ischemia, iatrogenic injury to blood vessels of the liver, following toxic exposure (acetaminophen, Amanita phalloides) and to many classes of medications (10). Conjugated hyperbilirubinemia results from impaired hepatic excretion and regurgitation of bilirubin from hepatocytes into the serum. However, in the setting of “ischemic hepatitis” or “shock liver,” the predominant picture is hepatocellular necrosis, with extremely high enzyme elevations.

### **Cholestasis**

Cholestasis describes any disturbance of the bile secretory process (extrahepatic or intrahepatic). Extrahepatic refers to an obstruction at the bile duct level. Obstruction may occur from cholelithiasis, inflammatory processes, or extraluminal compression (11,12). Intrahepatic cholestasis is more common than extrahepatic in the trauma and critical care setting. Intrahepatic cholestasis is sometimes referred to as benign postoperative jaundice, and may be secondary to prolonged hypotension and multiple blood transfusions among other causes. Intrahepatic inflammatory disorders such as sepsis, primary biliary cirrhosis, infiltrative or granulomatous disease, drug toxicity, and viral or alcoholic hepatitis may result in cholestasis (11,12).

Serum bilirubin can be elevated as high as 40 mg/dL in cholestasis (10). AP levels are elevated; however, aminotransferase levels, prothrombin time, and albumin levels are not initially altered in pure cholestasis. Although this process is usually self-limited, patients can progress to sepsis and multiorgan failure (10). In prolonged cholestasis, the delta fraction of circulating conjugated bilirubin is tightly bound to albumin, and may account for the prolonged resolution of bilirubin when other parameters are improving (7).

## **Tests of Hepatic Synthetic Function**

### **Albumin and Prealbumin**

Albumin is the predominant serum binding protein with a half-life of approximately three weeks (2,8). Production is 100–200 mg/kg/day, and is influenced by nutritional state, the presence of systemic disease, toxins, liver disease, and thyroid and glucocorticoid hormones (8). Albumin

levels reflect hepatic synthesis and volume of distribution, and may decrease with nephrotic syndrome, protein-losing enteropathy, severe burns, traumatic blood loss, peritoneal losses, exfoliative dermatitis, and gastrointestinal bleeding (2,8). Thus, the albumin concentration is limited as an acute indicator of liver disease severity (8). Prealbumin has a half-life of three to four days. However, a low prealbumin level is not specific for hepatic disease. Indeed, malnutrition in a patient with a normal liver will result in decreased prealbumin.

### **Prothrombin Time**

The prothrombin time measures the rate of conversion of prothrombin to thrombin, and reflects the activity of factors II, VII, IX, and X, the factors involved in the extrinsic coagulation pathway (7). Elevations of prothrombin time occur with vitamin K deficiency, warfarin, disseminated intravascular coagulation (DIC), acute and chronic liver disease, and chronic cholestasis with fat malabsorption (7). ⚡ **The coagulation factors have a short half-life, especially factor VII (five to seven hours); thus prothrombin time is a useful indicator of hepatic synthetic function providing vitamin K levels are normal (4,8).** ⚡

## **ETIOLOGY OF LIVER DYSFUNCTION IN THE TRAUMA/INTENSIVE CARE UNIT PATIENT**

### **Ischemic Hepatitis**

#### **Etiology and Pathogenesis**

##### **Trauma and Shock**

Ischemic hepatitis, or “shock liver,” refers to acute circulatory failure of the liver in the setting of trauma, major surgery, and critical illness (13–17). Liver cell necrosis occurs secondary to prolonged cellular hypoxia, due to arterial hypotension, hypoxemia, or passive venous congestion (16). Hypotension is the most important factor contributing to post-traumatic liver dysfunction and jaundice (13,17). Hypotension may be secondary to, or accompanied by, hypovolemia, hypoxemia, prolonged surgery, and anemia with the requirement for massive transfusion (13). Multiple etiologies are usually present in such situations.

Patients with ischemic hepatitis may present clinically with jaundice, encephalopathy, hepatomegaly, or acholic stools (13). Marked elevations of aminotransferases and LDH are common, with lesser elevations of AP (two to three times normal) and bilirubin (5–20 mg/dL) (14–16). Prothrombin time may be elevated two to three seconds (14). Elevations in LFTs occur within the first 12 to 24 hours, peak within one week of the inciting event, and resolve to normal in 7 to 10 days (Fig. 6) (15,16).

##### **Ischemic Hepatitis in Cardiac and Medical Patients**

Cardiogenic ischemic hepatitis occurs in the setting of overt cardiogenic shock or in heart failure patients with an acute decline in cardiac function (18–22). Elevations of serum ALT, AST (usually 10–20 times normal values) and bilirubin occur, as well as prolongation of prothrombin time. Abnormal values decrease by 50% within 72 hours.

Congestive liver fibrosis and congestive cirrhosis (cardiac cirrhosis) occur secondary to elevated venous pressure, hypoxia or hepatocellular necrosis, with varying degrees of fibrosis in different regions of the liver (18). The diagnosis is suggested by the triad of right heart failure,

**Figure 6** The course of aspartate aminotransferase (AST) elevation and normalization in ischemic hepatitis. Each of nine individual patients is represented by a separate symbol. All but one had AST values sore above 2000 U/L by postinsult day 3 (most reaching above 4–6000 U/L). All but one had values return to normal by day 10, with most demonstrating values below 250 U/L by day 7. *Source:* From Ref. 15.

hepatomegaly, and ascites with high protein content. Aminotransferases, AP, bilirubin, and albumin levels are usually initially normal (18).

#### **Pathology and Pathophysiology**

The hepatic arterial buffer response (HABR) is a compensation mechanism by which hepatic arterial dilation compensates for inadequate portal blood flow (19,22). Hepatic oxygen consumption is maintained due to the higher oxygen saturation of hepatic arterial blood (22). Following injury, splanchnic blood flow decreases as splanchnic vascular resistance is increased. Hepatic oxygen consumption may be maintained by an increase in oxygen extraction, which may actually exceed oxygen extraction in other areas of the body (17). Although the HABR is maintained early in hemorrhage, as blood loss exceeds 30%, splanchnic vasoconstriction becomes significant, and hepatic oxygen supply decreases (22).

Patients with acute circulatory failure secondary to organic heart disease demonstrate both hepatic hypoperfusion and hepatic venous congestion, which may further predispose the liver to ischemic injury (22).

♣ **Ischemic hepatitis is associated pathologically with centrilobular necrosis. This is described histologically as necrosis to hepatocytes surrounding the central vein (furthest away from the nutrients supply) and hence, most susceptible to ischemic damage (16).** ♣ The reticular framework of the lobule is preserved, however, and allows for regeneration after recovery of the hypoperfusion (16).

#### **Biochemical Liver Tests in the Differential Diagnosis of Ischemic Hepatitis**

Many other conditions that cause abnormalities of liver function may be present in the critically ill patient. These include viral hepatitis, sepsis, intravascular hemolysis, and venous

congestion. The time course and level of hepatic enzyme increases suggest an ischemic etiology. In benign postoperative cholestasis, bilirubin and AST levels will be lower and AP levels higher than in ischemic hepatitis. LDH levels may be useful in differentiating ischemic from viral hepatitis, as only a moderate rise in LDH occurs in viral hepatitis (16). Viral hepatitis has a longer time course than ischemic hepatitis (viral titers are required to make that diagnosis).

#### **Treatment**

Treatment of ischemic hepatitis is entirely supportive, including resuscitation, antibiotic treatment of infection and sepsis, control of gastrointestinal bleeding, nutritional support, and adjustment of medications for hepatic dysfunction (13,18). Mortality is increased when ischemic hepatitis occurs in patients with pre-existing chronic liver disease (16).

#### **Hepatic Response to Infection and Sepsis**

##### **Hepatic Blood Flow and Oxygen Consumption**

There is conflicting evidence related to hepatic blood flow in sepsis (Volume 2, Chapters 47 and 63). Several studies have demonstrated decreased hepatic blood flow secondary to mesenteric vasoconstriction, or to the hypovolemia and cardiac dysfunction that occurs with sepsis (22–24). Hepatic hypoperfusion may occur in the absence of hypotension, and may persist despite fluid resuscitation (25). In addition, there may be alterations in the regional distribution of hepatic blood flow that may lead to areas with decreased oxygen utilization (22). In some models of sepsis, there has been speculation that hepatic hyperperfusion may occur due to increased cardiac output and decreased systemic vascular resistance (25,26). In these models, hepatic hypoxia is postulated to occur from increased flow of desaturated portal blood (25).

Oxygen consumption is increased in sepsis. Increased splanchnic uptake of lactate, amino acids and free fatty acids, and concomitant increased splanchnic glucose output has been demonstrated after endotoxin bolus in humans (27). Because of increased amino acid and lactate concentrations, gluconeogenesis and glucose uptake are upregulated. The mismatch of hepatic blood flow and metabolic demand is a major etiology of sepsis-induced hepatic dysfunction (22–29).

##### **Hepatic Cellular Response to Bacteremia and Endotoxemia**

The hepatic cellular response to sepsis involves Kupffer cells, hepatocytes, and sinusoidal endothelial cells (24,30,31). The majority of the body's reticuloendothelial system surface area is contained within the liver, primarily the macrophage Kupffer cells that line the sinusoidal vascular network (24,30,31). The Kupffer cells scavenge and filter bacteria and endotoxins from portal vein blood, preventing them from entering the systemic circulation. Kupffer cells also limit the systemic inflammatory response by scavenging inflammatory mediators and cytokines (24,30). Spillover of bacterial, endotoxin, and inflammatory mediators leads to activation of the coagulation, kallikrein, and complement cascades, leading to generalized microvascular injury, the systemic inflammatory response syndrome, and when severe, irreversible shock and multiple organ dysfunction syndrome (Volume 2, Chapter 63) (24).

### **Hepatic Mediator Production and Secondary Cellular Dysfunction**

Kupffer cells produce and release mediators such as proinflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and interleukins-6 (IL-6), as well as nitric oxide, reactive oxygen products, and granulocyte colony stimulating factors (24,30,31).

Secondary hepatic dysfunction occurs in Kupffer cells as a result of tissue factor-induced fibrin deposition and microcirculatory disturbances, with resultant hepatocyte and endothelial cell injury. Endotoxin and TNF may induce cellular dysfunction, even without microcirculatory changes (24). Consumption of fibronectin as a result of reticuloendothelial system phagocytosis of particulate material may impair reticuloendothelial system efficiency (30). Mediators of reperfusion injury may cause additional injury to endothelial and parenchymal cells following resuscitation (21).

### **Effects of Infection and Sepsis on the Immune Response and Coagulation**

Hepatocytes have receptors for endotoxin, cytokines, inflammatory mediators, and vasoactive substances (24). Hepatocytes demonstrate increased synthesis and release of coagulation factors, complement and antiproteolytic enzymes (24). Acute-phase proteins such as C reactive protein, alpha-one antitrypsin, fibrinogen, and prothrombin are also increased. There is an overall procoagulant response secondary to enhanced inhibition of protein C, lower protein S, decreased synthesis of protein C and antithrombin III, increased tissue factor, and enhanced inhibition of fibrinolysis (24).

### **Lactate and the Liver**

While lactate production increases in settings of hypoperfusion, the presence of lactate in sepsis may represent the hypermetabolism that is stimulated by inflammatory mediators. The liver is both a source of lactate as well as the primary organ responsible for lactate clearance. Hepatic production of lactate is based on the presence of macrophages in the liver, increased hepatic neutrophil sequestration, and endotoxin-induced glucose uptake and synthesis of free radicals in hepatic phagocytes (32). Lactate metabolism by the normal liver usually results in negative lactate balance. However, lactate balance can be positive in the presence of underlying hepatic dysfunction or sepsis-induced hepatic dysfunction due to increased lactate production. ⚡ **The major source of hyperlactatemia in sepsis results from dysfunctional clearance of lactate by the liver (31,32).** ⚡

### **Sepsis and Cholestasis**

Intrahepatic cholestasis is the most common finding in bacteremic patients with jaundice (12,31,33). There are a number of mechanisms by which sepsis results in cholestasis. Bile flow and biliary excretion are reduced after exposure to endotoxin. Endotoxemia impairs the transport of organic anions at the sinusoidal and canalicular membranes. Endotoxin and proinflammatory cytokines may also lead to increased neutrophil migration and adhesion, resulting in hepatocyte injury and portal tract inflammation (12,30). It is likely that both decreased hepatic perfusion and decreased urinary excretion of conjugated bilirubin play a role.

### **Biochemical Liver Tests in the Hepatic Response to Infection and Sepsis**

In sepsis, LFTs commonly demonstrate intrahepatic cholestasis (12,30,34). Elevations of serum bilirubin occur in a high percentage of septic patients (34–36). Although peak serum bilirubin usually is in the 5–10 mg/dL range, mostly conjugated, levels may reach as high as 40 mg/dL. Often, there are only modest elevations of aminotransferases (34–37). The level of elevation of serum bilirubin and serum enzymes are often discrepant (33,35,36). AP is elevated one to three times normal, and rarely 5 to 10 times normal (34–37).

The differential diagnosis of sepsis-induced cholestasis includes gall stone disease, sludge, acute acalculous cholecystitis (AAC), drug-induced hepatitis, hemolysis, and cholestasis or jaundice associated with total parenteral nutrition (TPN) (30). Sepsis should be considered when fever and jaundice occur without aminotransferase elevations or evidence of primary hepatic or biliary tract disease. Although the level of bilirubin is not always predictive of outcome, persistent hyperbilirubinemia portends a poor prognosis (34–37).

## **PHARMACOLOGY AND HEPATIC DYSFUNCTION**

### **Hepatic Biotransformation**

#### **Pathways of Drug Elimination**

Three phases of drug elimination are accomplished by the liver. Phase I involves alteration of the parent molecule by oxidation, reduction, and hydrolysis. Phase II includes conjugation of a drug or metabolite with small, endogenous molecules such as glucuronic acid, glutathione acetate or glutathione sulfate, making the products water soluble, allowing excretion into the bile or urine. Conjugation usually detoxifies active metabolites. Phase III involves excretion of the parent compound or metabolite from the hepatocyte (37–40). Any or all of these three steps may be involved in drug elimination (37–40).

#### **Cytochrome P-450 System**

The cytochrome P-450 proteins (P-450) are responsible for most phase I reactions (37–40). In the reaction cycle, oxygen is bound and reduced, resulting in activated oxygen, which is incorporated in lipophilic substrates (drugs, toxins, fatty acids, and steroid hormones) (37–41). Chemically reactive intermediates (e.g., free radicals) are formed and reduced. There are more than 20 P-450 isozymes in the liver (37,41). Patient variation in drug metabolism is due to polymorphisms in the genes coding for P-450 (Volume 2, Chapter 4) (38). There are decreased P-450 levels in severe liver disease, with resultant decrease in drug clearance (38).

Enzyme induction is the synthesis of new enzyme proteins secondary to exposure of the P-450 system to lipophilic substances. Enzyme induction occurs with medications such as isoniazid, phenytoin, rifampicin, and St. John's wort, as well as commonly used agents such as alcohol, tobacco, and cannabis. Enzyme induction affects the metabolism of other drugs, as well as drug-drug interactions (37).

### **Mechanisms of Drug Toxicity**

#### **Intrinsic (Direct) Hepatotoxicity**

Toxic hepatic injury occurs with agents that damage liver cells of all exposed patients (intrinsic toxicity) (Table 2).

**Table 2** Mechanisms of Drug-Induced Liver Disease

Mechanism	Direct/indirect physiochemical destruction	Idiosyncratic toxicity	
		Aberrant metabolism leading to toxic metabolite	Hypersensitivity (drug allergy) reaction immune-mediated
Examples	Acetaminophen	Isoniazid Ketoconazole Troglitazone	Halothane Phenytoin Carbamazepine Valproate Sulfonamides
Clinical features	Fulminant (acute hepatitis)	Elevated LFTs, acute hepatitis, jaundice	Fever, rash, eosinophilia, arthralgias accompany hepatitis
Risk of injury	Very high (predictable)	Low (unpredictable)	Low (unpredictable)
Latency	Hours (acute)	Weeks-months (variable)	1–5 wk (fixed)
Dose dependency	Yes	No	No
Morphologic injury pattern	Usually necrosis	Broad spectrum	Broad spectrum, granulomas
Positive response to rechallenge	No	Possibly, delayed	Expected, prompt
Animal models	Yes	No	No

Abbreviation: LFTs, liver Function tests.

Source: From Ref. 43.

Intrinsic hepatotoxins cause predictable liver injury, either from the drug itself (as with *Amanita phalloides* mushroom, chloroform, and carbon tetrachloride) or from a toxic metabolite of the agent (as with acetaminophen toxicity), and are usually not related to host factors (Volume 1, Chapter 31). Most toxic hepatic injury results from the actions of active metabolites of the drug (37,41,42). Electrophilic radicals, the probable mechanism for injury from acetaminophen and isoniazid, bind to molecules of cell membranes and lead to necrosis (41). Most cases of acute drug-induced liver disease occur within days of a direct hepatotoxin (37,41).

### Idiosyncratic Toxicity

The majority of drugs associated with drug-induced liver disease are idiosyncratic hepatotoxins (37,38,40). Unstable drug metabolites may bind to cellular proteins or macromolecules that cause a direct toxic effect on hepatocytes (38,40). Idiosyncratic agents may be due to aberrant metabolism of the drug to a toxic intermediate that induces liver injury in the susceptible patient, or may be immunologic in nature (37,38,40–42).

### Metabolic Idiosyncrasy

Metabolic idiosyncrasy is the susceptibility of agents to formation of intrinsic toxins, resulting in hepatic cellular injury. These reactions usually result from genetic or acquired differences in drug metabolism (37,40,42). Agents associated with metabolic idiosyncrasy include isoniazid, fluconazole, troglitazone, fluoxetine, paroxetine, and trazodone.

### Immunoallergic or Hypersensitivity Reactions

Immunoallergic or hypersensitivity reactions involve the covalent binding of the drug to enzymes, forming adducts, which can serve as immune targets (40). Adducts can induce the formation of antibodies or induce direct cytolytic T-cell responses (40). The pattern of liver disease can be hepatic, cholestatic, or mixed (38,40,42). This reaction

occurs after a predictable sensitization period, usually one to five weeks (42). Rash, fever, and eosinophilia may accompany immunoallergic reactions.

Immunoallergic reactions have been reported with sulfonamides and anticonvulsants (37,40). Rare cases have occurred from barbiturates, beta-blocking agents, calcium-channel blockers, nifedipine, verapamil, diltiazem, and gastric acid suppression drugs such as cimetidine, ranitidine, and famotidine (37).

### Targets of Cellular Injury

Drug-induced hepatic injury can be classified by clinical, histologic or laboratory features, and depends on the area of the hepatobiliary tree that is injured. Covalent binding of a drug to intracellular proteins may occur and migrate to the cell surface, resulting in cell lysis. Enzyme-drug adducts can migrate to the cell surface and serve as targets for cytolytic T-cells or cytokines. Disruption of the actin filaments near the canaliculus, or interruptions of transport proteins that affect bile flow, may result in cholestasis. Interruption of transport pumps may prevent excretion of bilirubin and other compounds. Drugs may activate apoptotic pathways via TNF- $\alpha$ . Others may affect fatty acid oxidation and respiratory chain enzymes, leading to lactic acidosis and reactive oxygen species. Triglyceride accumulation within cells leads to steatohepatitis (aforementioned) (40). Many drugs cause a spectrum of features, however, and some produce mixed disorders (37).

### Presentations of Hepatic Injury

#### Hepatic Adaptation

Hepatic adaptation refers to alterations in hepatic function without significant liver injury. Patients are frequently asymptomatic (42). Drugs commonly involved include phenytoin, warfarin, and the statin class of cholesterol-lowering agents (37,42). Rash, eosinophilia, and fever are uncommon (37).

### **Hepatocellular Necrosis**

Acute hepatocellular necrosis is characterized by marked elevations in ALT and AST (8–100 times normal), with normal or minimally elevated AP (<3 times normal) (41,43). Serum bilirubin levels always increase, but the degree of elevation is quite variable. Patients with drug-induced hepatocellular necrosis may progress to fulminant hepatic failure, which carries a poor prognosis (41,43).

### **Steatosis and Steatohepatitis**

Steatosis is fatty liver, whereas steatohepatitis is fatty liver with inflammation of the hepatic cells. Steatosis is typically divided into two types, microvesicular (owing to mitochondrial problems), and macrovesicular (hepatic export/import and manufacturing abnormality). Steatosis can progress to steatohepatitis, fibrosis, and cirrhosis. Steatohepatitis may present with jaundice and elevations of aminotransferases, but levels are typically less than those seen with hepatocellular necrosis (41,42).

### **Cholestatic Liver Injury**

Drugs associated with cholestatic liver injury presumably result from immunologic activities against the bile ducts. The predominant histologic features are portal inflammation and biliary injury (38).

Cholestatic liver injury may present with anorexia, malaise, fatigue, jaundice, dark urine, and pruritis (37,38,40,42,43). Elevations of AP, GGTP, and 5'NT may indicate bile duct injury (37,43). There are modestly elevated aminotransferases and conjugated hyperbilirubinemia (37,41,42). The ratio of ALT to AP is <2:1 in cholestasis (37). ♂ **Drug-induced cholestatic injury has a better prognosis than hepatocellular injury, but may become fatal if the drug is continued after appearance of symptoms (40,41).** ♂

### **Common Drugs Associated with Hepatotoxicity in the Trauma/Intensive Care Unit Patient**

#### **Antibiotics**

Acute hepatic necrosis and liver failure may occur with isoniazid, rifampin, ketoconazole, and oxacillin (43,44). Sulfonamides are associated with hepatitis, especially in combination agents, such as sulfamethoxazole/trimethoprim (37). Fatalities have occurred with trovafloxacin (44). Ceftriaxone and linezolid have been associated with hyperbilirubinemia (44). Cholestasis may occur with erythromycin, trovafloxacin, sulfonamides, angiotensin converting enzyme (ACE) inhibitors, and tricyclics (37,44). Tetracycline hepatotoxicity is dose related (44). Many of the antiretroviral agents prescribed to HIV-positive patients are also associated with hepatotoxicity (37).

#### **Acetaminophen**

Acetaminophen overdosage is well known to cause liver failure. Liver toxicity is common with acetaminophen doses of 15 g or more, but doses as low as 6–10 g can also be toxic. Glutathione binds with acetaminophen metabolites, and acetaminophen overdose causes the amount of metabolite to exceed the amount of glutathione. Due to cytochrome induction, there are higher levels of a toxic quinone metabolite (37,43). Hepatic injury occurs at about 48 hours after ingestion. Elevations of AST and ALT to greater than 10,000 U/L can be seen (43). A characteristic feature is a large increase in AST compared with ALT (41). Acetaminophen

toxicity results in higher levels of aminotransferases than in viral hepatitis (40). Centrilobular necrosis and hepatic failure result.

Acetaminophen toxicity is exacerbated in patients with regular intake of alcohol, and therapeutic doses of acetaminophen in alcohol users can lead to severe toxicity (45). This enhanced reaction may be secondary to induction of cytochrome P-450 by ethanol, depletion of glutathione, alcohol-induced malnutrition, and the fasting state (45,46). Enhanced P-450 activity also occurs with isoniazid, rifampin, anticonvulsants, and zidovudine, and increases acetaminophen toxicity (43).

Acetylcysteine causes a repletion of glutathione (41), and can ameliorate liver injury if administered within 12 to 24 hours (37,41). Later administration of acetylcysteine can still reduce the mortality of hepatotoxicity (37). Some patients may require hepatic transplantation (47).

#### **Aspirin**

Aspirin (ASA) injury is dose-dependent, at 4 to 6 g/day or with blood levels of 25 mg/dL (37,43). ALT levels rise. Recovery is usually rapid following prompt discontinuation of the drug without occurrence of chronic liver disease (37). ASA has been identified in inducing Reye's syndrome in febrile children (37).

#### **Amiodarone**

Hepatotoxicity from the antidysrhythmic agent, amiodarone, has been described (37,48,49). The most common abnormality is a mild elevation of serum AST and ALT levels in 15% to 80% of patients. Acute liver failure occurs in 0.6% of patients. Most changes resolve spontaneously without discontinuation of the agent. Fatalities from liver dysfunction are rare (37,48).

The most typical lesion is steatohepatitis (37). Progression of the disease may occur even with discontinuation of the agents. Chronic liver disease may occur with prolonged use of amiodarone. Clinical presentation includes fatigue, nausea, vomiting, malaise, weight loss, ascites, hepatomegaly, jaundice, and bruising (37). Use of oral amiodarone may be safe in some patients who demonstrate acute hepatitis with the parenteral form of this agent (49).

#### **Anticonvulsants**

Carbamazepine, phenytoin, and phenobarbital have been associated with cytotoxic hepatic injury (37,38,50,51). These reactions occur with intermediate (usually one to eight weeks) or long latency (up to 12 months) after exposure, and may occur with rash, fever, eosinophilia, and lymphadenopathy (37,38,41–43). Aminotransferase levels are high (38), and fulminant hepatic failure may result (50). Effects may not be seen until after the drug is discontinued, or may be nonspecific; thus the drug is not discontinued. Diagnosis is made by a rechallenge of the agent. The incidence is 1/3000 exposures (43). Valproic acid is associated with severe hepatotoxicity, but usually in young children (37).

#### **Drugs of Abuse**

Phencyclidine, cocaine, angel dust, and 3,4 methylenedioxy-methamphetamine (MDMA) (ecstasy) have been associated with hepatic injury. Associated hyperthermia, rhabdomyolysis, respiratory, and renal failure may occur. Cocaine-induced liver injury is usually secondary to hypoxia, hypotension, and hyperthermia (37).

### **Anesthesia-Induced Hepatotoxicity (Exceedingly Rare)**

General anesthetics are not common sources of hepatitis. However, fulminant hepatic failure, secondary to immune-mediated toxicity, occurs very rarely. The oxidative metabolism of halothane by cytochrome P-450, to trifluoroacetyl chloride, leads to trifluoroacetylation of specific proteins which idiosyncratically act as antigens in the immune response. It is thought that patients who develop halothane hepatitis either produce unusually large amounts of hepatotoxic metabolites or have an idiosyncratic immunologic response that initiates the hepatic damage (52). An allergic etiology is suggested by the occurrence after repeated exposure in certain patients, and the occurrence of fever, rash, and eosinophilia (52). Halothane hepatitis is exceedingly rare and is a diagnosis of exclusion. Treatment is entirely supportive (38,52). Enflurane, isoflurane, and desflurane undergo less oxidation, and are thus associated with fewer cases of hepatotoxicity. There has not yet been any reported association between sevoflurane and hepatotoxicity (52).

### **Clinical Aspects of Drug-Induced Hepatic Disease**

The trauma/intensive care unit (ICU) patient may have numerous factors that influence the effects of drugs on the liver, such as age, previous excessive use of alcohol, poor nutritional status, and shock (37). In addition, the recognition of drug-induced liver disease in the surgical and trauma patient is complicated by the effects of surgery, trauma and hemodynamic instability on hepatic function, underlying medical conditions which impact on liver function, and the large number of medications which are used in the critically ill patient.

A drug reaction should be considered in any critically ill patient with hepatic dysfunction. Eliminating other causes of liver disease is essential. Temporal associations with new agents, and improvement after drug cessation, may aid in the diagnosis (40). If the offending agent is discontinued, acute hepatocellular injury is reversible and heals without sequelae (43).

Dechallenge and rechallenge may be used, but puts the patient at risk for severe injury (40,42). Findings on liver biopsy that suggest drug-induced hepatotoxicity include eosinophils in an inflammatory infiltrate, granulomatous hepatitis, hepatitis-like hepatocellular injury, cholestatic hepatitis, severe acute injury with zonal, and submassive or massive hepatic necrosis (42).

There is little effective treatment for drug-induced hepatotoxicity (37). Prevention, detection, and discontinuation of any possible hepatotoxic agents are critical (37). There is no data that corticosteroids are useful in immunologic reactions (40). Mortality may approach 10% in cases of hepatocellular necrosis or toxic steatosis. Agents that produce cholestatic injury rarely produce fatalities (43).

♣ **The presence of jaundice worsens the prognosis in hepatocellular injury. Patients with coagulopathy or with encephalopathy may be candidates for hepatic transplantation (40).** ♣

### **Alterations in Drug Dosing in the Trauma/Intensive Care Unit Patient with Hepatic Dysfunction Hepatic Drug Metabolism**

Hepatic clearance depends primarily on hepatic blood flow, enzyme activity and, to a lesser extent, protein binding. The

effects of changes in hepatic blood flow and enzyme activity are synergistic, not additive. When drug clearance is reduced, drugs can reach a higher steady-state concentration. Drugs with a high hepatic extraction rapidly undergo biotransformation and biliary excretion, and are sensitive to changes in hepatic blood flow. Thus, conditions associated with hepatic hypoperfusion, such as hemorrhagic shock, sepsis, application of positive end-expiratory pressure, and use of alpha-adrenergic agents, may prolong the metabolism of such agents (39).

Drugs with a low hepatic extraction are sensitive to variations of the activity of drug-metabolizing enzymes, and not to hepatic blood flow changes. Hepatic enzyme activity is an important factor in metabolism of drugs with low hepatic extraction, and may be altered in the absence of liver injury. Oxidative metabolism of drugs is primarily catalyzed by enzymes of the P-450 system, some of which are more susceptible to liver disease than others. Binding of drugs to albumin and alpha-1 acid glycoprotein is affected in critical illness, and thus drugs that are highly protein bound may have altered metabolism (39).

### **Analgesics**

The liver is responsible for the metabolism of many analgesic agents. Morphine metabolism is dependent on liver blood flow. Prolonged clearance can occur in severe cirrhosis and septic shock. The metabolite morphine-6-glucuronide can have a prolonged duration of action, especially in patients with renal failure or insufficiency (53).

Fentanyl is more highly lipid soluble, with increased volume of distribution and longer limitation half-life than morphine. Fentanyl is metabolized to inactive metabolites, which are eliminated by the kidney. Metabolism is affected by liver blood flow, thus decreased hepatic perfusion can affect clearance (53).

Meperidine is metabolized in the liver to normeperidine, and is renally excreted. Central nervous system toxicity limits its use in ICU patients with renal failure (53).

Hydromorphone is metabolized in the liver to hydromorphone-3-glucuronide. This metabolite may accumulate in renal failure and cause central nervous system toxicity. Metabolism is dependent on hepatic blood flow.

### **Sedatives**

Diazepam is highly lipid soluble and protein bound. The drug is metabolized to the active compound, desmethyldiazepam, which has a long half-life (100–200 hours) and is eliminated by the kidney. Diazepam metabolites are converted by oxidation, which undergo conjugation before elimination. The elimination half-life is thus prolonged in patients with liver disease (54).

Lorazepam is five to six times more potent than diazepam, and is 90% protein bound. It is metabolized to inactive products by hepatic glucuronidation, and thus there are fewer drug interactions than with other benzodiazepines. The half-life of 10 to 20 hours is prolonged in liver disease. Lorazepam clearance has shown variability, depending on the underlying trauma mechanism, increased after head and thermal injury, decreased after spinal cord injury (39).

Midazolam is 95% protein bound and three to four times more potent than diazepam. It is metabolized by hepatic microsomal oxidation (5). Midazolam has a prolonged clearance and half-life with severe liver disease (54).

Propofol has the largest volume of distribution of any sedative, with rapid return to consciousness after

discontinuation. Although metabolized by the liver, propofol recovery is not affected by liver disease (55).

### **Muscle Relaxants**

The effects of vecuronium, pancuronium, mivacurium, rocuronium, and *d*-tubocurarine are prolonged in patients with liver disease (56). A metabolite of vecuronium, 3-desacetylvecuronium, has muscle relaxant properties, and prolonged muscle relaxation can occur in renal failure (56).

### **Miscellaneous Agents**

Agents used in the ICU, which are also affected by liver disease, include metoclopramide and ondansetron. Cirrhosis can markedly affect the metabolism of the proton pump inhibitors lansoprazole, pantoprazole, and omeprazole. Patients with cirrhosis may have decreased sensitivity to loop diuretics.

✎ Although clearance of many drugs has been shown to be diminished after trauma, phenytoin and lorazepam clearance are normally increased after head trauma (39). ✎

## **SELECTED CLINICAL ISSUES IN LIVER DYSFUNCTION IN THE TRAUMA/SURGICAL PATIENT**

### **Total Parenteral Nutrition and Hepatic Function Steatosis**

Steatosis (fatty liver), the most common hepatic abnormality in adult patients receiving TPN, is reversible and benign providing additional insults do not occur, and duration is short (57,58). Onset is usually one to four weeks after initiation of TPN. Hepatic function tests reveal mild-to-moderate elevation of aminotransferases, and less pronounced elevations of serum AP and bilirubin (57). However, long-term steatosis may progress to steatohepatitis, fibrosis, and cirrhosis (57,58). Excessive calories from carbohydrates can stimulate insulin-induced lipogenesis, essential fatty acid deficiency, and choline deficiency (58). Reducing the calories of TPN solutions, cycling of TPN, and choline supplementation have been shown to reduce hepatic steatosis (58).

### **Cholestasis**

Long-term TPN is a risk factor for cholestasis (57,58). A mechanism in adults may relate to inadequate stimulation of cholecystokinin release, with resultant bile stasis in the gall bladder. Intestinal stasis may lead to small intestinal bacterial overgrowth, which results in transformation of chenodeoxycholate to lithocholate. Lithocholate has been shown in animals to impair bile flow and induce cholestasis (57). Lack of enteral nutrition may lead to intestinal hypoplasia, which increases lithocholate absorption and promotion of bacterial translocation across the gastrointestinal tract. Treatment options include the use of metronidazole to suppress bacterial overgrowth, and ursodeoxycholic acid to improve the fluidity of the bile (58). Cholestasis can lead to calculous gall bladder disease. Sludge is present in all patients after six weeks of TPN. Acalculous cholecystitis can occur in a small percentage of patients on long-term TPN (57,58).

### **Acalculous Cholecystitis**

#### **Definition and Incidence**

AAC is an acute inflammation of the gall bladder that occurs in the absence of gallstones (9,16,59,60). AAC occurs in the setting of trauma, burns, major intra-abdominal surgery,

and sepsis, often in patients who require mechanical ventilation, hemodynamic support, and multiple blood transfusions or TPN (9,16,59). As opposed to the equal incidence of calculous cholecystitis in men and women, the incidence of the acalculous form of cholecystitis is more common in men and in children (9,59).

#### **Etiology and Pathogenesis**

The pathogenesis of ACC is multifactorial, and includes bile stasis, infection, and ischemia. Prolonged fasting can lead to bile stasis secondary to reduced gallbladder emptying, and volume depletion may result in concentration of bile (9,59,61). Hypoperfusion secondary to sepsis, the use of vasoactive agents, and splanchnic vasoconstriction, combined with an increased metabolic requirement of the gall bladder epithelium, can result in ischemia of the gall bladder (9,16,59,60). Increased intraluminal pressure from inspissated bile can further exacerbate gall bladder ischemia (9,16,60). Mechanical ventilation may contribute to biliary stasis and decreased portal blood flow when continuous positive air way pressure (CPAP) is applied for prolonged periods or high levels (62). Multiple arterial occlusions are present histologically (63), and gangrene is present in 50% of the cases (9).

#### **Clinical Manifestations and Diagnosis**

The clinical presentation of AAC is usually nonspecific, and requires a high index of suspicion. Any combination of fever, leukocytosis, elevated hepatic function tests, and hyperbilirubinemia may be present. Patients may be septic, yet this may be a cause or a result of AAC. Perforation may occur in 10% to 20% (9,16,59).

Abdominal findings may be absent or difficult to ascertain in this patient population secondary to critical illness, endotracheal intubation, use of narcotics and sedatives, and the presence of previous abdominal pathology (9).

Ultrasound is the diagnostic test of choice. Findings are nonspecific, and may include a thickened gall bladder wall, gall bladder distention, biliary sludge, pericholecystic fluid, and a sonographic halo around the gall bladder without gallstones (9,59,64). Hepatic scintigraphy has a high incidence of false negative and false positive results. Prolonged fasting with decreased bile production and absence of gall bladder contraction, narcotic-induced contraction of the sphincter of Oddi, and biliary stasis secondary to TPN leads to nonvisualization of the gall bladder (64,65). CT has not been shown to be more accurate, and requires transport from the ICU, thus limiting its utility in diagnosing AAC (61,65).

#### **Treatment**

Cholecystectomy should be performed, but carries a high rate of complications and mortality. Thus, percutaneous cholecystostomy may be an option in an unstable critically ill patient. Percutaneous drainage has been shown to be effective as both a diagnostic and treatment modality in critically ill patients (66,67). The cholecystostomy tube is left in place for three weeks so a tract can form.

Antibiotic therapy should be directed against the common bacterial isolates, including *Escherichia coli*, *Klebsiella*, and *Enterococcus faecalis* (59). In patients with previous antibiotic therapy, resistant bacteria may be encountered. *Pseudomonas*, staphylococci, enterobacter, and anaerobic organisms may be recovered in such patients (59). However, patients with documented AAC may have negative bile cultures (64,66,68).

## Coagulopathy Associated with Liver Failure

### Etiologies of Coagulopathy

The liver is the site of synthesis of all the major coagulation factors except for factor VIII and vWF. In addition, antithrombotic factors protein C and protein S are synthesized by the liver. Antithrombin is produced in the liver, and can be decreased in patients with acute hepatic failure and cirrhosis. Decreased platelet counts are common in liver disease, but rarely result in bleeding (69).

The prothrombin time depends on prothrombin and the clotting factors synthesized in the liver, factors II (fibrinogen), V, VII, and IX (6,69). Vitamin K, a fat-soluble vitamin found in many foods and produced by intestinal bacteria, is required for many of these factors, and may be deficient in cases of malnutrition and malabsorption. Deficiency of vitamin K may occur in cases of biliary obstruction, cholestasis, and with antibiotic suppression of intestinal bacteria (2,6,70).

Coagulopathy can occur in cases of hepatic necrosis. Etiologies include increased tissue factor activity, decreased clearance of activated factors, and decreased synthesis of inhibitors (69). Patients with liver disease may demonstrate a reduction of coagulation factors and a quantitative or qualitative platelet defect.

DIC may be difficult to differentiate from bleeding secondary to advanced hepatic disease. DIC results from unopposed thrombin generation and action resulting from endothelial or tissue injury (69).

Clinical bleeding is unusual in toxic hepatitis, unless the hepatitis becomes fulminant or hepatic failure occurs (69). Coagulation factor deficiencies, especially factor VII, may occur. Hyperfibrinolysis can occur in patients with liver disease in whom there is increased reduction of physiologic inhibitors alpha 2-antiplasmin and PAI-1 combined with decreased clearance of activated factors (70).

### Coagulopathy Evaluation and Management

Coagulopathy is multifactorial in the patient with liver dysfunction. The plasma half-life of most coagulation factors is short, and thus prothrombin time is helpful in following the course of acute liver failure. When prolonged prothrombin time is secondary to vitamin K deficiency, administration of vitamin K will decrease prothrombin time by 30% within 24 hours (8). Vitamin K can be administered as a single dose

of 10 mg IV, at a rate of 1 mg/min (69). Intramuscular injection is not recommended in cases of coagulopathy (69). **In cases of parenchymal liver disease, there may be minimal or absent response to vitamin K.**

### Evaluation of Hepatic Dysfunction in the Trauma/Intensive Care Unit Patient

The etiology of post-traumatic and postoperative jaundice is often multifactorial. Critically ill patients have experienced any combination of hemodynamic instability, infection and/or sepsis, multiple blood transfusions, and have been exposed to potentially hepatotoxic medications.

### Evaluation of Biochemical Liver Function Tests

The initial step in the investigation of jaundice is to identify the pattern of biochemical LFTs. Jaundice may be classified on the basis of etiology, pathophysiology, or time course of appearance of jaundice. Evaluations based on pathophysiology would differentiate between increased pigment load, hepatic parenchymal disease, or intrahepatic or extrahepatic cholestasis (Table 3).

Unconjugated hyperbilirubinemia suggests hemolysis, resorption of hematomas or, less likely, inherited defects of conjugations (e.g., Gilbert's syndrome).

Patients who are critically ill usually have an element of hepatocellular dysfunction, and bilirubin is predominantly conjugated. Unconjugated bilirubin is always bound to albumin and is not filtered by the kidney (except in proteinuria states). Accordingly, bilirubin in the urine is conjugated and indicates hepatobiliary disease (6) in the absence of proteinuria.

Hepatocellular injury is characterized by elevations in direct bilirubin and amino-transferases, with only modest elevations of AP. A rise in conjugated bilirubin without an increase in AP suggests alcohol, drugs, viral hepatitis, or inherited disorders of bilirubin excretion (Dubin Johnson, Rotor's syndrome) (6). Cholestasis is identified by jaundice with bilirubin levels 2–10 mg/dL, a mild to moderate rise in AP, and smaller elevations in aminotransferases. Clinical evidence of encephalopathy does not occur.

Ischemic hepatitis and drug-induced liver disease are usually associated with higher levels of aminotransferases. Sepsis, extrahepatic biliary obstruction, calculus cholecystitis, and TPN should be considered.

**Table 3** General Patterns of Biochemical Liver Tests

Test	Hepatocellular necrosis		Biliary obstruction		Hepatic infiltration
Causative agent	Toxin/ischemia		Complete	Partial	
	Viral	Alcohol			
Examples	Acetaminophen, shock liver	Hepatitis A or B	Pancreatic carcinoma	Hilar tumor	Primary or metastatic carcinoma, TB, sarcoid, amyloidosis
Amino-transferases	50–100	5–50	2–5	1–5	1–5
AP	1–3	1–3	1–10	2–20	2–10
Bilirubin	1–5	1–30	1–30	1–30	1–5
Prothrombin time	Prolonged and unresponsive to vitamin K in severe liver disease		Often prolonged and responsive to vitamin K		Usually normal
Albumin	Decreased in subacute or chronic disease		Usually normal; decreased in advanced disease		Usually normal

Abbreviation: AP, alkaline phosphatase.

Source: From Ref. 1.

Measurements of conjugated and unconjugated bilirubin are of limited utility in distinguishing between intrinsic liver disease and biliary obstruction (6,8). Isolated marked elevations of AP with conjugated hyperbilirubinemia, is consistent with partial biliary obstruction and hepatic infiltration. Both GGTP and AP are typically elevated in cholestasis; the combination of an elevated AP and normal GGTP suggests that the AP is from bone (8). An isolated elevation of GGTP may result from certain drugs (8). In prolonged homeostasis, the delta fraction of circulating conjugated bilirubin is tightly bound to albumin, and may account for the prolonged resolution of bilirubin when other parameters are improving (6).

Unrecognized pre-existing liver diseases, including viral hepatitis, alcoholic hepatitis, and cirrhosis, are possible in the trauma population, and may contribute to hepatic dysfunction.

Timing of hepatic dysfunction is important. ✎ **While ischemic hepatitis has a short latent period and characteristic biochemical pattern, drug-induced liver disease may occur further into the patient's hospital course.** ✎

### **Diagnostic Imaging**

Ultrasound or computed tomography can reveal the presence of dilated ducts. If dilated ducts are present, endoscopic retrograde cholangiopancreatography (ERCP) can be performed (10). The advantage of ultrasound is that it is noninvasive and portable. No contrast agents are required. However, bowel gas may obscure visualization. Abdominal CT is also noninvasive, and has a higher resolution than ultrasound. However, the patient requires transport, and only calcified gallstones may be visualized. Contrast may be contraindicated in the patient with hypovolemia or renal dysfunction. ERCP provides direct imaging of the bile ducts and periampullary region. This test is technically difficult in the critically ill patient. Percutaneous cholangiography provides direct imaging of the bile ducts, but interpretation may be difficult with nondilated intrahepatic ducts (8).

### **Management Goals of the Trauma/Intensive Care Unit Patient with Hepatic Dysfunction**

Many trauma and ICU patients have abnormalities of biochemical LFTs with evidence of hepatic dysfunction. Prolonged elevations in biochemical LFTs may only reflect the severity of the patient's underlying condition, rather than intrinsic hepatic dysfunction. Most critically ill patients are at risk for intrahepatic cholestasis, which may persist as long as the patient remains critically ill. It is essential to continually review medications for possible drug-induced hepatic disease. Stabilization of the patient's hemodynamic status is essential in preserving hepatic blood flow. Metabolic and coagulation abnormalities should be treated as they arise. Medication doses should be adjusted for changes in hepatic function.

## **EYE TO THE FUTURE**

### **Evaluation of Hepatic Function in Critical Illness and Injury**

Patients who are critically ill or injured are at risk for multiple organ dysfunction, including hepatic failure. However, abnormal tests of hepatic function are often nonspecific and reflect multiple mechanisms of hepatic injury. Two

studies may prove to be useful in the early detection of disorders of hepatic function.

### **Indocyanine Green Clearance as an Evaluation of Hepatic Injury**

In an attempt to investigate hepatic perfusion, indocyanine green clearance was measured in patients with sepsis, and showed that indocyanine green elimination failed to increase in survivors. Measurement of indocyanine green clearance may be able to identify reversible liver injury early in the course of septic shock, and may predict patients with a poor outcome (71).

### **Cytochrome P-450 Activity as a Monitor for Liver Dysfunction in Trauma Patients**

Alterations in CYP activity can be evaluated by measuring metabolism of medications specific for CYP isoforms. The metabolism of medications that test different CYP isoforms were administered following resuscitation, stabilization and initial treatment of a group of critically injured adult patients. The metabolizing capacity of some of the CYP isoforms were found to be altered compared with control subjects, and several of these alterations correlated with measures of organ dysfunction and illness severity (72).

### **Improving Hepatosplanchnic Perfusion in Sepsis N-Acetylcysteine (NAC)**

The properties of NAC which make it a potentially useful agent in sepsis have been reviewed, including its antioxidant properties, modulation of the activity of inducible nitric oxide synthase, decreased formation of proinflammatory cytokines, and inhibition of neutrophil activation (73). Animal studies have shown positive effects of NAC on hepatosplanchnic perfusion (75), and clinical trials have demonstrated increased liver blood flow and function (74–76). However, other studies in human subjects have shown deleterious effects on cardiac and respiratory function (73). Further studies will be required to assess the utility of NAC on hepatic function and other organ systems in sepsis.

### **Fenoldopam and Dopexamine**

Studies using fenoldopam, a dopamine-1 receptor agonist, and dopexamine, an inotropic agent have shown conflicting results in improving hepatosplanchnic perfusion (22,77,78).

### **Bioartificial Support**

Bioartificial hepatic support has been in development since the 1950s. Extracorporeal liver perfusion, transplantation of hepatocytes, and hybrid liver support devices are among the modalities being studied (80–83). Meta-analysis has shown conflicting results in the effect of bioartificial liver support on mortality in acute-on-chronic liver failure and in hepatic encephalopathy (82). A prospective, randomized, multicenter controlled trial of the Hepatassist liver support system, an extracorporeal porcine hepatocyte-based BAL, has demonstrated improved survival in patients with fulminant and subfulminant hepatic failure (83). (Also see Volume 2, Chapter 38.)

## **SUMMARY**

Trauma and critical illness may affect all aspects of hepatic function, including energy, bilirubin and vitamin metabolism, biliary function, and production of plasma proteins

and coagulation factors. The trauma/ICU patient is at risk for hepatic ischemia secondary to hepatic hypoperfusion from hypotension and anemia. The liver of the septic, critically ill patient is subject to hypoperfusion and mismatch of oxygen delivery and consumption. Sepsis can result in Kupffer cell spillover of bacteria and inflammatory mediators, hepatic mediator production with secondary hepatocellular dysfunction, and a procoagulant response.

Jaundice is commonly seen in the critically ill patient, and may be secondary to bilirubin overload, hepatocellular dysfunction, or cholestasis. Elevations of aminotransferases reflect hepatocellular damage. Intrahepatic cholestasis is common in patients with sepsis. The level of elevation of serum bilirubin and serum enzymes are often discrepant. Persistent hyperbilirubinemia portends a poor prognosis.

Hepatic injury can occur from direct injury by intrinsic hepatotoxins, causing predictable hepatic injury, or from idiosyncratic reactions related to aberrant metabolism or immunoallergic reactions against drugs or their metabolites. Although drugs may affect hepatic function tests without significant liver injury, hepatocellular necrosis, steatosis, or cholestasis may occur. Drug effect must be considered in any critically ill patient with hepatic dysfunction.

Hepatic dysfunction may affect the pharmacokinetics and pharmacodynamics of many drugs. Analgesics, sedatives, and muscle relaxants may have prolonged metabolism in patients with hepatic dysfunction.

Identifying the pattern of biochemical LFTs is the initial step in investigating hepatic dysfunction in the critically ill patient's. Timing of hepatic dysfunction in relation to the patient course of illness may help differentiate etiologies of hepatic dysfunction. Measurements of conjugated and unconjugated hyperbilirubinemia are of limited value in distinguishing between intrinsic liver disease and biliary obstruction. Sepsis, extrahepatic biliary obstruction, acalculous cholecystitis, TPN, and drug effect should be considered as etiologies for hepatic dysfunction in critically ill patients.

## KEY POINTS

- ✎ The geographic position of hepatocytes and their exposure to gradients of nutrients and waste products leads to location-related variations in susceptibility to ischemia and drug toxicity (2).
- ✎ Acute hepatic disease will have a greater effect on proteins with rapid turnover (i.e., coagulation factors) than those that turn over more slowly, such as albumin (5).
- ✎ Aminotransferase levels of greater than 1000 IU/L are almost always due to hepatocellular injury, and can be seen with drug- or toxin-induced hepatic injury, ischemic liver injury, and acute viral hepatitis (7).
- ✎ In most hepatic injuries, the ratio of AST to ALT is usually 1:1; however, ratios of 2:1 or greater are common in alcoholic hepatitis.
- ✎ Normally, the total bilirubin is less than 1 mg/dL, and at least 70% is conjugated (direct reacting).
- ✎ The coagulation factors have a short half-life, especially factor VII (five to seven hours); thus prothrombin time is a useful indicator of hepatic synthetic function providing vitamin K levels are normal (4,8).
- ✎ Ischemic hepatitis is associated pathologically with centrilobular necrosis. This is described histologically as necrosis to hepatocytes surrounding the central vein

(furthest away from the nutrients supply) and hence, most susceptible to ischemic damage (16).

- ✎ The major source of hyperlactatemia in sepsis results from henobarbital clearance of lactate by the liver (32,33).
- ✎ Drug-induced cholestatic injury has a better prognosis than hepatocellular injury, but may become fatal if the drug is continued after appearance of symptoms (40,41).
- ✎ The presence of jaundice worsens the prognosis in hepatocellular injury.
- ✎ Although clearance of many drugs has been shown to be diminished after trauma, phenytoin and lorazepam clearance are normally increased after head trauma (39).
- ✎ In cases of parenchymal liver disease, there may be minimal or absent response to vitamin K.
- ✎ While ischemic hepatitis has a short latent period and characteristic biochemical pattern, drug-induced liver disease may occur further into the patient's hospital course.

### INTRODUCTION

Acute fulminant hepatic failure (FHF) is the abrupt onset of hepatocyte dysfunction, typically associated with massive necrosis of the liver, resulting in hepatic encephalopathy and multiple organ system dysfunction (MODS). It is a devastating condition associated with mortality rates as high as 80% in the absence of liver transplantation (1,2). Affected patients are often previously healthy, and thus without the typical stigmata of chronic liver disease or cirrhosis (Volume 2, Chapter 37), prior to illness.

Care is mainly supportive, however, a small number of important etiologies have specific treatments that will limit disease if begun early, and the full course of therapy is completed (e.g., *N*-acetylcysteine for acetaminophen toxicity). In addition, newer methods of extracorporeal support are being investigated to temporarily serve the function of the liver while it recovers. However, liver transplantation remains the only long-term life-saving therapy when hepatic failure is severe. Indeed, emergent liver transplantation has improved survival significantly for those eligible for the procedure, and FHF now accounts for 6% of adult liver transplants in the United States (3).

This chapter reviews the various etiologies of FHF, then discusses the diagnosis, classification, and prognosis. Next, the associated nonliver organ dysfunction syndromes are reviewed with a focus on both the pathophysiology and current management principles. Specific sections reviewing extracorporeal hepatic support and liver transplantation are also provided. The "Eye to the Future" section summarizes some of the new discoveries in diagnosis, monitoring, and management of liver failure currently on the horizon.

### ETIOLOGIES OF ACUTE FULMINANT HEPATIC FAILURE

A variety of causes can trigger acute FHF including infection, toxic ingestion, drug reactions, malignancy, veno-occlusive disease, and ischemia, among others (Table 1). Drug toxicity, idiosyncratic drug reactions, and viral infections produce the majority of cases of FHF. Recent data

indicate that acetaminophen toxicity has become the leading cause of FHF in the United States. This is an example of drug-induced liver injury that results from a direct hepatotoxic agent acting in a dose-dependent manner (4,5). Acetaminophen-induced liver failure typically results from intentional overdose; although significant toxicity can occur unintentionally with therapeutic doses of the drug in chronic ethanol abusers and those exposed to other enzyme-inducing medications such as phenytoin or isoniazid (6,7).

The majority of drugs that produce liver failure do so in an unpredictable, dose-independent pattern through a variety of mechanisms including immune-mediated allergic reactions and the production of toxic metabolites. Phenytoin and halothane represent examples of compounds that can produce such idiosyncratic drug reactions. There are multiple viruses capable of producing severe liver injury. The incidence of viral etiologies varies geographically with hepatitis B virus (HBV) being most common in the United States and other Western countries (5). Liver failure resulting from chronic hepatitis C virus (HCV) is also one of the most common causes of end-stage liver disease requiring liver transplant; however, it is an uncommon cause of FHF in Western countries.

✎ **A rapid diagnosis and identification of the etiologic agent increases the likelihood that specific therapy will be beneficial in the treatment of FHF.** ✎ Determining the etiology is particularly important in cases of acetaminophen toxicity as early treatment with *N*-acetylcysteine can be life-saving. The same is true for other toxic exposures that may benefit from temporary support by extracorporeal blood cleansing technologies (Volume 2, Chapter 38).

### DIAGNOSIS, CLASSIFICATION, AND PROGNOSIS

The diagnosis of FHF is based on the clinical findings of jaundice and encephalopathy with associated laboratory abnormalities such as elevated aminotransferases, bilirubin, ammonia, coagulopathy, and/or hypoglycemia. Histology is helpful in determining etiology in some circumstances, but the use of liver biopsy is limited by the risks imposed by coexisting coagulopathy.

**Table 1** Etiology of Fulminant Hepatic Failure

Type	Toxic agent
Infectious	Viral hepatitis: HAV, HBV, HCV <sup>a</sup> , HDV, HEV, HSV <sub>1</sub> , HSV <sub>6</sub> , EBV, CMV Bacterial toxin: <i>Bacillus cereus</i> , <i>Leptospirosis</i>
Drug toxicity	Direct Acetaminophen Alcohol Idiosyncratic Isoniazid Halothane Phenytoin Statins Sulfonamides Many others reported
Toxins	Amanita phalloides Organic solvents, for example, carbon tetrachloride Phosphorous Many others reported
Vascular/hemodynamic	Budd–Chiari syndrome Congestive heart failure Shock/ischemia
Infiltrative disease	Lymphoma Leukemia Metastatic carcinoma
Other	Acute fatty liver of pregnancy Wilson’s disease Reye’s syndrome Hyperthermia Autoimmune hepatitis

<sup>a</sup>HCV is virtually unheard of as a cause of FHF in Western countries, but has been occasionally reported to cause FHF in Asia.

**Abbreviations:** CMV, cytomegalovirus; EBV, Epstein–Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HSV<sub>1</sub>, herpes simplex virus type 1; HSV<sub>6</sub>, herpes simplex virus type 6.

Classification systems for FHF denote subdivisions based on the interval from the onset of jaundice to encephalopathy, a defining characteristic of FHF (Table 2). A short jaundice to encephalopathy interval has been correlated with a better outcome in some series (8,9). Other factors associated with survival include age, etiology, coagulation factors, pH, bilirubin, renal function, grade of hepatic encephalopathy, and neurologic status.

**Table 2** Classification Systems of Fulminant Hepatic Failure

Number of stages	Classification	Jaundice–encephalopathy interval (wk)
2	FHF	≤2
	Sub-FHF	2–12
3	Hyper-ALF	1
	Acute liver failure	1–4
	Subacute liver failure	5–12

**Abbreviations:** ALF, acute liver failure; FHF, fulminant hepatic failure.

**Source:** From Refs. 8, 9.

**Table 3** King’s College Criteria for Nonsurvival in Fulminant Hepatic Failure

Acetaminophen etiology	Arterial pH <7.30 (with adequate volume resuscitation) or arterial serum lactate level >3 mmol/L (6 mg%) or association with any of the following: INR >6.5 (PT >100 sec) Serum creatinine level >3.4 mg% Hepatic encephalopathy of grade 3 or 4
Non-acetaminophen etiology	INR >6.5 or any three of the following: Age <10 or >40 yr Interval between jaundice and encephalopathy >7 days Etiology of “drug-induced” or sero-negative hepatitis INR >3.5 (PT >50 sec) Total bilirubin >17.5 mg/dL

**Abbreviations:** INR, international normalization ratio; PT, prothrombin time.

**Source:** From Ref. 10.

✎ **Accurate assessment of severity and prognosis in FHF is particularly important for identifying those patients requiring liver transplantation.** ✎ Several schemes have been proposed to aid in transplant decision making, and the King’s College Hospital criteria are perhaps the best known and most widely used (10). The influence of acetaminophen as the cause of FHF is particularly important in this evaluation system (Table 3).

## SUPPORTIVE CARE TARGETING ASSOCIATED ORGAN SYSTEM DYSFUNCTION

FHF exerts its effects on multiple organ systems in the body through loss of the synthetic, metabolic, and immune-protective functions of the liver (Table 4). Herniation from intractable intracranial hypertension and sepsis with MODS remain important causes of death.

### Central Nervous System

✎ **Hepatic encephalopathy is a defining feature of fulminant liver failure.** ✎ The reversible metabolic encephalopathy that accompanies FHF manifests a broad range of neuropsychiatric abnormalities. Encephalopathy related to FHF is more complex than that associated with chronic liver disease in part because of elevations in intracranial pressure (ICP) and the neurologic sequelae of MODS that accompany FHF.

The severity of hepatic encephalopathy is traditionally classified into four stages (Table 5) (11). Behavioral changes in hepatic encephalopathy range from subtle personality disturbances to profound coma (stage IV). Motor changes include hypertonia and hyperreflexia in earlier stages and hypotonia and loss of deep tendon reflexes with progression. Asterixis, the classic “liver flap,” may be seen in early stages.

### Pathophysiology

The pathogenesis of encephalopathy in FHF is complex, multifactorial and includes cerebral edema as well as the effects of accumulating gut-derived encephalopathic substances that

**Table 4** Organ Dysfunction in Fulminant Hepatic Failure

Organ	Dysfunction	Treatment/comments
CNS	Hepatic encephalopathy	Lactulose, neomycin (or rifaxamine), aromatic amino acid, and protein restriction
	Cerebral edema, elevated ICP	Minimize (ammonia), elevate HOB, avoid hypotension, hypercarbia and hypoxia; ICP monitoring does not improve survival
Cardiovascular	Hyperdynamic circulation, vasodilation, hypovolemia, dysrhythmias, sepsis, septic shock, MODS	Fluid resuscitation (if hypovolemic) with invasive monitoring (if unstable) systemic vasopressor support if needed
Respiratory	Hyperventilation, aspiration, pneumonia, ARDS	Intubation, mechanical ventilation with PEEP
Metabolic	Hypoglycemia, metabolic acidosis, hypokalemia, hypomagnesemia	Glucose drip (if ↓ [glu]). Repletion of electrolytes feedings with low aromatic amino acid diet
Renal	ATN, functional renal failure (hepatorenal syndrome)	Maintenance of hemodynamics to preserve renal perfusion, avoid nephrotoxic drugs and infection; CVVHD if dialysis is needed
Hematologic	Coagulopathy, depletion of clotting factors, thrombocytopenia, platelet dysfunction, accelerated fibrinolysis, DIC, bleeding/anemia	Repletion of coagulation factors, treatment of infection, TEG monitoring may be useful, especially during OLT
GI bleed ID/immune	Worsens organ failure and hypovolemia Impaired phagocyte function Bacterial and fungal infections are easily acquired leading to sepsis and MODS	H <sub>2</sub> RA or PPI Surveillance for infection, prompt treatment of infections; there is a role for prophylactic antibiotics

*Abbreviations:* ARDS, acute respiratory distress syndrome; ATN, acute tubular necrosis; CNS, central nervous system; CVVHD, continuous venovenous hemodialysis; DIC, disseminated intravascular coagulation; H<sub>2</sub>RA, histamine 2 receptor agonist; HOB, head of bed; ICP, intracranial pressure; MODS, multiple organ dysfunction syndrome; OLT, orthotopic liver transplant; PEEP, positive end expiratory pressure; PPI, proton pump inhibitor; ↓, decreased; [glu], plasma glucose concentration; TEG, thromboelastogram;

are normally cleared by the liver. Ammonia is often implicated, and most patients will have elevated blood levels of this substance that crosses the blood–brain barrier (12). The role of ammonia in the pathophysiology of hepatic encephalopathy has been unclear in the literature, as plasma levels correlate poorly with severity, and many of the clinical and neurophysiologic disturbances induced by ammonia in other settings are not characteristic of hepatic encephalopathy (13,14). However, ammonia may exert some of its effects in FHF by potentiating gamma aminobutyric acid (GABA)-mediated neuronal depression and contributing to cerebral edema via increased conversion of glutamate to glutamine (15). Furthermore, arterial plasma ammonia levels have been shown to correlate with cerebral herniation (16).

**Table 5** Hepatic Encephalopathy

Grade	Neurologic status
I	Mild confusion, euphoria, depression, slowing of mental tasks, slurred speech, irritability, abnormal sleep pattern
II	Drowsiness, lethargy, gross deficits in mental tasks, personality change, inappropriate behavior, disorientation
III	Somnolent, unable to perform mental tasks, persistent disorientation to time and/or place, amnesia, incoherent speech, profound confusion, agitation
IV	Coma with or without response to painful stimuli

Source: From Ref. 2.

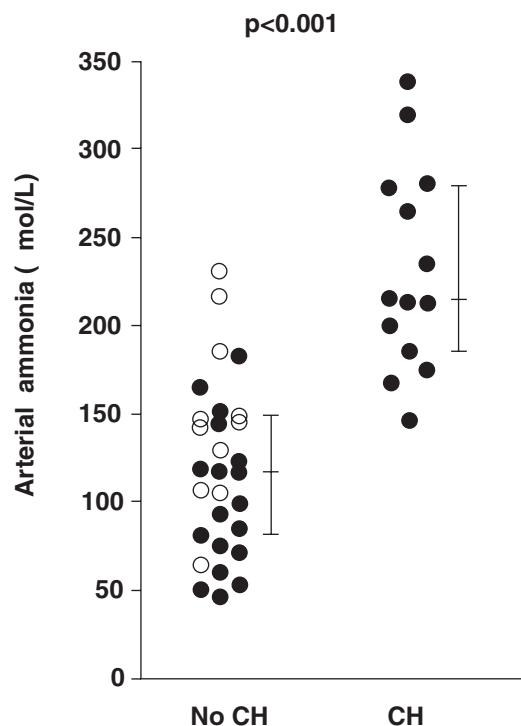

Many other substances have been proposed as causative agents in hepatic encephalopathy. For example, increased concentrations of mercaptans, fatty acids, phenol, tryptophan, octopamine, phenylethanolamine, and taurine have been found in increased concentrations in the setting of liver failure. The role, if any, for these substances in the pathogenesis of FHF-induced encephalopathy has not been well established (17).

GABA activity is believed to be very important in the pathogenesis of hepatic encephalopathy. Increased GABA activity in FHF has been demonstrated secondary to increased synaptic availability and increased synthesis (18). Increased concentrations of endogenous benzodiazepine receptor agonists have been found in the brain and plasma of patients with hepatic encephalopathy, and benzodiazepine receptor antagonists such as flumazenil provide transient improvement in clinical and electrophysiologic abnormalities in some patients (19,20). As noted above, ammonia may enhance GABA-receptor activity as well.

Many factors can exacerbate the neurologic dysfunction associated with hepatic encephalopathy. Use of central nervous system (CNS) depressants such as benzodiazepines for sedation can worsen the encephalopathic state, presumably via GABA-receptor activity. Gastrointestinal (GI) bleeding and excess protein loads present more substrate to the gut for the production of encephalopathic substances. Alkalosis further promotes the movement of ammonia into the brain. Sepsis, electrolyte abnormalities, and hypoglycemia are also common in FHF and impart additional neurologic dysfunction.

Cerebral edema is the most prominent feature of FHF, occurring in up to 80% of patients with stage IV encephalopathy (21). Elevated ICP distinguishes encephalopathy in FHF from that associated with chronic liver disease, and a short jaundice to encephalopathy interval is associated with a greater risk of cerebral edema. Uncontrolled ICP produces ischemic neurologic injury as well as the potential for herniation, a common event in nonsurvivors (22). Clinical signs of intracranial hypertension in encephalopathic patients may be difficult to detect. Computed tomography (CT) is useful in detecting abnormalities such as intracranial hemorrhage but unreliable in diagnosing elevated ICP (23). **Because of the potential for complications, ICP monitoring remains controversial in managing patients with stage III and IV encephalopathies.** Although it is important for optimizing patient's management, ICP monitoring via an epidural transducer is associated with fewer complications, whereas an intracranial transducer offers a higher fidelity and more reliable signal (24). Techniques to control serum ammonia levels may be beneficial, because arterial ammonia levels  $>200 \mu\text{mol/L}$  have been shown to predict cerebral herniation within 24 hours after the development of stage III/IV encephalopathy (Fig. 1).

Measurements of cerebral blood flow (CBF) vary widely in patients with FHF-induced encephalopathy (25). As encephalopathy worsens, uncoupling of cerebral metabolism and CBF develops. Autoregulation to blood pressure is lost, rendering CBF more passively pressure-dependent and the brain more sensitive to hypotension (26). An absolute hyperemia develops in some and has been correlated with worsening edema and mortality (27).

**Figure 1** Arterial plasma ammonia concentration in 30 patients with acute liver failure (ALF) who did not develop cerebral herniation (No CH), and 14 patients who died from cerebral herniation (CH). *Left side:* open circles indicate patients who underwent liver transplantation; full circles indicate patients who died from other reasons. *Source:* From Ref. 16.

Cerebral oxygen utilization and CBF can be inferred from jugular venous oximetry monitoring which is a more practical bedside technique than measurement of regional CBF. Increases in arterial-jugular venous oxygen ( $A_jVdO_2$ ) content difference imply low CBF and cerebral ischemia when oxygen utilization is constant. The assumption that cerebral oxygen consumption is constant in FHF may not be correct in all cases, however (25). A narrowed  $A_jVdO_2$  correlates with relative or absolute hyperemia. CBF has also been measured noninvasively with transcranial Doppler, although the utility of this technique has not been established relative to the use of jugular venous oximetry (28).

Electroencephalogram monitoring is useful in more severe cases, as subclinical seizure activity has been identified in FHF patients with advanced encephalopathy. It is also essential in managing patients who require barbiturate coma for control of intracranial hypertension (29).

### Management

**The most important aspect of treatment for encephalopathy in FHF is control or elimination of factors known to increase ICP and cerebral edema.** Maintaining an adequate cerebral perfusion pressure (CPP), the difference between mean arterial pressure (MAP) and ICP, is critical to preventing ischemia. A CPP less than 50 mmHg has been associated with poor outcome after hepatic transplantation, and values of 50 to 60 mmHg have been advocated as therapeutic targets (30–32). Efforts to improve CPP include reducing elevated ICP as well as increasing blood pressure with vasoconstrictors and/or inotropes. Maintaining adequate intravascular volume is important in maintaining cardiac output and MAP, but the optimum fluid regimen to use in patients with hepatic encephalopathy is unknown. Unnecessary free water is avoided, as it will exacerbate cerebral edema.

Although CPP improvement results from both ICP reduction and MAP augmentation, control of ICP also prevents herniation. Osmotherapy with mannitol is effective in reducing ICP in many patients, while corticosteroids have not been found to be helpful (33). Barbiturates are used to reduce refractory intracranial hypertension, however, hypotension from barbiturate-induced vasodilation and myocardial depression can compromise CPP. Therefore, aggressive hemodynamic monitoring and support may be necessary. Clinical neurologic examination is lost with barbiturate coma, and the drug effects can persist for a prolonged period of time in the face of impaired hepatic metabolism.

**Hypothermia has emerged as an integral supportive maneuver in the care of FHF patients.** Hypothermia has been used in other settings of intracranial hypertension (32–34°C) and mild hypothermia has been shown to reduce cerebral edema in animal models of FHF (34,35). Techniques employed to achieve hypothermia include use of cooling blankets, reducing room temperature, and reducing ventilator circuit temperature settings. Reductions in ICP with commensurate improvement in CPP have been reported in patients with liver failure treated with hypothermia although prospective outcome data are lacking (34,35).

A head-up position has been advocated by some to decrease ICP, although the optimal head position has not been established as CPP may actually be compromised despite the reduction in ICP. Phenytoin reduces subclinical

seizure activity as well as cerebral edema in some patients (29). Monitoring of phenytoin levels if used is warranted given the potential for alterations in hepatic metabolism and plasma protein levels in FHF.

Airway control and mechanical ventilation are required in comatose patients, and neuromuscular blockade can be necessary to prevent coughing and ventilator bucking with consequent increases in ICP and to protect the airways in patients considered for liver transplantation. Routine hyperventilation should be avoided as it may further reduce CBF in brain areas that are already marginally perfused. Lowering the PaCO<sub>2</sub> should be reserved for the subset of patients with hyperemia as identified by jugular venous saturation or CBF measurement.

Lactulose is commonly used to treat encephalopathy in patients with chronic liver disease. It is not clear whether there is any benefit in acute liver failure (ALF). However, ammonia exerts neurotoxicity via accumulation of glutamine within astrocytes (Fig. 2), and this rapid increase in astrocyte osmolarity triggers cerebral edema and cerebral hyperemia via unknown mechanisms (36).

The benzodiazepine receptor antagonist flumazenil has been shown to improve clinical and electrophysiological derangement in a significant proportion of patients with encephalopathy in both FHF and chronic liver disease (37). Unfortunately, the effects are transient (consistent with the drug's pharmacokinetics) and there is no improvement in prognosis.

Supportive measures also include correction/prevention of hypoxemia, hypoglycemia, and electrolyte abnormalities. *N*-Acetylcysteine improved oxygen transport in some studies of liver failure independent of its effects on acetaminophen metabolism and is used by some in FHF of any cause (31). The beneficial effect of *N*-acetylcysteine on oxygen transport has been challenged, and is currently under investigation in a multicenter clinical trial (38).

## Cardiovascular

☞ **Circulatory abnormalities in liver failure include a decreased effective intravascular volume, vasodilation, and a hyperdynamic circulation.** ☞ The decreased effective intravascular volume results from altered intake (particularly in encephalopathic patients), bleeding, and

**Figure 2** Astrocytic incorporation of ammonium into L-glutamine as first step for development of cell swelling, cerebral edema, and hyperemia. *Source:* From Ref. 36.

venodilation and third space of fluid due to circulating inflammatory mediators, hyponatremia, and later hypoalbuminemia. Systemic arteriolar dilation and afterload reduction contribute to the supranormal cardiac index in FHF. Supervening sepsis will exacerbate this vasodilated, hyperdynamic, state. Additionally, barbiturate therapy, if used for intracranial hypertension produces myocardial depression, vasodilation, and hypotension. Dysrhythmias occur frequently in FHF and include ventricular ectopy, A-V block, and atrial fibrillation (39).

## Pathophysiology

The pathophysiology of the cardiovascular changes in FHF is unknown. The decreased systemic vascular resistance (SVR) was first reported in 1953 by Kowalski and Abelmann (40). Since then, it has been documented that systemic shunts open up and that much of the increased cardiac output is circulating in muscle and skin, rather than through the liver. However, investigators have yet to determine if these shunts are opened up because of a substance that is elaborated by the injured liver, or by some substance that is not being cleared by the injured liver, or by the absence of some factor which is normally produced by a well-functioning liver.

Following liver transplantation, the shunts will close down and the SVR will subsequently normalize. In many patients, the increased cardiac output and decreased SVR has little deleterious impact. However, in the elderly, or those with severe coronary artery disease, the hyperdynamic circulatory state can trigger myocardial ischemia or low perfusion-related renal failure.

## Management

☞ **Hemodynamic management in ALF is aimed at providing adequate cerebral perfusion in the setting of intracranial hypertension, avoiding hemodynamically mediated deterioration in hepatic function, and preventing multiple organ failure.** ☞ Continuous intra-arterial blood pressure monitoring identifies hypotension quickly while facilitating blood gas analysis and calculation of parameters such as CPP. Pulmonary artery catheterization (PAC), while controversial, can help guide fluid and vasoactive drug therapy via preload assessment and cardiac output measurement when patients are unstable, and particularly when the cardiovascular parameters are confusing. However, there is no role for the PAC in routine management of stable patients with liver failure.

☞ **Maintaining intravascular volume and therefore cardiac preload is essential to preserve cardiac output and oxygen delivery.** ☞ In contrast, overly zealous fluid therapy risks exacerbation of cerebral edema, hepatic congestion, and worsening pulmonary edema in patients with acute respiratory distress syndrome (ARDS). Fluid choice is controversial and there is no clear evidence supporting the use of colloid over crystalloid solutions, although, as noted previously, excess free water should be avoided when cerebral edema is present. Red blood cell transfusion is indicated in bleeding and anemic patients and represents the ideal volume expander in such settings. A target hematocrit of 30% is advisable given the ongoing risks for multiple organ ischemia by providing a reasonable balance between oxygen carrying capacity and peripheral oxygen delivery.

☞ **Hypotension not responding to fluid therapy should be treated with vasoactive drug infusion.** ☞ Norepinephrine is being used more often as it combines potent

inotropy with vasoconstriction. Many other vasoactive drug and drug combinations have been used, however. The endpoints for resuscitation include maintenance of adequate CPP in patients with elevated ICP, restoration/maintenance of renal function, and relief of lactic acidosis. The practice of resuscitation to target values of oxygen delivery and consumption has been called into question in other settings and a role, if any, in FHF has not been established. Correction of electrolyte abnormalities, for example, hypokalemia and hypomagnesemia, may ameliorate cardiac dysrhythmias.

### Respiratory

Severe encephalopathic patients are at risk for pulmonary aspiration and upper airway obstruction. Respiratory alkalosis is often present early secondary to central hyperventilation, which can increase ammonia. Hypercapnic respiratory failure is more likely in later stages of hepatic encephalopathy.

### Pathophysiology

☞ **Gas exchange abnormalities in FHF result from transpulmonary shunting, and in some cases aspiration pneumonia, atelectasis, acute lung injury, or hepatopulmonary syndrome.** ☞ Patients with intracranial hypertension will be particularly sensitive to episodes of hypoxemia. The ARDS occurs in a significant number of patients and produces hypoxemia and reduced compliance (Volume 2, Chapter 24) (41). Ventilatory therapy in ARDS, particularly high PEEP levels, can exacerbate intracranial hypertension.

### Management

Endotracheal intubation for airway protection and patency will be necessary for comatose patients and those with intracranial hypertension who require mechanical ventilation while receiving paralytics, barbiturates, or hyperventilation therapy. Hypoxemia will exacerbate cerebral ischemia and should be treated aggressively with supplemental oxygen and ventilatory support. Mechanical ventilation has the potential to adversely affect hepatic function, particularly when high levels of positive end-expiratory pressure (PEEP) are used which impede hepatic venous drainage. High PEEP levels may also adversely affect ICP. Such patients should receive close ICP monitoring as ventilatory support is titrated.

### Coagulation System

#### Pathophysiology

Coagulopathy in acute hepatic failure results from a variety of causes. Loss of hepatic synthesis of the major plasma clotting factors is a prime reason. Levels of factors I, II, V, VII, IX, and X are reduced, ultimately leading to a prolonged prothrombin time (PT), and consequent elevated international normalization ratio (INR). Indeed, the PT serves as an important diagnostic and prognostic role. Platelet counts are reduced as is platelet function (42). Plasminogen, protein C, and protein S levels are reduced with evidence of disseminated intravascular coagulation (DIC) in many. Simultaneously, accelerated fibrinolysis is present, further contributing to the risk of hemorrhage (43).

### Management

☞ **Correction of coagulation and platelet abnormalities is necessary in bleeding patients and those undergoing invasive procedures such as ICP monitor placement or**

**surgery.** ☞ Routine correction of clotting factor deficiencies with fresh frozen plasma (FFP) and/or factor VII infusion is unnecessary and concern has been raised regarding the subsequent loss of the PT as a prognostic sign (36). Vitamin K should be administered, as biliary absorption of this clotting cofactor may be impaired. Prophylaxis with H<sub>2</sub> antagonists can reduce the risk of GI bleeding.

### Renal

Acute renal failure occurs in FHF with an incidence ranging from 30% to 70% and is associated with poor outcome particularly in those with severe encephalopathy (44–46). A variety of etiologies can contribute to renal failure singularly or as collective insults. Chief among these are prerenal states, hepatorenal syndrome, and toxin-induced acute tubular necrosis (ATN).

### Pathophysiology

Renal dysfunction in the setting of FHF is often multifactorial in origin but prerenal factors are implicated in the majority of cases. ☞ **Potentially reversible hepatorenal syndrome occurs in a significant proportion of FHF patients with renal dysfunction.** ☞ The hepatorenal syndrome is associated with the same laboratory findings as the prerenal state, for example, elevated blood urea nitrogen/Cr ratio, and low fractional excretion of sodium (FeNa), that is, typically <1.0. In contrast to the prerenal state, patients with hepatorenal syndrome will not improve their renal function following the restitution of intravascular volume alone. Rather, the hepatorenal state will only resolve if the liver injury recovers, or following liver transplantation. Hypovolemia and vasodilation are often present in patients with FHF. This state is often exacerbated by secondary sepsis, leading to further reductions in renal blood flow which can progress to ATN.

Renal injury can also result from a toxic ingestion that is the primary cause of liver failure (e.g., acetaminophen toxicity). Furthermore, numerous nephrotoxic drugs, such as aminoglycosides, and radiocontrast are utilized in the care of FHF patients, and can contribute to renal injury.

### Management

Prevention of acute renal failure is a major goal of the critical care management of patients with liver failure, and close monitoring of urine output via an indwelling bladder catheter is warranted. Cardiovascular resuscitation with fluids, prior to institution of supplemental vasoconstrictors and inotropes, is the best way to prevent acute renal failure. Furthermore, this therapy should be guided by hemodynamic monitoring data aimed at maintaining normal renal blood flow and perfusion pressure.

Nephrotoxic drugs such as aminoglycosides and nonsteroidal antiinflammatory drugs should be avoided whenever possible. *N*-acetylcysteine therapy for acetaminophen-induced FHF has been reported to reduce the incidence and severity of renal failure (47).

Patients who develop ATN often require some type of renal replacement therapy. Intermittent hemodialysis produces significant reductions in blood pressure and ICP elevations in the setting of FHF encephalopathy. Continuous renal replacement therapy (typically venovenous hemodialysis) is a better option than intermittent hemodialysis in patients with elevated (or potentially elevated) ICP because of the reduced risk of hypotension and ICP spikes (Volume 2, Chapter 43) (48).

### Metabolic

☞ Patients with ALF develop multiple metabolic and electrolyte abnormalities including hypoglycemia, hypokalemia, hypomagnesemia, hypophosphatemia, and metabolic acidosis. ☞

### Pathophysiology

Hypoglycemia occurs frequently as a result of impaired gluconeogenesis, persistent insulin effects, and decreased glycogenolysis. Neurologic dysfunction induced by low blood glucose can exacerbate or be confused with hepatic encephalopathy.

Metabolic acidosis is a poor prognostic factor in ALF. Lactate accumulation results from impaired hepatic metabolism as well as increased production by the liver and peripheral tissues. Uncorrected hemodynamic derangement and persistent hypoperfusion will exacerbate lactate production (49,50).

### Management

Frequent monitoring of blood glucose is necessary in FHF patients. Hypoglycemia is treated aggressively with intravenous 50% dextrose solution by bolus followed by continuous glucose infusions. Ten percent dextrose infusions are used commonly, whereas some patients may require more concentrated glucose solutions. Phosphate levels may dramatically decrease, following the administration of large volumes or high concentrations of dextrose solutions.

Improvement in lactic acidosis will follow adequate hemodynamic resuscitation, control of secondary sepsis, and improved liver function. Treatment of low pH levels with bicarbonate is only recommended when severe and associated with hyponatremia. Potassium and magnesium repletions are required to treat and prevent cardiac dysrhythmias.

### Infectious Disease

Sepsis is an ever-present risk in FHF that can be difficult to recognize. Serious infection contributes to the development of hyperdynamic shock, multiorgan failure, and death.

### Pathophysiology

Susceptibility to infection is increased due to poor phagocyte function, low complement levels, and invasive therapies (51). *Staphylococcus* and *Candida* species have become increasingly important causative organisms (52).

### Management

A high index of suspicion is necessary to detect and treat new infections. Whenever possible, therapeutic antibiotic choice should be based on culture results and sensitivities. Some centers advocate the use of prophylactic parenteral antibiotics for all FHF patients. Enteral decontamination does not appear to add additional protection (31).

## SPECIFIC DRUG THERAPY

Treatment and support strategies targeted directly at the liver in acute hepatic failure include prevention or attenuation of toxic liver injury with resuscitative drugs (e.g., for acetaminophen toxicity, antiviral, etc.) and extracorporeal substitution of hepatocyte function (following section).

### Acetaminophen Toxicity

Overdosage of acetaminophen should be treated with gastric lavage and activated charcoal within two hours of ingestion, the period of GI absorption. *N*-acetylcysteine is indicated in any case of known or suspected acetaminophen toxicity. Oxidation of acetaminophen by the cytochrome P-450 enzyme system produces *N*-acetyl-*p*-benzoquinoneimine (NAPQI), a highly reactive compound which binds to intracellular hepatocyte proteins producing injury and subsequent necrosis (53). *N*-acetylcysteine prevents or attenuates hepatocyte injury by serving as a glutathione source and substitute to which NAPQI binds producing nontoxic metabolites. Institution of therapy may be beneficial as late as 24 hours after ingestion (54). *N*-acetylcysteine is currently available in the United States as an oral or intravenous form, which is the preferred way of treatment. For oral use, it is given as a loading dose of 140 mg/kg, which is followed by 70 mg/kg maintenance doses at four-hour intervals. The duration of treatment is somewhat controversial. Food and Drug Administration (FDA) guidelines prescribe 17 doses of oral *N*-acetylcysteine given at four-hour intervals following the loading dose, however, shorter duration protocols using the intravenous form is preferred.

### Antiviral Therapy

Specific antiviral treatment markedly improves survival of herpetic hepatitis in immunocompetent patients. In a study of 93 patients, without antiviral therapy survival was only 11% with vidarabine, survival improved to 38% and with acyclovir survival was 57% (55). More recent results demonstrate approximately 40% survival rate (55). Patients with hepatitis caused by herpes virus may benefit from acyclovir therapy. Likewise, patients with cytomegalovirus (CMV) may benefit from gancyclovir.

There are four FDA approved treatments for hepatitis B infection in the United States, interferon alpha-2b, which is contraindicated in cases with HBV-FHF, lamivudine, adefovir dipivoxil, and entecavir (56). In cases of acute exacerbation or flare of hepatitis B, these drugs are the choice for therapy; however, in patients on long-time lamivudine who develop a flare, other drugs such as adefovir are probably better, as the flare likely represents a lamivudine-resistant mutation in the virus (57).

Hepatitis C is an uncommon cause of fulminant hepatitis, but a recent report demonstrated improved survival with a combined treatment of alpha interferon and ribavirin (58).

### Mushroom Toxin Support

The numerous syndromes associated with mushroom poisonings, along with their associated diagnostic and management principles, have recently been reviewed (Volume 1, Chapter 31) (59). Amanita mushroom poisoning has been treated with penicillin, which displaces amatoxin from protein-binding sites and may inhibit penetration into hepatocytes. Silibinin, which inhibits toxin binding, has also been used in amanita poisoning (60).

Combined treatment with silibinin and *N*-acetylcysteine appears to be more effective than other medical treatments in amatoxin poisoning (61). As a bridge to transplantation, and occasionally as a successful therapy in its own right, extracorporeal liver-cleansing techniques are beginning to show promise following mushroom intoxication as well as following other hepatic injuries (Volume 2, Chapter 38) (62,63).

### Other Specific Therapies

Autoimmune hepatitis has been treated with prednisone and azathioprine for over 30 years. However, there are a variety of types of autoimmune hepatitis, and more specific therapies are on the horizon (64). Each specific autoimmune disease has a specific regulatory dysfunction that can be targeted (65).

Galactosemia and fructosemia are etiologies of FHF, which are treated with dietary elimination. Hereditary tyrosinemia type I is treated with dietary elimination and 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione.

### EXTRACORPOREAL SUPPORT

A variety of techniques have been used in patients with ALF to temporarily replace hepatic function while awaiting spontaneous recovery or liver transplantation. Plasmapheresis decreases plasma concentrations of substances such as bilirubin, aminotransferases, and ammonia (66). In combination with plasma exchange, plasmapheresis can correct coagulation abnormalities and has been associated with improved survival in noncontrolled studies (67). Charcoal hemoperfusion and hemodiafiltration with charcoal or an albumin adsorbent circuit, the so-called "molecular adsorbent recirculating system" have also demonstrated improvement in various clinical and biochemical parameters (Volume 2, Chapter 38) (68).

Bioartificial livers incorporate hepatocyte cells in a synthetic framework through which whole blood, plasma, or a dialysate are perfused via an extracorporeal circuit. The hepatocytes used in these devices are derived from human hepatoblastoma cells [extracorporeal liver-assist device (ELAD)] or porcine livers ("Bioartificial Liver"). Improvement in mental status with the ELAD has been reported, however, a randomized, controlled trial did not show reduced mortality (69). Similarly, the bioartificial device has been associated with improved neurologic function, but improved survival has yet to be demonstrated (Volume 2, Chapter 38).

Extracorporeal perfusion of both human and porcine livers has been undertaken with improvement in encephalopathy and prolonged survival in small numbers of patients (70).

### LIVER TRANSPLANTATION

Liver transplantation offers the best hope for survival for patients with FHF. Given the limited availability of human donors, replacement of liver tissue has also been undertaken by implantation of hepatocytes, auxiliary liver transplantation, and xenotransplantation; techniques which have not had the success of allotransplantation.

#### Transplantation Types and Nomenclature

##### *Hepatocyte Transplantation*

Implantation of hepatocytes into the splenic bed has been carried out in a limited number of patients, and decreased ammonia levels, improved neurologic function, and a slight mortality advantage over controls have been described (71). Randomized trials have not been performed to date, however.

##### *Xenotransplantation*

Transplantation of animal livers has been performed as a bridge to human organ transplant in a very small number

of patients. Baboon, chimpanzee, and pig livers have been implanted with variable success including reports of graft function as long as 70 days (72). Rejection of the xenograft remains a significant problem along with concerns about transmission of infectious agents.

##### *Allotransplantation*

Allotransplantation denotes a species-to-species transplant, in this usage human-to-human. Liver transplantation with a human allograft has significantly reduced the mortality for patients with liver failure. Although survival following transplantation for patients with FHF is less than in other settings, one-year survival rates of 60% to 70% in FHF have been achieved (73). Patients with liver failure from acetaminophen fare somewhat better than those with FHF from other causes.

When the diseased liver is totally removed, and the transplanted allograft is positioned in the location of the native liver, it is referred to as an orthotopic liver transplant (OLT). OLT is the most commonly employed liver transplant. Heterotopic grafts refer to situations where the native diseased liver is left in place (because it might recover) and the transplanted liver is placed in another location (e.g., below the native liver) in the abdomen, and all connections are shared.

The shortage of donor organs remains the biggest hurdle to OLT. In response to the shortage of cadaveric donors, transplant centers have begun using "higher-risk" donor livers such as those from non-heart-beating donors (NHBDs) or with ABO incompatibility or from older donors or donors with fatty liver. Split-liver grafts from a single donor and living-donor transplantation are also being used (31).

Auxiliary transplantation allows the native liver to remain in place with the hope of eventual recovery and discontinuation of immunosuppressive therapy. While reported survival rates for the partial technique are similar to OLT, complications are more frequent with auxiliary transplantation (74). Although acute cellular rejection is a complication that is associated with a longer hospital stay, it rarely occurs in a severe form with the current immunosuppression protocols.

#### Perioperative Considerations for OLT in Acute Liver Failure Patients

Liver transplantation is the second most common transplant surgery, accounting for 21% of all organ transplants in the United States (75). In the period from 1997 to 2001, acute hepatic necrosis accounted for 9% of cadaveric liver transplants (76,77). In the last 20 years, emergency liver transplantation has emerged as the most beneficial therapeutic intervention for patients with ALF (78). Most of these are OLTs. Living donor transplants have increased since 1999. Management considerations for living donors will not be included in this discussion.

##### *Recipient Selection*

Accurate prediction of successful transplantation is an important goal in patient selection due to a small organ donor pool, lack of proven alternatives to transplantation, and lifelong complications secondary to immunosuppression (79).

The commonly used King's College Hospital criteria are the most utilized, and studies evaluating these criteria have shown positive predictive values ranging from 70% to 100% in predicting outcome as compared to other

prognostic scoring systems (80,81). In a recent meta-analysis, various prognostic criteria (Table 3) were compared in ALF patients (82). This included King's College Hospital criteria, elevated serum creatinine, encephalopathy, PT elevations, decreased factor V levels, the acute physiology and chronic health evaluation II scores, and Gc-globulin (vitamin D-binding protein, a liver-derived component of the actin scavenging system). The analysis indicated that King's College Hospital criteria and pH <7.3 alone were both fairly specific in predicting a poor outcome. Other proposed prognostic criteria include: (i) the severity of systemic inflammatory sepsis syndrome, (ii) alpha fetoprotein (AFP) levels, (iii) ratios of factors VIII and V, (iv) liver histology, (v) CT scanning of liver, (vi) cytokine levels, (vii) serum phosphate levels, and (viii) adrenal insufficiency. Further research is needed to determine the validity of each of these aforementioned prognostic variables.

Potentially helpful indicators of poor prognosis include: (i) based on etiology: drug injury, acute hepatitis B and autoimmune hepatitis, mushroom poisoning, Wilson's disease, Budd, Chiari syndrome (hepatic vein thrombosis), and grades III and IV encephalopathy on admission; (ii) based on King's College criteria (Table 3); (iii) model for end-stage liver disease (MELD) score (a logarithmic grading system based upon serum bilirubin, creatinine, and INR), introduced by the United Network for Organ Sharing in 2002 to prioritize organ allocation (83). MELD is an objective measurement that unlike the Child-Pugh scoring system, was not influenced by subjective assessments like hepatic encephalopathy. The MELD score has become a widely used tool for recipient selection and organ allocation but despite its objectivity and reliability, more studies regarding short-term and long-term outcomes are needed; (iv) the U.S. ALF group criteria is also predictive of mortality and categorizes the presence of three values: stage 3 or 4 hepatic encephalopathy, serum creatinine  $\geq 2.0$ ; and INR  $\geq 3.0$ . ALF patients with zero criteria have 4% mortality; 1 factor = 15% mortality; 2 factors = 50% mortality; and all 3 factors = 80% mortality (84).

In summary, currently available prognostic scoring systems do not perfectly determine recipient selection or predict outcome for liver transplantation; however, they are useful when combined with clinical judgment, and factored in with donor selection.

### Donor Selection

Standard criteria for donor selection initially excluded advanced age, obesity (body mass index >30), donor hypernatremia (serum sodium >155 meq/L), prolonged intensive care unit stay, large doses of vasopressor requirement, positive hepatic serologies, and the use of NHBDs.

However, over the last 20 years there is a growing disparity between demand and supply of organs. The expanded criteria for donors or marginal donors now include older livers, organs from the opposite gender, grafts with steatosis (obesity, alcohol use, diabetes), NHBDs, HCV-positive liver grafts, hepatitis B core antibody-positive grafts, donor hypernatremia, split liver grafts from deceased donors, and prolonged cold ischemia time (85). Marginal grafts have shown poorer immediate graft function, but careful matching of donors and recipients with these grafts has shown promising results in some centers.

### Preoperative Preparation

All patients with clinical or laboratory evidence of severe acute hepatitis should have the coagulation status evaluated and alterations in mental status closely monitored. If the

diagnosis of liver failure is established, transfer to the ICU facilitates optimum management, and in a center with a liver transplant program preparation for OLT. Exposure to viral infections, drugs or toxins, and history of chronic liver disease and alcohol intake is determined and all medications and supplements the patient used are reviewed.

A detailed history from the patient or the family and a physical examination is performed. The physical examination includes an assessment of neurologic status, the presence of jaundice, and stigmata of acute and/or chronic liver disease, right upper quadrant tenderness and palpable mass, ascites, edema, and congestive heart failure.

Laboratory examination consists of routine chemistries, complete blood counts, renal function tests, arterial blood gas measurements, blood typing and cross-matching, drug screens, viral hepatitis serologies, AFP levels, tests for Wilson's disease, autoimmune antibodies, HIV testing, and a pregnancy test in females. Plasma ammonia levels, lactate levels, and a liver biopsy via the transjugular route may also be indicated in certain clinical situations.

All the above is done to determine a precise etiology to help guide further management decisions. Once the etiology is determined, specific therapies should be initiated. A key factor for improving survival is early contact with a transplant center for transfer of patients.

### Therapy

Apart from focused therapy for the specific etiology, general supportive management should continue. Attention to fluid balance is of primary importance. Hemodynamic status should be monitored and treatment of infection should be carried out promptly. Metabolic parameters should be evaluated and GI prophylaxis for bleeding provided.

### Management of Raised Intracranial Pressure

In early stages of FHF, sedation should be avoided. Nonabsorbable disaccharides (e.g., lactulose) and antibiotics may be used, keeping in mind the possibility of bowel distention. If evidence of intracranial hypertension is present, the head should be elevated 30° and mannitol infusion is given. Patients progressing into grade III or IV hepatic encephalopathy should have airway protection and ICP monitoring established, particularly if they are considered for liver transplantation. Prompt treatment of seizures with benzodiazepines is recommended. Short-acting barbiturates and hyperventilation are temporary measures and are used only for short-term management of severe intracranial hypertension. Moderate hypothermia has been effective in reversing cerebral edema in some patients and is currently the subject of a clinical trial (34).

### Infection Screening and Antibiotic Prophylaxis

Patients with FHF are vulnerable to bacterial or fungal sepsis. This may preclude transplantation; hence periodic surveillance cultures should be performed and treated accordingly. Prophylactic antibiotics and antifungals have not been shown to improve overall outcomes.

### Coagulopathy

Patients are at increased risk for bleeding complications due to decreased synthesis and increased consumption of clotting factors. In preparation for liver transplant, use of FFP, vitamin K, platelet transfusions, and recombinant factor VII has been administered with temporary correction of coagulopathy. There are no reliable predictors of perioperative bleeding. It is known that patients who require more

perioperative transfusions are associated with lower graft and patient survival rates. This may be due to increased proinflammatory cytokine release, which worsens bleeding and worsens graft and patient survival.

The effort taken to temporarily normalize the coagulation status immediately prior to transplantation is generally worthwhile. Indeed all three phases of OLT are associated with metabolic and hemorrhagic derangements that can worsen any pre-existing coagulopathy. ⚡ **Sudden massive blood loss can occur intraoperatively and this in conjunction with baseline hyperfibrinolysis, coagulation factor deficiencies, and thrombocytopenia results in the need for massive blood and blood product transfusions with that have potentially severe consequences.** ⚡ Use of thromboelastogram (TEG) intraoperatively (Volume 1, Chapter 17) has been shown to decrease transfusion requirements during OLT surgery.

### **Intravascular Volume Status**

The high cardiac output, low SVR caused by a hyperdynamic circulation causes hypotension which may require inotropes and vasoactive drugs. Supportive therapy with fluid resuscitation and attempt to maintain intravascular volume is paramount. Monitoring should include an arterial blood pressure and pulmonary artery catheter to help guide fluid management perioperatively. Systemic vasopressor support with epinephrine, norepinephrine, or dopamine is preferred.

### **Intraoperative Management**

#### **Monitoring**

Invasive monitoring devices include a radial or femoral arterial line placed prior to induction. A pulmonary artery catheter is used routinely for perioperative fluid and hemodynamic management and for monitoring PA pressures. A transesophageal echocardiography (TEE) lead is placed for monitoring left ventricular filling, detection of air emboli during reperfusion, and assessing global left ventricular function. TEE is increasingly being used without reports of variceal bleeding after insertion.

Venous access is obtained with two 9-French introducers centrally. At UCSD, a rapid infuser circuit incorporating a cardiomy reservoir, roller pump, heat exchanger, and safety features for monitoring air embolism and occlusion is set up by a cardiovascular perfusionist. Use of the rapid infusion device allows rapid administration of warmed blood and fluids through large-bore central lines. Usual rates of transfusion are 200 cm<sup>3</sup>/min, but more rapid rates up to 1000 cm<sup>3</sup>/min can be administered.

The volume of infusion is guided by blood pressure, CVP, PA, and TEE. The composition of fluid replaced is determined by Hct, platelet count, PT/PTT, and TEG, as evaluated by the anesthesiologist.

#### **Veno-venous Bypass**

Venovenous bypass is used by some surgeons during liver transplantation to provide hemodynamic stability, decrease splanchnic congestion, improve renal perfusion, and decrease metabolic acidosis when the vena cava is clamped. Venous return from the femoral circuit and portal circulation is returned to the internal jugular/subclavian/axillary veins. In our center, percutaneous venovenous bypass lines are placed by the anesthesiologist prior to incision. A 17-French cannula is placed in the internal jugular vein and can be used for both bypass and for rapid infusion. Problems

with venovenous bypass include air embolism, thromboembolism, and inadvertent decannulation.

#### **Factor VII**

Recombinant factor VIIa seems to enhance local hemostasis by a local thrombin burst effect. Recombinant factor VIIa might have the potential to be an effective hemostatic measure in patients undergoing liver transplantation (86). This impression is based on clinical data from a limited number of case histories and small clinical trials. A recent study in patients undergoing hepatectomy showed that rfactor VIIa (rFVIIa) did not result in a statistically significant reduction in either the number of patients transfused or the volume of blood products administered (87).

Clinical trials are ongoing to determine the safety and efficacy of rFVIIa in patients undergoing OLT surgery, but no conclusive information has been obtained yet (Volume 2, Chapters 58–59) (88).

#### **Thromboelastogram**

In FHF patients receiving transplantation, pre-existing coagulopathy is often present secondary to decreased synthesis of coagulation factors and platelets, increased utilization of these, and decreased platelet function. During transplantation, this is complicated by fibrinolysis due to reduced clearance of activators of coagulation and after reperfusion of the grafted liver. A heparin-like effect is observed in one-third of patients following transplantation, and intraoperative changes in blood coagulation and TEG monitoring are also observed during liver transplantation.

Heparin used during venovenous bypass, heparin present in the grafted organ, and persisting fibrinolysis from poor graft function all may contribute to severe bleeding after reperfusion if the newly grafted liver is functioning poorly. TEG gives a global evaluation of clotting function and helps in assessing response to administration of corrective factors such as cryoprecipitate, platelets, or protamine (89,90). The TEG is also useful in detecting a prothrombotic state, as some patients are at a risk for hepatic arterial thrombosis after liver transplantation.

#### **Anesthetic Drugs**

Anesthetic induction incorporates a rapid sequence technique after three to five minutes of preoxygenation due to the increased risk of aspiration secondary to abdominal distension from ascites. Fentanyl is the opioid of choice and is useful to blunt the sympathetic response. Midazolam with its minimal hemodynamic effects is useful for amnesia. A balanced anesthetic technique is used in most centers, and volatile agents like isoflurane are used in low concentrations to minimize hypotension in patients with FHF. Isoflurane preserves splanchnic blood flow and is the preferred agent. Cisatracurium because of its organ-independent elimination, is used for neuromuscular blockade.

#### **Antifibrinolytics**

Reperfusion can trigger severe fibrinolysis, which requires cryoprecipitate and possibly antifibrinolytics. Earlier studies did not show any advantage to the use of prophylactic antifibrinolytics, but a European multicenter study showed decreased transfusion requirements with aprotinin and no thrombotic events in the aprotinin group (91).

**Table 6** Stages of Liver Transplantation

Preanhepatic (stage of dissection)	Anhepatic (stage of no liver)	Postanhepatic (stage of reperfusion)
Surgical incision to cross-clamp PV, HA, IVC	Occlusion of vascular flow to perfusion of grafted liver	Perfusion of new liver to completion of biliary reconstruction and closure of surgical incision
Blood loss	Hemodynamic changes due to clamping and then unclamping IVC	Hypotension
Hypoglycemia	Splanchnic congestion	Acidosis
Hypocalcemia	Decreased renal perfusion	Hypothermia
Coagulopathy	Hypocalcemia	Hyperkalemia
		Blood loss

Abbreviations: HA, hepatic artery; IVC, inferior vena cava; PV, portal vein.

### Stages of Liver Transplant Surgery

#### Preanhepatic Stage (Phase of Dissection)

The preanhepatic stage begins with surgical incision and ends with cross-clamp of portal vein, supra- and infrahepatic parts of the inferior vena cava, and hepatic artery (Table 6). Dissection and mobilization of the liver along with pre-existing coagulopathy result in blood loss and hypovolemia. Transfusions of blood and blood products are administered based on hematocrit, coagulation profile, platelet count, and TEG.

Metabolic parameters are monitored and treated. Citrate intoxication in the absence of hepatic function causes hypocalcemia from infusion of blood products. Hypoglycemia in acute hepatic failure and hyperkalemia secondary to renal dysfunction worsened by massive blood transfusion all need to be frequently monitored and corrected. Hypothermia should be avoided and hourly urine output monitored closely.

#### Anhepatic Stage

This begins with occlusion of vascular inflow and ends with perfusion of the grafted new liver. Hemodynamic changes dominate this stage when vena caval cross-clamping causes significant decreases in venous return, splanchnic congestion, metabolic acidosis, and decreased renal perfusion pressure.

Hemodynamic stability is maintained by administration of blood and blood products and correction of coagulopathy. This is important as the combined effect of absent clotting factors and fibrinolysis due to the unopposed

action of tissue plasminogen activator can cause severe coagulopathy in this stage.

#### Neohepatic Stage (Reperfusion Stage)

Reperfusion of the new liver through the portal vein begins the neohepatic stage and is associated with hypotension, hyperkalemia, acidosis, and hypothermia. One-third of patients experience profound hypotension after reperfusion. This can be due to metabolic abnormalities, vasodilatation, emboli (air or thrombotic), hypothermia, arrhythmias, or myocardial dysfunction (92,93). Some risk factors for this include suboptimal grafts and prolonged graft cold ischemia time. Hepatic artery followed by biliary tree anastomosis is done following portal vein anastomosis. Improvement in acidosis, decreasing requirements for calcium, improvement of coagulation function, rise in core body temperature, and bile output from the graft are indicators of a healthy graft.

#### Postoperative Complications

Early postoperative hemorrhage due to anastomotic leaks or laceration of the liver surface or coagulopathy results in reoperation in about 10% of transplanted patients. Vascular obstructive complications, particularly hepatic artery thrombosis, are a dreaded complication with the incidence ranging up to 10% in adults and 20% in children (due to the smaller vessel diameter). Other surgical and medical complications following OLT are shown in Table 7.

Postoperative management includes correction of coagulopathy, maintaining adequate volume status for vital organ perfusion, monitoring urine output, and prevention of infection. Immunosuppression is needed to prevent

**Table 7** Postoperative Complications after Hepatic Transplantation

Surgical complications	Medical complications	Immunological complications
Anastomotic or implantation site bleed	Early postoperative infections causing pneumonia and sepsis	Acute rejection
Hepatic artery/portal vein thrombosis	Acute cholangitis	Subacute rejection and graft dysfunction
Supra/infra hepatic vena caval obstruction	Viral infections especially CMV	Recurrence of Hep B and C
Biliary leakage/strictures	Immunosuppression-related toxicity	Recurrence of autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis
Wound infections, injury to bowel or other intra-abdominal organs	Acute renal failure	Chronic rejection

Abbreviations: CMV, cytomegalovirus; Hep, hepatitis.

**Table 8** Immunosuppressive Medications after Liver Transplantation

Drugs	Mechanism of action	Side effects
Corticosteroids	Suppress macrophage activation, powerful anti-inflammatory effect which suppresses immune response and acute graft rejection	Dose-related; fluid retention diabetes mellitus, osteoporosis, osteonecrosis, cataract, skin thinning Main concern: cardiovascular complications and promotion of virus replication in patients with viral hepatitis
Antimetabolites		
Azathioprine	Cytotoxic agents interfere with DNA and RNA synthesis of T and B lymphocytes	Bone marrow suppression, nausea, diarrhea
Mycophenolate	Interferes with synthesis of guanine nucleotides and DNA replication	
Calcineurin inhibitors		
Cyclosporine A	Inhibits calcineurin affecting T-cell activation	Renal dysfunction, diabetes, hypertension, headache and GI problems
Tacrolimus	Blocks T-cell proliferation and thereby interleukin synthesis	
Rapamycin	Blocks ligation of interleukin 2 to its receptor	Thrombocytopenia and hyperlipidemia
Monoclonal antibodies		
OKT3	Directed against CD3 complex of T cells	Diarrhea, nausea, myalgia, fever, tachycardia, dyspnea
Chimeric basiliximab	Selectively target the IL 2 receptor on activated T cells	Low toxicity and minor side effects
Humanized Daclizumab		

*Abbreviations:* DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

allograft rejection. These include corticosteroids, antimetabolites, calcineurin inhibitors, and monoclonal antibodies (Table 8).

Success of liver transplantation for FHF patients depends upon the status of both, the recipient, and the graft. A review has shown that the severity of multiorgan failure at the time of transplantation was the single best predictor of patient survival. Another analysis of 116 patients showed markedly poor outcomes in patients receiving marginal, size reduced, or ABO incompatible grafts.

## EYE TO THE FUTURE

Patient survival for deceased donor liver transplant recipients based on the annual report by the OPTN/SRTR registry was 86% by one year, 78% at three years, and 72% at five years after transplantation (94). The shortage of grafts, compared to the long list of waiting recipients, is causing many to expire prior to transplant.

Marginal and split grafts, living related donation, xenotransplantation, and stem-cell-derived organs are future options that need to be further explored due to the small pool of donor organs and the ever-increasing demand for organs. In reduced size liver transplantations, the left lateral segments and left lobe grafts are used for pediatric recipients. In split liver transplantation, the left graft is used for a pediatric patient and the right graft is placed into an adult recipient. The use of a single donor for two recipients has clear advantages, and some centers have shown improvement in outcomes with this technique. Long-term prevention of graft rejection is an important goal of liver transplantation and aside from refinement of pre-existing drugs there are several new drugs with specific

mechanisms of action under investigation. Basiliximab, a chimeric monoclonal antibody, has shown favorable outcomes, and may potentially reduce the need for maintenance immunosuppressants following transplantation (95). Gene therapy may soon open unexpected possibilities of immediate and long-term survival of the transplanted organ.

Continued evaluation and development of support technologies such as the biological and nonbiological liver support systems will allow more patients to survive long enough for spontaneous recovery of liver function or successful hepatic transplantation. Improving the supply and distribution of donor livers for patients with FHF is another area requiring ongoing emphasis.

## SUMMARY

FHF is a life-threatening condition that requires prompt diagnosis and rapid initiation of therapy to avoid deterioration in liver function, particularly in cases of acetaminophen toxicity. FHF patients require complex, coordinated critical care which is best provided in specialized centers especially for those patients who require liver transplantation.

Aggressive treatment of hepatic encephalopathy with control of ICP and management of cerebral perfusion is crucial in severe cases. This is accomplished in concert with adequate hemodynamic resuscitation and respiratory support. Six areas in which treatment advances have led to improved outcomes over the last 10 years include: awareness of ICP considerations, airway protection, infection standards, metabolic control (aggressive pharmacologic treatment of hypoglycemia), maintenance of MAP (avoidance of hypo- and hypertension), and institution of moderate hypothermia. More recently, additional measures have been

recognized as important for improving outcomes in all critically ill patients: use of high-intensity physician staffing, small tidal volume mechanical ventilation, use of low-dose corticosteroids, monitoring activated protein C, “tight” glucose control, and low-dose vasopressin. By using these measures in liver disease, improvements can be made to overall patient care (96).

Although early recognition and aggressive medical management may improve outcomes in subsets of FHF patients, liver transplantation has significantly improved the survival odds in these patients. Following investigation of etiology and careful consideration of prognostic indicators, all patients with FHF should be evaluated for transplant suitability although only 30% get transplanted.

## KEY POINTS

- ✦ A rapid diagnosis and identification of the etiologic agent increases the likelihood that specific therapy will be beneficial in the treatment of FHF.
- ✦ Accurate assessment of severity and prognosis in FHF is particularly important for identifying those patients requiring liver transplantation.
- ✦ Hepatic encephalopathy is a defining feature of fulminant liver failure.
- ✦ Because of the potential for complications, ICP monitoring remains controversial in managing patients with stage III and IV encephalopathies.
- ✦ The most important aspect of treatment for encephalopathy in FHF is control or elimination of factors known to increase ICP and cerebral edema.
- ✦ Hypothermia has emerged as an integral supportive maneuver in the care of FHF patients.
- ✦ Circulatory abnormalities in liver failure include a decreased effective intravascular volume, vasodilation, and a hyperdynamic circulation.
- ✦ Hemodynamic management in ALF is aimed at providing adequate cerebral perfusion in the setting of intracranial hypertension, avoiding hemodynamically mediated deterioration in hepatic function, and preventing multiple organ failure.
- ✦ Maintaining intravascular volume and therefore cardiac preload is essential to preserve cardiac output and oxygen delivery.
- ✦ Hypotension not responding to fluid therapy should be treated with vasoactive drug infusion.
- ✦ Gas exchange abnormalities in FHF result from transpulmonary shunting, and in some cases aspiration pneumonia, atelectasis, acute lung injury, or hepatopulmonary syndrome.
- ✦ Correction of coagulation and platelet abnormalities is necessary in bleeding patients and those undergoing invasive procedures such as ICP monitor placement or surgery.
- ✦ Potentially reversible hepatorenal syndrome occurs in a significant proportion of FHF patients with renal dysfunction.
- ✦ Patients with ALF develop multiple metabolic and electrolyte abnormalities including hypoglycemia, hypokalemia, hypomagnesemia, hypophosphatemia, and metabolic acidosis.
- ✦ Sudden massive blood loss can occur intraoperatively and this in conjunction with baseline hyperfibrinolysis, coagulation factor deficiencies, and thrombocytopenia

results in the need for massive blood and blood product transfusions that have potentially severe consequences.

- ✦ Early postoperative hemorrhage due to anastomotic leaks or laceration of the liver surface or coagulopathy results in reoperation in about 10% of transplanted patients.

## The Cirrhotic Patient

Marie L. Borum, Christopher R. Entwisle, and Todd N. Witte

Division of Gastroenterology and Liver Diseases, Department of Medicine, George Washington University, Washington, D.C., U.S.A.

### INTRODUCTION

Cirrhosis is the irreversible, final common pathway of many chronic progressive liver diseases. The incidence of cirrhosis in Western countries is approximately 15 to 25 per 100,000 people (1). It is the 10th leading cause of all mortality, and in individuals aged 45 to 64 years it is the fifth leading cause of death. Finally, cirrhosis is implicated in approximately 30,000 deaths each year in the United States alone (2,3).

Although patients with chronic liver diseases are often managed in the outpatient setting with occasional acute hospitalizations, it is not uncommon for the cirrhotic patient to be hospitalized in the surgical intensive care unit (SICU). Life-threatening conditions such as variceal hemorrhage, hepatic encephalopathy, or hepatorenal syndrome (HRS) frequently necessitate SICU management. If not involved earlier, critical care physicians may become involved with a cirrhotic patient postoperatively. Additionally, such physicians will manage a cirrhotic patient who has been involved in a trauma. In general, individuals with chronic liver disease and cirrhosis who require admission to an intensive care unit often have poor outcomes, as can be predicted by established scoring systems such as Child–Pugh or acute physiology, age, and chronic health evaluation (APACHE) (4,5).

In an era of rapidly expanding medical knowledge and rising healthcare costs, the critical care physician is expected to care effectively and efficiently for the cirrhotic patient. This chapter provides an overview of the pathophysiology, underlying conditions, presentation, complications, and management critical to caring for the critically ill cirrhotic patient.

### PATHOPHYSIOLOGY

#### Basic Science

Cirrhosis is a fibrosis of the liver parenchyma that occurs as a response to liver injury from a variety of agents and results in a broad range of clinical manifestations. It is classified histologically as either macronodular (>3 mm nodules) or micronodular (<3 mm nodules) (6).

The normal liver has an extracellular matrix consisting of collagens, glycoproteins, and proteoglycans. This matrix is critical to the functions of the liver. The development of fibrosis in chronic liver injury causes this matrix to transform from a low-density matrix to a high-density matrix (Fig. 1). There are several factors involved in this process. During injury, there is a downregulation of matrix metalloproteinase-1 and upregulation of gelatinase A and gelatinase B,

resulting in breakdown of basement membrane collagen and an amassing of interstitial collagens. As the hepatic environment changes, stellate cells become activated.

Stellate cells are found in the subendothelial space of Disse and are the principal storage site for retinoids. Stellate cells can also migrate to areas of injury through several potential chemoattractants including platelet-derived growth factor (PDGF) and monocyte chemoattractant peptide-1 (7). Upon activation, the stellate cell transitions into a proliferative, fibrogenic, and contractile myofibroblast (8). This may be initiated by paracrine stimuli from surrounding cells. Endothelial cells may convert latent transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) to a profibrogenic form through the activation of plasmin (Table 1) (9). Hepatocytes produce lipid peroxides that may also promote activation. Kupffer cells can stimulate matrix synthesis, cell proliferation, and release of retinoids by stellate cells (10). Platelets produce and release several important mediators including PDGF, TGF- $\beta$ 1, and epidermal growth factor. In addition, during early activation there is an upregulation of the NF-kappa-gene expression, which can lead to the activation of a number of genes, including the transcription factor AP-1, c-Jun kinase, and matrix metalloproteinase-2 (11,12).

The hepatic stellate cells can progress into a perpetuation stage (13). This may result from an upregulation of many mitogenic factors and their receptors. In addition, PDGF, a potent mitogen, and its receptors are upregulated during injury. Other mitogens that may be involved include endothelin-1, thrombin, and fibroblast growth factor (11,12).

The contraction of hepatic stellate cells is likely the mechanism for the development of portal hypertension by impedance of portal blood flow. Endothelin-1 appears to be an important contractile stimulus to stellate cells (14). Nitric oxide (NO) is a physiologic antagonist to endothelin-1 and may be less active in portal hypertension (15,16). Alpha smooth muscle actin levels have also been found to be increased during stellate cell activation and may participate in their contractility.

✎ The fibrotic tissue in cirrhosis consists of extracellular matrix molecules, collagen types I and III, sulfated proteoglycans, and glycoproteins. ✎ TGF- $\beta$ 1 is the most potent fibrogenic factor in the liver and is upregulated during injury (17).

#### Etiologies

There are a large number of potential causes of cirrhosis (Table 2). Major categories include toxins (such as alcohol), viral hepatitis, metabolic disorders, autoimmune etiologies, nonalcoholic steatohepatitis (NASH), and miscellaneous

**Figure 1** Fibrotic changes occurring in the space of Disse in cirrhosis. The figure shows the morphologic changes associated with stellate cell activation and collagenization of the space of Disse, namely loss of endothelial fenestrae and flattening of the microvillus border of the hepatocyte. *Source:* From Ref. 174.

causes, the common thread being injury to hepatocytes followed by scarring of residual tissue.

Fibrosis is a normal component of repair following injury. It provides a structural scaffold and temporary support during repair, and also interacts with other cells to signal remodeling and other events involved in the healing process. When injury is limited in duration, the fibrotic scaffolding is dismantled by matrix proteinases during final stages of healing at six to seven weeks (Fig. 2). However, in the setting of multiple recurrent injuries, or chronic inflammation, pathologic fibrosis is propagated, and residual fibrous remains when the next cycle of injury occurs. Ultimately fibrotic processes become dominant and too extensive for suitable remodeling, and cirrhosis results. A discussion of the major causes of cirrhosis is offered.

**Alcohol-Induced Cirrhosis**

Consumption of ethanolic [exposed to alcohol (ETOH)] alcohol can lead to a variety of hepatic changes, ranging from fatty liver to cirrhosis. Steatosis or fatty liver can develop after even a single ETOH binge and is likely to progress with continued alcohol use (18). Accumulation of membrane-bound fat droplets, proliferation of smooth endoplasmic reticulum, and gradual distortion of mitochondria can occur (19). Increased lipolysis and reduced oxidation

of hepatic fatty acids contribute to its development (20). Alcoholic hepatitis may develop with continued alcohol ingestion. Patients may present with fever, hepatomegaly, jaundice, and anorexia. The hallmarks of this disease include liver cell necrosis, the presence of Mallory bodies and neutrophils, and a perivenular distribution of inflammation (21). In alcoholic cirrhosis, perivenular inflammation becomes fibrosis and can progress to panlobular cirrhosis (6).

**Table 2** Causes of Cirrhosis

Cause	Examples
Drugs	Alcohol Amiodarone Isoniazid Methyldopa methotrexate Vitamin A
Infection	Hepatitis B Hepatitis C Schistosomiasis Syphilis
Biliary obstruction	Cholangiocarcinoma Cystic fibrosis Pancreatitis (chronic) Pancreatic carcinoma Primary biliary cirrhosis Sclerosing cholangitis Strictures
Cardiovascular	Budd–Chiari syndrome Right heart failure (chronic) Veno-occlusive disease
Metabolic	Alpha-1-antitrypsin E. protoporphyria Hemochromatosis Wilson’s disease
Miscellaneous	Sarcoidosis Hereditary hemorrhagic telangiectasia Cryptogenic Nonalcoholic steatohepatitis Autoimmune hepatitis

**Table 1** Summary of Cirrhosis Pathophysiology

The stellate cell is the major cell involved in the process of liver fibrosis. It becomes a proliferative, fibrogenic, and contractile myofibroblast

TGF-β1 is the most potent fibrogenic factor in the liver

Example of alcohol induced cirrhosis

Alcohol → fatty liver → alcoholic hepatitis → alcoholic cirrhosis

Hallmarks of alcoholic cirrhosis

- Liver cell necrosis
- Presence of Mallory bodies and neutrophils
- Perivenular distribution of inflammation

*Abbreviation:* TGF-β1, transforming growth factor-β1.

**Figure 2** Schematic representation of inflammation (*lighter area*) and fibrosis (*darker area*) in acute or chronic liver injury. When inflammation is limited in time (acute injury), fibrosis resolves completely after approximately seven weeks. When inflammation is chronic with recurrent exacerbations, the level of fibrosis varies but rises over time. Examples of chronic exposure causing cirrhosis include heavy alcohol use with periods of heavy binges, or recurrent hepatitis from chronic active hepatitis B.

Source: From Ref. 175.

There are several theories related to the pathogenesis of alcohol-mediated liver injury. The metabolism of ethanol acetaldehyde increases lobular oxygen consumption which may cause hypoxia and cell damage in the pericentral zones. The neutrophils present during alcohol-induced fibrosis may cause hepatocyte injury via cytokines and proteases. Additionally, acetaldehyde-protein adducts may serve as neoantigens causing an autoimmune reaction against hepatocytes. Alternative pathways for ethanol metabolism may also generate free radicals (6).

### Infections

A number of infectious agents have been reported as potential etiologies for the development of cirrhosis. The most important infectious causes of cirrhosis in the United States include the hepatotropic viruses, hepatitis B and C. Less common, but important other viral etiologies of hepatitis include cytomegalovirus, Epstein-Barr, herpesvirus-6, and varicella zoster. Additionally, tertiary *Syphilis* and *Schistosoma japonicum* have been reported to cause hepatic fibrosis and cirrhosis; however, these infectious agents are infrequent causes of cirrhosis in the United States.

Chronic infections with both the hepatitis B and C viruses can lead to liver cirrhosis. Approximately 85% of patients infected with hepatitis C will develop a chronic infection, with up to 50% of these developing cirrhosis (22–24). ⚡ **The development of cirrhosis is most often silent until complications of significant hepatic dysfunction occurs (22).** ⚡ Several host factors are important determinants of disease progression in hepatitis C virus (HCV)-infected individuals. Coinfected HIV patients may progress more rapidly (25,26). Infection via blood transfusion has been reported to increase the risk of disease progression (27,28). Infection after the age of 40 years may be associated with a more rapid course (29,30). Coinfection of hepatitis C with hepatitis B is likely to accelerate the progression. Alcohol consumption has also been reported to promote the progression of chronic hepatitis C infection and should be avoided in all patients with this infection (29).

Chronic hepatitis B virus infection results in cirrhosis less commonly than hepatitis C in the United States. It is estimated to occur in approximately 15% to 40% of individuals infected with hepatitis B. The rate of progression to cirrhosis is determined by the replicative activity of the virus and whether there is a superinfection with another hepatotropic virus, such as hepatitis delta virus or hepatitis C (31).

### Drug-Induced

Liver damage from pharmacologic agents accounts for about 2% to 5% of patients requiring hospitalization for jaundice and 10% of cases of hepatitis in all adults (32). Drug-induced injury can result in severe necrosis with the development of cirrhosis. Some agents are intrinsic hepatotoxins and may result in both aminotransferase elevations up to 500 times normal. Examples are carbon tetrachloride, chloroform, tannic acid, and troglitazone, which have been voluntarily removed from the market (33). Other drugs show a dose-related toxicity. These include acetaminophen, ethanol, methotrexate, intravenous tetracycline, and azathioprine (34). In addition, a hypersensitivity reaction may occur with many pharmacologic agents, resulting in eosinophilic or granulomatous inflammation with hepatocyte necrosis and cholestasis. These may include phenytoin, amoxicillin-clavulanate, sulfonamides, halothane, and dapsone (35). Liver injury may also be secondary to abnormal drug metabolism in which toxic metabolites may accumulate and lead to cellular necrosis. Agents such as ketoconazole, diclofenac, valproate, propylthiouracil, isoniazid, and amiodarone may cause hepatic toxicity through abnormal drug metabolism (33,36).

### Hereditary (Inborn) Errors of Metabolism

There are multiple metabolic causes of liver disease. Hereditary enzymatic abnormalities can lead to accumulation of toxic substances resulting in liver damage, injury, and cirrhosis. Hemochromatosis, Wilson's disease, and alpha-1-antitrypsin (AAT) deficiency are the most often cited metabolic abnormalities that cause cirrhosis. *Erythropoietic protoporphyria* has also been reported as an etiology of cirrhosis. Other causes of cirrhosis in pediatric patients include galactosemia, hereditary fructose intolerance, glycogen storage disease type IV, and tyrosinosis.

### Hereditary Hemochromatosis

Hereditary hemochromatosis (HHC) leads to an abnormal accumulation of iron in parenchymal organs, including the liver, heart, and pancreas. It is the most common genetic disorder among caucasians and is inherited as an autosomal-recessive trait on chromosome 6. Although the exact pathophysiology is unknown, the mutation may cause abnormal cell interaction with  $\beta 2$ -microglobulin resulting in increased iron absorption with accumulation in the liver. Classically, patients present in the third and fourth decades with hepatomegaly, skin pigmentation, arthritis,

and weakness. A fasting serum transferrin saturation greater than 60% in men or 50% in women is highly specific for HHC. Serum ferritin is often elevated. Liver biopsy with a measurement of hepatic iron concentration is the most sensitive diagnostic test. Individuals with HHC are at ~200-fold increased risk for developing hepatocellular carcinoma. Early diagnosis is essential to prevent progression to cirrhosis in the patient with hemochromatosis. Therapeutic phlebotomy remains the mainstay of therapy. Iron chelation, with agents such as deferoxamine, may be useful in anemic patients. Newer oral agents, such as deferasirox, are also being investigated (37). Liver transplantation is indicated for individuals who progress to end-stage liver disease (38).

#### **Wilson's Disease**

Wilson's disease is an autosomal-recessive disorder of reduced biliary excretion which results in copper accumulation. It is estimated to occur worldwide in 30 people per million population (39). Copper is normally incorporated into copper-containing enzymes, including ceruloplasmin, in the liver. Excess copper is normally excreted in the bile. The defective gene product is a P-type ATPase which is referred to as Wilson's disease. This is normally a copper transporter and is necessary for copper incorporation into ceruloplasmin and excretion into bile. In Wilson's disease, ceruloplasmin levels and copper bile concentrations are reduced. Copper eventually appears in dense granules in lysosomes and leads to chronic hepatitis and fibrosis. Over time the liver is progressively damaged and eventually becomes cirrhotic. Liver disease is often the presenting manifestation, but neuropsychiatric disease may also be the presenting feature in up to 10% of cases. The type of the liver disease can be highly variable, ranging from only biochemical abnormalities to fulminant hepatic failure.

Fulminant hepatic failure, sometimes referred to as a Wilsonian crisis, has characteristic features which include Coombs-negative hemolytic anemia with bilirubinemia, coagulopathy, renal failure, low alkaline phosphatase (Alk phos), and elevated aminotransferases. A useful clue to this disease may be the ratio of Alk phos (IU/L) to total bilirubin (T-bili) (mg/dL) of less than 2 (40).

Measurement of hepatic tissue copper concentration will provide the diagnosis in most patients, however, this requires a biopsy. A low ceruloplasmin is supportive, but not specific. An elevated serum copper and 24-hour urine copper level may be helpful as a screening test. Kayser-Fleischer rings may support the diagnosis, but such ophthalmologic findings may be absent in 50% of patients (40). Copper chelators, such as penicillamine and trientine, are the mainstays of therapy and are more effective when combined with a low copper diet (41). Patients with fulminant hepatic failure require urgent liver transplantation to survive.

#### **Alpha-1-Antitrypsin**

AAT deficiency is a homozygous disorder affecting multiple organ systems. In adults, the most common manifestation is asymptomatic cirrhosis. Although there are many different alleles in AAT, the M and Z alleles have been shown to confer a risk for the development of liver disease. From 10% to 15% of at-risk newborns develop hepatic disease (42). Although the exact mechanism is unclear, the pathogenesis is thought to be related to the accumulation of AAT molecules in the rough endoplasmic reticulum of hepatocytes (43).

#### **Autoimmune Hepatitis**

Autoimmune hepatitis is a chronic inflammation of the liver of unknown etiology. There is continued hepatocellular injury that can progress to necrosis, with fibrosis that may ultimately lead to cirrhosis and liver failure. It may present with a variety of clinical features, histologic findings, immunogenetic phenotypes, and circulating autoantibodies. It most often occurs in female adolescents and women, although the disease can occur in males. The classic characteristic laboratory feature is an elevation in antinuclear or antismooth muscle antibodies with elevated serum globulins, particularly gamma globulins (44). Immunosuppressant therapy with steroids and/or azathioprine is the mainstay of therapy.

#### **Biliary Obstruction**

Diseases that cause chronic biliary destruction can result in hepatocellular injury with fibrosis that can progress to cirrhosis. Primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are presumed immunomediated diseases that result in significant hepatocellular injury. Other acquired disorders that produce chronic biliary obstruction can also result in cirrhosis.

#### **Primary Biliary Cirrhosis**

Primary biliary cirrhosis is an immune-mediated disorder that is characterized by a T-lymphocyte-mediated injury affecting the intralobular bile ducts (6). The presence of anti-mitochondrial antibodies is the hallmark of this disorder. The cause of this injury remains unknown, but most likely involves both genetic and environmental factors. As the biliary ducts are destroyed, impairment of biliary flow develops. This can result in portal and parenchymal inflammation, liver cell necrosis, scarring, and eventually to cirrhosis and liver failure (45). The mainstay of therapy includes ursodeoxycholic acid and liver transplantation.

#### **Primary Sclerosing Cholangitis**

PSC is a chronic cholestatic disease affecting the liver and bile ducts. Patients will often present with pruritus, steatorrhea, and symptoms of vitamin deficiencies. Antinuclear and anticytoplasmic antibodies with a perinuclear staining pattern (P-ANCA) occur in up to 80% of patients with PSC. There is a strong association with inflammatory bowel disease, particularly ulcerative colitis. The diagnosis can often be made by cholangiography that shows diffuse, multifocal strictures, and focal dilation of the bile ducts (46). At present there are no pharmacologic agents that have been conclusively proven to decrease the progression of the disease; however, high-dose ursodeoxycholic acid (20–30 mg/kg/day) is being further studied based on encouraging preliminary results (47,48).

#### **Nonalcoholic Steatohepatitis (NASH)**

With rising obesity rates in the United States and other industrialized countries, about 20% to 30% of adults have excess fat in the liver, called nonalcoholic fatty liver disease (NAFLD). At least 10% of these individuals meet histologic criteria for NASH (49). The prevalence of this disease may be markedly higher in select patients with the risk factors of severe obesity, diabetes mellitus, hyperlipidemia, and metabolic syndrome (50). By definition, patients do not drink significant amounts of alcohol. There is great variability as to what is considered significant intake, however, a level of two drinks per day has been suggested (49).

Although progression to cirrhosis is rare in mild NAFLD, excess fat accumulation in the liver may sensitize the liver to injury from other causes. This is summarized by the multihit hypothesis, in which insulin resistance is believed to be central to the first hit of hepatic steatosis (51). There is no conclusive therapy for NASH, although modification of risk factors, such as obesity, hyperlipidemia, and poor diabetic control are generally used. Lifestyle modification being a challenge, sustained liver injury leads to progressive fibrosis and cirrhosis in up to one third of patients with NASH (49).

The evolution of NAFLD to NASH and subsequently cirrhosis may be accompanied by a loss of the typical histologic features, which include hepatic steatosis with mixed lobular inflammation and hepatocellular ballooning (49,52,53). Thus, as much as 80% of cases of cryptogenic cirrhosis likely represent burned-out NASH (52,54–56).

### PHYSICAL EXAM AND STUDIES

An assessment of the cirrhotic patient begins with obtaining a thorough history. The patient will frequently be able to provide information that can offer insight into the etiology of the liver disease. Details regarding comorbid medical conditions, medications, previous blood transfusions, alcohol and intravenous drug use, and toxin exposure may also assist in the differential diagnosis of possible etiologies. Family history can be important to assess for potential familial disorders, such as Wilson's disease, hemochromatosis, or autoimmune liver diseases. Important key points in the history are summarized in Table 3. A review of systems should seek symptoms of malignancy such as weight loss or anorexia.

There are several physical stigmata on the examination of the cirrhotic patient that may indicate the presence of liver disease. (Fig. 3) The patient's mental status may be altered due to advanced liver disease and hepatic encephalopathy. A flapping tremor of asterixis can be seen. Jaundice, including icterus, typically occurs when the total serum bilirubin is above 3 mg/dL. Clubbing can also occur with advanced liver disease. Purpura and bruising can be present in the cirrhotic patient with coagulopathy.

In men, cirrhosis results in hypogonadism with a decrease in serum testosterone and a relative increase in circulating estrogens. The clinical features of this feminization can be demonstrated by decreased muscle mass, testicular atrophy, gynecomastia, and reduced secondary sexual hair. Telangectasias, known as spider angiomas, may be seen on the upper body while erythema is seen on the thumbs, proximal phalanges, and palms.

**Table 3** Important Historical Clues to Cirrhosis

Patient's understanding of the etiology
Comorbid medical conditions
Medications
Transfusion history
Use of alcohol
Use of intravenous drugs
Family history of liver disorders
Recent weight loss or anorexia

**Figure 3** Physical stigmata found in cirrhosis. Every organ system is affected, and many of the stigmata are seen in the body habitus, and external surface of the patient. Others (e.g., varices) are seen within the gastrointestinal tract. *Source:* Drawing by Todd N. Witte.

Portal hypertension with resultant portosystemic shunting through umbilical and paraumbilical veins causes the classically distended abdominal wall veins, or “caput medusae,” seen radiating outwards from the umbilicus. Less commonly, hemorrhoidal varices can be appreciated. Hypoalbuminemia will exacerbate any degree of peripheral edema, and when the serum albumin is low enough, edema develops de novo. The liver may be enlarged in early cirrhosis, but is more commonly shrunken in advanced disease. Auscultation over the liver, xiphoid process, or umbilicus may reveal a venous hum signifying portal hypertension. Splenomegaly may also occur in individuals with portal hypertension (57,58).

Laboratory abnormalities frequently seen in the routine investigation of the cirrhotic patient may include abnormal aspartate amino transferase (AST), alanine amino transferase (ALT), Alk phos, and T-bili (Table 4). The ratio of AST to ALT can often be a clue to the underlying etiology of the disorder as an AST/ALT ratio greater than two is classically seen in acute alcoholic hepatitis. AST/ALT is usually less than one in patients with other etiologies of chronic hepatitis and cholestatic liver diseases, however the transaminases can return to near normal values in patients with cirrhosis. In this setting, the AST/ALT is often greater than 1 (59). Anemia, thrombocytopenia, elevated prothrombin time (PT), and an extended bleeding time are also not uncommon. The definitive diagnosis of cirrhosis is made by histologic exam of liver biopsy specimen.

**Table 4** Laboratory Abnormalities Frequently Found in Cirrhosis

---

↑ AST
↑ ALT
AST/ALT > 2.0 = consistent with alcoholic hepatitis
↑ Alk phos
↑ T-bili
↓ hemoglobin
↓ platelets
↑ PT
↑ Bleeding time

---

*Abbreviations:* AST, aspartate amino transferase; ALT, alanine amino-transferase; Alk Phos, alkaline phosphatase; T-bili, total bilirubin; PT, prothrombin time.

## ASCITES

Ascites, the accumulation of fluid in the peritoneal cavity, is the most common complication of cirrhosis (60). It can be complicated by spontaneous bacterial peritonitis (SBP), hyponatremia, HRS, and other fluid collections (e.g., pleural and pericardial effusions).

### Pathophysiology

Portal hypertension is present in all patients with ascites. A portal pressure gradient greater than 12 mmHg is required for ascites to develop (61). There are three major theories regarding the pathogenesis of ascites formation. These theories are the underfill theory, the overflow theory, and the arterial vasodilation hypothesis. Although each theory may be relevant, the arterial vasodilation hypothesis has become the most accepted.
