Examples of underactivity of the anticlotting system are deficiencies of protein C, protein S, plasminogen, factor XII, AT III, or heparin cofactor II (8). In the trauma patient, VTE has a 13-fold increased incidence compared to normal patients (9). The increased risk results from systemic hypercoagulation that manifests itself locally in areas of stasis induced by immobilization (10). The hypercoagulability is due to both activation of coagulation and reduced levels of coagulation inhibitors and increased levels of fibrinolytic inhibition (11).

**Endothelial Damage**

Endothelial damage is a key element of Virchow’s triad, yet is difficult to separate out as an independent risk factor in patients following trauma or surgery who may have other predisposing factors, such as immobility, that lead to clot formation. It is clear, however, from the discussion below of indwelling catheters that intimal damage done by

**Table 1** Hereditary Causes of Hypercoagulation

Increased levels or activity	Decreased levels or activity
Factor V Leiden	Protein S
Factor IX	Protein C
Factor XI	Antithrombin III
Thrombin activatable fibrinolysis inhibitor	Heparin cofactor II
Fibrinogen	Plasminogen
Homocysteine	Factor XII
Prothrombin gene variant	

penetration of the vein wall or its continuous irritation with an indwelling foreign body predisposes to clot formation. Of all the major operations performed, the ones that involve the major blood vessels of the pelvis and lower extremities, such as hip arthroplasty, cystectomy, major vascular procedures, and total knee arthroplasty (12), carry the highest risk of VTE that develops in this area. This suggests that injury to these vessels confers an independent risk factor. Intravenous drug abuse, which is not associated with the major morbidity of surgery or trauma, has also been shown to be associated with DVT, indicating that intimal damage alone can lead to clot formation (13).

### Venous Stasis

☞ **Venous stasis is probably the most important risk factor for VTE in patients who are critically ill or recovering from trauma or surgery. Since these patients are often bedridden, sedated, or paralyzed, they have sluggish blood flow and poor venous return. Blood flow may also be compromised by low cardiac output, abdominal compartment syndrome, and elevated intravenous pressure from right heart failure (14).** ☞

Indeed, all of the conditions that contribute to patient immobility, such as mechanical ventilation, complex drains, paralytic drugs, sedatives, indwelling catheters, or traction, have been associated with an increased risk for VTE (15). Knudson et al. recently completed a retrospective analysis of the risk factors associated with VTE in 1602 trauma patients (Table 2) of the >450,000 patients in the ACS-NTDB (5). Days on mechanical ventilation and venous injury emerged as the most significant risk factors. Other risk factors that have traditionally been considered important [e.g., spinal cord injury (SCI), pelvic fractures, etc.] were also found to be important, but not to the same degree of significance (5).

The diagnosis of VTE is difficult to make in critically ill patients because their comorbidity often leads to edema, respiratory compromise, decreased sensorium, pain, decreased perfusion, and other signs that are important clinical indicators of DVT or the resultant emboli. Estimates of VTE range from 5% to 35% in ICU patients (14). However, these percentages likely underestimate the true incidence of VTE due to the reasons enumerated earlier. It is clear, however, that one or more elements of Virchow's triad are

**Table 2** Risk Factors Associated with Venous Thromboembolism (Univariate Analysis)

Risk factor (number with risk)	Odds ratio (95% confidence interval) <sup>a</sup>
Age ≥ 40 yrs ( <i>n</i> = 178,851)	2.29 (2.07–2.55)
Pelvic fracture ( <i>n</i> = 2707)	2.93 (2.01–4.27)
Lower extremity fracture ( <i>n</i> = 63,508)	3.16 (2.85–3.51)
Spinal cord injury with paralysis ( <i>n</i> = 2852)	3.39 (2.41–4.77)
Head injury (AIS ≥ 3) ( <i>n</i> = 52,197)	2.59 (2.31–2.90)
Ventilator days >3 ( <i>n</i> = 13,037)	10.62 (9.32–12.11)
Venous injury ( <i>n</i> = 1450)	7.93 (5.83–10.78)
Shock on admission (BP <90 mm Hg) ( <i>n</i> = 18,510)	1.95 (1.62–2.34)
Major surgical procedure ( <i>n</i> = 73,974)	4.32 (3.91–4.77)

Abbreviation: AIS, abbreviated injury scale.

Source: From Ref. 5.

present in the majority of critically ill patients, making diagnosis, prevention, and treatment of this disorder a top priority for these patients.

Nontrauma-specific medical conditions that affect critically ill patients also come into play. A rare prothrombotic risk factor is the presence of a congenital or acquired venous malformation, which decreases venous return. Examples of this phenomenon are IVC webs seen in Budd–Chiari syndrome (BCS) and left common iliac occlusions seen with May–Thurner syndrome, both of which are discussed later.

### UPPER EXTREMITY

DVT of an upper extremity may result from an indwelling foreign body, such as an intravenous catheter, or may occur spontaneously (i.e., Paget–Schroetter syndrome). Of the two entities, the former is of far greater significance for critically ill trauma patients. Indeed, these patients often have catheters placed in their central veins for intravenous resuscitation, administration of medications, parenteral nutrition, hemodynamic monitoring, cardiac pacing, or hemodialysis. The two veins most commonly involved are the axillary and subclavian, therefore, the term axillosubclavian vein thrombosis (ASVT) is generic for this condition.

The incidence of upper extremity venous thrombosis has been reported to occur in 0.06% of unselected hospitalized patients (16). This incidence is higher in selected populations such as those with indwelling central venous catheters or malignancy (17).

#### Catheter-Induced Vein Thrombosis

Because of its relative ease of performance, central access is usually obtained via percutaneous puncture of veins in the groin, antecubital fossa, subclavian region, or base of the neck. This leads to direct damage to and the presence of a foreign body adjacent to the intima of the femoral, brachial, axillary, subclavian, or superior vena caval veins. When thromboses result, the consequences range from minor swelling of an extremity to life-threatening superior vena cava (SVC) syndrome.

The incidence of ASVT is highest in patients with indwelling intravenous catheters. The incidence in this subset of patients is related to the material used for the catheter as well as the position of the catheter. ☞ **Polyethylene and polyvinyl chloride catheters are more prone to pulmonary emboli than polyurethane or siliconized catheters (18), whereas the heparin-bonded catheters seem to be better than those without heparin bonding (19). Additionally, catheters placed so that the tips are in the SVC or the right atrium have a lower incidence of thrombi than those placed in the innominate or subclavian veins.** ☞

#### Spontaneous Thrombosis

Spontaneous thrombosis of the upper extremity (Paget–Schroetter syndrome) is most often seen in young, active people who use their upper arms and shoulders in repetitive sports or professional activities. The thrombogenic state is believed to result principally from overuse of an upper extremity; hence, it is also called “effort thrombosis.” Alternatively, when clotting occurs in the axillary vein due to anatomic compression as the vein passes through the thoracic outlet, it may be called “thoracic outlet” syndrome (though this term is usually used to describe subclavian arterial obstruction). In any case, “spontaneous thrombosis” may be a misnomer insofar as a predisposing condition is

often identified. Often, more than one thrombogenic condition will be present, for example, a tennis player with a vein compressed by a small thoracic outlet.

Spontaneous thrombosis has no particular significance for the critically ill patient, but must be differentiated from catheter-related thromboses described earlier. It is important to search for hypercoagulable states in all patients who develop DVT and treat promptly because it may otherwise progress to long-term disability (20).

### Clinical Signs

The clinical signs and symptoms of upper extremity DVT are chiefly pain and swelling. In critically ill or sedated patients, swelling may be the only clue. Fever is also associated, but is nonspecific, because it is often present for other reasons following trauma and critical care. Occasionally, thrombi, even when they totally occlude the vein, may be asymptomatic. This is more likely to occur in a critically ill patient with other comorbidities and unable to recognize that an arm is swollen or painful (i.e., the head-injured patient). In these patients, signs such as asymmetric arm edema or distended upper arm and chest wall veins may be seen. Less commonly, venous thrombus of the upper extremity may present as PE, which occurs in 20% of catheter-related thrombi (21). Similar to DVT in the lower extremities, emboli that break off of upper extremity thrombi can also travel through a right to left shunt in the left heart to embolize to the brain or coronary arteries (22). **When emboli originate from the vessel wall they are termed mural thrombi. When emboli originate from an indwelling catheter they are termed sleeve emboli. Sleeve emboli have a greater chance of embolizing.**

### Diagnosis

Diagnosis of an intravenous thrombosis is most easily made in patients who have the thrombosis related to the presence of an indwelling catheter. In these patients, it is not possible to withdraw blood from the catheter. Although this phenomenon may be caused by catheter kinking, it is more often caused by an intravenous thrombus. Regardless of etiology, the first diagnostic test of upper extremity vein thrombosis should be venous Doppler ultrasound (VDU) which has high specificity (94–100%) but only moderate sensitivity (56–100%) (23). This test is noninvasive, portable, and relatively inexpensive. It can be used for initial diagnosis and may be used sequentially to follow the progress of the disease or monitor the efficacy of treatment.

The gold standard for diagnosing upper (and lower) extremity thrombi is venography. **Although a properly performed venogram has close to 100% sensitivity and 100% specificity, it is done only infrequently because VDU is safer, less expensive, and usually sufficient.**

Venography is an invasive procedure, which carries risks such as renal toxicity and allergic reactions. It may also be difficult to access small veins in the hand or distal extremity to inject contrast material. Digital subtraction venography allows studies to be done with less contrast material and is associated with fewer side effects than plain venography (24). Venography is more comprehensively reviewed in the section devoted to diagnostic tests of the lower extremity, but the upper extremity is particularly suited to this modality because of the inaccessibility of the axillary, subclavian, and innominate veins to physical examination and other noninvasive tests.

### Treatment

**When the thrombi occur as a result of an indwelling catheter, the cornerstone of treatment is removal of the catheter and anticoagulation (when not contraindicated).**

Of course, this removes access to the central circulation, which may cause problems in itself. For these patients, there must also be a strategy for obtaining alternative access to the circulation if it is still needed. Another strategy is to leave the catheter in place and keep the patient anticoagulated (25). Patients who do not respond to anticoagulation alone may have a fibrinolytic agent infused through the catheter (26). However, fibrinolytics are associated with more bleeding complications than heparin alone, and are relatively contraindicated following acute trauma to the central nervous system. Prior to surgical treatment of an anatomic obstruction, fibrinolysis must be initiated acutely to prevent a chronic disability. Surgical procedures for the upper extremity are usually reserved for conditions caused by extrinsic compression such as effort vein thrombosis (27) or thoracic outlet syndrome. If the injury is recognized and treated promptly with fibrinolysis, surgical opening of the thoracic outlet is usually successful (28). If the injury is recognized late, vein patch angioplasty or replacement of permanently damaged subclavian or axillary vein with saphenous grafts may be necessary. Although thrombosis caused by intimal damage, such as occurs with ASVT, may go on to produce permanent problems, surgical intervention is not usually necessary unless there are predisposing anatomic problems that must be addressed (29).

Otherwise, treatment for upper extremity thrombi is similar to treatment of lower extremity thrombi discussed later. Medical treatment consists of acute anticoagulation with unfractionated heparin (UFH) or low molecular weight heparin (LMWH) followed by chronic anticoagulation by warfarin. Intravascular filters may be placed to prevent embolization (30), but the possibility of creating a swollen extremity is more debilitating when it occurs in an upper extremity. Dissolution of the clot with a fibrinolytic agent such as tissue-type plasminogen activator or recombinant urokinase may be done in the upper extremity as well as the lower extremity. However, these drugs are generally contraindicated within a few days after acute trauma.

### SUPERIOR VENA CAVA

Although thrombosis can occur anywhere in the vena cava, it is more likely to occur in areas of low flow and/or partial obstruction. A variety of medical etiologies besides trauma and/or catheter-related conditions are known to increase the risk of VTE, each requiring a different treatment depending on their location (Table 3). SVC syndrome may be caused by thrombi originating within the SVC or may be initiated by external compression of the SVC. It is a relatively common complication of thoracic or mediastinal malignancies, but there are other benign causes of this syndrome as well (31). More recently, the increased use of intravenous catheters has made intrinsic causes of thrombi more common so that a careful workup must be done before definitive treatment can be initiated.

### Malignancies

Malignancy is still the most common cause of SVC syndrome. The malignant conditions most often associated with SVC syndrome are bronchogenic carcinoma and

**Table 3** Medical Etiologies and Treatment of Vena Cava Thromboses

Location	Etiology	Treatment
Superior vena cava	Malignancy	Treat malignancy
	Bronchogenic CA	Endoluminal stenting
	Lymphoma	Thrombolysis
Inferior vena cava	BCS	Anticoagulation
		Thrombolysis
	TIPPS (BCS)	
	Surgery	
	Nephrotic syndrome	Anticoagulation
		Thrombolysis
	Behcet's disease	Surgical thrombectomy
Variable		

*Abbreviations:* BCS, Budd–Chiari syndrome; CA, cancer; TIPPS, transjugular intrahepatic portosystemic shunting.

lymphoma. The etiology of the SVC obstruction in patients with these diseases is almost always external compression by a tumor or direct growth of the tumor into the SVC. Thus, DVT does not play a major etiologic role in the development of this syndrome for these malignancies. Recent advances in endoluminal stenting, however, have made thrombolysis and stent placement an alternative treatment for this condition (32). Stenting may be particularly appropriate for critically ill patients who are too ill to wait for resolution of symptoms of SVC syndrome by radiation or chemotherapy and cannot undergo surgical procedures.

### Catheter-Related Superior Vena Cava Syndrome

♣ Although catheter-related thrombosis represents a relatively small percentage of patients who develop SVC syndrome, it is commonly seen in critically ill trauma patients who have multiple indwelling catheters for fluids, monitoring, pacemakers, and cardiac defibrillators. ♣ Although the phenomenon of catheter-related thrombus was described in the section on upper extremity DVT, SVC thrombosis is more serious than upper extremity thrombosis because of the hemodynamic consequences of an obstructed SVC.

Catheter-related obstructions are true thrombi and are important to recognize early because they can be treated effectively by catheter removal or thrombolytics. If the clot is diagnosed within five days of symptoms, then it can usually be lysed successfully (33). It is also important to diagnose catheter-related SVC syndrome because it usually develops acutely. When SVC syndrome develops slowly, as occurs with many malignant conditions, collateral circulation, especially through the azygous system, may develop to return blood to the right atrium. When the clot forms acutely around an indwelling line collaterals do not have time to develop and the hemodynamic consequences of the obstruction are more severe.

### Other Benign Conditions

Historically, infectious conditions such as syphilitic aortic aneurysms and untreated fungal conditions caused most SVC obstructions. Although improved antimicrobial treatment has decreased the number of patients who present with these causes of SVC syndrome, there are still patients who develop the syndrome from fibrosing mediastinitis,

usually related to untreated or under-treated granulomatous and fungal conditions (34,35).

## INFERIOR VENA CAVA

♣ Thrombosis may occur anywhere in the inferior vena cava (IVC), such as with Behcet's disease (36). However, most IVC clotting occurs near the hepatic veins as a consequence of BCS or adjacent to the renal veins as a consequence of nephrotic syndrome. ♣

### Budd–Chiari Syndrome

Although BCS may be loosely defined as any process that causes obstruction of hepatic blood outflow, it is more typically reserved for thrombosis of the hepatic veins and adjacent IVC (37). Numerous inciting events can lead to veno-occlusive disease of the hepatic veins, including myeloproliferative disorders, malignancies, infections, oral contraceptives, and other conditions causing hypercoagulable states (38). Mechanical obstruction may play a role in some of these conditions; however, hypercoagulability is the primary etiologic factor leading to BCS.

BCS may present as an acute or chronic condition. When it is acute there is often hepatomegaly and severe right upper quadrant pain. The chronic form presents more gradually and patients may complain only of vague abdominal pain. These patients usually have a better prognosis (39). Ascites and variceal bleeding may occur with either presentation; however, the pattern of biochemical test abnormalities differs. Patients with acute BCS have elevations of their aminotransferases and alkaline phosphatases, whereas those with chronic disease experience hypoalbuminemia and elevated prothrombin times.

As with deep vein thrombosis in other anatomic locations, diagnosis is most easily made with noninvasive studies such as Doppler ultrasonography, magnetic resonance imaging, and computed tomography (CT). The gold standard for diagnosis remains venography that may be needed when the noninvasive tests are inconclusive. Liver biopsy is also helpful and may be needed to determine the extent of cirrhosis and to guide treatment.

Treatment options for thromboses in other anatomic locations are similar and include medical management, anticoagulation, radiographic interventions, and surgical procedures. Due to the unique involvement of the liver in this condition, the medical management includes controlling symptoms of liver failure. Radiographic treatment of BCS includes transjugular intrahepatic portosystemic shunting (TIPSS) as well as all of methods described later such as thrombolysis, stenting, and angioplasty. Surgical approaches to BCS are particularly challenging because of the inaccessible location of the hepatic veins and the retrohepatic IVC. Portosystemic shunting and liver transplantation, however, do offer some hope for these patients (40).

### Nephrotic Syndrome

Nephrotic syndrome is characterized by proteinuria greater than 3.5 g/m<sup>2</sup>/day. Hypoalbuminemia, edema, hyperlipidemia, and lipiduria may also be seen but are variable in expression. ♣ There is a high incidence of renal vein thrombosis with nephrotic syndrome for reasons that are not clear. Patients with nephrotic syndrome are hypercoagulable and have an increased occurrence of generalized arterial and venous thromboemboli; however,

**the incidence of clotting is highest in the renal veins.** ♂  
This may be due to the decreased perfusion of the kidneys seen in NS and resultant low flow and hemoconcentration in the postglomerular circulation.

Diagnosis of renal vein thrombosis is similar to that of BCS insofar as noninvasive ultrasonography is the preferred screening technique (41), whereas invasive venography has the highest sensitivity and specificity.

Treatment of thromboembolism for nephrotic syndrome is similar to that of BCS when the IVC is involved. Treatment for renal vein thrombosis, however, is limited to anticoagulation and, in unusual circumstances, surgical thrombectomy (42).

## LOWER EXTREMITY AND PELVIC VEINS

The lower extremity has two systems of venous drainage, the deep and superficial systems. The superficial system is comprised of the lesser and greater saphenous veins (GSVs), and the deep system is comprised of paired common femoral veins (CFVs), superficial femoral veins, profunda femoral veins, popliteal veins, and tibial veins (43). The superficial veins communicate with the deep system via venous perforators and directly at the saphenofemoral junction. Thrombosis of the deep veins of the lower extremity can propagate into the iliac system and further into the IVC. DVTs are also classified by the location in the lower extremity with proximal (thigh) veins being considered more clinically important than distal (calf) veins in terms of potential for subsequent PE (44).

Thrombosis of the iliac veins has the greatest risk of massive PE. ♂ **DVTs occur more commonly in the left common iliac vein. This is explained anatomically because the right common iliac artery compresses the left common iliac vein as it crosses over it. Repetitive pulsations may cause a “web” or “spur” to form and make this vein more prone to thrombosis. This condition has been termed May–Thurner syndrome (45).** ♂

### Diagnostic Tests

The diagnostic workup of suspected VTE must be initiated based on clinical suspicion and must proceed systematically from bedside examination to noninvasive [i.e., impedance plethysmography (IPG) or VDU] and, in some circumstances, invasive testing (Table 4).

### Physical Exam

Classic findings of DVT are the following: pain, swelling, and variable discoloration of the involved extremity. In the ICU setting, symptoms may be difficult to illicit from a sedated, paralyzed, or endotracheally intubated patient. Therefore, a high index of suspicion must be maintained and physical examination revealing unilateral swelling, a palpable cord, or superficial venous dilation must be followed by further testing (46,47). Clinical examination and grouping patients into low, moderate, and high-risk groups prior to testing (Table 5) has been shown to increase diagnostic accuracy (48,49).

### Ultrasound/Duplex

VDU examination of the lower extremity is useful in that it is noninvasive and can be done at the bedside, thus eliminating

**Table 4** Diagnostic Tests of Lower Extremity Deep Venous Thrombosis

Test	Findings
Physical exam	Pain Swelling Discoloration Unilateral swelling Palpable cord
VDU	Visualization of clot Response to compression Echodensity Duplex flow
IPG	Resistance related to obstruction
Venography	Normal anatomy Intraluminal filling defect

*Abbreviations:* IPG, impedance plethysmography; VDU, venous Doppler ultrasound.

the need to transport critically ill patients. Venous interrogation is most accurate when compression ultrasonography (50,51) is used. The vein is identified and followed along its course until the thrombus is found. The chronicity of the thrombus can be inferred from its appearance on ultrasonography as older clots have a more echodense appearance (52). Finally, the vein is compressed during duplex scanning to determine if there is an appropriate flow response. The obvious limitation of compression ultrasonography is in imaging veins that cannot be compressed by the probe, such as those above the inguinal ligament.

**Table 5** Pretest Probability of Deep Vein Thrombosis

Clinical feature	Score <sup>a</sup>
Active cancer (treatment ongoing or within the previous 6 mo or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bed-ridden for more than 3 days or major surgery, within 4 wks	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling by more than 3 cm when compared to the asymptomatic leg (measured below tibial tuberosity)	1
Pitting edema (greater in the symptomatic leg)	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis as likely or more likely than that of deep venous thrombosis	-2

*Note:* This clinical model has been modified to take one other clinical feature into account: a previously documented deep vein thrombosis (DVT) is given the score of 1. Using this modified scoring system, DVT is either likely or unlikely as: DVT likely = 2 or greater; DVT unlikely = 1 or less.

<sup>a</sup>A score of 3 or higher indicates that the probability of deep vein thrombosis is likely; a score of 1 or 2 indicates that the probability is moderate; and a score of 0 or less indicates that the probability is very unlikely.

*Source:* Adapted from Ref. 115.

☞ **Serial VDU studies should be performed if the initial exam is negative because 2% of patients with an initially negative study will have a positive result when studied seven days later (3,53).** ☞ A carefully done ultrasound examination has been found in one series to have a 100% sensitivity and 99% specificity (54).

### Impedance Plethysmography

IPG is another noninvasive test, which is useful to define venous obstruction. A pneumatic cuff is placed around a patient's thigh and two electrodes are placed on the calf. The cuff is inflated and then rapidly deflated while the resistance between the electrodes is measured. The outflow fraction, which is related to the degree of obstruction, may be calculated (55).

The sensitivity and specificity of this technique is 91% and 96% in some series (56); however, significant variabilities have been demonstrated in the same patient (57). In addition, patients must be correctly positioned and immobile for two minutes, which might be difficult in an agitated ICU patient. Finally, as the success of ultrasound increases, the use of plethysmography decreases and fewer people are familiar with the technique.

### Venography

Contrast venography is still the "gold standard" for the diagnosis of DVT. Adequate imaging requires visualization of the deep venous structures from the calf veins to the IVC. ☞ **The most reliable venographic finding indicating a DVT is an intraluminal filling defect seen on two or more views of the same area (58).** ☞ In one study, only 1.3% of patients developed a DVT following an initially negative venogram over a six-month follow-up (59). However, due to the invasive nature of the study and the need to transport ICU patients to an interventional suite, venography is not the first choice of studies for critically ill patients. If the ultrasound is read as inconclusive (such as "suspicious for but not diagnostic" of iliac or pelvic vein thrombosis) or is unavailable, then contrast venography can be used. It is also not recommended for patients with renal insufficiency unless other studies are inconclusive and the risk of empiric anticoagulation is great.

### Prevention and Treatment

The prevention and treatment of DVT should be considered for every hospitalized patient. The approaches used vary from simple preventative measures such as anticoagulation and early ambulation to more invasive treatments such as mechanical devices, interventional radiology, and surgery (Table 6). In the absence of a major contraindication, LMWH is indicated for the prophylaxis of trauma patients with at least one risk factor for VTE (3). Those with a contraindication to LMWH because of active bleeding or high risk of hemorrhage should receive mechanical prophylaxis (described later).

DVT is the most common complication of HIT, and, therefore, symptoms or signs of DVT in a patient receiving antithrombotic prophylaxis with UFH or LMWH should prompt consideration of this diagnosis, including determination of the platelet count and comparison with previous values.

### Anticoagulants

Primary therapy for DVT centers on anticoagulation and there is a wide variety of anticoagulants available that

**Table 6** Prevention/Treatment of Lower Extremity Deep Vein Thrombosis

Anticoagulation	UFH LMWH Heparinoids Thrombin inhibitors Enzyme inhibitors Factor inhibitors Warfarin
Mechanical devices	Elastic stockings Sequential compression Intravascular filters
Interventional radiology	Fibrinolysis Balloon angioplasty Stenting Clot extraction
Surgery	Direct thrombectomy Cross-over saphenous bypass
Early ambulation	Postoperative protocols Travel ambulation

*Abbreviations:* DVT, deep vein thrombosis; UFH, unfractionated heparin; LMWH, low molecular weight heparin.

vary in dosing, monitoring, and limitations (Table 7). The main anticoagulant used is UFH, which is an indirect thrombin inhibitor, as it combines with AT III to accelerate the inactivation of thrombin and factor Xa. This inactivation involves the formation of a ternary complex in which heparin binds to both AT III and to thrombin. This requires an adequate saccharide length, which occurs commonly in UFH preparations, but less so with LMWH (60).

☞ **UFH is the first choice in treatment for DVT but has limitations, which include a narrow therapeutic window and variable dose–response that requires frequent monitoring.**

☞ The half-life of UFH is approximately 30 to 60 minutes (61). The dosing of UFH usually involves a weight-adjusted nomogram (Table 8) with an initial bolus of 80 units/kg followed by 18 units/kg/hour (62). The rate is then adjusted to maintain an activated partial thromboplastin time (APTT) that is about 1.5 to 2.3 times higher than normal. However, in patients in whom there is a concern for bleeding (e.g., a recent postoperative patient), a smaller bolus or no bolus may be used. Complications of UFH include bleeding, immune HIT, and, with chronic use, osteoporosis. Bleeding can occur without a supratherapeutic APTT, especially in patients who have undergone trauma or surgery (63). If a patient is bleeding while receiving UFH, protamine sulfate can reverse the anticoagulant effects using a dose of 1 mg of protamine sulfate for every 100 units of heparin administered within the past few hours.

Two types of HIT are known. Type I is not immune-mediated and is manifested by a fall in the platelet count within 48 hours with a return to normal with or without discontinuation of heparin. Type II is immune-mediated and is caused by antibodies that recognize a platelet granule protein (platelet factor 4) complexed to heparin. Usually, platelets do not recover unless heparin is discontinued. Thrombotic events rather than bleeding are typical for type II HIT. Two to five percent of patients receiving UFH and 0–1% of patients receiving LMWH for one to two weeks develop immune HIT. ☞ **All forms of heparin (including LMWH) should be discontinued when HIT is diagnosed**

**Table 7** Anticoagulants

Agent	Dosage <sup>a</sup>	Monitoring	Limitations
UFH	80 units/kg/hr, IV bolus 18 units/kg continuous IV	APTT	IV infusion HIT
LMWH			
Enoxaparin			
Daltiparin			
Tinzaparin	1.5–2 mg/kg/day, SQ	None needed	HIT (less than with UFH)
Heparinoids			
Danaparoid	2250 units SQ, BID	Antifactor Xa assay	Expensive (but less than thrombin inhibitors)
Thrombin inhibitors	Variable	APTT	Expensive No antidote
Lepirudin (hirudin)			No antidote
Bivalirudin			
Argatroban			
Warfarin	2–10 mg, QD or QOD <sup>b</sup>	PT	Variable dose–response slow to reverse

<sup>a</sup>Therapeutic, rather than prophylactic, dosing is shown.

<sup>b</sup>The first dose of warfarin should not exceed 5 mg.

*Abbreviations:* APTT, activated partial thromboplastin time; BID, 2 times per day; HIT heparin-induced thrombocytopenia; IV, intravenous; LMWH, low molecular weight heparin; PT, prothrombin time; QD, once daily; QOD, 4 times per day; SQ, subcutaneous; UFH, unfractionated heparin.

#### and nonheparin based anticoagulation should be instituted (64). ♂

The other commonly employed forms of heparin are LMWHs. These smaller molecules are made by treating UFH with a variety of depolymerization reactions. The ones that are currently approved for use by the FDA include enoxaparin, dalteparin, and tinzaparin. Like UFH, they are all indirect factor Xa inhibitors, but in contrast to UFH, LMWHs inhibit thrombin to a lesser extent (binding poorly to AT III) and, as a result, do not usually prolong the APTT. LMWHs are given subcutaneously and their anti-Xa activities correlate well with body weight, allowing a fixed dosing regimen to be used. Laboratory monitoring is not necessary unless the patient is pregnant or has renal insufficiency. Additionally, LMWHs cause less immune

thrombocytopenia. Normal dosing for full anticoagulation is 1 mg/kg twice per day or 1.5 mg/kg once a day (65). Although LMWHs can be given subcutaneously, UFH is usually given by a constant IV infusion, making conversion to an oral anticoagulant necessary for outpatient treatment.

Nonheparin agents may be used for anticoagulation and are particularly helpful when HIT develops. Two large classifications of agents are the heparinoids and the direct thrombin inhibitors (DTIs). Danaparoid is a low molecular weight heparinoid that is a more selective factor Xa inhibitor than LMWH. Its activity can be measured by a chromogenic antifactor Xa assay. Unlike heparin, danaparoid is not effectively neutralized by protamine. Danaparoid is not available in the United States. Currently, the two FDA-approved anticoagulants for treatment of HIT are DTIs, lepirudin and argatroban. Lepirudin is a recombinant form of hirudin, the natural polypeptide anticoagulant from the saliva of the medicinal leech. Argatroban is a synthetic small-molecule thrombin inhibitor derived from arginine. A third DTI available in the United States, bivalirudin (analogue of hirudin), is not approved for treatment of HIT, but has, except during angioplasty, seen limited use for this indication. Unlike other anticoagulants, these drugs are sometimes difficult to monitor with standard laboratory tests, as the APTT does not always reliably estimate drug levels. No antidotes exist for these DTIs (66).

The standard oral anticoagulation drug is the vitamin K antagonist, warfarin. Its mechanism of action is to reduce the synthesis of functional levels of the vitamin K-dependent procoagulant factors, II (prothrombin), VII, IX, and X. There is the potential for a hypercoagulable effect occurring within the first few days after initiating treatment due to the reduction in synthesis of two vitamin K-dependent anticoagulant factors, protein C and protein S; this results particularly from the relatively short half-life of protein C compared with the other vitamin K-dependent factors. The peak effect of anticoagulation does not occur with warfarin until 36 to 72 hours after the first dose, but the effect on

**Table 8** Weight-Based Nomogram for Intravenous Heparin Infusion

Initial dose	80 U/kg bolus, then 18 U/kg/hr
APTT < 35 sec ( $< 1.2 \times$ control)	80 U/kg bolus, then increase infusion rate by 4 U/kg/hr
APTT 35–45 sec ( $1.2–1.5 \times$ control)	40 U/kg bolus, then increase infusion rate by 2 U/kg/hr
APTT 46–70 sec ( $1.5–2.3 \times$ control)	No change
APTT 71–90 sec ( $2.3–3.0 \times$ control)	Decrease infusion rate by 2 U/kg/hr
APTT > 90 sec ( $> 3.0 \times$ control)	Hold infusion 1 hr, then decrease infusion rate by 3 U/kg/hr

*Note:* Each laboratory should establish the appropriate APTT range that corresponds to a therapeutic level of heparin (which may or may not correspond to the APTT ranges used in the nomogram shown above).

*Abbreviation:* APTT, activated partial thromboplastin time.

*Source:* From Ref. 116.

the individual factors varies (Fig. 4). Dosing is monitored using the prothrombin time, expressed as the International Normalized Ratio (INR), which is usually maintained at 2.0 to 3.0 for DVT therapy. Complications include bleeding (especially with excessive INR prolongation) or necrosis (either skin necrosis or venous limb gangrene, which are secondary to microvascular thrombosis related to warfarin-associated decreases in protein C and/or protein S). To avoid complications of warfarin-induced hypercoagulation, UFH and LMWH are usually overlapped for at least five days with warfarin. If a patient requires immediate reversal of anticoagulation while receiving warfarin, fresh frozen plasma or prothrombin complex concentrates should be administered. Rapid (within a few hours) reversal of anticoagulation can be achieved by slow (over 30–60 minutes) intravenous infusion of vitamin K (67).

### Mechanical Devices

#### Intermittent Pneumatic Compression

☞ Intermittent pneumatic leg compression has both local and systemic effects. Locally, it acts by simulating the calf muscle pump and, thus, preventing venous stasis. Systemically, it acts by inhibiting plasminogen activator inhibitor-1 (68) and increasing the body's fibrinolytic activity. ☞ For this reason, compression devices placed on an arm may convey some benefit in preventing clot formation in the lower extremities.

Although there is little risk in using pneumatic leg compression devices, they should be used with caution in patients with severe peripheral vascular occlusive disease. In addition, some clinicians believe they should not be started on patients who have been at bed rest for greater than 72 hours prior to obtaining a noninvasive evaluation of pre-existing DVT, due to the possible dislodging of a previously formed clot. The literature has clearly demonstrated benefits of intermittent pneumatic leg compression

in moderate risk patients following trauma, and those undergoing general surgical, cardiac, and neurosurgical procedures (69,70). Compression should be initiated preoperatively in elective cases and be used throughout the postoperative period until the patient is ambulatory.

#### Intravascular Filters

Interruption of the IVC was first described by Trousseau in 1868 (71). Since that time IVC filters have evolved and are routinely placed in high risk trauma patients, and those with DVT but a contraindication to anticoagulation. There are many different types of IVC filters which are all designed to trap clots but allow blood flow (Fig. 5). As the technology has advanced, the delivery system has become smaller, making deployment of the filters easier. The use of IVC filters in addition to anticoagulation has been investigated and found to cause a decrease in incidence of short-term PE but no difference in incidence of long-term PE or survival (72). IVC filters are not routinely used for patients without evidence of thromboembolism. ☞; The indications for placement of filters are the following: (i) acute VTE in a patient who has a contraindication for anticoagulation, (ii) VTE in a patient who is already anticoagulated, (iii) patients who have a compromised pulmonary vascular bed in whom a VTE would not be tolerated, (iv) patients with a high fall risk in whom anticoagulation could cause bleeding, and (v) trauma patients with a prolonged high risk for VTE due to prolonged immobility (e.g., quadriplegia) and severe traumatic brain injury (TBI) (73). ☞

Retrievable vena cava filters are now clinically available for use in patients with a short anticipated duration of need for protection against PE. One such device is the Günther Tulip™ Vena Cava Filter (Cook, Inc., Bloomington, IN, US) (Fig. 6). Because these devices are still under study, and complications have been reported, retrievable venacaval filters are discussed later in the “Eye to the Future.”

**Figure 4** Effect of warfarin on blood-clotting proteins. The activity of various clotting proteins (logarithmic scale) is shown here as a function of time after ingestion of warfarin (10 mg/day PO for four consecutive days) by a normal subject. Factor VII activity, to which the prothrombin time is most sensitive, is the first to decrease. Full anticoagulation, however, does not occur until factors IX, X, and prothrombin are sufficiently reduced (at least four days). Protein C activity falls quickly, and, in some patients, a transient hypercoagulable state may ensue resulting in microvascular thrombosis (e.g., coumarin necrosis). The half-life of protein S (not shown) resembles that of prothrombin (60 hours).

### Interventional Radiology

Although there have been controlled trials for the use of thrombolytics in patients who have suffered a VTE, the data on its use in DVT alone are minimal. The potential benefits of complete clot lysis, the lower incidence of post-phlebitic syndrome, and reduced chances for potential PE must be weighed against the potential bleeding complications that may occur with thrombolytics. In addition, many patients may not be candidates for thrombolysis, such as those who have undergone recent surgery or trauma (74). The main thrombolytic agents that have been studied are streptokinase, urokinase, and tissue plasminogen activator. Most of studies are small and conclusions about optimal dosing and expected results cannot be drawn (75–77).

In the setting of acute DVT, the use of catheter-directed thrombolysis is becoming more popular. This technique is commonly employed for iliofemoral DVT by passing a wire across the thrombus, placing an infusion catheter with side-holes, and infusing a thrombolytic substance directly into the thrombus. By employing this method, the amount of thrombolytic agent given is less than with

systemic dosing and several series have reported excellent success rates (78,79).

DVTs are more frequently located in the left lower extremity due to the anatomic compression resulting in the May–Thurner syndrome (80) as described earlier. Treatment of a thrombus at this location usually involves catheter-directed thrombolysis, balloon angioplasty, and placement of a stent due to the recurrent nature of thrombosis. May–Thurner syndrome and acute DVTs causing a threatened limb (phlegmasia cerulea dolens) are the two most common indications for peripheral thrombolytics (81). Thrombolytic therapy also increased thrombin generation, and thus concomitant anticoagulation, at least in low doses, is usually given.

♣ In addition to May–Thurner syndrome, endoluminal stenting and balloon angioplasty have been described in other types of iliofemoral venous occlusive disease. Although these procedures are uncommonly performed, they offer nonsurgical options for trauma and critically ill patients with VTE disease. ♣

### Surgery

In the situation of a threatened limb such as phlegmasia cerulea dolens, in which the patient cannot wait for catheter-directed thrombolysis, surgical thrombectomy should be considered. The GSV is identified and followed to the saphenofemoral vein junction. The CFV is then opened and a Fogarty catheter is used to extract the thrombus while the patient is under general endotracheal anesthesia. Some recommend a pulmonary end expiratory pressure of 10 cm water to decrease the risk of PE (though this mechanism is entirely speculative). After the thrombus is removed, the GSV is attached to the femoral artery to create an AV fistula to help keep the vein open. A completion venogram is performed to ensure the patency of the thrombectomized vein. The procedure should include fasciotomies to relieve a potential compartment syndrome and anticoagulation is continued throughout the postoperative period (82).

If the thrombus is chronic and the vessel cannot be surgically recanalized, other surgical procedures such as the crossover saphenous vein bypass (Palma procedure) can be performed. This procedure involves dissecting the contralateral GSV but keeping it attached to its saphenofemoral junction. It is then tunneled to the affected groin where an anastomosis is made to the CFV proximal to the occlusion. In addition, an end-to-side anastomosis between the ipsilateral saphenous vein and adjacent femoral artery is performed to create an arteriovenous fistula to keep the outflow tract open (83).

In this era of interventional radiology and other nonsurgical alternatives, however, surgical thrombectomy should be reserved for dire circumstances and the unusual cases noted earlier.

### Early Mobilization

Of the triad of risk factors Virchow identified as causative for VTE, the one that is most easily addressed is venous stasis. It is also the risk factor that is most often seen in critically ill, traumatized, anesthetized, or postoperative patients. It is clear that prevention is the most important strategy to use against the development of VTE and the prevention of venous stasis should be the primary focus of this strategy.

♣ Although elastic compression and pneumatic compression devices restore some of the lost blood flow, mobilization and, specifically, ambulation provides

**Figure 6** Günther Tulip™ retrievable vena cava filter (Cook, Inc., Bloomington, Indiana, U.S.A.). The Günther Tulip filter is conical in shape and consists of four legs that contain additional wire loops attached to each leg. A hook is present at the apex of the filter, which is used in the retrieval process. It can be placed via a femoral or jugular vein approach. However, inferior vena cava filters must be retrieved from the jugular approach. *Source:* From Ref. 106.

**complete restoration of flow and the greatest protection against VTE.** ⚡ Although there are numerous studies demonstrating the protective effects of prophylactic anticoagulation and mechanical compression, there is very little documentation of the benefits of early ambulation. This effect of ambulation must be inferred from studies that show that lack of ambulation in patients with no other comorbid conditions, such as those who have prolonged periods of sitting, traveling, or lying in a bed, results in stasis and VTE (84,85). This information is the basis for many surgical protocols which call for early ambulation. Despite many protocols calling for early operative intervention and early restoration of ambulation in bedridden patients, there has been no convincing evidence that this approach decreases VTE (86). The recent interest in minimally invasive surgical procedures is partially inspired by the benefits of reduced postoperative morbidity leading to early ambulation.

There is another aspect of ambulation that has been studied in a more systematic way. Early ambulation versus bed rest after a DVT has developed has been subjected to several recent studies. These studies challenge the previously held notion that patients should be sedentary until a clot becomes adherent to the vein to prevent it from dislodging and embolizing. ⚡ **There have been several recent**

studies that have demonstrated that bed rest does not decrease the incidence of PE following DVT (87). Future prospective studies will have to be conducted to determine whether a period of bed rest or early ambulation should be recommended for patients with documented DVT. ⚡

## PULMONARY EMBOLISM

Of all the complications caused by DVT, PE is the most serious, with 500,000 cases diagnosed per year in the United States alone (88). Untreated PE is associated with a 30% mortality. When timely diagnosis and treatment occurs, mortality is reduced to approximately 5% (89). Much of the diagnosis, prevention, and treatment of DVT is, therefore, aimed at decreasing the incidence and lethal consequences of PE.

### Diagnosis

The most common clinical findings in PE are related to obstructed blood flow through the heart and lungs and the resultant compromise of oxygen delivery. The signs and symptoms of this disorder include tachypnea, rales, tachycardia, fourth heart sound, pleuritic chest pain, dyspnea, cough, hemoptysis, and mild fever. Unfortunately, these findings are relatively nonspecific (and may be completely absent) so that confirmatory testing is almost always warranted when PE is clinically suspected. When one or more of these signs is present in a patient at risk for VTE, an arterial blood gas (ABG), chest X ray (CXR), and electrocardiogram (EKG) are commonly obtained. Although the ABG typically shows hypoxemia, hypocapnia, and a respiratory alkalosis, a major PE may lead to hypercapnia and respiratory acidosis. Other patients with PE have close to normal oxygenation. Other lab values such as WBC, ESR, LDH, SGOT, troponin, and brain natriuretic protein may be elevated, but the utility of these nonspecific findings is questionable. The most frequently observed CXR pattern with PE is atelectasis or a pulmonary parenchymal injury, which has been observed almost as frequently in patients who were determined not to have a PE (90). Findings on electrocardiography such as nonspecific ST segment and T wave changes are frequently found but are also insensitive and nonspecific. The greatest utility of EKG in diagnosing PE may be to rule out other cause of chest pain such as myocardial ischemia.

Because of the nonspecificity of the clinical findings, and of these routinely ordered lab tests, further diagnostic testing is usually warranted. In patients with essentially normal chest radiographs, a ventilation perfusion ( $\dot{V}/\dot{Q}$ ) scan is a useful screening test. This test may be read as high probability (80–90% probable), moderate probability (40% probable), or low probability (15% probable). In the setting of patients with initially abnormal chest radiographs (i.e., most critically ill trauma patients),  $\dot{V}/\dot{Q}$  scans are rarely helpful. Furthermore,  $\dot{V}/\dot{Q}$  results may not be sensitive or specific enough to direct treatment such as anticoagulation, which can be associated with significant morbidity.

Helical CT, especially when complemented with intravenous contrast administration (CT angiography), is currently the most commonly employed study to diagnose PE. The technique, however, is operator-dependent and only experienced centers show sensitivities and specificities approaching pulmonary angiography (91). Emboli that occlude segmental and larger vessels are more likely to be

detected by helical CT scanning, whereas emboli in subsegmental vessels may easily be missed.

Pulmonary angiography, similar to venography for DVT, remains the "gold standard" for diagnostic tests of PE but is decreasingly used. It is the most invasive and expensive test and should only be used when other tests (including helical CT) are nondiagnostic, and making the diagnosis is important enough to justify the potential complications of the procedure. Complications of pulmonary angiography include injuries related to catheter placement, contrast reactions, cardiac dysrhythmias, or respiratory compromise (73).

The risks and benefits of all diagnostic tests should be weighed carefully for critically ill patients with suspected PE. A combination of clinical signs, lab tests, EKG findings, and a documented DVT by methods outlined in the previous sections may be enough to start treatment for PE.  $\dot{V}/\dot{Q}$  scanning and helical CT may be used in situations where there is uncertainty about the initial diagnosis, the patient is stable enough to be transported to the radiology suite, and the risk of treatment (e.g., anticoagulation) outweighs the risk of the added diagnostic techniques. In a minority of patients with suspected PE (about 20%), pulmonary angiography will be needed to make a definitive diagnosis.

The occurrence of PE in a patient receiving UFH or LMWH antithrombotic prophylaxis should prompt consideration of HIT, and warrants measurement of the platelet count, as HIT confers a 40-fold increased risk of PE (by odds ratio) and requires use of a nonheparin anticoagulant such as lepirudin or argatroban.

## Treatment

Treatment for documented PE embolus is similar to treatment for documented DVT and includes anticoagulation, thrombolytic therapy, invasive radiology, and, rarely, surgical intervention. Anticoagulation following PE is no different from that described earlier for DVT except that the duration of anticoagulation after a documented PE is somewhat longer. Those patients with a known risk factor for PE (e.g., postoperative patients) should be anticoagulated for three to six months if the risk factor is reversed. If there are no known risk factors, then anticoagulation should be continued for the entire six months. If there is a risk factor that cannot be reversed, then anticoagulation should be permanent (92).

Thrombolysis, similar to its employment for DVT, is used only when there is a severe compromise of blood flow in the pulmonary arteries that cannot wait for the body's natural fibrinolytic system to clear the obstruction. It requires catheterization of the pulmonary arteries and direct infusion of a thrombolytic agent, such as streptokinase, urokinase, or tissue plasminogen activator, adjacent to or into the blood clot. As well as the acute resolution of hemodynamic and radiographic abnormalities, there is some evidence that patients who receive thrombolytic therapy have lower pulmonary artery pressures and lower pulmonary artery resistances years after treatment when compared to those who receive anticoagulation alone (93). IVC filters, which are described earlier, are usually placed for the prevention of initial or recurrent PE.

When the patient has significant hemodynamic compromise from a large embolus and thrombolysis is contraindicated, interventional radiologists may use a variety of catheters to both fragment and aspirate the clot (94). Similar to treatment of DVT, surgical intervention is

usually the last option. Surgical removal of a clot from the pulmonary artery is a heroic maneuver with very high morbidity and mortality. Although it is easiest to do on cardiac bypass, it has been done without extracorporeal circulation (95).

There is a risk of mortality and morbidity associated with every treatment used for PE. For this reason, some investigators have suggested that treatment for PE may be withheld in patients who have a small embolus, adequate cardiopulmonary reserve, and a contraindication to anticoagulation (96). These patients should be followed with serial noninvasive leg studies to demonstrate the absence of recurrent DVT. This strategy should be considered experimental and must be evaluated further before it is used outside of a clinical trial.

## AMERICAN COLLEGE OF CHEST PHYSICIANS RECOMMENDATIONS FOR VENOUS THROMBOEMBOLISM PROPHYLAXIS FOLLOWING TRAUMA

Decision-making regarding VTE prophylaxis in trauma patients has been recently reviewed by "the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy: Evidence-Based Guidelines" published their evidence-based recommendations (Table 9) (3).

The strength of their recommendations was assigned a numerical grade (1 or 2) based upon the trade-off between the benefits of a therapy and the risks and burdens (and costs) of that treatment. If the benefits outweigh the risks, burdens, and costs, treatment is recommended.

The uncertainty associated with the risk/benefit (R/B) equation determined the strength of the recommendations. If the R/B equation was clearly demonstrated in the literature, a strong recommendation (Grade 1) was assigned. When they were less certain of the R/B equation, a weaker (Grade 2) recommendation was assigned.

The methodological quality of their recommendations was also assigned an alphabetical grade as follows: Randomized clinical trials (RCTs) with consistent results and a low likelihood of bias are classified as Grade A, whereas, RCTs with inconsistent results, or with major methodological weaknesses, were assigned Grade B recommendations. Grade C recommendations come from observational studies or from a generalization from one group of patients in an RCT to a different (similar) group of patients who did not participate in the trials. When the generalization from RCTs was considered secure, or the data from observational studies overwhelmingly compelling, the Grade of C+ was assigned. Otherwise, a simple grade of C was assigned.

Most of the recommendations in the ACCP Guidelines are supported by this review and are in concert with the EAST guidelines released two years prior (4). Both our review of the literature and the EAST guidelines suggest a slightly more aggressive rule for IVC filters (Table 8). Accordingly, we have supplemented recommendation 5a with 5b, which we believe reflects the current thinking. Additionally, the role of retrievable IVC filters is evolving (see Eye to the Future).

In the most extensive review of the ACS-NTDB to date, Knudson et al. reviewed the risk factors associated with VTE in 1602 trauma patients (5). The list of risk factors evaluated was developed by prospective studies conducted at San Francisco General Hospital and also identified by a consensus panel of VTE experts led by Dr. Lazar Greenfield. Of

**Table 9** Recommendations for Prevention of Venous Thromboembolism Following Trauma

Topic	Recommendation <sup>a</sup>	Grade
≥1 Risk factor	Trauma patients with at least one risk factor for VTE should receive thromboprophylaxis, if possible.	1A
LMWH indications	In the absence of a major contraindication, LMWH prophylaxis is indicated starting as soon as it is considered safe to do so.	1A
Mechanical prophylaxis	Mechanical prophylaxis with IPC devices, or possibly with GCS alone should be used if LMWH prophylaxis is delayed or if it is currently contraindicated due to active bleeding or a high risk for hemorrhage.	1B
VDU screening	VDU screening in patients who are at high risk for VTE (e.g., in the presence of a SCI, lower extremity or pelvic fracture, major TBI, or an indwelling femoral venous line) and who have received suboptimal prophylaxis or no prophylaxis.	1C
IVCF Indications	Per the ACCP recommendations, IVCFs should not be used as primary prophylaxis in trauma patients.	1C
EAST <sup>b</sup> rec's and Our view	The EAST recommendations, and the view of the authors of this review, are that high-risk patients (see VDU) with contraindication to LMWH should receive an IVCF. When the high risk for VTE is anticipated to be of short duration (e.g., severe polytrauma including pelvic fracture and thoracic injuries, but without SCI or TBI), a retrievable IVCF may be best.	1C See ETTF
Prophylaxis duration (normal mobility)	Thromboprophylaxis should continue until hospital discharge, including the period of inpatient rehabilitation.	1C +
Prophylaxis duration (impaired mobility)	Thromboprophylaxis should continue after hospital discharge with LMWH or a VKA (target INR, 2.5; INR range, 2.0–3.0) in patients with major impaired mobility.	2C

<sup>a</sup>Recommendations mainly distilled from Ref. 3.

<sup>b</sup>EAST recommendations from Ref. 4.

*Abbreviations:* ACCP, American College of Chest Physicians; EAST, Eastern Association for the Surgery of Trauma; rec, recommendations; GPC, graduated compression stockings; INR, international ratio; IPC, intermittent pneumatic compression; IVCF, inferior vena cava filter; LMWH, low molecular weight heparin; SCI, spinal cord injury; TBI, traumatic brain injury; VDU, venous doppler ultrasound; VKA, vitamin K antagonists; VTE, venous thromboembolism.

the total 450,375 patients studied, 1602 had VTE (998 had a DVT, 522 had a PE, 82 had both). Nine risk factors were significantly associated with VTE using univariate analysis ( $P < 0.0001$ ), summarized in Table 2 (5). However, only six risk factors were identified as independently significant using multivariate logistic regression (Table 10). Days requiring mechanical ventilation  $>3$  and venous injury carried the highest individual risk (by odds ratio). Knudson et al. utilized the data garnered in this comprehensive analysis, along with a complete review of the literature including most of the references cited by the ACCP recommendations (3) and the EAST Guidelines (4) to develop an algorithm for VTE prophylaxis (Fig. 7) (5). This algorithm is supported by the reviewed literature in this chapter and represents the current state of practice at most Level I trauma centers. The only caveat being the emphasis on temporary (retrievable) IVC filters.

Our expectation is that the “very high risk factor” arm of the algorithm will be further modified based upon prospective data now being gathered regarding these removable IVC filters. One of the key questions beyond safety is the expected duration that very high risk factors persist. For example, patients age  $\geq 40$  years with SCI might benefit more from a permanent IVC filter, whereas,

a 20 year old with, SCI might be best served with a retrievable IVC filter until other risk factors have abated. The ultimate answers to these questions await RCTs. Another important question is the maximum time these “retrievable” filters may remain in place before they can no longer be removed (discussed further in Eye to the Future).

## EYE TO THE FUTURE

### Medical Treatment

LMWH is increasingly viewed as the anticoagulant of choice for DVT prophylaxis (97). Many are commercially available now and undoubtedly many more will be developed and marketed in the future.

As the coagulation cascade has become better understood, the problems that lead to thrombophilia have been addressed more directly. The newest generation of antithrombotic agents target single elements of the procoagulant cascade such as thrombin (e.g., hirudin, lepirudin, argatroban, bivalirudin) and factor Xa (e.g., fondaparinux). Although some are in use now, many more are in development. These anticoagulants, due to their specificity,

**Table 10** Independent Risk Factors for Venous Thromboembolism (Multivariate Logistic Regression)

Risk factor	Odds ratio (95% CI)	P value
Age ≥40 yr	2.01 (1.74–2.32)	<0.0001
Lower extremity fracture (AIS ≥3)	1.92 (1.64–2.26)	<0.0001
Head injury (AIS ≥3)	1.24 (1.05–1.46)	0.0125
Ventilator days >3	8.08 (6.86–9.52)	<0.0001
Venous injury	3.56 (2.22–5.72)	<0.0001
Major operative procedure	1.53 (1.30–1.80)	<0.0001

Note: Presents independent risk factors for venous thromboembolism (multivariate analysis).

Abbreviations: AIS, abbreviated injury scale; CI, confidence interval.

have efficacy and safety profiles that are better than conventional anticoagulants (98).

Other factors involved in the coagulation scheme such as tissue factor, factor VII, factor V, and factor VIII will be targets for future anticoagulation strategies. Agents that inhibit these molecules are in development or in active trials now and will certainly be part of the VTE prevention and treatment armamentarium of the future.

Hyperhomocysteinemia is known to be associated with thrombophilia. Trials are under way now to determine if treatment with folate, which decreases homocysteine levels in the blood, will reverse the thrombophilia (99).

**Diagnostic Studies**

Ultrasonography is the best screening test for DVT whereas venography has the highest sensitivity and specificity. Other noninvasive imaging studies such as magnetic resonance imaging and CT have not proven to be very useful due to their low sensitivity, especially in the case of nonocclusive mural thrombi (100). In the situation where a patient is being scanned for other reasons, one

of these imaging studies may occasionally prove useful for making the diagnosis of DVT, but they should not be considered screening studies or primary diagnostic modalities. As the sensitivities of these procedures increase, however, they may find uses in diagnosing DVT in patients who have absolute or relative contraindications for venography.

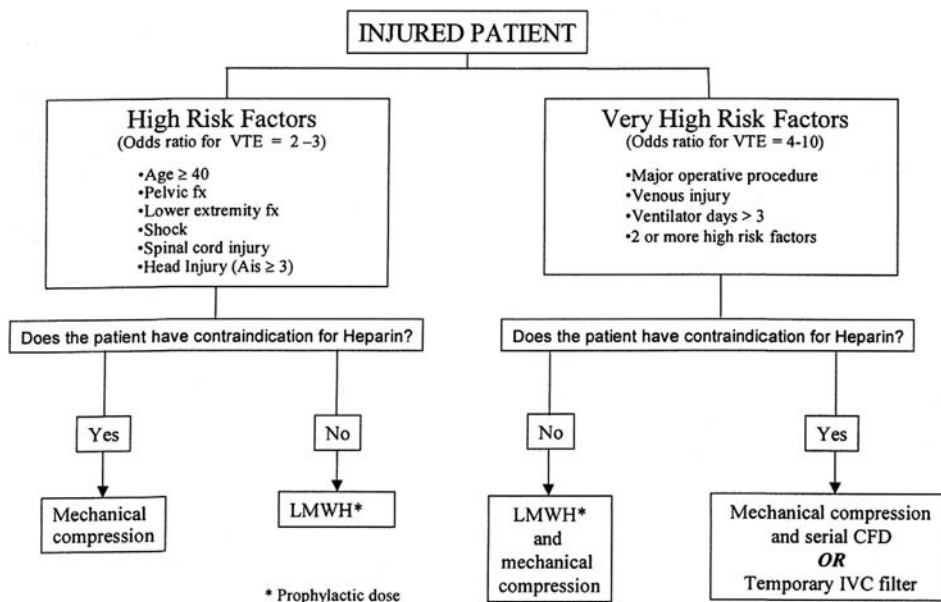

Computerized tomography pulmonary angiography (CTPA) is a test that is often used in patients with suspected PE. Many of the current protocols for CTPA now involve scanning through the pelvis and upper thigh as well as the chest. DVTs in the pelvic and lower extremity vessels have been identified using this technique (101); however, it is not used in most cases of suspected DVT because it requires a significant contrast load. It is a useful adjunct, however, and should be reserved for situations when all other tests are inconclusive and the suspicion of DVT is high.

Another promising imaging test is magnetic resonance venography. Studies comparing it to contrast venography have been small, but indicate that the test is very accurate (102). The main limitations to this study are transport issues in critically ill patients and the cost of the study.

**Retrievable Inferior Vena Cava Filters**

Interventional radiologists routinely place IVC filters, but because these filters are associated with complications such as iliofemoral and IVC thrombosis (103), there has been interest in removable IVC filters, especially in trauma patients. Critically ill trauma patients at high risk for VTE of short anticipated duration (e.g., severe polytrauma including pelvic fracture and thoracic injuries, but without SCI or TBI) are candidates for a retrievable IVC filter (Fig. 6). The Günther Tulip™ Vena Cava Filter (Cook, Inc., Bloomington, IN, U.S.) has been used in Europe since 1992 as a retrievable filter (104), and has begun to be used in the United States over the last couple years in selected cases. However, several aspects of its use are not yet known.

Recently, Yamagami studied the deployment and retrieval of the Günther Tulip™ in 10 patients being

**Figure 7** Algorithm for VTE prophylaxis proposed by Eastman AB (based upon data generated in Ref. 4). Abbreviations: VTE, venous thromboembolism; LMWH, low molecular weight heparin; IVC, inferior vena cava.

treated for DVT (105). All were successfully retrieved and there were no complications. In a larger study involving 55 trauma patients among 130 studied, Morris et al. showed the Günther Tulip™ to be relatively safe with only one major complication in 130 patients and 136 filter placements (106). The average duration between placement and removal was 19 days (range, 11–41 days). The mean age of patients selected prospectively for filter removal (29 years; range, 18–71 years) was significantly lower than the mean age (49 years; range, 19–82 years) of trauma, surgical, and intracranial hemorrhage patients selected for placement of prophylactic permanent filters ( $P < 0.002$ ; 95% confidence interval, 18.0–22.4) (106).

The maximum duration that these “removable” filters can remain in place, and still be retrievable, is not yet known. The manufacturer suggests that the Günther Tulip filter can be safely removed within 14 days of implantation or it can remain in place as a permanent filter. However, numerous investigators have now reported removal of the filter far beyond the 14 days recommended by the manufacturer. In an effort to address this question, Terhaar et al. evaluated the Günther Tulip vena cava filter with regard to ease of retrieval over relatively long time periods (107). Nineteen patients underwent attempted retrieval of their filter. Sixteen attempts were successful (84%). In three patients, the filter could not be removed due to extensive filter thrombus in two patients and firm attachment to the wall in one patient. Median implantation time for retrievable filters was 34 days (range, 7–126 days) (107). In the study by Morris et al., the longest duration of deployment prior to removal was 41 days (106). However, Binkert et al. recently reported retrieval of an IVC filter 317 days after deployment. Clearly, the maximum duration is unknown, and the time before removal generally becomes technically difficult requires additional study (108).

Another important question under study is the period of time a patient remains at risk for VTE and PE following trauma. Greene et al. recently recommended that the IVC filter should not be removed until the patient has fully recovered from the trauma and critical illness, or that there is objective data to show that the VTE risk is low (generally at least 30 days after the trauma) (109). Accordingly, there is much still to be learned about these retrievable filters, including the migration rate to the right ventricle and pulmonary artery in large populations of mobile patients. Furthermore, there is a trend toward placing these filters at the bedside in critically ill ICU patients (i.e., too unstable for transport to radiology) (110).

### **Percutaneous Mechanical Thrombectomy**

More recently, the use of mechanical thrombectomy devices has been employed to remove thrombus from the vein. The advantage of these devices is that their use avoids the use of thrombolytics with their attendant bleeding complications and, if successful early in the course of the disease, will prevent development of postphlebotic syndrome (111).

Percutaneous mechanical retrieval of venous thrombi is usually not necessary due to dissolution that occurs following anticoagulation therapy. However, systemic anticoagulation is often contraindicated in severely injured trauma patients. When a large, potentially lethal DVT is diagnosed in a trauma patient with contraindications to anticoagulation, an IVC filter is generally placed (as discussed earlier). However, occasionally, the thrombus extension may be so severe that venous drainage from

vital organs (e.g., liver, kidneys), becomes obstructed, or lower extremity swelling becomes so significant that healing and clearance of infection is impaired. In these conditions, clot retrieval via percutaneous devices may become useful (112). Percutaneous mechanical thrombectomy devices fall into two categories: rotational and hydrodynamic.

Rotational thrombectomy devices use a high-speed rotating basket or impeller to fragment the thrombus. The ground thrombus particles then travel to the pulmonary circulation (suboptimal for critically ill patients with impaired pulmonary function) (113). Examples of rotational thrombectomy instruments are the Amplatz thrombectomy device (Microvena), the Arrow-Terrotola percutaneous thrombolytic device (Arrow), and the Cragg-Castaneda thrombolytic brush (Microtherapeutics) (112).

Hydrodynamic, or “jet,” devices are based on the Venturi effect created by high-speed saline jets directed retrograde. The jets fragment the thrombus and the material is then aspirated into the device. Devices based on this mechanism are presumed to produce less endothelial damage than rotational thrombectomy instruments, but this has not been studied. Examples of hydrodynamic recirculation devices include the AngioJet (Possis), the Hydrolyzer (Cordis), and the Oasis Thrombectomy System (Boston Scientific Corporation). In a study of 37 patients, Kasirajan et al. reported >50% thrombus extraction in 59% of patients treated with these devices and symptomatic improvement in 82% (111).

The Bacchus Trellis (Bacchus Vascular) is a relatively recent device, consisting of a catheter with proximal and distal occlusion balloons and a sheath designed to aspirate contents between the balloons (114). A sinusoidal nitinol wire placed within the catheter is rotated to mix the blood between the balloons. The Trellis device combines a high concentration of thrombolytic drug with mechanical disruption of the clot and has been shown to rapidly remove thrombus in patients with DVT (114). The occlusive balloons limit leakage of thrombolytic drug into the systemic circulation, reducing the risk of bleeding complications, whereas the central balloon is engineered to reduce embolization of particulate debris into the pulmonary circulation. A combination of these technologies may be useful in the management of high-risk critically ill trauma patients in the future.

### **SUMMARY**

VTE refers to thrombi forming in the venous system and the emboli that may become dislodged from these thrombi and travel to other areas of the venous network. The pelvis and lower extremities are the most common places for DVTs to develop, although DVTs may occur in the upper extremities, SVC, and IVC. Embolization of a DVT to the pulmonary circulation and the PE syndromes are the most dreaded complications of VTE.

Venous thrombus forms in veins when one or more of three causative factors (Virchow’s triad) are present. These factors (hypercoagulation, intimal injury, and venous stasis), occur commonly in post-trauma, postoperative, systemically inflamed, infected, or anesthetized patients. Clotting is stimulated by a series of procoagulant events that are counteracted by coordinated anticlotting and fibrinolytic activities. The balance between these events will determine whether clots will form and enlarge or will be lysed. Hypercoagulation occurs when the procoagulant system is

hyperactive or when the anticlotting or lytic systems are underactive. Examples of the former are the presence of factor V Leiden or high levels of homocysteine, Factors VIII, IX, and XI, TAFI, and fibrinogen. Examples of the latter are deficiencies of protein C, protein S, plasminogen, factor XII, or heparin cofactor II.

The endothelial damage that occurs with operations or penetrating trauma predispose to VTE. Patients who have trauma to the pelvis and lower extremities, in particular, have a greater risk for developing clots in these areas. Intimal damage alone has been reported to result in DVT. Hypercoagulation is another important cause of DVT, which is seen quite often in critically ill patients. Strategies aimed at restoring blood flow with vein compression or early ambulation have been successful in decreasing the incidence of DVT. This clinical triad of findings for DVT may be masked by the presence of edema, pain, discoloration, dyspnea, hypotension, tachycardia, and other clinical signs often seen in critically ill patients. Because the consequences of a missed diagnosis may be devastating, critical-care practitioners must have a high index of suspicion and employ prophylactic measures to prevent or minimize VTE.

In the upper extremities, the axillary and subclavian veins are most often involved with DVT and the clots are usually caused by indwelling catheters. Spontaneous clots caused by anatomic variations such as a narrowed thoracic outlet have no particular significance for the ICU patient other than that they must be differentiated from the thrombi caused by indwelling catheters. Similar to lower extremity thrombi, upper extremity thrombi may embolize to the lungs. Diagnosis of an upper extremity thrombus is usually made by ultrasonography, but venography is occasionally required. The area of the shoulder and neck is less accessible and the full range of diagnostic maneuvers such as compression ultrasound and plethysmography that are used in the lower extremities is not possible. Catheter-related thrombi can usually be treated by removing the catheter. Clot lysis using the catheter to deliver the thrombolytic agents is another strategy that is particularly helpful when the catheter cannot be removed for therapeutic reasons.

The SVC is another anatomic location for clot formation. Many of these are formed around catheter tips and the diagnosis and treatment of these clots are similar to those that form in the more peripheral veins. Of note, catheters that end in the subclavian or innominate veins are more likely to form clots than those positioned with their tips in the SVC close to the right atrial junction. SVC obstruction can also be caused by malignancies of the mediastinum that either compress or invade the SVC. Although DVT is not the primary etiology of these obstructions, clotting may be secondarily involved, making stenting and thrombolysis therapeutic alternatives for critically ill patients.

IVC thrombus is typically seen with BCS or nephrotic syndrome. The prognosis in both cases is more dependent on the effect of the diseases on hepatic and renal function, respectively. Clots in the IVC are not easily accessible and treatment usually involves anticoagulation, thrombolysis, and only rarely, surgical intervention.

Most DVTs occur in the veins of the pelvis and lower extremities. The iliac veins have the greatest risk of massive embolism to the lungs. Clots form more often in the left iliac vein due to compression on this side by the right iliac artery. The diagnosis of a lower extremity DVT may be accomplished by careful physical exam, but in the case of critically ill patients with significant comorbidity, other methods may be required. Ultrasonography, combined

with Doppler technology and physical maneuvers such as compression, is the best screening exam. It has the advantages of being relatively inexpensive and portable. IPG is also useful, but has been largely supplanted by ultrasound. Contrast venography is the most sensitive and specific exam; however, it is invasive and is associated with a number of complications, such as renal failure.

Prevention and treatment of lower extremity VTE generally starts with anticoagulation. UFH is used most often for acute situations, but it requires lab tests for monitoring and an intravenous drip for full therapeutic anticoagulation. LMWH preparations are now available that may be given by subcutaneous injection without lab monitoring, making them useful for outpatient management. Both forms of heparin can cause immune thrombocytopenia (less so with LMWH) so alternative medications such as DTIs are sometimes required. VTE is the most common sequela of HIT, and thus signs or symptoms of DVT or PE in a patient receiving antithrombotic prophylaxis with UFH or LMWH should prompt diagnostic consideration of HIT.

Mechanical devices that prevent or treat VTE include elastic or pneumatic compression stockings and a variety of intravenous filters. Interventional radiologists have developed a number of strategies for dealing with venous obstruction related to DVTs. Catheter-directed thrombolysis using urokinase, tissue plasminogen activator, or streptokinase is the mainstay of radiographic intervention. Thrombolytics may be delivered directly adjacent to the clots or sometimes within the clot, with a side-holed catheter. Balloon angioplasty and stenting may be added to thrombolysis in circumstances when a stricture or narrowing may compromise flow. Surgery is not done very commonly due to the success of the less invasive procedures noted earlier. When surgery is necessary (e.g., an acutely threatened limb), thrombectomy of the ipsilateral side or venous bypass to the contralateral side is possible. Despite the large number of therapeutic options available, the major thrust of treatment should be preventative. For this reason, prevention of venous stasis by early ambulation should be encouraged in all bed-bound or minimally ambulatory patients.

## KEY POINTS

- ☞ The components of Virchow's triad (hypercoagulation, endothelial injury, and venous stasis) have long been recognized as the etiological factors for VTE. When one or more of these factors are present, there is an initiation of the coagulation cascade and increased risk of clot formation.
- ☞ As soon as clot formation begins, processes are initiated to turn off (or downregulate) clotting [AT III and proteins C and S] or dissolve the already formed clots (plasmin and tissue plasminogen activator). Proper regulation of clotting and clot dissolution will minimize the risk of VTE.
- ☞ Overactivity of the procoagulant system or underactivity of the anticlotting or fibrinolytic systems results in a hypercoagulable state, also termed thrombophilia (Table 1).
- ☞ Venous stasis is probably the most important risk factor for VTE in patients who are critically ill or recovering from trauma or surgery. Since these patients are often bed-ridden, sedated, or paralyzed, they have sluggish blood flow and poor venous return. Blood flow may also be compromised by low cardiac output, abdominal

compartment syndrome, and elevated intravenous pressure from right heart failure (14).

Polyethylene and polyvinyl chloride catheters are more prone to pulmonary emboli than polyurethane or siliconized catheters, whereas the heparin-bonded catheters seem to be better than those without heparin bonding. Catheters placed so that the tips are in the SVC or the right atrium have a lower incidence of thrombi than those placed in the innominate or subclavian veins.

When emboli originate from the vessel wall they are termed mural thrombi. When emboli originate from an indwelling catheter they are termed sleeve emboli. Sleeve emboli have a greater chance of embolizing.

Although a properly performed venogram has close to 100% sensitivity and 100% specificity, it is done only infrequently because VDU is safer, less expensive, and usually sufficient.

When the thrombi occur as a result of an indwelling catheter, the cornerstone of treatment is removal of the catheter and anticoagulation (when not contraindicated).

Stenting may be particularly appropriate for critically ill patients who are too ill to wait for resolution of symptoms of SVC syndrome by radiation or chemotherapy and cannot undergo surgical procedures.

Although catheter-related thrombosis represents a relatively small percentage of patients who develop SVC syndrome, it is commonly seen in critically ill trauma patients who have multiple indwelling catheters for fluids, monitoring, pacemakers, and cardiac defibrillators.

Thrombosis may occur anywhere in the IVC, such as with Behcet's disease. However, most IVC clotting occurs near the hepatic veins as a consequence of BCS or adjacent to the renal veins as a consequence of nephrotic syndrome.

There is a high incidence of renal vein thrombosis with nephrotic syndrome for reasons that are not clear. Patients with nephrotic syndrome are hypercoagulable and have an increased occurrence of generalized arterial and venous thromboemboli; however, the incidence of clotting is highest in the renal veins.

DVTs occur more commonly in the left common iliac vein. This is explained anatomically because the right common iliac artery compresses the left common iliac vein as it crosses over it. Repetitive pulsations may cause a "web" or "spur" to form and make this vein more prone to thrombosis. This condition has been termed May-Thurner syndrome (45).

Serial VDU studies should be performed if the initial exam is negative because 2% of patients with an initially negative exam will have a positive study when studied seven days later (3,51).

The most reliable venographic finding indicating a DVT is an intraluminal filling defect seen on two or more views of the same area (58).

UFH is the first choice in treatment for DVT but has limitations, which include a narrow therapeutic window and variable dose-response that requires frequent monitoring.

All forms of heparin (including LMWH) should be discontinued when HIT is diagnosed and nonheparin based anticoagulation should be instituted (64).

Intermittent pneumatic leg compression has both local and systemic effects. Locally, it acts by simulating the calf muscle pump and, thus, preventing venous stasis. Systemically, it acts by inhibiting plasminogen activator inhibitor-1 and increasing the body's fibrinolytic activity.

The indications for placement of filters are the following: (i) acute VTE in a patient who has a contraindication for anticoagulation, (ii) VTE in a patient who is already anticoagulated, (iii) patients who have a compromised pulmonary vascular bed in whom a VTE would not be tolerated, (iv) patients with a high fall risk in whom anticoagulation could cause bleeding, and (v) trauma patients with a prolonged high risk for VTE due to prolonged immobility (e.g., quadriplegia) and severe traumatic brain injury (TBI) (73).

In addition to May-Thurner syndrome, endoluminal stenting and balloon angioplasty have been described in other types of iliofemoral venous occlusive disease. Although these procedures are uncommonly performed, they offer nonsurgical options for trauma and critically ill patients with VTE disease.

Although elastic compression and pneumatic compression devices restore some of the lost blood flow, mobilization and, specifically, ambulation provides complete restoration of flow and the greatest protection against VTE.

There have been several recent studies that have demonstrated that bed rest does not decrease the incidence of PE following DVT.

## Leukocytosis and Leukopenia

Theodore E. Warkentin

Departments of Pathology and Molecular Medicine, McMaster University School of Medicine,  
and the Transfusion Medicine Service, Hamilton Health Sciences,  
Hamilton, Ontario, Canada

### INTRODUCTION

☞ **Leukocytosis or leukopenia is often the first clue that a post-trauma or critically ill patient has an infection or a severe inflammatory process.** ☞ Leukocytosis is an abnormally high white blood count (WBC), whereas leukopenia denotes a reduced WBC (1–3); either laboratory finding constitutes a potentially consequential event in a critically ill patient. For example, abrupt onset of leukopenia could signify acute bacterial invasion of the blood, or perforation of a viscus; the decrease in leukocyte count reflects margination of neutrophils and their egress into tissues, a process that is sufficiently rapid so as to precede the (eventual) leukocytosis expected from increased production and release of granulocytes from the marrow storage pool. In other situations, however, abrupt and transient leukopenia is not unusual or unexpected, such as during the initial phase of cardiopulmonary bypass (CPB) (4).

The ubiquity of automated cell counters, with their computerized digital and graphical displays summarizing patient laboratory data, facilitates clinician awareness and interpretation of such important *quantitative* leukocyte changes. However, evaluation of *qualitative* leukocyte abnormalities requires nonautomated human action; indeed, the review of a peripheral blood film by an experienced “morphologist” is the single most useful laboratory evaluation performed in hematology (1). It is crucial that important information regarding leukocyte abnormalities evident within the blood film be communicated from the laboratory to the critical care practitioner.

This chapter reviews quantitative leukocyte disorders of particular relevance to the post-trauma and critically ill postsurgical patient. The reader should consult other sources for detailed information on pre-existing leukocyte disorders, particularly of neoplastic origin (leukemia, lymphoma, myeloma, etc.).

### DEFINITION OF LEUKOCYTOSIS AND LEUKOPENIA

☞ **Leukocytosis is defined as a WBC count above the upper limit of the normal laboratory range (about  $11 \times 10^9/L$ ), whereas leukopenia is defined as a WBC count below the lower limit of the normal laboratory range (about  $4.0 \times 10^9/L$ ).** ☞ Higher leukocyte counts are normal in children, especially neonates; moreover, the relative proportion of lymphocytes is greater in children (2). Proper evaluation of leukocytosis and leukopenia requires consideration of

the relative distribution of the various types of leukocytes (i.e., evaluation of the differential leukocyte count) and any abnormal morphological features.

### LEUKOCYTE CLASSIFICATION

Leukocytes are classified by their morphologic appearance into granulocytes, monocytes, and lymphocytes (Fig. 1) (1–3). Table 1 lists terms used to describe specific quantitative abnormalities of the various leukocyte types. Table 2 lists an overview of trauma-associated and other diagnostic considerations based upon the type of leukocyte involved in the quantitative abnormality.

#### Granulocytes

Granulocytes (polymorphonuclear leukocytes) consist of neutrophils, eosinophils, basophils, and their respective morphologically distinguishable precursors within the bone marrow. Mature neutrophils are about 13  $\mu\text{m}$  in diameter, and circulate in the peripheral blood in the largest relative numbers [40% to 80%; percentages relate to the fraction of the total WBC count (absolute:  $1.5\text{--}8.0 \times 10^9/L$ )]. They are also known as “polys” or “segmented” leukocytes, based upon the characteristic appearance of the nucleus, which consists of 2 to 5 lobes separated by thin chromatin strands (1,3). A somewhat earlier stage, known as band cells (or “bands”), possesses the horseshoe-shaped nucleus that precedes nuclear segmentation seen in the polys. These cells are normally absent or found in low levels (<5%) in the peripheral blood, but their increase is a characteristic early finding in infections or inflammatory states. Normal polys and bands have light pink cytoplasm and fine azurophilic granules. Progressively more immature granulocytes (metamyelocytes, myelocytes, promyelocytes, myeloblasts) are only found in the bone marrow in normal situations. The production of neutrophils involves several growth factors, primarily granulocyte colony-stimulating factor (G-CSF), and to a lesser extent, granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF).

Other granulocytes that circulate normally in the peripheral blood in small numbers are eosinophils [1% to 5% (absolute: <0.4%)], characterized by their numerous orange/red-staining granules, and basophils [<1%; (absolute: <0.2%)], which have darkly-staining purple-black granules (2,3). Eosinophils contain three different types of granules, but their characteristic appearance results from

**Figure 1** (A) Neutrophil granulocyte, (B) eosinophil granulocyte, (C) basophil granulocyte, (D) lymphocyte, (E) monocyte.

so-called “specific” (secondary) granules bearing proteins, toxic to metazoan parasites [major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil derived neurotoxin (EDN)]. Eosinophils (and their precursors) resemble morphologically their neutrophil counterparts, except for their distinct granules and bilobed nuclei. They play a major role in the pathogenesis of several allergic, parasitic, and malignant disease processes.

Previously, basophils were regarded simply as circulating tissue mast cells. However, basophils mature in the bone marrow and then circulate in the peripheral blood, whereas mast cells mature in the tissues. Like eosinophils, basophils (and mast cells) have roles in mediating certain

types of allergic and inflammatory diseases, and in defense against parasites. Basophils are the only peripheral blood mononuclear cells with the ability to release preformed IL-4 rapidly in response to appropriate stimuli, such as cell surface IgE cross-linking, which may play a role in amplifying ongoing immune response to helminth infections in the presence of antigen-specific IgE (5).

### Monocytes

Monocytes [2% to 10% (absolute:  $0.2\text{--}1.0 \times 10^9/\text{L}$ )] are of similar size as granulocytes, but have oval, lobulated nuclei with a slate-grey, convoluted cytoplasm containing a

**Table 1** Hematologic Terms Used to Describe Various Profiles of Leukocyte Increase and Decrease

Type of leukocyte	Increased number	Decreased number
Leukocyte	Leukocytosis	Leukopenia
Granulocyte <sup>a</sup>	Granulocytosis	Granulocytopenia Agranulocytosis <sup>b</sup>
Neutrophil <sup>a</sup>	Neutrophilia	Neutropenia
Eosinophil <sup>a</sup>	Eosinophilia	Eosinopenia
Basophil <sup>a</sup>	Basophilia	Basopenia
Monocyte <sup>a</sup>	Monocytosis	Monocytopenia
Lymphocyte	Lymphocytosis	Lymphocytopenia

<sup>a</sup>Myeloid cells consists of granulocytes and monocytes, as well as red cells and platelets, and their precursors, all arising from a common committed progenitor cell, the colony-forming unit, granulocyte/erythroid/monocyte/megakaryocyte (CFU-GEMM).

<sup>b</sup>Agranulocytosis indicates complete or near-complete absence of granulocytes, especially neutrophils and their immediate precursors.

few, very fine granules (1,3). Monocytes can be identified also by their staining positive for nonspecific esterase. Cytoplasmic vacuolation, which can occur *ex vivo* as monocytes, adhere to the glass slide and undergoes activation occurs normally with monocytes, whereas its presence is abnormal in granulocytes. Following their release into the circulation, some monocytes will migrate into tissues, where they attain a larger size, transforming into long-lived tissue macrophages.

**Lymphocytes**

Lymphocytes (20% to 40% [absolute: 1.5–4.0 × 10<sup>9</sup>/L]) comprise two morphologically-distinct forms (1). Most lymphocytes are small, with a diameter similar to that of red cells (about 8 μm), and with a central round nucleus surrounded by a thin light blue cytoplasmic rim. About 10% of lymphocytes are larger (diameter 8–16 μm), with the nucleus occupying only about half the cell, and usually containing 5–10 large azurophilic granules. This latter type of lymphocyte

is also called a “large granular lymphocyte” and corresponds to the “natural killer” (NK) cell.

**LEUKOCYTE PRODUCTION AND FUNCTION**

**Hematopoietic Stem Cells**

♂ All blood cells ultimately are derived from self-renewing pluripotential stem cells that are able to differentiate into lineage-committed stem cells that themselves differentiate into mature blood cells (6). ♂ Normal human marrow contains only about one million of the earliest such cells. Previously, their existence was inferred by patterns of growth of cellular “colonies,” e.g., burst-forming unit-erythroid (BFU-E), but now cell surface markers (particularly, high expression of CD34 antigen) can identify cells that are likely to represent true stem cells.

Myeloid cells (red cells, neutrophils, eosinophils, basophils, monocytes-macrophages, platelets, and their precursors) are derived from a pluripotent stem cell known as colony-forming unit, granulocyte/erythrocyte/monocyte/megakaryocyte (CFU-GEMM). The more committed stem cell, colony-forming unit, granulocyte/monocyte (CFU-GM), can give rise to either the neutrophil or monocytic pathways, depending on cytokines and growth factors.

Lymphocytes are also cells of the hematopoietic system, but the lymphoid lineage diverges at an early time point from the myeloid lineage (7). There are three classes of lymphocytes: T (thymus-derived) cells, which confer cellular immunity; B (bone marrow-derived) cells, which provide humoral immunity; and NK cells, which are able to kill cells infected by microbes that try to evade immune recognition by downregulating the cell’s major histocompatibility complex class I molecules. Historically, the “B” in B cells refers to the bursa of Fabricius in which the corresponding avian cells develop.

**Granulocyte Production and Function**

A normal bone marrow has about a 3:1 ratio of myeloid to erythroid cells. However, about 95% and 5% of peripheral blood cells are erythrocytes and platelets, respectively, and

**Table 2** Differential Diagnosis Based upon Type of Increased Leukocyte

Type of leukocyte	Clinical interpretation
Neutrophilia	Trauma-associated: bacterial infection (most common cause; viral infections generally do not cause neutrophilia); fungemia (can cause marked neutrophilia); inflammation; surgery/postoperative state; physiologic stress; postsplenectomy; corticosteroids; epinephrine; hemolysis (see Table 4 for less common causes, as well as nontrauma-associated causes)
Eosinophilia	Trauma-associated: drug-induced allergic (or hypersensitivity) reaction; corticosteroid-induced reactivation of latent parasitic infection Other: parasitic infections; atopic/allergic disorders (e.g., asthma); vasculitis; pulmonary and cutaneous eosinophilic disorders; hypereosinophilic syndrome; myeloid leukemia; lymphoma (especially Hodgkin’s disease)
Basophilia	Trauma-associated: post-splenectomy Other: myeloproliferative disorders; urticaria; hypothyroidism; ulcerative colitis; drug reactions
Monocytosis:	Trauma-associated: bacterial infection, including chronic infections (abscess); post-splenectomy Other: infection (e.g., rickettsia, brucellosis, tuberculosis, syphilis, subacute bacterial endocarditis, malaria); autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis); vasculitis; ulcerative colitis; sarcoidosis; malignancy; chronic severe neutropenia
Lymphocytosis	Trauma-associated: marker of severe trauma; transfusion-associated cytomegalovirus infection; post-splenectomy Other: viral and nonviral infections (e.g., pertussis, tuberculosis, brucellosis); allergic drug reactions; dermatitis herpetiformis; hyperthyroidism

only about 0.5% are leukocytes. The high relative numbers of mature granulocytes and their precursors within the bone marrow, and their relative paucity within the peripheral blood, attests to their short physiologic lifespan within the circulation and, consequently, very rapid cell turnover (more than 100 billion granulocytes are synthesized daily).

♣ **The brief neutrophil lifespan within the circulation (about 6–8 hours) is one major reason why granulocyte transfusions are impracticable.** ♣

Granulocytes are an important component of the innate host defense, providing a “first line of defense” against invading microbial pathogens through their primary function of phagocytosis (2,3). Unlike macrophages, which are resident phagocytic cells within certain organ and tissue sites including alveoli, liver, spleen, or bone marrow, granulocytes are circulating marauders that travel through the bloodstream, thus focusing their antimicrobial activities to sites of infection (2).

Most (75%) of the 90 billion granulocytes within an average-sized adult are mature and maturing neutrophils within the marrow storage pool, with most of the remainder (about 20%) in the myeloid precursor pool also within the marrow. About 3% comprise the marginated (endothelium-adherent) pool (3%), leaving only 2% to circulate within the blood. Awareness of this distribution helps in understanding various explanations for neutrophilia and neutropenia, such as increased demargination and mobilization of marrow storage pool neutrophils (e.g., corticosteroid therapy) or increased margination and neutrophil egress into tissue sites (e.g., burns, systemic complement activation). Increased granulocyte production (e.g., infection, inflammation, myeloproliferative disorders) or decreased granulocyte production (e.g., drug-induced agranulocytosis) are other causes of granulocytosis and granulocytopenia, respectively.

Neutrophils ultimately effect their primary role of phagocytosis through multiple complex processes (3). These include cell-cell and cell-matrix adhesion (e.g., allowing margination to endothelium and subsequent entry into tissues); chemotaxis (chemically-directed cell movement, as in migration of neutrophils toward microbes or sites of inflammation); recognition by neutrophils of immunoglobulin and/or complement-tagged (opsonized) microbes through specialized neutrophil immunoglobulin and complement surface receptors; associated triggering of complex downstream cell signaling events (e.g., immunoglobulin receptor cross-linking induced tyrosine phosphorylation); degranulation and secretion (release of storage granules into phagocytic vacuoles and into the extracellular space, respectively); and phagocytic killing.

Neutrophil mediated phagocytic killing is accomplished by (i) synthesis of highly toxic, microbicidal derivatives of molecular  $O_2$  species [superoxide anion ( $O_2^-$ ), hydrogen peroxide ( $H_2O_2$ ) and, especially, hydroxyl radical ( $OH^-$ )], through activation of the normally latent NADPH oxidase system (“the respiratory burst”), (ii) generation of highly-reactive nitric oxide (NO) through nitric oxide synthase (NOS), and (iii) the delivery of stored neutrophil microbicidal proteins (both nonenzymic, e.g., bacterial permeability-increasing protein [BPI], defensins, lactoferrin, and enzymic, e.g., proteinase 3, cathepsin, azurocidin, lysozyme, elastase) into the vacuoles containing engulfed microbes (3). Some of these mechanisms are also responsible for clearing senescent and apoptotic cells, and in mediating effects of inflammation even in the absence of infection (3).

Eosinophils are derived from myeloid precursors in response to several T-cell derived cytokines and growth factors, most notably IL-5, whereas for basophils, the major growth and differentiation factor is IL-3 (3).

### Monocyte Production and Function

Monocytes are the circulating version of the tissue macrophage; together with their bone marrow progenitors, they comprise the mononuclear phagocyte system (MPS; formerly known as the reticuloendothelial system). Monocytes and tissue monocyte-macrophages play an important role in host defense, although it is worth noting that monocytopenia does not connote the high risk of infection that neutropenia does. Production of monocytes is regulated by IL-3 and GM-CSF produced by T-lymphocytes, and M-CSF produced by endothelium and monocytes themselves. This may help explain the association of monocytes with certain chronic infections in which T-lymphocyte activity has been increased (8).

Macrophages reside predominantly within certain organ and tissue sites including alveoli, liver, spleen, or bone marrow. Exposure of macrophages to cytokines, growth factors, and environmental stimuli from microorganisms will lead to their activation, which stimulates their proliferation, phagocytic, and microbicidal activities.

### Lymphocyte Production and Function

Lymphocytes are usually long-lived cells which confer certain special properties, e.g., long-lived immunologic “memory.” They are produced mostly in lymphoid organs, such as lymph glands, splenic “white” pulp, and certain regions of the small bowel. Immune specificity is conferred through T-cell receptor and immunoglobulin gene rearrangements, which create molecules with reactivity against foreign antigens (and, sometimes, autoantigens). Volume 2, Chapter 52 provides more information regarding immune system function and dysfunction in normal states and in the critically ill trauma patient.

## LABORATORY EVALUATION

### Leukocyte Differential

♣ **The first step in evaluating any abnormal increase or decrease in WBC is to determine the leukocyte differential, and thereby classify the process as a neutrophilia, eosinophilia, monocytosis, or lymphocytosis (marked basophilia is rare) or, conversely, a neutropenia or lymphopenia (monocytopenia, eosinopenia, and basopenia are rare).** ♣ Previously, the differential was determined by a morphologist who counted 200 to 300 leukocytes, but now automated assessment is routine. However, for reliable detection of abnormal circulating cells, such as nucleated red cells (normoblasts) or leukemic cells, manual assessment of the blood film is required.

### Morphologic Abnormalities

Manual assessment of a peripheral blood film by a technologist and/or hematologist (hematopathologist) is the only way that important leukocyte morphologic abnormalities can be recognized. These features often provide important diagnostic clues regarding infection or severe inflammation in post-trauma or critically-ill patients (Table 3). ♣ **Morphologic granulocyte abnormalities, such as shift-to-the-left, toxic granulation, pale blue cytoplasmic inclusions**

**Table 3** Morphologic Features Seen in Peripheral White Blood Cells Indicating Infection or Inflammatory Processes

Morphologic feature <sup>a</sup>	Description
Shift-to-the-left	Relative increase in young polymorphonuclear leukocytes, most often band cells, occasionally also metamyelocytes and myelocytes, and in extreme situations, promyelocytes and myeloblasts
Toxic granulation	Increase in number and size of cytoplasmic granules within granulocytes
Döhle bodies	Small, pale blue 1–2 μm cytoplasmic inclusions
Vacuolation	Open spaces in cytoplasm of polymorphonuclear leukocytes
Leukemoid reaction	Leukocytosis >50 × 10 <sup>9</sup> /L
Leukoerythroblastosis	Circulating nucleated red cells (normoblasts) and granulocytic shift-to-the-left (additional presence of “tear drop” red cells suggests infiltrative marrow process)
Pelger-Huët anomaly	Benign variant of autosomal dominant inheritance and 1/6000 frequency in which the neutrophils have a “pince nez” (spectacles clipped to the bridge of the nose) appearance that can resemble bands and thus mimic a left-shift

<sup>a</sup>These features are generally seen in non-neoplastic inflammatory conditions.

**(Döhle bodies), or vacuoles can indicate serious infectious/inflammatory problems.** ⚡ The shift-to-the-left most commonly presents as an increase in bands, but can also involve the appearance of the earlier granulocytes, metamyelocytes and myelocytes, and in extreme infectious/inflammatory situations (or with certain hematologic neoplasia), promyelocytes and myeloblasts. Sometimes, these abnormal cells are seen even when the WBC is normal. The more “toxic” the overall leukocyte picture, the more likely the patient has a bacteremia/fungemia or noninfective but severe proinflammatory picture (e.g., systemic inflammatory response syndrome (SIRS).

⚡ **Severe proinflammatory states can produce a “leukemoid reaction,” defined as a leukocyte count above 50 × 10<sup>9</sup>/L.** ⚡ Leukoerythroblastosis indicates the presence of granulocytic shift-to-the-left and circulating nucleated red cells (normoblasts), and can be seen in overwhelming pathophysiologic “stress” (e.g., severe lactic acidosis or hypoxemia, severe hemolysis); the additional presence of “tear drop” red cells suggests an infiltrative marrow process (e.g., metastatic carcinoma).

A major increase in eosinophils or basophils typically indicates allergic reaction/parasitic infestation/neoplastic hypereosinophilia or myeloproliferative/systemic mast cell disorder, respectively. Abnormal monocytes can indicate certain monocytic leukemias, whereas increased numbers of normal-appearing monocytes are seen in certain infections or inflammatory disorders. In some acute viral infections, or certain autoimmune disorders, lymphocytes transform towards plasma cells (“plasmacytoid lymphocytes”), and show evidence of immunoglobulin synthesis (eccentric nucleus implying presence of Golgi apparatus; dark blue cytoplasm inferring the presence of ribosomes producing immunoglobulin).

### Ancillary Investigations

Besides WBC quantitation by automated or manual determination of the leukocyte differential, and manual assessment of leukocyte morphologic abnormalities, there are relatively few routine studies to evaluate leukocyte abnormalities. The bone marrow aspirate is often performed to diagnose drug-induced agranulocytosis (in which normal or increased marrow cellularity, with “maturation arrest” at the metamyelocyte or band stage is characteristic), or to investigate any other unexplained persistent neutropenia. Both marrow aspiration and biopsy are usually performed when hematologic neoplasm is suspected. Cell marker studies,

performed with leukocyte-containing fluid (blood, marrow, pleural, peritoneal, cerebrospinal), can detect neoplastic clones [e.g., clonally-restricted (κ or λ light chain-bearing) lymphocytes or plasma cells indicating a neoplastic lymphoproliferative disorder or plasma cell dyscrasia, respectively; absence of CD59 antigen on a clonal population of red cells and granulocytes indicates paroxysmal nocturnal hemoglobinuria (PNH)]. Measuring leukocyte alkaline phosphatase (“LAP score”) can help distinguish a neoplastic myeloproliferative disorder from a “reactive” process, with the former situation having an abnormally low score; unfortunately, a patient with an underlying myeloproliferative syndrome who is post-trauma or critically ill can develop a normal (or even elevated) LAP score, limiting its diagnostic usefulness in this setting. In unusual situations, specialized investigations may be required [detection of antineutrophil antibodies in severe neutropenia; measurement of neutrophil capacity to reduce nitroblue tetrazolium (NBT slide test), which is impaired in chronic granulomatous disease]. Although elevated serum lysozyme or lactoferrin levels corroborate increased neutrophil destruction in many acquired neutropenias, these tests are not of practical help.

### DIAGNOSTIC CONSIDERATIONS

#### Leukocytosis and Leukopenia

As highlighted earlier, the first step in evaluating any abnormal increase or decrease in WBC count is to determine the leukocyte differential. Both neutrophilia and lymphocytosis can occur abruptly in a patient with severe trauma, although the former suggests acute infection, most often with bacteria. A moderate leukopenia may be the first clue that the patient has virtually no circulating neutrophils (but normal lymphocyte numbers), thus suggesting the diagnosis of acute drug-induced agranulocytosis. ⚡ **Leukopenia must prompt evaluation of the leukocyte differential to determine the absolute neutrophil level, since acquired severe neutropenia in a hospitalized patient usually signifies drug-induced agranulocytosis, a life-threatening adverse drug reaction.** ⚡

The magnitude and rate of leukocyte increase or decrease should be considered. Sometimes, obtaining previous complete blood counts (CBCs) from hospital or family physician records reveals that an abnormal leukocyte count preceded hospitalization.

⚡ **Pre-existing causes of leukocytosis in a trauma patient could include a chronic myeloproliferative or**

**lymphoproliferative disorder; splenomegaly is often present in this situation. Pre-existing causes of leukopenia in a trauma patient can include hypersplenism (usually due to chronic liver disease), HIV-associated, Felty's syndrome (autoimmune neutropenia complicating rheumatoid arthritis), or benign chronic neutropenia (normal variant). ✎**

Evaluation for infection (fever? chills? tachycardia? hypotension? organ dysfunction? mottling? obvious source?) should be sought, and blood along with other appropriate fluids (e.g., CSF, ascites, pleural fluid, respiratory secretions, nasal sinus secretions, synovial fluid, etc.) cultured. Hematologist or pathologist review of a peripheral blood film can help in quickly pointing to whether leukocytosis is likely to be "reactive" or neoplastic. Splenomegaly and leukocytosis often indicate a neoplastic myeloproliferative or lymphoproliferative syndrome, although in a post-trauma setting various non-neoplastic explanations are plausible (e.g., hypersplenism and superimposed infection, nosocomial bacterial endocarditis). Leukopenia is a common feature of acquired immunodeficiency syndrome, and often reflects multiple causative factors (virus-induced lymphopenia, drug-induced cytopenia, antineutrophil antibodies, hypersplenism, etc.) (9,10).

### Neutrophilia

In general, the more rapid and marked the leukocyte increase, the more severe the proinflammatory stimulus. The more marked the leukocyte morphologic abnormalities (leukocyte shift-to-the-left < toxic granulation < Döhle bodies < cytoplasmic vacuolation < leukoerythroblastosis), the more severe the infectious or proinflammatory process.

Common causes of neutrophilia are listed in Table 4. Acute infection, particularly with bacteria, leads to increased production and release of the marrow storage pool of maturing granulocytes, and is a common cause of neutrophilia, especially when there is concomitant shift-to-the-left and other morphological evidence of granulocytic response. Some scenarios representative of post-trauma patients include: sinusitis complicating nasotracheal or

nasogastric tube use (11), esophageal rupture (12), intra-abdominal abscesses posthepatic trauma (13), post-traumatic acalculous cholecystitis (14), among many others. To some extent, viral and fungal infections also can produce granulocytosis.

Numerous inflammatory disorders, both acute and chronic, can result in increased numbers of neutrophils. Blunt trauma, such as might lead to rupture of an internal organ (15) or viscus, can lead to rapid changes in neutrophil count that precede establishment of infection. Chronic inflammatory processes, such as abscesses, can produce neutrophilia and/or monocytosis. Numerous acute and chronic noninfectious inflammatory disorders, ranging from acute gout (16) or acute pancreatitis to chronic non-neoplastic [e.g., giant cell arteritis (17)] to neoplastic [e.g., lung carcinoma (18)] can also produce significant neutrophilia.

"Stress" situations commonly lead to neutrophilia, at least in part as a result of neutrophil demargination, ranging from mild [e.g., exercise (19), catecholamine injection (20)] to moderate [e.g., postoperative state (21)] to marked [e.g., status epilepticus (22), heat stroke, neuroleptic malignant syndrome (23) see Volume 1, Chapter 40].

Certain drugs cause neutrophilia, most notably corticosteroids (24) (via demargination and increased mobilization of marrow storage pool neutrophils) and lithium (25). Tetracyclines have also been implicated in a drug-induced leukemoid reaction (26).

Granulocytosis is a feature of marrow stimulation, e.g., in marked hemolysis (27,28) and recovery from myelosuppression, including from antineoplastic chemotherapy or drug-induced agranulocytosis (29).

Neutrophilia and thrombocytosis are characteristically seen in a patient with hyposplenism or asplenia (because of decreased splenic pooling) (30,31). However, marked granulocytosis and left-shift could indicate the rare, but highly lethal complication of overwhelming post-splenectomy sepsis (OPSS) (32). The vaccination principles aimed at decreasing the risk of OPSS in postsplenectomy trauma patients are discussed in Volume 2, Chapter 52.

**Table 4** Causes of Neutrophilia

Category	Description and comments
Secondary (thus, more likely to occur in trauma patients)	<p>Acute or chronic infection</p> <p>Acute or chronic inflammatory disorders (including nonhematologic malignancy such as lung carcinoma)</p> <p>"Stress" (e.g., exercise, catecholamines, surgery/postoperative period, postictal state, heatstroke, neuroleptic malignant syndrome)</p> <p>Drugs (e.g., corticosteroids, lithium, tetracycline)</p> <p>Asplenia (e.g., s/p splenectomy/hyposplenism)</p> <p>Increased general marrow response (e.g., hemolysis, recovery from myelosuppression)</p>
Primary (unlikely to be present in a trauma patient)	<p>Chronic myeloproliferative disorders</p> <p>Chronic myeloid leukemia</p> <p>Polycythemia vera</p> <p>Essential thrombocythemia</p> <p>Agnogenic myeloid metaplasia</p> <p>Hereditary neutrophilia</p> <p>Congenital anomalies (with leukemoid reaction)</p> <p>Idiopathic</p> <p>Leukocyte adhesion deficiency</p> <p>Familial cold urticaria and leukocytosis</p>

**Table 5** Causes of Neutropenia in Trauma Patients

Frequency	Cause and comments
Common	Hemodilution from resuscitation or surgery Acute infection (usually transient) Acute, severe inflammatory process (e.g., perforation of a viscus, aspiration pneumonitis) Complement-mediated (e.g., acute burns, hemodialysis, membrane oxygenator, cardiopulmonary bypass, transfusion reactions)
Occasional	Drug-induced agranulocytosis Drug-induced aplastic anemia Megaloblastic anemia (e.g., folate deficiency, nitrous oxide anesthesia) Aplastic anemia (e.g., from radiation injury, or drug-induced aplastic anemia)
Pre-existing causes of neutropenia (selected list)	Common: Hypersplenism (usually secondary to cirrhosis) Myelodysplasia HIV-associated Rare: Autoimmune neutropenia (e.g., Felty's syndrome, systemic lupus erythematosus, other collagen vascular diseases), pure white cell aplasia Large granular lymphocytosis (T-lymphoproliferative syndrome; some have rheumatoid arthritis, splenomegaly) Neoplastic marrow disorders (e.g., paroxysmal nocturnal hemoglobinuria) Congenital and familial neutropenias [multiple, rare syndromes, e.g., Kostmann syndrome (congenital agranulocytosis), cyclic neutropenia]

## Neutropenia

♣ **Neutropenia is classified based on the absolute neutrophil count as mild ( $1.0\text{--}1.5 \times 10^9/\text{L}$ ), moderate ( $0.5\text{--}1.0 \times 10^9/\text{L}$ ), or severe ( $<0.5 \times 10^9/\text{L}$ ). Infection risk increases exponentially with decreasing neutrophil numbers.** ♣ However, this relationship is seen most clearly when neutropenia results from impaired marrow production, rather than immune-mediated destruction or margination (2).

A classification system for neutropenia occurring in post-trauma patients is provided in Table 5. Categories are separated according to the estimated frequency of occurrence, and whether the neutropenia predates admission to hospital. A common cause of neutropenia in a post-trauma patient is an abrupt-onset infectious or severe inflammatory process, such as acute bacteremia, aspiration pneumonitis, or rupture of a viscus. Such events lead to neutrophil margination and their rapid egress into tissues. The resulting leukopenia and neutropenia are usually mild-to-moderate and transient, with recovery usually seen within 24 to 48 hours, as increased granulocyte production and mobilization from the marrow storage pool leads to subsequent leukocytosis and neutrophilia. Hemodilution during trauma resuscitation from rapid large-volume replacement by crystalloids, colloids, and blood products also can contribute to transient neutropenia.

Complement activation with generation of C5a leads to neutrophil activation, margination, adherence, and aggregation (including within the pulmonary circulation), resulting in usually transient neutropenia (33,34). This can result from acute burns, hemodialysis, membrane oxygenators, CPB, and transfusion reactions.

An occasional cause of acquired neutropenia in a critically ill post-trauma patient includes acute folate deficiency (35). In folate deficient patients, neutropenia can potentially be exacerbated by megaloblastosis induced by prolonged exposure to nitrous oxide during anesthesia (36).

Prominent neutropenia as a component of pancytopenia is a feature of aplastic anemia from radiation injury (37),

or as a very rare adverse immune-mediated drug reaction (discussed subsequently) (38–42). One of the most common causes of neutropenia, antineoplastic chemotherapy or radiation, is an uncommon factor in the trauma or normal post surgical patient.

## Agranulocytosis

♣ **Severe neutropenia (neutrophil  $<0.5 \times 10^9/\text{L}$ ) that begins during hospitalization is a life-threatening emergency usually resulting from an immune-mediated adverse drug effect (drug-induced agranulocytosis) (38–42).** ♣ A thorough drug history, particularly focused on agents newly started in the past two weeks and known to cause agranulocytosis (Table 6) is important when reviewing a patient with leukopenia, especially if the neutropenia is severe (43,44). The most commonly implicated drugs are antithyroid agents (e.g., carbimazole, methimazole) and sulfonamides, but other reported triggers that could be used in a trauma patient include other antibiotics (e.g., penicillins, cephalosporins, chloramphenicol), antiseizure medications (e.g., carbamazepine, valproate, phenytoin) and, possibly  $\text{H}_2$  antagonists (e.g., ranitidine, cimetidine) (2,38–44). The antipsychotic, clozapine, has an exceptionally high incidence of agranulocytosis estimated at 1%, and has a genetic, rather than immune, basis (42). The mortality rate is about 10%, but is higher if the occurrence of septicemia precedes recognition and discontinuation of the causative agent. ♣ **Hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) appear to hasten recovery from agranulocytosis (45).** ♣

## Eosinophilia and Basophilia

♣ **Eosinophilia that develops in a post-trauma or critically ill patient usually signifies an allergic drug reaction.** ♣ In some instances, the eosinophilic response is sufficiently dramatic to be termed an eosinophilic leukemoid reaction, as has been reported for carbamazepine (46) and minocycline (47). Nonhematologic effects, such as exfoliative

**Table 6** Drugs Known to Cause Agranulocytosis

Drug class	Drugs
Analgesics and NSAIDs	Aminopyrine, benoxaprofen, diclofenac, diflunisal, dipyrrone, fenoprofen, indomethacin, ibuprofen, noramidopyrine, phenylbutazone, piroxicam, sulindac, tenoxicam, tolmetin
Antibiotics	Cephalosporins, chloramphenicol, ciprofloxacin, clindamycin, tetracyclines, ethambutol, gentamicin, imipenem, isoniazid, lincomycin, metronidazole, nitrofurantoin, novobiocin, penicillins, rifampicin, sulfamethoxazole, streptomycin, thiacetazone, tinidazole, vancomycin
	Chloroquine, flucytosine, dapsone, hydroxychloroquine, levamisole, mebendazole, pyrimethamine, quinine, quinacrine
	Acyclovir, zidovudine, terbinafine
Anticonvulsants	Carbamazepine, ethosuximide, phenytoins, trimethadione, valproic acid
Antihistamines	Brompheniramine, chloropheniramine, cimetidine, famotidine, methaphenilene, ranitidine, tripelenamine, thenalidine
Antipsychotics, sedatives, antidepressants	Amoxapine, chlordiazepoxide, clozapine, diazepam, haloperidol, imipramine, meprobamate, phenothiazines, risperidone, tiapridal, upstene
Antiplatelet agents	Ticlopidine, aspirin
Antithyroid drugs	Carbimazole, methimazole, potassium perchlorate, thiocyanate, thiouracils
Cardiovascular drugs	Aprindine, captopril, flubiprofen, furosemide, hydralazine, methyl dopa, nifedipine, phenindione, procainamides, propafenone, propranolol, quinidine, spironolactone, thiazide diuretics, ticlopidine, lisinopril
Heavy metals	Arsenic compounds, gold, mercurial diuretics
Others	Acetazolamide, allopurinol, aminoglutethimide, benzafibrate, colchicine, flutamide, methazolamide, levodopa, oral hypoglycemic agents, penicillamine, retinoic acid, most sulfamides, tamoxifen, deferiprone Chinese herbal medicines, DDT, dinitrophenol, hair dye, insecticides, mustard

*Abbreviations:* NSAIDs, nonsteroidal anti-inflammatory drugs; DDT, dichloro-diphenyl-trichloroethane.

*Source:* From Refs. 43 and 44.

dermatitis or hepatitis, can be present (47). Another potential explanation for eosinophilia in a patient who has resided in certain third-world environments is reactivation of a dormant parasitic infection following the administration of corticosteroids or some other immunosuppressive agents in a trauma patient. For example, disseminated strongyloidiasis can present as colonic infiltration and bleeding can present as eosinophilia or even as gram-negative meningitis due to polymicrobial colonic invasion (48).

Uncommon causes of eosinophilia in a trauma patient, but which could represent a pre-existing disorder, include various parasitic infections, allergic disorders (including atopic asthma), various pulmonary or cutaneous eosinophilic disorders, vasculitis, hypereosinophilic syndrome, myeloid leukemia, lymphoma, and so forth (3).

Basophilia is most commonly seen in patients with myeloproliferative disorders, such as chronic myeloid leukemia. Rare forms of acute leukemia have high basophil levels. Other non-neoplastic causes include ulcerative colitis and myxedema. Transient basophilia can accompany recovery from acute illness or with drug reactions (3).

### Monocytosis

Some degree of monocytosis is observed in about 30% of patients with acute bacterial infection (49). The frequency and degree of monocytosis may even be higher in certain chronic infections mediated by T-lymphocytes, such as tuberculosis and syphilis (50), as well as subacute bacterial endocarditis. ⚡ **Monocytosis that develops in a post-trauma or critically ill patient can signify the development of a “chronic” inflammatory process, such as abscess.** ⚡

Monocytosis is a feature of certain autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis), vasculitis (e.g., temporal arteritis, polyarteritis),

miscellaneous inflammatory disorders (e.g., ulcerative colitis, sarcoidosis, myositis), neoplasia (e.g., monocytic leukemia/myelodysplasia, lymphoma, histiocytosis, carcinoma), and postsplenectomy (3). Monocytosis can occur as a secondary response in a large proportion of patients with congenital or chronic autoimmune neutropenia (51). Interestingly, even though intense hematophagocytosis, as shown by bone marrow macrophages engulfing normoblasts, neutrophils, and platelets is a feature of severe infection-associated cytopenias, patients do not necessarily evince peripheral monocytosis, despite the suspected pathogenesis of infection-associated increase in M-CSF (52).

### Lymphocytosis and Lymphopenia

⚡ **Trauma can cause a rapid increase in lymphocyte number, which reflects an increase in T-lymphocytes and NK cells (53–55).** ⚡ The presence of trauma-associated lymphocytosis appears to confer an adverse prognosis (55). Acute viral infections, such as transfusion-associated cytomegalovirus infection, can produce very high lymphocyte counts in a post-trauma patient (56). Nonmalignant causes of lymphocytosis include certain nonviral infections that are rare in trauma patients (e.g., pertussis, tuberculosis, brucellosis, syphilis, cat scratch fever, toxoplasmosis), as well as allergic drug reactions, post-splenectomy, dermatitis herpetiformis, and hyperthyroidism (7).

Lymphopenia is found in many diverse clinical settings, ranging from many types of infection, nutritional deficiency, uremia, neoplasia, autoimmune disorders, myasthenia gravis, aplastic anemia, sarcoidosis, severe right heart failure, and numerous other acute and chronic illnesses (7). Lymphopenia can also occur transiently through lymphocyte redistribution as a result of corticosteroid

therapy, or chronically in various rare primary immunodeficiency disorders.

## THERAPEUTIC CONSIDERATIONS

### Leukocytosis

There are few specific therapeutic implications of leukocytosis besides the goal of treating the underlying cause, such as treatment of infection. Leukopheresis is a rarely applied therapy that may be indicated in extreme leukocytosis associated with neoplasia, and is essentially never appropriate in non-neoplastic situations. Consultation with a hematologist is indicated when the cause of leukocytosis is inapparent, or if neoplasia is suspected.

### Leukopenia

Treatment of the underlying cause of acute leukopenia is the major therapeutic intervention. Administration of folate or vitamin B<sub>12</sub> is indicated when either deficiency is suspected to be the cause of leukopenia.

In suspected drug-induced agranulocytosis, it is important to discontinue promptly all plausible causal agents. Empiric use of broad-spectrum antibiotics is indicated pending neutrophil recovery. The use of hematopoietic growth factors [e.g., G-CSF (Filgrastim)] may reduce the mortality associated with this disorder (45). G-CSF may also be helpful in selected patients with other severe neutropenic disorders (e.g., autoimmune neutropenia, HIV-associated, congenital neutropenia).

Granulocytes are very labile, difficult to separate from other blood cells, and have short circulating lifespans (57). "Buffy coats" from at least ten blood donors are required to produce a single therapeutic dose of granulocytes for an adult recipient, which will be "contaminated" by the two units of red cells and 2.5 pools of platelets. Thus, for practical reasons, granulocytes concentrates obtained from single donors using apheresis is the only satisfactory way to obtain a therapeutic dose for a neutropenic patient, and this is rarely performed. Administration of G-CSF and corticosteroids to leukocyte donors increases yield about 10-fold.

## EYE TO THE FUTURE

Relatively few developments appear imminent in relation to diagnosis or management of leukocytosis or leukopenia. Automated detection of important leukocyte morphologic abnormalities could hasten communication to the clinician that a patient has a severe developing infection or inflammatory process. Rapid nucleotide-based blood or tissue analyses may help determine whether an infection is present, and which type of microbe in particular could be responsible for neutrophilia. The "holy grail" of achieving satisfactory granulocyte transfusions on a large scale for severely-infected, neutropenic patients could represent a major therapeutic advance. Perhaps, leukocytes harvested from the peripheral blood stem cells of the patient or (related or unrelated) donors could be transfused. Newer and more effective preparations of hematopoietic growth factors could be developed.

## SUMMARY

Leukocytosis and leukopenia are common and important clues suggesting that a trauma patient may have a serious infection or inflammatory state. Evaluation of quantitative leukocyte abnormalities requires determination of the leukocyte differential, whereas examination of the blood film by an experienced physician or technician morphologist is necessary to recognize important qualitative granulocyte abnormalities such as shift-to-the-left, toxic granulation, Döhle bodies, cytoplasmic vacuolation, and leukoerythroblastosis. Neutrophilia, especially when accompanied by some of these qualitative abnormalities, most commonly indicates the presence of infection (usually bacterial) or a severe inflammatory process. Leukopenia requires determination of the leukocyte differential, as it could indicate severe neutropenia indicating the life-threatening syndrome of drug-induced agranulocytosis. Sometimes, increased number of a less common type of leukocyte has diagnostic significance, e.g., eosinophilia indicating allergic drug reaction or corticosteroid-induced reactivation of a latent parasitic infection.

## KEY POINTS

- ☞ Leukocytosis or leukopenia is often the first clue that a post-trauma or critically ill patient has infection or a severe inflammatory process.
- ☞ Leukocytosis is defined as a WBC count above the upper limit of the normal laboratory range (about  $11 \times 10^9/L$ ), whereas leukopenia is defined as a WBC count below the lower limit of the normal laboratory range (about  $4.0 \times 10^9/L$ ).
- ☞ All blood cells ultimately are derived from self-renewing pluripotential stem cells that are able to differentiate into lineage-committed stem cells that themselves differentiate into mature blood cells (6).
- ☞ The brief neutrophil lifespan within the circulation (about 6–8 hours) is one major reason why granulocyte transfusions are impracticable.
- ☞ The first step in evaluating any abnormal increase or decrease in WBC is to determine the leukocyte differential, and thereby classify the process as neutrophilia, eosinophilia, monocytosis, or lymphocytosis (marked basophilia is rare) or, conversely, neutropenia or lymphopenia (monocytopenia, eosinopenia, and basopenia are rare).
- ☞ Morphologic granulocyte abnormalities, such as shift-to-the-left, toxic granulation, pale blue cytoplasmic inclusions (Döhle bodies), or vacuoles, can indicate serious infectious/inflammatory problems.
- ☞ Severe proinflammatory states can produce a "leukemoid reaction," defined as a leukocyte count above  $50 \times 10^9/L$ .
- ☞ Leukopenia must prompt evaluation of the leukocyte differential to determine the absolute neutrophil level, since acquired severe neutropenia in a hospitalized patient usually signifies drug-induced agranulocytosis, a life-threatening adverse drug reaction.
- ☞ Pre-existing causes of leukocytosis in a trauma patient could include a chronic myeloproliferative or lymphoproliferative disorder; splenomegaly is often present in this situation. Pre-existing causes of leukopenia in a trauma patient can include hypersplenism (usually

due to chronic liver disease), Felty's syndrome (auto-immune neutropenia complicating rheumatoid arthritis), or benign chronic neutropenia (normal variant).

Neutropenia is classified based on the absolute neutrophil count as mild ( $1.0\text{--}1.5 \times 10^9/\text{L}$ ), moderate ( $0.5\text{--}1.0 \times 10^9/\text{L}$ ), or severe ( $<0.5 \times 10^9/\text{L}$ ). Infection risk increases exponentially with decreasing neutrophil numbers.

Severe neutropenia (neutrophil  $<0.5 \times 10^9/\text{L}$ ) that begins during hospitalization is a life-threatening emergency, usually resulting from an immune-mediated adverse drug effect (drug-induced agranulocytosis) (38–42).

Hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) appear to hasten recovery from agranulocytosis (45).

Eosinophilia that develops in a post-trauma or critically ill patient usually signifies an allergic drug reaction.

Monocytosis that develops in a post-trauma or critically ill patient can signify the development of a "chronic" inflammatory process, such as abscess.

Trauma can cause a rapid increase in lymphocyte number, which reflects an increase in T-lymphocytes and NK cells (53–55).

### INTRODUCTION

Disseminated intravascular coagulation (DIC) is a condition whereby the coagulation cascade is activated in an accelerated and uncontrolled manner. The resulting intravascular fibrin deposition and microvascular thrombosis leads to tissue ischemia and multiple organ dysfunction syndrome (MODS). Clot production is magnified through the generation of serine proteases whose interactions with proinflammatory mediators are a key component of the organ dysfunction seen with DIC (1).

While the precise definition of DIC varies among different investigators, with some focusing more upon the bleeding sequale, the majority have emphasized the clotting aspects of the syndrome. The Subcommittee on DIC of the International Society on Thrombosis and Hemostasis (ISTH) has suggested the following definition for DIC: "An acquired syndrome characterized by the intravascular activation of coagulation with loss of localization arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction (2)."

The loss of regulatory mechanisms that normally control coagulation further exacerbates the thrombotic process. The consumption of platelets and coagulation factors ultimately results in bleeding from multiple sites, a common clinical finding with severe DIC. However, it is the clotting of microvascular beds that underlies most of the long-term damages associated with DIC. Indeed, it is the failure to perfuse tissues of critical organ systems that leads to ischemia and ultimately to MODS.

This chapter reviews the normal physiology of hemostasis, as well as the major pathologic conditions that alter coagulation, including the common etiologies of the DIC. The clinical presentation, laboratory diagnosis, and management of DIC are surveyed. Finally, new drugs and diagnostic techniques are reviewed in the "Eye to the Future" section.

### NORMAL PHYSIOLOGY OF HEMOSTASIS

Normal coagulation can be conceptualized as occurring in overlapping phases. Vascular injury prompts platelets to become "sticky" and coalesce into a plug at the site of injury. Formation of this "platelet plug" is propagated by a series of enzyme amplifications as part of the coagulation cascade. The clot is normally prevented from occupying the entire vascular bed by antithrombotic control mechanisms, and removal of excess clot debris through fibrinolysis.

### The Coagulation System

The coagulation cascade is traditionally divided into "intrinsic" and "extrinsic" pathways (Fig. 1). This division actually reflects the laboratory measurements of the coagulation system components to a greater degree than it describes the specific physiology of clotting. The two limbs of the coagulation cascade can be activated by various triggers. The "intrinsic pathway" is activated by endothelial damage or contact with a foreign surface, as with the use of glass in the measurement of activated partial thromboplastin time (aPTT). The "extrinsic pathway" is activated by "tissue factor" exposed at the site of injury.

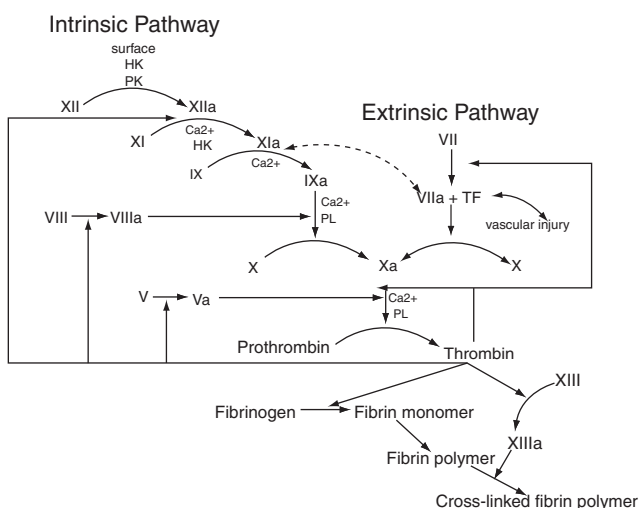

The intrinsic and extrinsic pathways join in a common activation of factor X. In Figure 1, note the multiple feedback loops that accelerate the process, amplifying the original stimulus many times over accelerating the process of hemostasis. Factor Xa binds with factor Va, calcium, and phospholipid to form a complex that converts prothrombin into thrombin. Thrombin (factor IIa) then acts to cleave fibrinogen into fibrin. In Figure 2, note the central role of thrombin in upregulating the coagulation cascade as well as activating protein C in the anticoagulation response.

### The Anticoagulation System

#### *Protein C, Protein S, Antithrombin*

The anticoagulant pathways regulate the production of thrombin. The plasma protein, antithrombin (AT; formerly antithrombin III) normally circulates as a weak inhibitor of thrombin. The reactive portion of AT is an arginine residue that is normally in a "low-activity" conformation. However, in the presence of heparin (which binds to a lysine site on AT), a conformational change occurs and AT becomes very active, with its arginine reactive center binding to the serine moiety of thrombin, inhibiting it as well as other serine proteases involved in the coagulation cascade (including IXa, Xa, XIa, XIIa, and plasmin). When AT binds to free thrombin, thrombin-AT complexes are formed, permanently disabling thrombin's proteolytic activity (3).

In addition, thrombomodulin forms a complex with thrombin, which activates protein C. When "activated protein C" (APC) is bound with its cofactor, protein S, it degrades activated factors Va and VIIIa (3). Lastly, tissue factor pathway inhibitor (TFPI), expressed on the microvascular endothelium, also plays a role in the inhibition of the coagulation pathway (4). The pathogenic pathways involved in DIC are illustrated in Figure 3, including exuberant formation of fibrin and (in some patients) inhibition of the fibrinolytic system, thereby resulting in decreased removal of fibrin.

**Figure 1** The coagulation cascade. The coagulation cascade has multiple interacting components and two major routes of activation: the intrinsic (i.e., contact activation) pathway and the extrinsic (i.e., tissue factor) pathway, both leading to fibrin formation. It was previously believed that two arms of the coagulation cascade were of equal importance. It is now recognized that the primary pathway responsible for the initiation of blood coagulation is the tissue factor (extrinsic) pathway. Note the major role played by thrombin as the enzyme responsible for converting fibrinogen to fibrin monomer, as well as its involvement at numerous other areas of factor conversion to the activated form. *Abbreviations:* HK, high molecular weight kininogen (aka HMWK); PK, prekallikrein; TF, tissue factor.

**The Fibrinolytic System and Its Inhibitors**

The fibrinolytic system normally prevents excessive clot formation, and helps eliminate old clot during tissue repair through the degradation of fibrin. Plasmin, the activated form of plasminogen, is synthesized in the liver and is the key protein in fibrinolysis. Circulating fibrin, produced in clot formation, binds plasminogen. The resulting fibrin-plasminogen complex accelerates endothelial cell release of tissue plasminogen activator (tPA), and fibrin plasminogen

tPA complexes form. Within these ternary complexes, the conversion of plasminogen to its active form, plasmin, proceeds.

In the absence of fibrin, tPA does not activate plasminogen, limiting fibrinolysis to the sites of fibrin deposition (3). Plasmin is a proteolytic enzyme that degrades fibrin into small fragments known as D-dimers (5). Plasmin also cleaves fibrinogen and other plasma proteins and clotting factors (5). In addition, fibrinolysis is triggered by the intrinsic coagulation pathway as kallikrein converts plasminogen to plasmin.

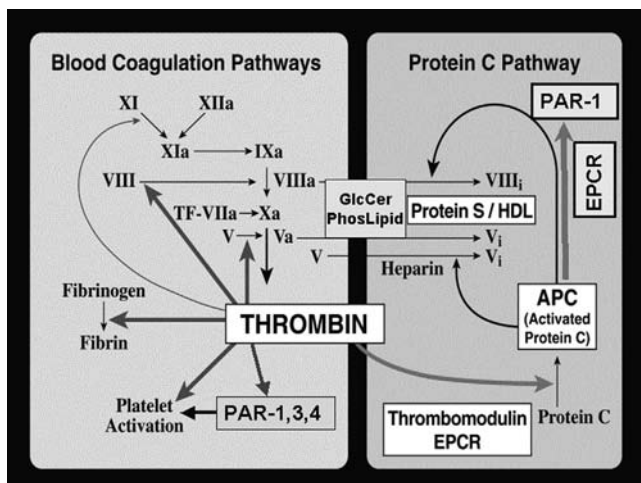

The inhibitors of the fibrinolytic pathway, which include plasminogen activator inhibitor and alpha 2-antiplasmin, serve to further regulate fibrinolysis. Plasminogen activator inhibitor, which is released from platelets and endothelium, binds to tPA, thus preventing its binding to, and activation of, plasminogen to plasmin. Alpha 2-antiplasmin binds and neutralizes plasmin (6). Exogenous agents such as streptokinase, which causes an alteration of the plasminogen active site, and urokinase, which has direct proteolytic activity on plasminogen, can also alter fibrinolysis. This complex system of amplification feedback loops and inhibition is extraordinarily stable in the healthy subject. However, in catastrophic illness or trauma the clotting system can go wildly out of control, and become very difficult to restore to order, without first resolving the primary underlying insult.

Just as inflammatory mediators can serve as triggers for DIC, it is not uncommon in coagulopathic states for inflammatory mediators to be markedly elevated, as there is extensive “cross-talk” between these two systems, as illustrated in Figure 4. Indeed, patients with severe coagulopathic states and DIC can proceed to the systemic inflammatory response syndrome (SIRS) (7). The critical initiator of inflammation-induced thrombin generation is tissue factor, and its inhibition abrogates inflammation-induced coagulation activation (7). Proinflammatory cytokines (TNF- $\alpha$ , IL-1 $\beta$ , and IL-6) increase coagulation and will be described in greater detail below (also see Volume 2, Chapters 47 and 63) (7).

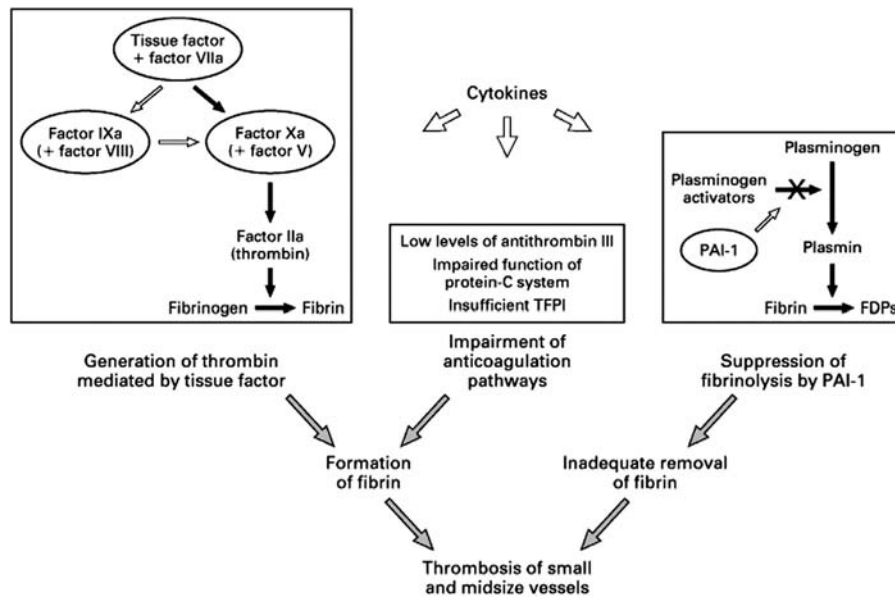

**PATHOPHYSIOLOGY OF DISSEMINATED INTRAVASCULAR COAGULATION**

**Tissue Factor**

**$\sigma^*$  Tissue factor is expressed on the surface of activated monocytes and endothelial cells activating the extrinsic pathway by complexing with factor VII. The uncontrolled release of tissue factor appears to be one of the principal initiating steps in DIC (3,4).**  $\sigma^*$  Primate studies suggest that only small amounts of tissue factor circulate in healthy animals (8). In trauma conditions, tissue factor is an important trigger, especially the release of brain tissue thromboplastin in severe traumatic brain injury (TBI) (9), or massive tissue destruction (e.g., crush injury). In patients with endotoxemia, trauma, neoplasm, and other severe disorders, this prothrombotic protein complexes with factor VII and begins the coagulation cascade. In baboons, infusion with *Escherichia coli* or endotoxin results in activation of the coagulation cascade, as indicated by elevated levels of fibrin degradation products (FDPs), protein C, and thrombin-antithrombin complexes (10). Infusion of monoclonal antibody to tissue factor inhibits the augmentation of thrombin generation (7,11–14). Many diseases associated with DIC also demonstrate increased tissue factor activity. For example, production or release of tissue factor from wounds sustained during trauma, or from leukemic cells

**Figure 2** The central role of thrombin in upregulating the coagulation cascade and protein C. *Abbreviations:* EPCR, endothelial protein C receptor; GlcCer, glucosylceramide I, inactivated; PAR, protease-activated receptor.

**Figure 3** Pathogenetic pathways involved in DIC. Tissue factor, expressed on the surface of activated mononuclear cells and endothelial cells, binds and activates factor VII. The complex of tissue factor and factor VIIa can activate factor X directly (black arrows) or indirectly (white arrows) by means of activated factor IX and factor VIII. Activated factor X, in combination with factor V, can convert prothrombin (factor II) to thrombin (factor IIa). Simultaneously, all three physiologic means of anticoagulation, antithrombin (shown as the old term antithrombin III in this figure), protein C, and TFPI are impaired. The resulting intravascular formation of fibrin is not balanced by adequate removal of fibrin because endogenous fibrinolysis is suppressed by high plasma levels of plasminogen-activator inhibitor type 1 (PAI-1). The high levels of PAI-1 inhibit plasminogen-activator activity and consequently reduce the rate of formation of plasmin. The combination of increased formation of fibrin and inadequate removal of fibrin results in disseminated intravascular thrombosis. FDPs denote fibrin-degradation products. *Source:* From Ref. 36.

in acute leukemia, is associated with an increased incidence of DIC. Other triggers include thromboplastic substances released from the dead fetus in intrauterine fetal death, and endotoxin-mediated inflammation in sepsis (15).

### Abnormalities in Coagulation Inhibitory Pathways

Abnormalities in coagulation inhibitory pathways also play a role in DIC. ⚡ **Levels of coagulation pathway inhibitors including TFPI, AT, and Protein C are all decreased in patients with DIC, hence perpetuating thrombosis.** ⚡

#### Tissue Factor Pathway Inhibitor

The primary site of TFPI elaboration is at the microvascular endothelium where it is released into the plasma and circulates in low concentrations, thereby serving to inhibit tissue factor/factor VIIa complexes at the initiation stage of the tissue factor pathway cascade (16). In patients with DIC, higher levels of TFPI are associated with a better outcome (17). It is unclear whether these observations represent a protective effect of TFPI, a different severity of disease, or different pools of circulating TFPI. Plasma levels of TFPI are an incomplete and thus inaccurate reflection of the true functional concentration. Trauma-associated coagulopathy (discussed below) is an entity with a few distinct differences from common DIC; measurement of factor VIIa levels may ultimately prove to be more predictive and useful in this condition (once they become available clinically).

#### Antithrombin

Most of the inhibitory effects of AT are exhibited during the propagation phase of coagulation, whereby it binds with

thrombin (and other activated coagulation factors, e.g., factor Xa) during its rapid phase of production (16). Patients with DIC have increased concentrations of thrombin-AT complexes (18) and lower levels of AT are associated with poorer outcomes (8,19). Accordingly, patients with congenitally low AT are at increased risk for thrombotic complications [e.g., deep venous thrombosis (DVT)], and have a worse outcome with DIC and sepsis.

#### Protein C Anticoagulant Pathway

The protein C anticoagulant pathway plays a critical role in the regulation of coagulation, fibrinolysis, and inflammatory pathways. The complex formed by thrombin and the endothelial surface cofactor, thrombomodulin, increases the rate of protein C activation more than 1000-fold, while simultaneously blocking the ability of thrombin to catalyze fibrin formation, platelet activation, and feedback activation of coagulation cofactors (20). The APC binds with cofactor protein S, and this complex then inactivates factors Va and VIIIa, thus limiting the generation of thrombin (21).

⚡ **Protein C levels are decreased in both sepsis and DIC (19,22,23). The decrease in sepsis-related mortality by using APC, as demonstrated in the PROWESS study (23), suggests the possibility of using it to treat DIC.** ⚡

#### Activated Protein C—Profibrinolytic Effect

APC also has profibrinolytic activity by neutralizing plasminogen activator inhibitor 1 (PAI-1) and by preventing the thrombin activatable fibrinolysis inhibitor. PAI-1 is responsible for neutralizing tPA and plasmin (24) and increased levels of PAI-1 decrease in fibrinolysis and the ability to clear fibrin clots from circulation (20). In a

**Figure 4** Schematic representation of activation of coagulation and inflammation. Exposure of tissue factor-bearing inflammatory cells to blood results in thrombin generation and subsequent fibrinogen to fibrin conversion. This example uses rupture of an atherosclerotic plaque, but the same mechanism would result from tissue injury. Simultaneously, activation of platelets occurs, both by thrombin and by exposure of collagen (and other subendothelial platelet-activating factors) to blood. Binding of tissue factor, thrombin, and other activated coagulation proteases to specific PARs on inflammatory cells may affect inflammation by inducing release of proinflammatory cytokines, which will subsequently further modulate coagulation and fibrinolysis. Coagulation pathways are indicated by straight arrows; inflammatory mechanisms by dashed arrows. *Source:* From Ref. 7.

chimpanzee sepsis model, PAI-1 levels remained elevated after injection of endotoxins, suppressing fibrinolytic activity (25). Elevated levels of PAI-1 have been associated with a poor prognosis in patients with DIC (8). In addition, depressed levels of plasmin–alpha 2 antiplasmin complexes, which inhibit the ability of plasmin to cleave fibrin, were found more often in DIC patients with multiple organ failure (26).

### Consumption of Coagulation Factors

As these various cascades begin accelerating out of control, the consumption of coagulation factors and platelets depletes endogenous stores exceeding the body's regenerative ability to replace them. Quantitative studies have shown accelerated turnover rates for fibrinogen, platelets and prothrombin. **Plasma levels of factor V, factor VIII, prothrombin, and fibrinogen are universally reduced in severe DIC, though fibrinogen levels can be maintained until late in the process.**

Thrombocytopenia, which can often be severe in DIC, is probably multifactorial. Platelets are consumed by the thrombotic lesions and adhere to damaged endothelial surfaces; megakaryocyte production is decreased (15). In the setting of trauma or other conditions involving hemorrhage, further platelet and coagulation factor loss occurs with shed blood. This depletion of coagulation factors and platelets magnifies the bleeding complications clinically manifested in DIC.

### Impairment of Procoagulant Clearance

The impairment of clearance mechanisms of procoagulant material may also play a role in DIC. Products of intravascular coagulation (i.e., fibrin degradation products, tissue factor, endotoxin, activated coagulation factors, etc.) are removed from the circulation by the reticuloendothelial system, particularly, the Kupffer cells of the liver and splenic macrophages. It is hypothesized that some forms of DIC may saturate the system's ability to clear these products, due to its overwhelming production (27).

### Proinflammatory Mediators and Coagulation

Our understanding of the interactions between proinflammatory mediators and coagulation is improving (13,28–30). Proinflammatory cytokines (IL-6 and IL-8) increase expression of tissue factor (28,29), and inhibit expression of thrombomodulin and endothelial cell protein C receptor; both are important regulators of the coagulation cascade (31). Elastase, released by activated neutrophils, destroys AT and C1 esterase inhibitor (32). C1 esterase inhibitor is responsible for regulation of the contact factors of the intrinsic clotting system. C-reactive protein, an acute phase reactant, promotes tissue factor expression and increases levels of  $\alpha$ -1 antitrypsin, which decreases APC levels (33,34). The acute phase complement C4b binds to, and inactivates, protein S (33,35). Release of tumor necrosis factor (TNF- $\alpha$ ) results in increased expression of PAI-1 and hence inhibition of fibrinolysis (36). All of these actions combine to form a hypercoagulable state.

**Coagulation Mediated Proinflammatory Effects**

Concurrently, coagulation can have many proinflammatory effects. The decreased levels of AT and protein C increase cytokine synthesis as well as increase neutrophil aggregation and adherence (31,37). APC inhibits both TNF- $\alpha$  and macrophage migration inhibitory factor in vitro (38). More importantly, APC has been shown to suppress nuclear factor  $\kappa$ B (NF- $\kappa$ B), which is the principal nuclear regulatory mechanism that modulates expression of proinflammatory factors (24,39). Thrombin generation promotes upregulation of P-selectin and E-selectin, which result in increased neutrophil-platelet aggregation and neutrophil-endothelial interactions (30,40). Thrombin activatable fibrinolysis inhibitor inactivates C5a (which promotes neutrophil chemotaxis) (41,42). The relationship between the two complex systems of coagulation and inflammation remains under intense investigation.

**Chronic or Compensated Disseminated Intravascular Coagulation**

Chronic or compensated DIC is similar to acute DIC, except there tends to be a weak or intermittent stimulus (15). Chronic DIC has been associated with many conditions, including intrauterine fetal death, vasculitis, large abdominal aortic aneurysms, giant hemangiomas, amyloidosis, some malignancies, and hydatidiform moles. There is a wide spectrum of clinical and laboratory findings, and a high index of suspicion is required to make the diagnosis.

**COMMON TRIGGERS OF DISSEMINATED INTRAVASCULAR COAGULATION**

DIC is associated with many conditions found in trauma and critical illness. Table 1 lists many of them and the degree of DIC they are often associated with. **The persistence of SIRS, rather than the number of SIRS criteria met, appears to be a more important prognostic factor in determining which trauma patients develop DIC, emphasizing the importance of early appropriate treatment of these patients.**

**Tissue Injury**

Major tissue injuries, such as severe head trauma (9,43–45), extensive burns, or soft tissue damage, and fat embolism from multiple fractures (46), are all associated with inflammatory activation of tissue factor and DIC. This can result from direct endothelial damage or release of fat and phospholipids from the tissue into the circulation (36). The persistence of SIRS rather than the number of SIRS criteria that are met appears to be a more important prognostic factor in determining which trauma patients develop DIC and, the development of DIC correlates well with the onset of MODS (42).

**Severe Sepsis/Systemic Inflammatory Response Syndrome**  
**DIC occurs in a variety of clinical settings associated with trauma, infection being one of the most common.**

Recently, we have developed a better understanding of the complex physiology that occurs during severe sepsis and its activation of the coagulation and inflammatory cascades (see Volume 2, Chapters 47 and 63 for further discussion in the interaction between sepsis and SIRS) (7).

**Table 1** Table of Diseases Associated with Disseminated Intravascular Coagulation

Fulminant DIC	Low-grade DIC
Burns	Cardiovascular diseases
Crush injuries and tissue necrosis	Autoimmune diseases
Trauma	Renal vascular disorders
Intravascular hemolysis	Hematologic disorders (e.g., HIT)
Hemolytic transfusion reactions	Inflammatory disorders
Major hemolysis (e.g., TTP)	
Massive transfusions	
Septicemia	
Gram-negative (endotoxin)	
Gram-positive (mucopolysaccharides)	
Acute liver disease	
Obstructive jaundice	
Acute hepatic failure	
Prosthetic devices	
Leveen or denver shunts	
Aortic balloon assist devices	
Obstetric accidents	
Amniotic fluid embolism abortion	
Retained fetus syndrome eclampsia	
Placental abruption	
Viremias	
HIV CMV hepatitis	
Varicella	
Metastatic malignancy	
Vascular disorders	

*Abbreviations:* CMV, cytomegalovirus; HIT, heparin-induced thrombocytopenia; TTP, thrombotic thrombocytopenic purpura.

*Source:* Adapted from Ref. 64a.

All microorganisms have the potential to cause DIC, however the release of endotoxin (the membrane constituent of gram-negative bacteria) is best recognized (46). Other bacterial triggers of activation are the mucopolysaccharide coats and exotoxin in gram-positive organisms (36). Viremias, including varicella, hepatitis, cytomegalovirus and HIV, have all been associated with DIC (47,48). The presence of DIC with severe sepsis confers a graver prognosis.

**Obstetrical Complications Associated with Disseminated Intravascular Coagulation**

There are numerous obstetrical complications associated with DIC. Amniotic fluid embolism (AFE) is one of the most catastrophic, accounting for 10% of maternal deaths in the United States (46). The syndrome presents an acute onset of respiratory distress and circulatory collapse. In 80% of patients, the syndrome presents during labor (49). AFE is caused by entry of amniotic fluid, (which includes tissue factor), entering the maternal circulation after rupture of the placental membranes. If meconium is present in the fluid, it can precipitate a more intense form of DIC (50). For those who survive the initial event, DIC typically follows within four hours (46). The mortality rate for

the mother ranges between 60% and 80%, and approximately 50% of the survivors develop permanent neurologic sequelae (51). Abruptio placentae may also induce DIC through a similar mechanism, releasing tissue factor into the maternal circulation. Fortunately, rapid delivery of the fetus and removal of all placental material often halts the progression of DIC in this scenario (52,53).

Pre-eclampsia, eclampsia, and the "hemolysis, elevated liver enzymes, low platelets" (HELLP) syndrome, which can be considered as a continuum of one disease process, are also associated with DIC. Pre-eclampsia is characterized by hypertension and proteinuria; in the presence of seizures, the term is eclampsia. The pathophysiology is unclear, but endothelial dysfunction, as well as neutrophil and platelet activation may play a role (2). DIC is present in 11% of patients with eclampsia and often remains low-grade; however, in 10% to 15% of women, the process becomes fulminant (54–56). In addition, placental abruption will occur in approximately 16% of women with pre-eclampsia and eclampsia, further increasing the likelihood of DIC (56). Therapy usually involves immediate delivery, removal of the placenta, and supportive care.

Retained fetus syndrome usually presents as low-grade, compensated DIC. Fetal tissue slowly leaks into the maternal circulation, causing a smoldering procoagulant state that is somewhat compensated by the fibrinolytic system (46). If a dead fetus is retained in utero for longer than 5 weeks, the incidence of DIC approaches 50% (52,53,57). Women with a septic abortion are at risk for DIC, again because of entry of products of conception into the maternal circulation, as well as associated infection.

### Malignancy

Patients with both solid tumors and hematologic malignancies have a high incidence of DIC. The type of tumor can determine the underlying pathophysiology and sometimes the clinical presentation (i.e., hemorrhage vs. thrombosis). Approximately 50% of acute leukemias will be complicated by DIC, most commonly promyelocytic leukemia. Leukemic (promyelocytes, myeloblasts) cells themselves release procoagulant material (58), contrasting with prostate cancer, which directly or indirectly stimulates the fibrinolytic system leading to a primary fibrinolytic syndrome. This explains why patients with prostate cancer and DIC present with hemorrhage instead of thrombosis (58). DIC has been described in carcinomas of the lung, breast, colon, ovary, stomach, and gallbladder, and malignant melanoma. In patients with adenocarcinoma-associated DIC complicated by thrombosis, heparin but not warfarin is often effective in managing thrombocytopenia and thrombosis. Initiation of chemotherapy is associated with acceleration of DIC, presumably related to accelerated thrombin generation from necrosis of the tumor (46).

### Chronic Liver Disease and Other Inflammatory Conditions

Bleeding complications, and a low level of chronic DIC, are common findings in patients with chronic liver disease; however, this may not be solely attributable to diminished factor production. The inability to synthesize AT and loss of activated factor clearance from the liver are likely contributors to the increased susceptibility to DIC in this population (46). Other conditions known to cause DIC include large volume transfusions of blood products (59), giant hemangiomas, and large aortic aneurysms (36).

## CLINICAL PRESENTATION

In the trauma patient, the development of DIC is multifactorial, likely resulting from a combination of direct tissue injuries and massive hemorrhage [with dilution and loss of endogenous factors, along with transfusions of exogenous clotting factors, platelets and packed red blood cells (PRBCs)]. All these factors lead to a rise in microvascular coagulation as DIC becomes established (the special case of trauma coagulopathy is further reviewed below).

Due to the multiple contributing factors, the trauma patient's course and presentation can be variable. Since acute DIC can present as bleeding or thrombosis, the key to making the diagnosis is having a high index of suspicion. Most patients with fulminant DIC will bleed from at least three unrelated sites simultaneously (58), frequently presenting with hemoptysis, hematuria, gastrointestinal bleeding, epistaxis, gingival bleeding, and/or oozing from indwelling needle or catheter sites. There may be petechiae, purpura, or generalized ecchymosis. Thrombosis often occurs in small distal vessels and can present as generalized mottling or as acral cyanosis, with discoloration of the fingers, toes, and ears (15).

End-organ damage can also be a manifestation of vessel occlusion, most commonly, renal, pulmonary, and neurologic dysfunction (58). In chronic or low-grade DIC, there is often minor bleeding from the skin or mucous membranes. Recurrent thrombophlebitis is an especially common presentation in patients with underlying adenocarcinoma (15).

## LABORATORY DIAGNOSIS

✎ The complex pathophysiology of DIC, and high prevalence of coagulopathy in trauma and critical care, makes it difficult for a single laboratory test to confirm the diagnosis. ✎ The tests commonly used to diagnose DIC are listed in Table 2 in the order of reliability. However, not all tests listed are available with the rapid turnaround required in all locations. The combination of tests, the

clinical presentation, and knowledge of the underlying disease increases the sensitivity and specificity of diagnosis. Table 3 lists the most common tests and their relative usefulness in diagnosing DIC, both individually and in combination. A proposed scoring system to integrate clinical events with laboratory findings is provided in Table 4.

**Fibrin Degradation Products**

The FDPs are elevated in virtually all patients with DIC (53,54). The FDPs represent the breakdown of fibrin(ogen) by plasmin, but are not specific for DIC as increased FDPs are also seen in DVT, pulmonary embolus, myocardial infarction, and oral contraceptive use (53,54). A somewhat

Source: From Ref. 61.

more specific test is the D-dimer assay, which measures the product of plasmin digestion of cross-linked fibrin. ⚡ **The D-dimer appears to be the most reliable of the commonly available tests for the diagnosis of DIC, and when combined with FDP has a sensitivity of 91% and specificity to 94% (60,61).** ⚡

Low fibrinogen levels are relatively specific for DIC, but because it is an acute phase reactant, plasma levels may be in a normal range despite significant ongoing DIC, making it relatively insensitive (36). The protamine plasma paracoagulation (PPP) test is rapid, inexpensive, and may be the most specific assay for DIC, as it detects fibrin monomers in plasma. However, the PPP test is not widely used due to its semi-quantitative nature and significant operator-dependence.

**Reliability of Prothrombin Time, Activated Partial Thromboplastin Time, and Thrombin Time**

The use of PT and aPTT is unreliable in the setting of DIC. The PT may be prolonged in only 50% to 75% of patients with DIC, and the aPTT is prolonged in only 50% to 60% of patients (49). These low sensitivities may be related to the presence of circulating activated clotting factors that cause the test to register as normal (53,54). Prolonged PT and aPTT are more a reflection of the late consumptive stage of coagulation factors than the activation of the procoagulant system (61). Thrombin time has similar sensitivity as PT and PTT and can be normal, especially if the fibrinogen level is not decreased.

**Thrombocytopenia, Antithrombin Assay, Schistocytes**

Thrombocytopenia is a common finding in DIC. However, a progressive drop in platelet count is sensitive, but not specific, for DIC. The decline in numbers may represent ongoing thrombin-induced activation and platelet use or a reflection of the underlying disease process, such as sepsis or malignancy (36). AT is a low-specificity test for the diagnosis of DIC because levels decline in many systemic illnesses (61). However, there is some correlation between the severity of DIC and low levels of AT, as well as increased levels of thrombin-AT complexes (18,61). Schistocytes are seen in 50% of individuals with DIC (62). Table 5 displays a summary of laboratory tests by groups.

**Molecular Markers**

The protean laboratory and clinical findings in DIC has led to increasing interest in the use of molecular markers. Prothrombin fragment 1+2 is an intermediate product of the conversion of prothrombin to thrombin, now measurable by ELISA. Fibrinogen peptide A is a proteolytic compound of fibrinogen and may be used as a reliable marker for presence of thrombin acting on fibrinogen (63,64). Decreased levels of alpha-2-antiplasmin and increased levels of plasmin-alpha-2-antiplasmin complexes provide direct evidence of both fibrinolytic activation and inhibitor consumption (49).

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis for DIC includes hemodilution, primary fibrinolysis, chronic liver disease, and microangiopathic hemolytic anemias (MHA). Most of these diseases do not present with such an abrupt onset of bleeding, or with the wide array of coagulation abnormalities. Patients with fibrinogenolysis or primary fibrinolysis, which is an acquired condition, will have abnormal PT and PTT, decreased fibrinogen, and increased FDP. However, the

<sup>a</sup>Only one abnormality each is needed in groups I, II, and III and at least two abnormalities are needed in group IV tests to satisfy criteria for a laboratory diagnosis of DIC.

<sup>b</sup>The D-dimer is reliable only for this purpose if using the correct assay and monoclonal antibody.

Source: Adapted from Ref. 64a.

platelet count and D-dimer levels are often only mildly abnormal, helping to distinguish it from DIC (15).

### Chronic Liver Disease

The laboratory findings in patients with chronic liver disease may be difficult to differentiate from DIC (36). Thrombocytopenia and coagulation abnormalities are common in this population and high levels of FDP are seen in patients with cirrhosis. However, unlike most causes of DIC, the D-dimers should be normal (or only mildly increased) in liver disease.

### Microangiopathic Hemolytic Anemias

MHA, including thrombotic thrombocytopenic thrombotic purpura (TTP) and hemolytic-uremic syndrome (HUS), may also mimic DIC. Clinically, the microthrombotic events may resemble DIC with the presence of thrombocytopenia and schistocytes. However, none of these conditions exhibits marked abnormalities in coagulation or fibrinolysis. Marked elevation in lactate dehydrogenase (LDH) indicating hemolysis is a useful differentiating laboratory parameter.

### Heparin-Induced Thrombocytopenia

☞ **Heparin-induced thrombocytopenia (HIT) can mimic the clinical appearance of DIC with thrombosis and thrombocytopenia.** ☞ In its most severe form, HIT can result in overt (decompensated) DIC, with severe thrombocytopenia, elevated PT, hypofibrinogenemia, and schistocytes (65). Tests for HIT antibodies include antiplatelet factor 4/heparin ELISA and washed platelet activation assays. HIT should be considered in any patient with falling platelet counts or thrombosis that begins 5–14 days after initiation

of heparin therapy (66). As DIC and HIT are not mutually exclusive, HIT should be considered in the appropriate clinical scenario even when DIC from another cause is a likely cause of thrombocytopenia (also see Volume 2, Chapter 55).

### Inherited Disorders of Coagulation

Inherited disorders of coagulation can cause excessive bleeding in trauma and critically ill patients. Although patients with these life-long coagulation disorders are generally capable of alerting their doctors of their condition, this is not necessarily true in the acute trauma or emergency setting. Patients who present with obtunded mental status are unable to provide a history, and important underlying diagnosis (e.g., hemophilia) may not become known to the ED physician, anesthesiologist, or trauma surgeon, unless the patient is bearing a medication alert (med-alert) bracelet or card or other information.

The common inherited disorders of coagulation are summarized in Table 6. These coagulation disorders have specific trauma and perioperative management considerations, which are beyond the scope of this chapter, and which usually require hematologist consultation. However, the presence of some of these disorders can exacerbate the severity of DIC, and therefore the most common will be briefly summarized.

The hemophilias are inherited disorders resulting from the deficiency of specific coagulation factors. Increased bleeding is experienced following trauma, during surgery, or with conditions increasing the risk of developing a bleeding condition that can mimic DIC. Hemophilia A results from factor VIII deficiency, while hemophilia B is due to reduced levels of factor IX. Hemophilia C (factor XI deficiency) is an autosomal recessive condition occurring in approximately 5% of Ashkenazi Jews, whereas both hemophilias A and B are X-linked recessive disorders, and thus affect almost exclusively males.

von Willebrand disease results from abnormal production of von Willebrand factor (vWF), a protein produced in endothelial cells (and found in  $\alpha$  granules of platelets). vWF serves as an adhesion molecule between platelets and the subendothelium, and as a carrier molecule for factor VIII.

von Willebrand disease is generally mild, and associated with bleeding only, following surgery or trauma. When severe, it can be associated with spontaneous hemarthroses and mucocutaneous bleeding. vWF is an acute phase reactant and is increased during pregnancy, thus women generally require no specific therapy for normal spontaneous vaginal delivery, or for Caesarian sections performed at term pregnancy. Additionally, desmopressin (DDAVP) 0.3  $\mu$ g/kg can be administered 60 minutes preoperatively, increasing vWF and factor VIII to near normal values, although avoidance of free water administration is important to minimize risk of desmopressin-induced hyponatremia.

### Trauma-Associated Coagulopathy vs. Disseminated Intravascular Coagulation

The development of coagulation abnormalities early after trauma is common, and is an independent predictor of mortality (67). Indeed, an initial elevated PT increases the adjusted odds of dying by 35% and an initial elevated PTT increases the adjusted odds of dying by 326% (67).

**Table 6** Inherited Disorders of Hemostasis

Disorder	Factor(s) deficient	Inheritance pattern	Incidence per: million	Treatment
Hemophilia A	Factor VIII	X-linked recessive	100	For minor surgery DDAVP 0.3 µg/kg. For major surgery factor VIII concentrate or recombinant Factor VIII
Hemophilia B (Christmas disease)	Factor IX	X-linked recessive	20	Factor IX concentrate
Hemophilia C	Factor XI	Autosomal recessive	5% Ashkenazi Jews	FFP has adequate factor XI levels alternatively, factor XI concentrate (only target 70% normal factor IX levels) <sup>a</sup>
von Willebrand disease	vWF	Autosomal recessive or dominant	>100	DDAVP 0.3 µg/kg purified vWF if severe
Afibrinogenemia	Factor I		1	Per hematologist recommendations
Dysfibrinogenemia	Factor I	Autosomal dominant	1	
Prothrombin deficiency	Factor II	Autosomal recessive	1	
Factor V deficiency	Factor V	Autosomal recessive	1	
Factor V plus VIII deficiency	Factors V and VIII		1	
Factor VII deficiency	Factor VII	Autosomal recessive	1	
Factor X deficiency	Factor X	Autosomal recessive	1	
Factor XIII deficiency	Factor XIII		1	

<sup>a</sup>>70% factor XI repletion levels can cause a hypercoagulable state in hemophilia C patients.

Abbreviations: DDAVP, des-amino, D-arginine vasopressin (synthetic vasopressin analogue); vWF, von Willebrand's factor.

Coagulation abnormalities associated with acute trauma have several injury-specific factors (not typically seen with common DIC) that uniquely contribute to the acute trauma-associated coagulopathy, including: (i) hemorrhage—resulting in loss of factors to the external environment, without necessarily having an opportunity to be consumed in clot; (ii) hemodilution—due to resuscitation with noncoagulation factor containing fluids; (iii) acidosis—from under-perfusion of tissues (including liver), and (iv) hypothermia—due to environmental exposure and the administration of nonheated fluids.

At the same time, there are conditions occurring with trauma that are common to other forms of DIC. These include consumption of clotting factors and platelets at sites of vascular injury, the release of tissue thromboplastin (containing tissue factor), and other inflammatory and/or procoagulant factors. The release of these DIC triggers is particularly prominent in those who suffer massive crush injuries, fat embolus syndrome, or TBI (68).

Patients with severe TBI are at particular risk for the development of DIC, and the incidence increases with the severity of the cerebral insult. Thrombocytopenia and coagulopathy often occur upon admission in patients with particularly severe TBI. However, DIC can emerge on subsequent laboratory examinations in a number of patients with TBI who had documented normal coagulation studies on the initial blood draw in the resuscitation bay (69).

Trauma-associated coagulopathy can be further exacerbated by resuscitation with non-coagulation containing fluids (e.g., isotonic crystalloids, colloids, red cells) that dilute the supply of clotting factors, elevate blood pressure, and reduce viscosity, washing out previously formed clots and exacerbating hemorrhage. Some of these solutions (e.g., hetastarch) can directly impair coagulation (see Volume 1, Chapter 11) (69).

That a DIC state can occur in trauma patients prior to resuscitation with fluids was demonstrated in a recent retrospective evaluation of trauma patients admitted on a helicopter service. This study design incorporated appropriate physician review during the pre-hospital period, and demonstrated that acute traumatic coagulopathy [PT >18 seconds, APTT >60 seconds, or TT >15 seconds (1.5 times normal)] not related to fluid administration did occur early following severe trauma. Furthermore, coagulopathy was shown to be a marker of injury severity and mortality (70).

In an effort to determine the relative contributions of acidosis and hypothermia to coagulopathy, Martini et al. recently demonstrated that acidosis, hypothermia, or both caused the development of coagulopathy in pigs, as indicated by 47%, 57%, and 72% increases in splenic bleeding time ( $P < 0.05$ , pre vs. post). Plasma fibrinogen concentration was decreased by 18% and 17% in the acidotic and combined groups, respectively, but not in the hypothermic pigs. Hypothermia caused a delay in the onset of thrombin generation, whereas acidosis primarily caused a decrease in thrombin generation rates (71). Additional research is required to further delineate the relative contributions of each of these many insults on trauma-associated coagulopathy.

## MANAGEMENT

☞ The cornerstone of treatment for DIC is an aggressive attempt to remove the underlying disorder or precipitating factor. ☞

### Removal of Underlying Disorder

Therapy for DIC begins with identification of the triggering etiology and treating or eliminating it. Common examples

include debridement of necrotic and or infected tissues (e.g., abscess, necrotizing fasciitis, infected hematoma). Additional categories of DIC that can resolve within a few hours of removing the trigger factor include severe TBI and several obstetric causes (e.g., placental abruption). For many other conditions, such as sepsis, DIC can take days to fully resolve despite appropriate treatment of the underlying infection (72). Specific therapy varies based upon the severity and location of the primary process (TBI vs. pancreatitis vs. ischemic extremity with necrotic and infected tissues), as well as the general health of the patient.

A more complete understanding of the pathophysiology of DIC is beginning to emerge. In knowing that the key event in DIC is dysregulated thrombin production, with resulting microvascular thrombosis, rational approaches at interrupting the intravascular clotting process have emerged. Pharmacologic treatment options for acute DIC are mostly supplementary to treatment of the primary disorder and include: (i) administering anticoagulants, (ii) supplementing missing inhibitors of coagulation (e.g., AT, APC), (iii) administering general inhibitors of coagulation (e.g., heparin), (iv) administering consumed blood components (e.g., fibrinogen, etc.), and (v) administering antifibrinolytics (which should be used rarely and with extreme caution, as discussed below).

☞ **Currently, heparin is the most common agent directed at DIC, typically administered as a low dose infusion with no loading dose.** ☞

### Heparin

Heparin in its various forms has been the agent most commonly utilized, though seldom in controlled clinical trials. By binding to AT, heparin inhibits thrombin and its production. The use of low dose subcutaneous heparin has been effective in DIC, and is the first line agent for some because of the minimal chance of hemorrhage when administered in this fashion (49,54,73). Some clinicians advocate low molecular weight heparin (LMWH), with its lower risk of HIT, as it has been found to be efficacious in limited studies (52–54). The use of moderate dose heparin infusions have been successful in chronic DIC and in some animal studies (74), but results in acute DIC have been less conclusive (15,75). Although the theoretical risk of administering an anticoagulant to a bleeding patient in DIC exists, clinical studies have not shown an increased incidence of bleeding complications (15,36).

### Activated Protein C

The role of APC and the possible benefits of supplementation in patients with DIC are currently being evaluated. APC has had some initial success in the treatment of sepsis through control of microvascular thrombosis and inflammation, and may hold promise for patients with DIC from other causes (20,24). The use of recombinant TFPI (rTFPI) to control coagulation associated with severe sepsis and subsequent DIC has been studied extensively (4,76–79). A recently completed phase II study showed a relative reduction in day 28 all-cause mortality in rTFPI treated patients when compared with placebo (80). Further studies are currently underway.

### Thrombin Inhibitors (Antithrombin, Hirudin)

The use of AT concentrates in patients with DIC and sepsis has shown overall improvement in the DIC and organ dysfunction, with a modest reduction in mortality, often not

**Table 7** Properties of Heparins and Hirudins

Property	Heparins	Hirudins
Thrombin inhibition	Indirect (requires AT)	Direct
Clot-bound thrombin	Not inhibited	Inhibited
Immune thrombocytopenia	Associated	Not associated
Effect on PT	Weak	Moderate
Effect on aPTT	Yes (weak with LMWH)	Yes
Metabolism and/or excretion	Liver, kidney	Kidney
Antidote	Protamine (60% reversal of LMWH)	None

Abbreviations: AT, antithrombin; LMWH, low molecular weight heparin; PT, prothrombin time; aPTT, activated partial thromboplastin time.

reaching statistical significance (72,81–84). More recent trials have used supernormal levels of AT (36). Larger randomized control trials are necessary before this can be advocated as a standard therapy.

Hirudin, a thrombin inhibitor extracted from the salivary glands of the medicinal leech, *Hirudo medicinalis*, is currently under investigation as an AT agent to be used in the treatment of DIC (85–87). Hirudin is currently available in three different recombinant DNA forms: (i) recombinant hirudin (lepirudin, desirudin); (ii) hirugen; and (iii) bivalirudin.

Natural and recombinant hirudin binds to both the catalytic site and the fibrinogen binding exosite of thrombin, as is true for bivalirudin, whereas hirugen binds to only the exosite. These molecules inhibit thrombin conversion of fibrinogen to fibrin as well as thrombin-induced platelet aggregation (the advantages and disadvantages of various hirudins compared to heparin are shown in Table 7).

### Replacement of Missing and Consumed Components

☞ **Repletion of coagulation factors should be limited to the treatment of clinically significant bleeding in conjunction with laboratory abnormalities. However, abnormal lab values alone should rarely be treated.** ☞

The replacement of missing and consumed components is controversial. The common belief that the infusion of products may actually exacerbate DIC has never been proven in clinical studies. While it is recognized that low levels of platelets and coagulation factors can contribute to bleeding in DIC, early or overzealous factor replacement can itself produce complications.

It is only when active bleeding is present, and not solely laboratory abnormalities, that platelets and fresh frozen plasma should be administered (72). Patients with DIC may have an acquired storage pool defect of platelets, as well as FDP inhibition of platelets, and may require a higher platelet count for adequate hemostasis (15). Repletion of fibrinogen with cryoprecipitate again should be reserved for patients with hypofibrinogenemia and significant bleeding. Transfusion of PRBC should, as always, be based on the severity of hemorrhage; target hematocrits should be dictated by symptoms and co-existing disease.

**Antifibrinolytics—for Selected Cases Only**

☞ Only in rare circumstances should inhibition of the fibrinolytic system with antifibrinolytic agents be considered for the treatment of DIC. ☞

In approximately 3% of patients with DIC, there is resolution of the intravascular coagulation and fibrin deposition but the patient continues to bleed due to secondary fibrinolysis (49). The agents currently available to inhibit inappropriate fibrinolysis include ε-aminocaproic acid (EACA) (49), tranexamic acid, and the protease inhibitor aprotinin (46). The therapeutic effects of these agents must clearly outweigh the risk of thromboembolic effects, prior to initiating therapy.

Aprotinin inhibits fibrinolysis by directly binding to plasmin, and also by inhibiting a series of other serine proteases, including kallikrein (88). Aprotinin is thought to reduce bleeding through inhibiting the contact phase activation of hemostasis, preventing fibrinolysis (89), and reducing thrombin generation (90). Aprotinin has been shown to decrease blood loss following cardiac surgery, including those at highest risk (re-do open heart surgeries) (91), and those on aspirin and with renal failure (92). EACA is a lysine analog that inhibits plasmin activity by preventing plasminogen from binding to fibrin, thereby suppressing fibrinolysis (93).

Tranexamic acid, or 4-(aminomethyl) cyclohexane carboxylic acid (AMCA), is another lysine analog with a similar mechanism of action, except AMCA has a seven-fold to 10-fold greater potency than EACA (94). These agents reduce blood loss in cardiothoracic surgery (95,96), following liver transplantation (97), and following orthopedic surgery.

In addition, recent attention has focused on its potential anti-inflammatory properties of the antifibrinolytic drugs in patients undergoing CPB because both plasmin and kallikrein amplify the inflammatory response by activating key components of the complement cascade (98–100). However, minimal work has been done to establish the safety and efficacy of any of these antifibrinolytic agents in the trauma setting (101).

The use of antifibrinolytic agents should be used with extreme caution, as they may lead to fatal disseminated thrombosis. This select trauma patient population should have been previously treated with heparin and have clear documentation that ongoing inappropriate fibrinolysis has continued (15).

**Recombinant Activated Factor VII for Treatment of Trauma-Associated Coagulopathy**

Recombinant activated factor VII (rFVIIa) is approved for the use in hemophilia (with inhibitors) in North America, and in Europe a few additional medical indications are also approved (102). The initial results of rFVIIa use in trauma have been very promising, although most studies have been limited to case series and anecdotal reports (102). Consequently, as of this printing, the use of rFVIIa for trauma patients remains investigational, or “off-label.”

Recently, Dutton et al. showed that rFVIIa therapy lead to an immediate clinical reduction of coagulopathic hemorrhages in a retrospectively reviewed series of trauma cases conducted at the Maryland Shock-Trauma Center (103). Friederich et al. reported their successful experience in the first prospective double blinded, randomized controlled trial (RCT), describing use of rFVIIa in radical prostate surgery documenting reduced blood loss and decreased transfusion after a single preoperative dose (104).

**Table 8** Causes of Disseminated Intravascular Coagulation

Category	Example
Trauma	Brain tissue destruction Extensive crush injury Severe burns
Infections	Meningococemia Other gram negative or gram positive bacteria Rocky mountain spotted fever Viral
Environmental causes	Heat stroke Snake bites
Hemolytic transfusion reactions	ABO blood group incompatibility
Liver disease	Cirrhosis, acute hepatic necrosis
Obstetric complications	Amniotic fluid embolus Placental abruption Uterine rupture (Possibly 2° trauma) Retained dead fetus or septic abortion
Malignancy	Metastatic carcinoma (esp. adenocarcinoma) Hematological (especially PML)
Activation	Mechanical heart valves
Mechanical destruction	Aortic aneurysms CPB
Platelet activation disorders	Heparin-induced thrombocytopenia <sup>a</sup> Thrombotic thrombocytopenic purpura <sup>a</sup>

<sup>a</sup> Overt (decompensated) DIC is seen only in a minority of severely-affected patients.

Abbreviations: CPB, cardiopulmonary bypass; PML, promyelocytic leukemia.

Source: Adapted from Ref. 64a.

More recently, two prospective placebo-controlled, double-blind RCTs, one in blunt trauma (*n* = 143) and the other in penetrating trauma (*n* = 134) were completed by Boffard et al. in South Africa (105). In blunt trauma, PRBC transfusion was significantly reduced with rFVIIa relative to placebo (estimated reduction of 2.6 PRBC units, *P* = 0.02), and the need for massive transfusion (>20 units of PRBCs) was reduced (14% vs. 33% of patients; *P* = 0.03). In penetrating trauma, rFVIIa use resulted in similar trends toward reducing PRBC transfusion (estimated reduction of 1.0 PRBC units, *P* = 0.10) and massive transfusion (7% vs. 19%; *P* = 0.08). Trends toward a reduction in mortality and critical complications were observed. Adverse events including thromboembolic complications were evenly distributed between treatment groups (105). Additional studies are required to further clarify the dose, duration, and specific patient populations that will benefit the most from rFVIIa.

☞ While not recommended for all causes of DIC, rFVIIa appears to be useful in severe trauma-associated coagulopathy and diffuse hemorrhage. ☞

**Treatment of Chronic Disseminated Intravascular Coagulation**

As with acute DIC, first-line management of chronic DIC is to treat the underlying disorder. Processes such as aortic

aneurysms may require operative management to cure. Malignancy and other chronic disorders may require ongoing therapy. Both unfractionated and LMWH have been used successfully in patient groups requiring long-term anticoagulation therapy. In circumstances where heparin or warfarin are contraindicated (e.g., brain metastases), antiplatelet agents such as clopidogrel and acetylsalicylic acid have also been used (49).

## EYE TO THE FUTURE

Through better understanding of the pathophysiology of DIC, advances continue to be made to identify this syndrome at its early stages via more sensitive laboratory tests and molecular markers. This may allow intervention before the procoagulant and inflammatory cascades advance beyond therapeutic benefit.

New assays are currently under investigation, including the thrombin precursor protein, performed by ELISA, which detects circulating soluble fibrin polymer, and a new radioimmunoassay of B-beta 15–42, which is a cleavage product of fibrinogen in the presence of plasmin. These tests, in addition to prothrombin fragment 1+2 and fibrinogen peptide A (previously mentioned) may become part of the standard work-up for DIC in the near future.

Hirudin and argatroban, direct thrombin inhibitors used in treatment of HIT, have shown promise in early studies of use in DIC (106,107). Defibrotide, a polydeoxyribonucleotide is an adenosine receptor agonist that increases endogenous prostaglandins (PGI<sub>2</sub> and E<sub>2</sub>), stimulates expression of thrombomodulin in endothelial cells, modulates platelet activity, and increases the function of endogenous tPA while diminishing the activity of PAI-1. This compound has a relatively low risk of bleeding as a side effect of the drug and is in early studies for efficacy in DIC.

Finally, simplification of the scoring systems for DIC has been evolving over the last decade with the ISTH endorsing simpler systems, with the most recent iteration utilizing just platelet count and PT. While this system may work for most medical causes of DIC, it is not necessarily reliable in the trauma setting. Additional studies are underway.

## SUMMARY

DIC is a complex syndrome, and only recently has a greater understanding of its pathophysiology emerged. Tissue factor, which is expressed on the surface of activated monocytes and endothelial cells, activates the extrinsic pathway, and its uncontrolled release appears to be one of the principal initiating steps in DIC. Inhibitors of the coagulation pathways, including TFPI, AT, and APC are present in lower levels in patients with DIC, hence perpetuating thrombosis. As protein C levels are decreased in both DIC and sepsis, and given the recent successful PROWESS trial of APC in severe sepsis (23), there is the potential for a similar benefit with APC for treating DIC of other causes. The persistence of SIRS, rather than the number of SIRS criteria met, appears to be a more important prognostic factor in determining which trauma patients develop DIC (emphasizing the importance of success in early treatment of these patients).

The complex pathophysiology of DIC and the high prevalence of coagulopathy in the ICU population make it difficult to rely on any single laboratory test to make the diagnosis of DIC. The D-dimer levels appear to be the most reliable of the commonly available tests for DIC, and the combination with FDP has a sensitivity of 91% and specificity to 94%. HIT can mimic DIC and should be considered in the setting of thrombosis and thrombocytopenia that bears a temporal relationship beginning 5 to 14 days after starting heparin.

The cornerstone of treatment for DIC is aggressive treatment of the underlying disorder. For some disorders, removing the precipitating factor can have dramatic effects. AT, APC, and other agents are being studied for use in DIC. Currently, heparin is the most common agent directed at DIC, most commonly as a low dose infusion with no loading dose. Some clinicians advocate LMWH, with its lower risk of HIT, for anticoagulation in DIC. Anti-fibrinolytic agents should be used rarely and with extreme caution. Replacement of coagulation factors should be limited to the treatment of clinically significant bleeding, not to correct laboratory abnormalities.

Despite improvements in understanding DIC and pharmacological developments in manipulating the coagulation and fibrinolytic systems, the mortality associated with this process has not changed substantially in the last decade. However, with new treatment modalities on the horizon, improved patient outcomes may also occur in the near future. Until more effective specific therapy becomes available, aggressive treatment of the underlying disease and early recognition of DIC remain the mainstay of therapy.

## KEY POINTS

- ☞ Tissue factor is expressed on the surface of activated monocytes and endothelial cells activating the extrinsic pathway by complexing with factor VII. The uncontrolled release of tissue factor appears to be one of the principal initiating steps in DIC (7).
- ☞ Levels of coagulation pathway inhibitors including TFPI, AT, and protein C are all decreased in patients with DIC, hence perpetuating thrombosis.
- ☞ Protein C levels are decreased in both sepsis and DIC (19,22,23). The decrease in sepsis-related mortality by using APC, as demonstrated in the PROWESS study (23), suggests the possibility of using it to treat DIC.
- ☞ Plasma levels of factor V, factor VIII, prothrombin, and fibrinogen are universally reduced in severe DIC, though fibrinogen levels can be maintained until late in the process.
- ☞ The persistence of SIRS, rather than the number of SIRS criteria met, appears to be a more important prognostic factor in determining which trauma patients develop DIC, emphasizing the importance of early appropriate treatment of these patients.
- ☞ DIC occurs in a variety of clinical settings associated with trauma, infection being one of the most common.
- ☞ The complex pathophysiology of DIC, and high prevalence of coagulopathy in trauma and critical care, makes it difficult for a single laboratory test to confirm the diagnosis.
- ☞ The D-dimer appears to be the most reliable of the commonly available tests for the diagnosis of DIC, and

when combined with FDP has a sensitivity of 91% and specificity to 94% (60,61).

- ✎ Heparin induced thrombocytopenia (HIT) can mimic the clinical appearance of DIC with thrombosis and thrombocytopenia.
- ✎ The cornerstone of treatment for DIC is an aggressive attempt to remove the underlying disorder or precipitating factor.
- ✎ Currently, heparin is the most common agent directed at DIC, typically administered as a low dose infusion with no loading dose.
- ✎ Repletion of coagulation factors should be limited to the treatment of clinically significant bleeding in conjunction with laboratory abnormalities. However, abnormal lab values alone should rarely be treated.
- ✎ Only in rare circumstances should inhibition of the fibrinolytic system with antifibrinolytic agents be considered for the treatment of DIC.
- ✎ While not recommended for all causes of DIC, rFVIIa appears to be useful in severe trauma-associated coagulopathy and diffuse hemorrhage.

Daniel Scheidegger

Department of Anesthesiology, University of Basel School of Medicine, Basel, Switzerland

### INTRODUCTION

Blood transfusion is the most important medical advance of World War I (1). The quantity of blood shipped (2000 units a day) to U.S. troops during World War II in March 1945 is the highest rate of blood transported in U.S. military history, and was required to support the 12 million military personnel who sustained 30,000 casualties in that month alone (2,3). The benefits of blood in saving lives of those injured were fully recognized by British and American medical units, yet the United States entered the Korean War without a formal military blood program. In Vietnam, the most frequent mode of transfusion was two to five units of red blood cells (RBCs), usually given as packed RBCs (PRBCs), but small amounts of fresh whole blood were drawn on site for production of platelets or direct administration to coagulopathic casualties. More than 100,000 universal donor group O uncross-matched RBCs were transfused in Vietnam without a single fatal hemolytic transfusion reaction. The nine reported fatal transfusion reactions all followed misidentified cross-matched blood (4). Although small stores of PRBCs are available, large quantities of blood are also collected and administered as whole blood to military trauma victims.

**✦ The requirement for blood in military and disaster situations is largely determined by the number of injured that survive long enough to present for care. ✦**

In Vietnam, only 16% of casualties required transfusion. In Iraq and Afghanistan, the transfusion rates are likely to be in a similar range, though current numbers are not available. In modern civilian trauma centers the transfusion rates are lower. Only 9% of trauma patients admitted to the University of Maryland Shock Trauma Center in 2000 required transfusion. One to two units of blood transfusions are the most frequent mode of military and civilian trauma center blood transfusions (2).

This chapter reviews the current transfusion triggers for blood transfusion in trauma and critical care, as well as the monitoring considerations for tissue oxygenation and perfusion. The various blood components that are available for transfusion are surveyed, and distinctions are made regarding the special situations of emergency and massive transfusion conditions. The complications of blood transfusion, along with newer data on the tolerance for acute anemia, are also included. The "Eye to the Future" section previews newer artificial blood now under development.

### TRANSFUSION TRIGGERS

The traditional indication for administration of blood to trauma patients occurs when hemoglobin (Hb) values fall below 10 g/dL (5). This became known as the *transfusion trigger* and was used by clinicians to guide their decision about whether or not to administer blood. More recently, the benefits of blood transfusion have been questioned. The concept of a single laboratory value as a rigid transfusion guide has been reassessed due to the belief that the decision to transfuse is influenced by many factors including co-morbidities (especially cardiac and diabetes), age, the acuteness of blood loss, expectations for continued future blood loss, and the physiological changes that the current amount of blood loss has produced (6).

Recent transfusion practices among U.S. anesthesiologists indicate that more than half of them measure Hb or hematocrit (Hct) values before red cell transfusion (7): Among the 862 survey respondents, 6% indicated that they transfuse when Hb falls below 10 g/dL (or Hct <30%), 39% indicated they would transfuse when Hb <8 g/dL (or Hct <24%), and 6% indicated that they would transfuse when Hb <6 g/dL (or Hct <18%). The remaining 46% indicated "other" with conditional responses due to the factors identified above as influencing their transfusion decision (7).

### Liberal vs. Restrictive Transfusion Practices in Critical Care

The Canadian Critical Care Trials group compared the outcome of a liberal strategy to a restrictive strategy of blood transfusion (8,9). In the first study of euvoletic critically ill patients, they compared mortality in just over 400 patients randomized to each of two groups, one to be transfused if Hb was less than 7 g/dL within 72 hours after their admission, the other if their Hb fell below 10 g/dL. They found that overall 30-day mortality was similar (18.7% vs. 23.3%) (8). However, mortality rates were significantly lower with the restrictive transfusion strategy among patients who were less acutely ill [with Acute Physiology and Chronic Health Evaluation (APACHE) score  $\leq 20$ ] and among patients less than 55 years of age. The in-hospital mortality rate during hospitalization was also significantly lower in those randomized to the restrictive strategy. Although the restrictive strategy appears superior to the

liberal transfusion protocol, patients with acute myocardial infarction and unstable angina can be exceptions to this rule.

In their follow-up study of critically ill patients with cardiovascular disease, they again compared restrictive and liberal transfusion strategies (9). Mortality rates were similar in the two groups. However, changes from baseline in the multiple organ dysfunction scores were significantly less in the restrictive group (transfusion trigger of 7 g/dL). In 257 patients with severe ischemic heart disease, the restrictive group had a lower but nonsignificant absolute survival rate compared to patients in the liberal group. Further, the restrictive policy in these patients significantly reduced the average number of red cells transfused from  $5.2 \pm 5.0$  units to  $2.4 \pm 4.1$ —a 53% reduction.

### General Transfusion Guidelines

The transfusion guideline produced by the National Institutes of Health (NIH) Consensus Panel, published in 1988, was that red cell transfusion should occur at a Hb value of 7 g/dL in patients free of cardiac and cerebral disease (10). The American College of Physicians, with many of the same participants, also identified 7 g/dL, as an appropriate level for red cell transfusion (11). The American Society of Anesthesiology (ASA) proposed a range of 6 g/dL, when blood must be transfused, to 10 g/dL, when it should not be transfused (12). The recently published survey of U.S. Anesthesiologists suggests that current transfusion practices are, in general, consistent with ASA guidelines (7). The Canadian Medical Association identified 8 g/dL as the guideline for transfusion (13). Thus, the consensus panels are inconsistent, further discrediting the concept of a single laboratory value to guide the need for transfusion. The College of American Pathologists Practice Guidelines recommends that in acute anemia, a fall in Hb below 6 g/dL or a rapid blood volume loss of more than 30% to 40% requires RBC transfusion in most patients (14).

### Transfusion Trends in Trauma Patients

Another way to examine guidelines for transfusion in trauma patients is to review actual clinical practice. Compared to other populations, trauma patients are more likely to be transfused (15). In an article from the Trauma Program at the University of Toronto, Farion et al. (16) described trends in the use of blood among adults admitted during 1991, 1993, and 1995 (Fig. 1). On admission in each year, there were between 500 and 560 patients with similar Hb levels and injury severity scores. A significant reduction was found in the average 24-hour Hb levels, the lowest Hb levels, and the discharge Hb concentrations during the years 1993–1995. Discharge Hb levels fell significantly from 11.5 to 11.0 g/dL, lowest Hb levels from 9.6 to 9.2 g/dL (Fig. 2) (16). These trends indicated significant reductions in both the number of trauma patients receiving blood products and the total number of units transfused. More than 300 fewer blood units were transfused when 60 more patients were treated in 1995 with similar injury severity scores compared to 1991 (Fig. 1). There was also more cross-matched blood and less type-specific and uncross-matched blood used in 1995, indicating that clinicians had become more tolerant of acute anemia.

Recent studies continue to indicate that blood transfusion is a confirmed independent predictor of mortality in trauma patients (17). Indeed, a recent retrospective evaluation of 316 patients with blunt hepatic and/or splenic injuries, after being controlled for shock and injury severity, found both mortality and hospital length of stay to be significantly increased with each unit of blood transfused

**Figure 1** Trends in the type of blood transfused at the University of Toronto Trauma Program in 1991–1995 as a proportion of total blood. A reduction is seen in the use of type-specific and type O blood as well as a reduction in overall cross-matched blood administration between the three years. Source: From Ref. 16.

( $p < 0.001$  and  $p = 0.005$ , respectively) (18). Yet, once the threshold of massive transfusion was reached (discussed below) other factors such as base deficit became stronger predictors of mortality (19). Indeed, Vaslef et al. (19) found that among trauma patients who had received >50 units of blood products, mortality rates were not different between those who received 51 to 75 units and those who received >75 units on the first day of admission.

**The concept of a single transfusion trigger is flawed. Comorbidities, especially cardiac, age, injury severity, and magnitude of hemorrhage should all be considered.**

### Strategy for the Bleeding Trauma Patient

The low limits of Hb used in restrictive transfusion strategies, whereas generally being acceptable in elective surgical

**Figure 2** The mean hemoglobin concentration of trauma patients on admission, after 24 hours, on hospital discharge as well as their hemoglobin nadirs among the University of Toronto Trauma Program 1991–1995. Patient discharge hemoglobin levels fell significantly over these years. Source: From Ref. 16.

cases or in a nonischemic critical care patient, may not be appropriate in the management of a bleeding trauma patient for the following reasons. First, cardiac output may be inadequate in the bleeding trauma patient because of a low circulating blood volume as occurs with hemorrhagic shock. Second, in low cardiac output states with low circulating blood volume, the maldistribution of blood flow potentially places vital organs at risk for ischemia (20). Third, ongoing blood loss will continue to stress the patient. Some of this blood loss may be hidden when in association with fracture sites or may result from coagulopathies—especially likely when associated with hypothermia and/or prolonged high blood loss surgery. Fourth, multiple trauma patients exhibit inadequate erythropoiesis in response to low hemoglobin, and have a hypoferric state secondary to a complex network of bleeding and inflammatory mediators appearing within 12 hours of injury and lasting for more than nine days (Fig. 3) (21). Finally, there is always an element of uncertainty in estimating future blood loss.

## MONITORING OXYGENATION AND PERFUSION

### Organ-Specific Monitors of Oxygenation and Perfusion Are Lacking

The two major organs at risk for impaired oxygenation are the brain and the heart. The brain is not usually monitored in any quantitative way during anesthesia; although transcranial cerebral oximetry and jugular venous oximetry may have some merit, these are not often monitored in the acute setting (22). And although cardiac ischemia can be followed by ST segment analysis transesophageal echocardiography and troponin measurements, very few clinicians actually do this in the midst of a busy resuscitation or anesthetic for a patient with significant bleeding.

Monitoring of urine output is an imprecise indicator of renal resuscitation. Indeed urine production can be high despite intravascular depletion in the setting of hyperglycemia, alcohol intoxication, and mannitol or other diuretic usage. Further, in more chronic settings, high output renal failure (the frequent precursor to oliguric renal failure) is accompanied by increased urine flow in combination with decreased creatinine clearance (23).

The gut has less autoregulation capability than other organs. Accordingly, when blood pressure falls in a bleeding trauma patient, the bowel becomes ischemic with the resulting changes likely to contribute to multi-organ dysfunction syndrome and peritonitis. The gut can be monitored by tonometers, but these require initial and sometimes repeated calibration, and more stable conditions than are usually present during trauma resuscitation. Thus, clinicians tend to err on the cautious side of 8 to 10 g/dL Hb levels during management of the acutely bleeding trauma patient.

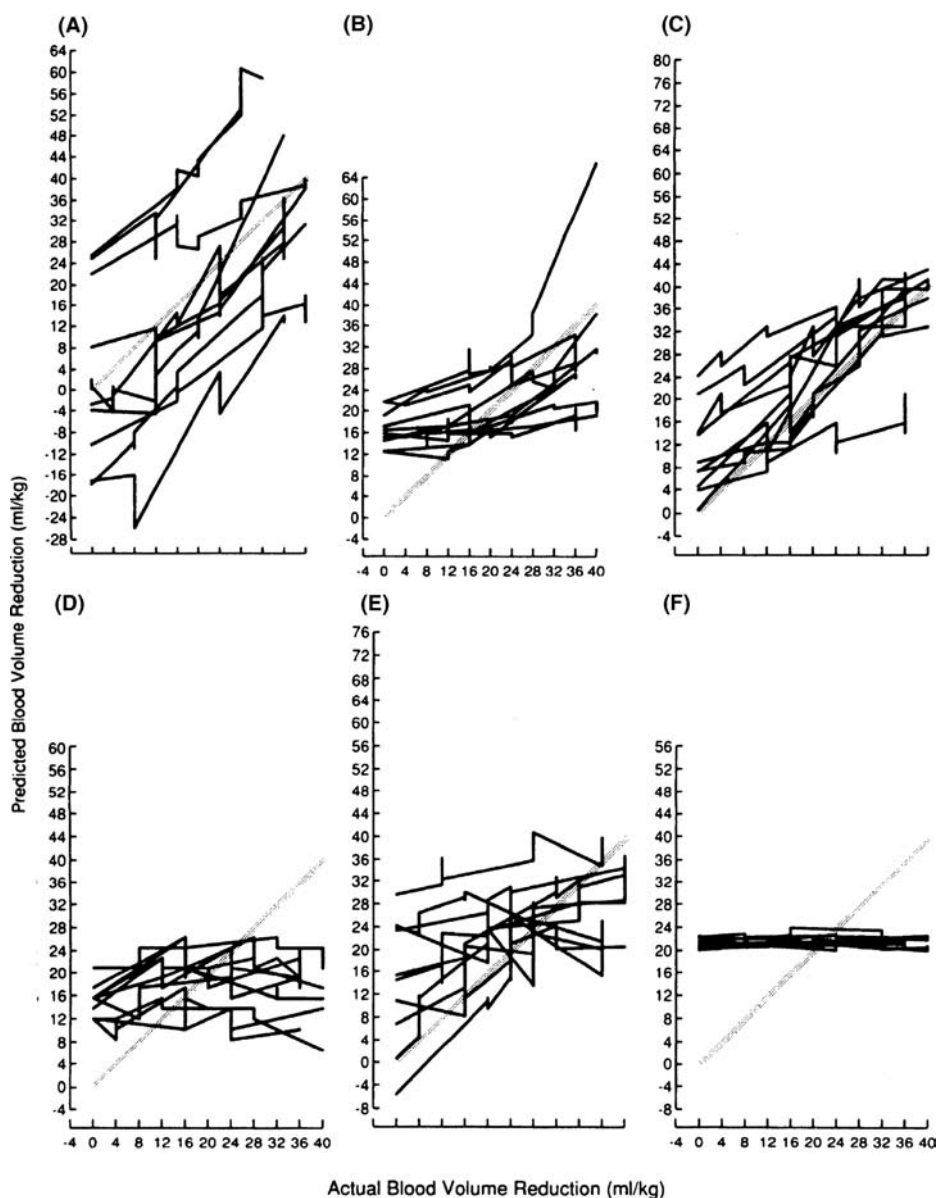

### Global Indicators of Oxygenation and Perfusion

In an NIH sponsored study, the accuracy of common physiological parameters was evaluated, in relation to their predictability of actual blood loss during progressive blood removal in awake, chronically instrumented dogs. In the perfect model, the measure shown on the horizontal axis of these graphs (Fig. 4) would be related to the volume of blood loss (shown on the vertical axis of the graph) by a line of identity. The correlation between hemorrhage volume and base deficit was best during progressive increments of blood loss. Even though there is a wide variance, the trend in each individual animal relates base-deficit to blood loss.

In another study in which animals were bled to different levels of  $O_2$  debt, base deficit was an excellent predictor of different levels of  $O_2$  debt (with  $-17$  base deficit and  $9.40$

**Figure 3** The y-axis shows a log plot of erythropoietin ( $\mu/L$ ) and the x-axis is hemoglobin in g/dL. Sixty-three patients with primary hemopoietic disorders (triangles) are compared to 138 multiple trauma patients (black dots). As hemoglobin decreases in patients with primary hemopoietic disorders, so erythropoietin levels rise (line of identity shown) exponentially. For trauma patients, there is no increase of erythropoietin as hemoglobin levels decrease. *Source:* From Ref. 21.

**Figure 4** Comparison of model predictions versus actual blood volume reductions for six representative parameters [arterial base deficit (A), arterial lactate (B), mean arterial pressure (C), heart rate (D), hemoglobin (E), and mixed venous  $\text{PCO}_2$  (F)]. Solid black lines represent individual animal ( $n = 10$ ). Gray bar represents an ideal model slope in which model predictions equal actual blood volume reductions. For mean arterial pressure, predictions at large volume hemorrhage were more accurate than predictions with small volume bleeds. Models such as heart rate and lactate both showed significant variability before hemorrhage among animals and flat slopes (e.g., mixed venous  $\text{PCO}_2$ ) indicated fixed-volume predictions regardless of actual degree of hemorrhage. Source: From Ref. 24.

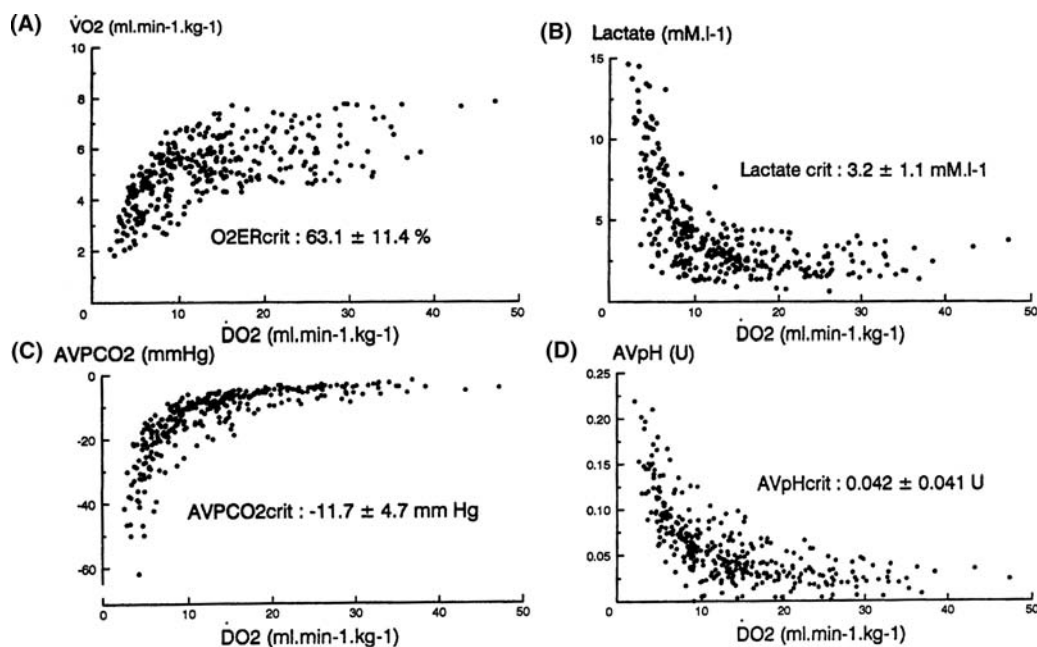

lactate levels being associated with 25% mortality) (25). The correlation coefficient with hemorrhage volume was higher with base deficit than with lactate in both studies. Arteriovenous pH and  $\text{PCO}_2$  differences, as a measure of adequacy of resuscitation, was also useful as a simple evaluation of the onset of tissue ischemia (26). In animal data both arteriovenous pH and arterio-venous  $\text{CO}_2$  differences have a high correlation with critical  $\text{O}_2$  delivery ( $\text{DO}_2$ ) and lactate (Fig. 5) (26). The practical measurement of these values is easy with venous samples for pH and  $\text{P}_v\text{CO}_2$  being obtained from a central vein, not the pulmonary artery. The use of a colorimetric hemoglobin meter in the operating room for serial monitoring of Hb concentration is also a sensible monitor of the anemia status. In addition to the above

measures, a fiberoptic intramucosal  $\text{PCO}_2$  monitor sublingual  $\text{PCO}_2$ , transcranial cerebral oximetry, and ST segment analysis capability on the electrocardiogram (ECG) monitor, provide optimum current state-of-the-art monitoring for management of the hemorrhaging patient following trauma.

## BLOOD AND COMPONENTS FOR TRANSFUSION

### Red Blood Cells

RBCs can be stored in several different ways, including whole blood, PRBCs, frozen, and lyophilized cells. Whole blood is rarely needed or available in civilian practice but

**Figure 5** (A) and (B): Pooled response of  $\dot{V}O_2$  and AV  $PCO_2$  to the progressive reduction in  $\dot{D}O_2$ .  $O_2Ercrit$  and AV  $PCO_{2crit}$  were determined in each animal. (C) and (D): Pooled response of blood lactate and AV pH to the progressive reduction in  $\dot{D}O_2$ . Lactate crit and AV pHcrit were determined in each animal. *Abbreviations:* AV  $PCO_2$ , arteriovenous gradient for  $PCO_2$ ; AV  $PCO_{2crit}$ , arteriovenous gradient for  $PCO_2$  at critical point; AV pH, arteriovenous gradient for pH; AV pHcrit, arteriovenous gradient for pH at critical point;  $\dot{D}O_2$ , oxygen delivery; Lactate crit, blood lactate level at critical point;  $O_2Ercrit$ ,  $O_2$  extraction ratio at critical point;  $\dot{V}O_2$ , oxygen uptake. *Source:* From Ref. 26.

is used in military situations when it is drawn on site from military personnel (2). In austere situations, whole blood transfusion may be the only effective way to obtain platelets and clotting factors. Frozen RBC storage at  $-80^\circ C$ , with the high-glycerol method to prevent red cell lysis, allows storage for several years. However, deglycerolization is very resource intensive, needing several hours of preparation before these red cells can be transfused (27). Rapid freeze-drying of red cells (lyophilization) also results in the need to process the product before it can be transfused. Recent advances in storage of PRBC by use of additive solution EAS-76 with 45 mEq/L NaCl allows RBC storage for 12 weeks with acceptable recovery, and 0.6% hemolysis and normal 2,3-diphosphoglycerate (2,3-DPG) concentrations for two weeks (28). Specialized blood units, such as cytomegalovirus negative, irradiated, and leukoreduced preparations have not been shown to be generally required in adult trauma. However, leukoreduction is beneficial for limiting febrile reactions, and irradiation can decrease graft versus host disease (GVHD). Irradiation decreases blood storage time and increases the potassium concentration of each unit, so it is best done immediately prior to transfusion (a process that could slow availability of the blood by approximately 15 minutes).

## Platelets

The normal adult platelet count is in the range of 150 to  $400 \times 10^9/L$ . During trauma, platelets are lost with shed blood, consumed in wounds, and diluted by resuscitation fluids (see Volume 1, Chapters 11 and 12). The anticipated platelet count decline is difficult to predict during massive hemorrhage due to the multifactorial nature of the losses. Once the patient's blood losses are controlled, and in the absence of ongoing platelet losses, thrombocytopenia

persists for two to four days. Subsequently, the platelet count should begin to increase, resulting in a thrombocytosis from increased marrow production (see Volume 2, Chapter 55).

## Activity, Administration, and Half-Life

One platelet concentrate unit will generally increase the platelet count by approximately  $5$  to  $10 \times 10^9/L$  in the average adult. Because the usual therapeutic dose is one platelet concentrate per 10 kg body weight, typically, 10 concentrate units are pooled and administered at a time.

Apheresis (single-donor) platelet units also have wide variation in platelet yield. The content of each random-donor unit may vary from  $5.5$  to  $8.5 \times 10^{10}/L$  platelets (29). The American Association of Blood Banks' standards require a minimum of  $3.0 \times 10^{11}/L$  platelets in each platelet-pheresis collection (30). When yields are greater than  $6 \times 10^{10}/L$ , the collections are often split into two "doses" (31). The *in vivo* activity of stored platelets in a recipient is estimated to be reduced by 75% to 80% of their activity on collection. Platelets should be given through an unused infusion set with a 170 micron filter. The transfused platelets have a half-life of only about two days (32).

♣ **One platelet concentrate increases the platelet count by 5 to  $10 \times 10^9/L$ . *In vivo* platelet activity is decreased 75% from collected activity. Transfused platelets have a half-life of about two days.** ♣

## Single vs. Pooled Platelet Donors

The advantages of single-donor platelets over pooled random-donor platelets include reduction in the rate of alloimmunization and transfusion transmitted infection, fewer transfusion reactions, and easier logistics (33). The risk of bacterial contamination is lower in single-donor platelets than in pooled random-donor platelets, but nevertheless was 0.42% in one

study (34). White blood cell reduction appears to be related causally to a reduction in alloimmunization, regardless of whether single or pooled concentrates of platelets are used (35). The NIH consensus document on platelet transfusion therapy is under revision (36).

☞ **Single-donor platelets have a lower rate of alloimmunization, transmitted infections, and transfusion reactions.** ☞

### Platelet Transfusion Trigger

The consensus is that a platelet count of  $10 \times 10^9/L$  ( $10,000/mm^3$ ) provides a safe lower limit for the prescription of prophylactic platelet transfusion in a routine (nontrauma, noncritical illness) setting (31,33). A threshold of  $20 \times 10^9/L$  should be used for those with fever, infection, and related conditions, with a therapeutic threshold of  $50 \times 10^9/L$  for surgery or invasive procedures (31). Although the ASA believes that this level should be taken into consideration, counts between 50 and  $100 \times 10^9/L$  should merit platelet transfusion on the basis of individual patient risk for bleeding (13). If thrombocytopenia occurs due to massive transfusion or persists in the intensive care unit, platelet infusion will be required. Thrombocytopenia due to consumption or dilution of dysfunctional platelets may increase morbidity and mortality from surgical and traumatic hemorrhage.

In nonsurgical and some nontrauma patients, spontaneous microvascular bleeding from gums, submucosa, and percutaneous catheter sites rarely occur with platelet counts above  $20 \times 10^9/L$  (37). In massively transfused patients receiving more than 20 units of blood, 75% had platelet counts less than  $50 \times 10^9/L$ , whereas no patients receiving less than 20 units had counts less than  $50 \times 10^9/L$  (38).

Since six units of platelets contain the equivalent of 1.5 to 2 units of fresh frozen plasma (FFP), clotting and coagulation improvement following platelet transfusion may not be solely due to platelets (39). Forty-one patients randomized to receive platelets ( $n = 22$ ) or FFP ( $n = 19$ ), 32 of whom were trauma patients, were prospectively studied after an average of more than 20 units of modified whole blood units (range 12–39 for platelet group and 14–41 units for FFP group). One patient randomized to FFP had microvascular bleeding after 20 units of modified whole blood (from which platelets and/or cryoprecipitate are salvaged before storage), which was thought to be due to dilutional thrombocytopenia (40). Two patients receiving platelets and one other patient receiving FFP required multiple doses of platelet concentrates and the authors concluded that prophylactic platelet administration was not warranted in massive transfusion (40). However, patients with massive transfusion beyond that studied would likely need platelet transfusion.

The ASA task force concluded that the need for platelet transfusion is dependent on multiple risk factors, and not a single laboratory value such as platelet count. The risk for surgical patients is defined by the type and extent of surgery, the ability to control bleeding, the consequences of uncontrolled bleeding, the actual and anticipated rate of bleeding, and the presence of other factors adversely affecting platelet function (12). Although the ASA task force did not single out trauma patients separately from surgical patients, these conclusions seem applicable to nonsurgical bleeding trauma patients. Their final conclusion is that platelet transfusion is justified in bleeding patients, despite an apparently adequate platelet count, if there is known platelet

dysfunction, microvascular bleeding, or otherwise increased risk of bleeding.

☞ **Transfusion of greater than 20 units of blood will reduce platelets to less than  $50 \times 10^9/L$  in 75% of patients. The decision to transfuse platelets is usually based on evidence of microvascular bleeding or in a patient judged to be at high risk of bleeding, rather than on the level of the platelet count per se.** ☞

In certain groups of trauma patients, including those with intracranial bleeding or those who require intracranial or intraocular surgery, it is recommended by the British Committee for Standards in Haematology that efforts should be made to maintain platelet counts above  $100 \times 10^9/L$  (41). Clinicians appear to support this recommendation, if intracranial bleeding is deemed a possibility (31,42). Clinicians also identified difficulty obtaining platelets in emergencies for trauma patients in Britain (32). In the United States, an audit of underutilization of platelets at one hospital was defined as failure to administer platelets when the platelet count was less than  $10 \times 10^9/L$ , but this was found in only one patient among 89 during the 14-month period when 3967 units of apheresis platelets were transfused (43).

☞ **In the setting of acute intracranial bleeding, platelet counts greater than  $100 \times 10^9/L$  should be maintained.** ☞

### Drug-Induced Thrombocytopenia and Platelet Dysfunction

Immune-mediated thrombocytopenia can be induced by heparin and other drugs (44,45). However, the clinical picture and therapeutic implications of heparin-induced thrombocytopenia (HIT) differ considerably from other drug-induced immune thrombocytopenic purpura (D-ITP). Whereas HIT tends to give a moderate thrombocytopenia (median platelet count nadir,  $60 \times 10^9/L$ , with a range between 15 and  $150 \times 10^9/L$  in 90% of affected patients), the majority of patients with D-ITP have a platelet count nadir below  $15 \times 10^9/L$  (46). Moreover, patients with HIT do not have petechiae or mucocutaneous bleeding, whether or not such clinical evidence of thrombocytopenic bleeding is typical of D-ITP. Further, HIT is a hypercoagulability state with greatly increased risk of venous and arterial thrombosis (47). Platelet transfusions are considered to be *contraindicated* in HIT, as they may confer greater risk of thrombosis or other complications (48). In contrast, platelet transfusions (with or without high-dose intravenous gammaglobulin) would be an appropriate treatment option in a symptomatic patient with severe D-ITP. Although HIT induced by unfractionated heparin is a relatively common adverse drug reaction (46), D-ITP is very rare (frequency <1000–10,000), but has been implicated with several drugs (e.g., quinine, quinidine, sulfa antibiotics, vancomycin, carbamazepine, certain penicillins and cephalosporins, rifampin, ibuprofen, ranitidine, among others).

Ketamine inhibits agonist-induced aggregation by suppression of platelet inositol 1,4,5-triphosphate formation, guanosine 5-triphosphatase activity, and calcium currents (49). The *in vitro* concentrations to produce the inhibition were in excess of the *in vivo* clinical concentrations; accordingly clinical relevance is indeterminate (50). Other intravenous induction agents, volatile anesthetics, and local anesthetics may also modestly inhibit platelet function. However, these effects are not thought to be clinically relevant under normal conditions. Aspirin clearly has antiplatelet action and may worsen bleeding in trauma patients.

However, in elective coronary artery by-pass graft (CABG) patients, it remains unclear to what extent aspirin increases bleeding complications (51).

### **Thrombocytopenia Associated with Massive Transfusion**

Thrombocytopenia associated with trauma and massive transfusion is almost always due to platelet consumption, blood loss, and hemodilution. The relative rate of bleeding and mechanism of injury determine which of these etiologies is most predominant (see Volume 2, Chapter 55).

Prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) is a vasodilator with antiplatelet and anti-inflammatory properties. PGE<sub>1</sub> was tested to see if such an infusion would prevent thrombocytopenia in association with massive transfusion for major orthopedic surgery (52). PGE<sub>1</sub> infusion resulted in decreased platelet aggregation and prevented decline in platelet count. The 22 patients who received PGE<sub>1</sub> in doses up to 30 ng/kg/min for 72 hours after surgery had no reduction in platelet counts after more than 10 units of red cell infusion, whereas the control groups of 23 patients had a significant drop in platelet counts three and five days after surgery, necessitating platelet transfusion. The PGE<sub>1</sub> treated group was more stable and required fewer postoperative blood transfusions, suggesting that PGE<sub>1</sub> might inhibit transfusion-induced coagulation disturbances (53). Although this orthopedic surgery patient study is intriguing, its application to less controlled trauma situations is unknown, and potentially dangerous.

### **Fresh Frozen Plasma**

FFP contains all of the major plasma proteins, including the labile factors (V, VIII). In 1997, 3,320,000 units of FFP/single-donor plasma were transfused in the United States. A recent audit, using the Canadian Medical Association's published recommendations, found that FFP transfusions were appropriate for 167 patients (47%), probably appropriate for 31 (9%), and inappropriate for 160 (45%) (54,55). The Canadian Medical Association guidelines recommended transfusion of FFP in three specific situations: (i) for patients with significant coagulopathy because of acquired deficiencies of multiple coagulation factors in whom serious bleeding has occurred or for whom emergency surgery or other procedures are planned, (ii) for treatment of thrombotic thrombocytopenic purpura (TTP), and (iii) for treatment of acquired single factor deficiencies where a product containing the single factor is unavailable or ineffective (55).

An NIH consensus conference concluded that FFP was indicated for documented coagulation protein deficiencies, for selected patients with massive transfusion as well as patients with multiple coagulation defects (e.g., liver disease) in conjunction with therapeutic plasma exchange for TTP, for infants with protein losing enteropathy, and for selected patients with other immunodeficiencies. FFP use in other situations was discouraged (56). They noted that there was little scientific evidence to support the increasing clinical use of FFP.

The Canadian Committee stated that use of FFP as a volume expander or for wound healing was contraindicated (55). The British Committee for Standards in Haematology noted that four units of FFP will usually promote coagulation in adults (41). The ASA task force recommended FFP for correction of microvascular bleeding secondary to coagulation factor deficiency in patients transfused with more than one blood volume or for correction of bleeding in the presence of elevated (>1.5 times normal)

prothrombintime (PT) or partial thromboplastin time (PTT) (12). The dose should be that to achieve a minimum of 30% of plasma factor concentration (usually achieved with administration of 10 to 15 mL/kg FFP). The ASA Task Force notes that four to five platelet concentrates, one unit of single-donor apheresis platelets, or one unit of whole blood provide a quantity of coagulation factors similar to that found in one unit FFP (12).

In contrast, during elective surgical conditions where normovolemia and normal core temperature are maintained, FFP transfusions are seldom required. However, during rapid or massive blood loss conditions associated with trauma, more liberal use of FFP is warranted. Indeed, once one blood volume has been replaced, consideration should be given to administering PRBCs and FFP together in a 1:1 ratio (57).

☞ **An FFP dose of 10 to 15 mL/kg will usually increase plasma coagulation factor concentration by 30% (the minimum level required for hemostasis for most of the coagulation factors).** ☞

### **Cryoprecipitate**

In 1997, 816,000 units of cryoprecipitate were transfused (58). Cryoprecipitate contains factor VIII, fibrinogen, fibronectin, Von Willebrand factor, and factor XIII, and is used for correction of inherited and acquired coagulopathies. One unit of cryoprecipitate per 10 kg body weight raises the fibrinogen concentration by approximately 50 mg/dL. The Canadian Committee recommended cryoprecipitate transfusion in bleeding patients with hypofibrinogenemia, Von Willebrand disease, and patients with hemophilia A (when factors VIII concentrate is not available) (55). The British Committee recommends that cryoprecipitate should also be given to massively transfused patients when fibrinogen is less than 80 mg/dL.

The ASA Task Force had three recommendations about cryoprecipitate: (i) prophylaxis in nonbleeding perioperative or peripartum patients with congenital fibrinogen deficiencies, or Von Willenbrand disease unresponsive to desmopressin—in consultation with a hematologist; (ii) bleeding patients with Von Willebrand disease; and (iii) correction of microvascular bleeding in massively transfused patients with fibrinogen concentrations less than 80 to 100 mg/dL or when fibrinogen concentrations cannot be measured in a timely fashion (12). After the loss of 1.5 blood volumes, in massively bleeding patients, cryoprecipitate (10–12 cryoprecipitate packs) should be administered after every 10 to 15 units of PRBCs and FFP to maintain fibrinogen levels.

☞ **One unit cryoprecipitate per 10 kg body weight increases fibrinogen 50 mg/dL in stable patients, and is indicated for massively bleeding or transfused patients with fibrinogen below 80 to 100 mg/dL.** ☞

### **Recombinant Factor VIIa**

Recombinant factor VIIa (rFVIIa) induces coagulation at the sites of vascular injury where it reacts with exposed tissue factor to induce platelet activation and allow the platelet plug to form and reduce bleeding (59). Initially it was used to treat hemophiliac patients with inhibitors to factor VIII. A potential adverse effect is promotion of thrombosis (60). In a prospective, randomized trial in prostatectomy patients, rFVIIa was shown to decrease blood loss (61).

The use of rFVIIa in trauma patients is usually restricted to situations in which conventional means of hemorrhage control, including surgery and angiographic

embolization, have failed. The appropriate dose and time of administration remains uncertain. Early experience was reported by Dutton et al. (62), where its use was generally found to be beneficial. A subsequent report by this group wherein 81 patients were treated with rFVIIa showed that 61 (75%) had sustained improvements in their coagulation status and 20 had persistent coagulopathy ("nonresponders") (63). The nonresponders were significantly more acidotic and had lower platelet counts than the responders (63).

In a recent multicenter randomized trial, rFVIIa was found to significantly decrease RBC transfusion in both blunt ( $p = 0.03$ ) and penetrating trauma ( $p = 0.08$ ) (64). The incidence of adverse events did not significantly increase in the study population, but then mortality did not significantly improve either (64). In summary, rFVIIa is effective in achieving hemostasis in a large number of trauma patients, but additional studies are required to clarify target population, dosing, efficacy, and safety (65).

## EMERGENCY AND MASSIVE TRANSFUSION

### Emergency Transfusion

In a trauma setting, several administrative decisions should be made jointly by the clinicians and the blood bank regarding policy and procedures for emergency compatibility testing (ABO and Rh typing, antibody screening, and cross-matching). In decreasing order of preference, options include: type-specific, partially cross-matched blood; type-specific uncross-matched blood; and, lastly, type O Rh-negative ("universal donor"), uncross-matched blood (66,67).

Partially cross-matched blood includes ABO-Rh typing and an "immediate-spin" cross-match that takes one to five minutes and eliminates serious hemolytic reactions due to errors in ABO typing. Type-specific uncross-matched blood requires a blood sample from the patient to determine ABO and Rh type. This blood will be released by the blood bank if the physician indicates the emergency need for blood. Meanwhile, compatibility testing is completed while the blood is being transfused. An advantage of type-specific blood is that it saves type O/Rh-negative blood. As many as 1 in 1000 patients have antibodies detected on cross-match that may make transfusion of ABO-Rh type specific uncross-matched blood hazardous; previous exposure to RBC antigens increases this risk tenfold (66,67).

Universal donor (type O) blood, which lacks both A and B antigens, avoids risk of ABO-mediated hemolysis in a blood group A, B, or AB recipient who has the antithetical anti-B or anti-A (or both) alloantibodies. In many trauma centers, O-negative blood is available in the trauma patient resuscitation area, which can be transfused emergently once a sample of patient blood is withdrawn for transfusion investigations. This patient blood sample is essential for subsequent units to be type-specific, and to determine if significant red cell alloantibodies are present (68). After administration of uncross-matched universal donor blood, the decision to transfuse the patient's corresponding ABO/Rh blood type is made when the blood bank determines that passively transfused anti-A and/or anti-B antibodies have fallen to levels low enough to permit the safe transfusion of type-specific blood. At the Shock Trauma Center in Baltimore in 2000, 161 of 501 patients who received blood products were given at least one unit of uncross-matched group O, including 52 of the 80 blood transfused patients

who died within the first 24 hours after admission. The maximum number of uncross-matched units administered to any one patient was 14, and a total of 581 units were given to the 161 patients. These 581 units represented 11% of all PRBCs administered at the Shock Trauma Center and 18% of those given in the first 24 hours to those patients who had a mortality of 45% (69).

### Massive Transfusion

Massive transfusion is defined as replacement of a patient's blood volume within 24 hours, for example, about 5000 mL blood or 3000 mL (10 units) of PRBCs in an average-size adult (70,71). Trauma accounts for at least one-third of massive transfusion situations (70,71). In the United States, 10% to 15% of all PRBCs transfused are used to treat injured patients. Massive transfusion protocols in trauma centers support the transfusion service and their activation identifies a need for better hemorrhage control modalities. These massive transfusion protocols include use of additional personnel and provide rapid infusion system technicians to enable administration of large quantities of warmed blood. Massive transfusion protocols ensure that cross-matching policies are streamlined, automated thawing of FFP is initiated, and platelets become readily available (66,67).

### Massive Transfusion Protocols

Massive transfusion protocols should be invoked judiciously, as it may limit blood transfusion services to other patients in need. A massive transfusion protocol used by the UCSD trauma center mobilizes 45 units of blood (66). The initial four units may be O Rh negative. Following this, type-specific blood will be used to the extent possible, with the decision to use compatible but nontype-specific blood (e.g., O for type B recipient; A or O for type AB recipient) made by the blood bank. Due to limited supplies of Rh-negative blood, it may be necessary to use Rh-positive blood in an Rh-negative individual, especially in males or post-menopausal females, for whom implications of Rh-sensitization is less of a concern. To prevent confusion, a single individual on the trauma team should be designated to communicate with the blood bank. Following the immediate resuscitation period, standard procedures for blood ordering should be followed (66).

### Hemostasis and Component Therapy During Massive Transfusion

Hemostatic defects are often related to dilution and consumption of platelets and coagulation factors. In the absence of trauma, disseminated intravascular coagulation (DIC), or pre-existing coagulopathy, patients who bleed up to 1.5 blood volumes (in a 70 kg male approximately 15 units of PRBC and 3–5 L crystalloid) generally do not have clinically relevant hemostatic defects. Consequently, prophylactic transfusion of platelets, FFP, or cryoprecipitate should not be given to patients simply because they have received 10 to 15 units of PRBC (67).

However, the presence of a pre-existing coagulopathy, acute trauma with extensive tissue damage, or DIC increases the likelihood that hemostatic support will be required (72). Trauma patients whose blood loss is  $>1.5$  blood volume should be carefully monitored for clinical signs of microvascular bleeding (i.e., oozing from IV sites or wounds), as well as by laboratory monitoring. When the coagulation assays are abnormal (PT  $>17$  seconds, PTT  $>55$  seconds: fibrinogen  $<150$  mg/dL, platelets  $<75 \times 10^9/L$ ), empirical

use of FFP in a 1:1 ratio of FFP to PRBCs in the setting of ongoing massive bleeding (57). Platelets contain associated plasma factors equivalent to one to two units of FFP for each plateletpheresis bag.

Following initial therapy, it is important to evaluate clinical and laboratory parameters for response. There is no universal formula to guide hemostatic replacement therapy. However, in patients who bleed in excess of two blood volumes (>20 units of PRBC), it is prudent to transfuse sufficient platelets to keep the platelet count  $>75 \times 10^9/L$ , and sufficient FFP to maintain fibrinogen  $>150 \text{ mg/dL}$ , and/or the PT  $<18$  seconds; PTT  $<55$  seconds.

It is usually not necessary to give cryoprecipitate unless there is a disproportionate decrease in fibrinogen or factor VIII, for example, in the setting of DIC, because a unit of FFP supplies about twice as much fibrinogen and factor VIII as a unit of cryoprecipitate. The most common error in the management of massively bleeding patients is to apply outdated, rote formulae without monitoring Hct, platelet, and coagulation factor levels. This results in inadequate replacement therapy in some, whereas others are treated unnecessarily (66).

## COMPLICATIONS OF BLOOD TRANSFUSION

✎ **Inadvertent transfusion of ABO incompatible blood and transfusion-associated acute lung injury (TRALI) are life-threatening, noninfectious hazards of blood transfusion.** ✎

### Infections

More than 12 million units of blood are transfused annually in the United States (73,74). In 1999, the risks for acquiring viral infection from a unit of blood were:  $<1/1,000,000$  for HIV, 1:103,000 for hepatitis C, and 1:63,000 for hepatitis B (Fig. 6) (73). The incidence of viral transmission from blood transfusion is decreasing, with current infection rates even lower (73). Indeed, the risk of viral infection from blood is much lower than the risk of a patient being given the wrong unit of blood due to clerical error within the blood bank or in the ward, which occurs at a rate of about 1:37,000, resulting in one fatality per 1.8 million units transfused (75,76).

### Noninfectious Hazards of Transfusion

Besides inadvertent transfusion of ABO-incompatible blood, hemovigilance programs in the United Kingdom, France, and the United States demonstrate that patients suffer other significant noninfectious transfusion-related morbidity and mortality (77), an issue that has gained increasing attention, given the dramatic reduction in viral transmission from blood (e.g., 10,000-fold reduced risk of HIV and hepatitis over the past few decades) (76).

Current data probably underestimate noninfectious transfusion risk. Febrile nonhemolytic transfusion reactions are common, occurring in up to 10% to 30% of transfusions, especially with nonleukoreduced platelet transfusions (78).

A prospective study of transfusions identified substantial underreporting of bedside transfusion errors in Belgium with a rate of unintended recipients of RBCs being one in 400 units (79). This Belgian study concluded that current passive reporting systems underestimate the true frequency of hazard from blood transfusion by 30-fold. Even fatal transfusion mishaps are significantly underreported. In a study of 355 transfusion-associated deaths from 1976–1985, no fatalities were reported to the

**Figure 6** The risks of transfusion-related transmission of human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) in the United States. Each unit represents exposure to one donor. The risk of each of these infections has declined dramatically since 1983, the year the criteria for donor screening were changed; at that time the prevalence of HIV infection among donors was approximately 1%. Further declines have resulted from the implementation of testing of donor blood for antibodies to HIV beginning in 1985; surrogate testing for non-A, non-B hepatitis beginning in 1986–1987; testing for antibodies to HCV beginning in 1990; and testing for HIV p24 antigen beginning in late 1995. *Source:* From Ref. 74.

FDA (80). Yet, the FDA-reported transfusion-related death rate due to hemolytic reactions alone was two times that due to all infectious hazards combined (81).

Circulatory overload is a significant problem in trauma, and may be associated with red cell transfusion. A seven-year retrospective study at a single institution found the incidence to be 1:3168 patients (82). In another study, 1% of orthopedic surgery patients developed circulatory overload, sometimes necessitating transfer to an intensive care unit (83). Extrapolating these data nationally, it has been estimated that 30,000 to 40,000 patients annually might have circulatory overload as an avoidable complication of transfusion (82,83). When two groups of critical care unit patients were randomized to a liberal or restrictive use of blood, the patients randomly assigned to a more liberal strategy had a significantly higher incidence of cardiac and pulmonary morbidity (8).

✎ **Noninfectious transfusion risk exceeds infectious hazard by 100- to 1000-fold.** ✎

### Transfusion-Related Acute Lung Injury

TRALI is defined as acute post-transfusion noncardiogenic pulmonary edema, and is characterized by severe bilateral patchy pulmonary alveolar infiltrates, hypoxia, tachycardia, and fever. It clinically resembles adult respiratory distress syndrome (ARDS). TRALI occurs one to six hours after transfusion of blood products, especially FFP. TRALI often

requires mechanical ventilation, and may be fatal. It was the third most common cause reported of transfusion-related mortality (84,85). In the FDA reports, 31 cases (9%) were attributed to acute pulmonary dysfunction (85). In another study, 46 of 2430 platelet transfusions (2%) were associated with severe respiratory reaction over a two-year period (86). The FFP donated by women with a history of  $\geq 3$  pregnancies resulted in a significantly lower oxygen extraction ratio, and in four out of 100 patients an acute pulmonary transfusion reaction was noted, suggesting an immunological etiology (antigranulocyte alloantibodies) (also see Volume 2, Chapter 52) (87).

The development of ARDS following transfusion in trauma patients has recently been prospectively reviewed (88). The amount of transfused blood in these patients was independently associated with both the development of ARDS and hospital mortality. ARDS developed in 21% of severe trauma patients who received zero to five units of PRBCs, in 31% of those who received 6 to 10 units, and in 57% of those who received  $>10$  units ( $p = 0.007$ ) (88). The association between the amount of transfused blood and the development of ARDS remained significant even after accounting for differences in the severity of illness, type of trauma, race, gender, and base deficit ( $p = 0.002$ ; odds ratio, 14.4; 95% confidence interval, 3.2–78.7). Patients who received more units of PRBCs during the first 24 hours also had a higher hospital mortality rate ( $p = 0.03$ ) (88).

### Graft vs. Host Disease

Over 200 cases of transfusion-associated GVHD have been reported, with a fatality rate of about 90% (89). In contrast to TRALI, where the etiology appears to involve passively-acquired antigranulocyte alloantibodies and possibly other toxins, GVHD is related to transfusion of live white blood cells that become engrafted within the recipient. In a recent prospective study by Utter et al. (90), 53% (24 of 45) trauma patients who received  $>2$  units of PRBCs developed evidence of microchimerism when studied using polymerase chain reaction technology. However, clinically-evident GVHD is one of the rarest of transfusion reactions. Irradiating cellular blood components will prevent this problem, but irradiation has detrimental effects on erythrocytes and there is no current standard for irradiation dosing.

☞ **Transfusion-associated GVHD has high mortality (>90%), but is extremely rare; irradiating blood components can prevent this complication, but is not practical in the acute trauma setting.** ☞

### Exchange Transfusion

In neonates, exchange transfusion increases existing metabolic derangements and causes hypoglycemia (91). Among pediatric recipients of massive transfusion, hyperkalemia and hypocalcemia are more common, and when untreated may cause cardiac arrest. Among 140 exchange transfusions that included 106 neonates, more than 34% of the infants had documented hypoglycemia, 1/20 had ECG changes related to hypocalcemia, and one had a cardiac arrest. In 25 ill neonates, 12% had severe complications (including two deaths) attributed to transfusion (92).

### Undertransfusion

Undertransfusion indicates risk for morbidity and mortality associated with a lack of transfusion when Hb concentration was less than 6 g/dL. This issue is complex, because, in one

study, mortality was even lower in patients transfused when Hb was  $<7.0$  g/dL compared to  $<10$  g/dL (93).

However, evidence for risk of undertransfusion was seen in one study of 190 patients undergoing radical prostatectomy in which myocardial ischemic episodes occurred in 61 (34%) of 181 evaluable patients (94). After adjustments for other risk factors, the authors concluded that a Hct  $<28\%$  was independently associated with a risk for myocardial ischemia during and after noncardiac surgery.

In cardiac bypass patients randomly assigned to receive either blood and colloid or crystalloid fluids, the patients given crystalloids had delayed myocardial lactate extraction compared to the patients receiving blood, indicating that anemia had a potentially deleterious effect on the heart (95).

In peripheral vascular surgery, among 13 of 27 patients with a Hct  $<28\%$ , 10 patients had myocardial ischemia and six sustained a morbid cardiac event, and there was an overall incidence of 37% cardiac ischemia (96). A Hct of  $<28\%$  was significantly associated with myocardial ischemia and morbid cardiac events.

☞ **Blood transfusion does not reduce mortality in stable critically ill patients with Hb 8 to 10 g/dL, except for a subset with coronary artery disease.** ☞

### Inappropriate Transfusion

Transfusion of blood products has come under increased scrutiny because of concerns over safety, product shortages, rising costs of specialized blood components, and questions about transfusion efficacy. The usefulness of behavioral interventions to reduce inappropriate transfusion was reviewed by Wilson et al. (97). They identified nine studies describing different types of interventions: prospective audit ( $n = 2$ ), education ( $n = 4$ ), transfusion algorithm ( $n = 1$ ), retrospective audit ( $n = 1$ ), and patient-specific decision support ( $n = 1$ ). Using Hct levels  $>36\%$  as an indicator for overtransfusion, all studies showed an impact of the intervention on reducing inappropriate transfusion.

Compared to 1994, the gross domestic blood supply in the United States, in 1997 (12,602,000 units) decreased by 5.5% (97). The 1997 collection included 11,741,000 units allogeneic community blood, 643,000 units autologous blood (5.5% of total), and 205,000 units of allogeneic-directed donation. The rate of whole blood collections in 1997 per 1000 members of the population aged 18 to 65 years was 12.6% lower than 1994. However, the red-cell transfusion rate per 1000 members of the population in 1997 remained nearly unchanged, raising concerns about progressive supply shortfalls (97).

☞ **Blood collection in 1997 fell 12.6%, but the rate of transfusion remained the same as in 1994.** ☞

### Blood Storage Abnormalities

Progressive deterioration in blood quality occurs upon storage and may impair flow through the microcirculation and decrease cellular  $\dot{D}O_2$ . Increased splanchnic ischemia occurs following transfusion with old blood in patients with ischemia (98). In septic rats, old blood failed to increase  $\dot{V}O_2$ , whereas fresh blood caused  $\dot{V}O_2$  to increase (99). Storing blood decreases 2,3-DPG concentration, reducing the deformability of the red cell and increasing aggregation, thereby decreasing flow through the microcirculation and impairing cellular  $\dot{D}O_2$  (100).

## Immunosuppression

Transfusion-induced immunosuppression is increasingly being recognized as an important adverse effect of blood. Decreased cell-mediated immunity occurs by reducing nonkiller cell activity, suppressing macrophage antigen presentation, altering T-cell ratios, and decreasing the concentrations of cytokines (TNF, IFN- $\gamma$ , and GM-CSF) vital to the immune response (101). There is evidence linking this immunosuppression to white cells within the transfused blood. Transfusion of leukodepleted blood to patients undergoing colorectal surgery resulted in a lower incidence of postoperative infection (102). There is a significant association between the number of blood transfusions and the risk of subsequent infection in burn patients and a variety of elective and significant emergency procedures. This increased morbidity is associated with longer hospital stays and higher costs. In addition, patients with malignancy may have sooner recurrences and lower survival rates when they receive blood transfusion (105).

## TOLERANCE FOR ACUTE ANEMIA

### Compensatory Mechanisms

There are three main mechanisms by which global  $\dot{V}O_2$  is maintained during acute, progressive anemia: (i) increased  $O_2$  extraction, (ii) reduction in  $O_2$  affinity with shift of the oxy-hemoglobin disassociation curve to the right due to increased 2,3-DPG (Fig. 7), and (iii) increased cardiac output. A fourth mechanism is the use of 100%  $O_2$  to increase the amount of oxygen carried in the plasma. In hemodiluted children undergoing orthopedic surgery, 37% of the oxygen delivered came from the plasma (106). In fact, at a Hb of 3 dg/dL and normal cardiac output, 62% of the actual  $\dot{V}O_2$  can be provided by  $O_2$  dissolved in the plasma. In addition, extraction of  $O_2$  from plasma is much more efficient than from Hb exceeding 85% removal (Table 1). As with the acellular hemoglobin-based  $O_2$  carrying solutions, the presence of larger quantities of  $O_2$  in solution facilitates the diffusion of  $O_2$  into the mitochondria by minimizing the  $O_2$  gradient between Hb in the red cell and tissues (106,107). So, high

**Figure 7** Shows the relationship between cardiac index, hemoglobin levels, and 2,3-diphosphoglycerate (2,3-DPG). At a hemoglobin level of 8 to 9 g/dL cardiac index remains low, while 2,3-DPG levels are greater than 18 mM/g hemoglobin. Source: From Ref. 121.

$FiO_2$  in excess of 80% should be used when Hb is low. There is value in small quantities of added nitrogen, such as are found in air, to minimize the microatelectasis that occurs with 100% inspired  $O_2$  caused by the resulting alveolar nitrogen washout with 100%  $O_2$ . Thus, 100%  $O_2$  should not be used unless the Hb concentration is below about 5 g/dL (108).

## Human Data on Anemia Tolerance (Jehovah's Witnesses)

Jehovah's Witness patients comprise a group of patients in whom effects of extremely low Hb levels can be observed. Since blood transfusions are not permitted, treatment approaches include deep sedation, mechanical ventilation, and avoiding unnecessary blood sampling. Although erythropoietin is often given, reticulocyte counts begin to improve only after two to three weeks. There is a reported 20% mortality rate associated with a Hb concentration of 5 g/dL. However, there are a few reports of Jehovah's Witnesses surviving with a Hb concentration near 3 g/dL, but most patients with a Hb concentration of 3 g/dL die (109).

In some settings, very low Hb levels occur because of a lack of available blood or refusal to receive blood. In one report, pregnant women in West Africa with Hb values greater than 4.5 g/dL had no mortality or cardiac failure (110). In another study in Romania, there was no postoperative mortality in 72 patients with Hb levels above 5 g/dL (111). In one of two studies in the United States, 48 pediatric patients undergoing cardiac surgery had no mortality despite blood being withheld, provided Hb was greater than 7 g/dL (Table 2). In the other U.S. study, 59 patients successfully underwent surgery after refusing transfusion, with no postoperative mortality when the blood loss was less than 500 mL and Hb greater than 8 g/dL (112,113).

## Critical Oxygen Delivery in Hemodiluted Animals

In animals that were hemodiluted and monitored at intervals, as Hb decreased from 14 to 10, 8, 5, and then 2.4 g/dL, it was only at a Hb of 2.4 g/dL that a significant difference in brain pH and  $pCO_2$  was detected compared with baseline. At the 2.4 g/dL Hb level, there was also a significant decrease in mean arterial pressure and increase in central venous pressure (Table 3). Brain  $O_2$  consumption (cerebral oxygen metabolism) was also significantly lower and cerebral blood flow significantly higher than baseline. Both were restored to normal baseline ranges by transfusion.

Critical Hct values for intestinal  $O_2$  consumption were measured by Van Bommel et al. and compared with the critical values for intestinal microvascular  $O_2$  ( $uPO_2$ ). The critical values were almost identical at  $15.8 \pm 4.6$  and  $16.0 \pm 3.5$   $uPO_2$  respectively. These Hcts represent a Hb value just above 5 g/dL (Fig. 8) (106).

## Critical Oxygen Delivery in Anesthetized Humans

At the Children's National Medical Center, eight ASA I children undergoing scoliosis correction surgery were hemodiluted by exchanging whole blood for 5% albumin in 0.7% saline. On 100%  $O_2$  ventilation, Hb fell from 10 to 3 g/dL, while mixed venous  $O_2$  saturation decreased from 90% to 72%, and  $O_2$  extraction increased from 17% to 44%, and  $\dot{V}O_2$  decreased from 532 mL/min/M<sup>2</sup> (Fig. 9). When hemodiluted, one child had Hb fall to 2.1 g/dL and this was associated with ST segment depression, which resolved on re-infusion of autologous blood. The authors concluded

**Table 1** Hemoglobin, Hematocrit, and Acid–Base Status During Hemodilution and Reinfusion

Variable (range)	T <sub>0</sub>	T <sub>1</sub>	T <sub>2</sub>

that Hb of 3 g/dL was safe in anesthetized and monitored children, and that one should not hemodilute below a mixed venous saturation of 60% as levels above this have never been shown to produce lactic acidosis or compromise cardiac function (114). The “critical point” of global  $\dot{D}O_2$  below which  $\dot{V}O_2$  becomes linearly dependent on  $\dot{D}O_2$  in anesthetized humans is estimated at 330 mL/min/m<sup>2</sup> by Shibutani (115), as 300 mL/min/m<sup>2</sup> by Komatsu et al. (116), while Van Woerkens (117) found that critical  $\dot{D}O_2$  was lower in hemodilution when cardiac output was maintained. Rheological changes in blood were impaired with hemodilution and increased capillary O<sub>2</sub> delivery and a critical value of 184 mL/min/m<sup>2</sup> was obtained in a patient with a Hb of 4 g/dL (Table 4). However, these studies were carried out either in anesthetized humans or when cardiac output was maintained. Such states are not representative of recently injured patients who may be hypovolemic and have significant catecholamine and other stress responses activated. Whether the existence of critical  $\dot{D}O_2$  states can be identified in such trauma patients also remains controversial. Recently, a study in animals showed that multivariable analysis of critical delivery may help determine the physiological oxygenation boundary at the whole body level (118). This may assist in finding therapeutic triggers on an individual basis using systemic markers of the transition from aerobic to anaerobic metabolism (118).

### Relationship Between Oxygen Delivery and Consumption

Some patients may benefit from the increased  $\dot{D}O_2$  that is expected to occur after blood transfusion. The anticipated, concomitant increase in O<sub>2</sub> consumption has only been shown in a limited number of studies, possibly in part due to the frequency of such studies being carried out in septic patients rather than in impaired  $\dot{D}O_2$  settings such as hemorrhagic shock. Surrogate markers to quantitate benefit from blood transfusion have been suggested, including lactate washout and decrease in O<sub>2</sub> debt, but confounding variables occur because when blood is infused reperfusion occurs and lactate rises (119,120). States with impaired O<sub>2</sub> extraction (e.g., sepsis) limit the usefulness of such surrogate measures. The relationship of transfusion for anemia or ischemia with oxygen metabolism is shown in Figure 10. Factors alleviating ischemia include increased O<sub>2</sub> supply (and by inference, but not always true, reduced O<sub>2</sub> debt) and decreased O<sub>2</sub> demand, such as can occur with sedation, anesthesia, and decreased cardiac afterload (11). Increased afterload, increased blood viscosity, and decreased 2,3-DPG levels in stored blood will aggravate ischemia. Hemoglobin levels per se are nonlinearly related to cardiac index and 2,3-DPG with lowest cardiac index associated with greatest 2,3-DPG levels occurring about 8 g/dL (Fig. 7) (121). Because data on O<sub>2</sub> extraction are difficult to obtain in humans in emergency circumstances, much of this work has been done on animals. There are

**Table 2** Natural History of Untreated Anemia

Study (reference)	Year	Patients, <i>n</i>	Site	Setting	Finding
Fullerton and Turner (59)	1969	Unknown	West Africa	Pregnant woman; no available transfusions	No mortality or cardiac failure in patients with hemoglobin >4.5 g/L
Gollub and Bailey (61)	1966	5	New York City	Jehovah's Witness patients undergoing cardiac surgery	No postoperative mortality in patients with hemoglobin >7.0 g/L

extraordinary compensatory abilities in the hemorrhagic shock model. O<sub>2</sub> extraction increased to more than 70% in anesthetized dogs exsanguinated of more than 60% of their estimated blood volume during a two hour period when systolic blood pressure was maintained at 50 mmHg (122). Resuscitation with volumes of shed blood or Hb-based O<sub>2</sub> carrying solutions produced supranormal cardiac index with all these fluids, but only blood normalized O<sub>2</sub> extraction and cardiac index six hours later. Total Hb concentration fell with the O<sub>2</sub> carrying solutions due to endothelial and other interactions causing red cell sequestration.

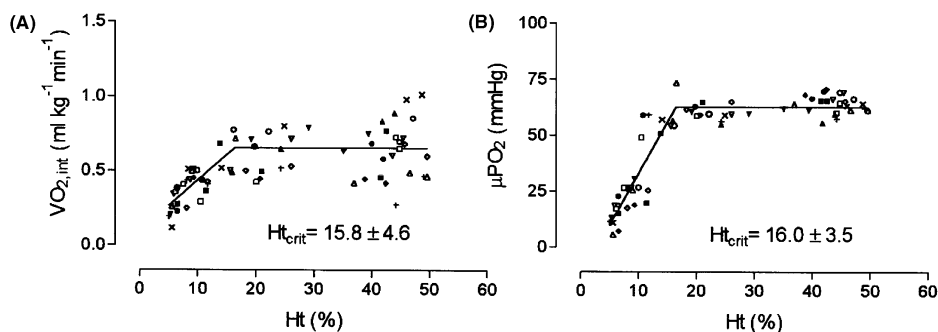

### Anemia and the Brain

The other major organ besides the heart, at risk during anemia, is the brain. In a study in rabbits, Morimoto et al. (123) continuously monitored brain tissue pH PCO<sub>2</sub> and PO<sub>2</sub> during production of anemia (Table 3). They found that as Hb progressively fell from 10 to 7, to 5, and then to a mean low of 2.4 g/dL, brain tissue PO<sub>2</sub> fell from 27 to 12 mmHg, pH decreased from 7.22 to 7.12, cerebral blood flow almost doubled to 66 mL/100 g/min, and cerebral metabolic rate more than halved to under 2 mL/100 g/min. At this level of anemia (2.4 g/dL), the authors concluded that increases in cerebral blood flow and cerebral O<sub>2</sub> extraction were only partially able to compensate for the decreased O<sub>2</sub> carrying capacity (Fig. 11). Postoperative visual loss has been associated with many factors including anemia, blood loss, and hypotension (124,125).

### Anemia in Trauma and Critically Ill Patients

In bleeding but otherwise healthy trauma patients, cardiovascular compensation should be adequate for Hb levels as low as 5 g/dL. As blood loss continues and Hb falls further, compensatory responses begin to fail (126,127). Mortality rates range from 50% to 95% when the Hb falls below 3.5 g/dL (126,128). Anemia is a common problem in critically ill patients. In part, anemia can be explained by an average of 41 ± 39.7 mL blood samples drawn per 24 hours. In a major European study involving 3534 patients, there was a positive correlation between organ dysfunction and the number of blood draws and volume drawn. The mean Hb on critical care unit admission was 11.3 ± 2.3 g/dL with 29% (963/3295) having a Hb <10 g/dL. The transfusion rate was 37% (1307/3534). Older patients and those with longer critical care unit stay were more commonly transfused. Both critical care unit and overall mortality rates were significantly higher in patients who received a transfusion (critical care unit rates 18.5% vs. 10.1%; overall mortality 29% vs. 14.9%). For similar degrees of organ dysfunction, patients who had a transfusion also had a higher mortality rate. For matched patients, the 28-day mortality was 22.7% among patients receiving blood transfusions and 17.1% among those without ( $p = 0.02$ ) (129).

✎ In bleeding, otherwise healthy trauma patients, cardiovascular compensation may be adequate to a Hb as low as 5 g/dL. However, any further compensation is inadequate with mortality 50% to 95% at Hb <3.5 g/dL. ✎

Abbreviations: DO<sub>2</sub>, oxygen delivery; Hgb, hemoglobin concentration; VO<sub>2</sub>, oxygen consumption. Source: From Ref. 114.

**Risk of Mortality with Anemia**

In a study of 2738 sequential isolated coronary artery bypass surgery patients, there was a significantly increased risk of mortality for Hct <14%. For high risk patients, Hct <17% had increased mortality after adjusting for other risk factors (130). A meta-analysis of several studies of Jehovah’s Witnesses found that of 50 reported deaths, 23 were primarily due to anemia. Except for three patients who died after cardiac surgery, all other patients died with Hb concentrations <5 g/dL (109).

**EYE TO THE FUTURE**

Progress is needed not only in the avoidance of complications of blood transfusion, but also in strategies to reduce the need for blood and component therapy. The potential methods of achieving this include: improved

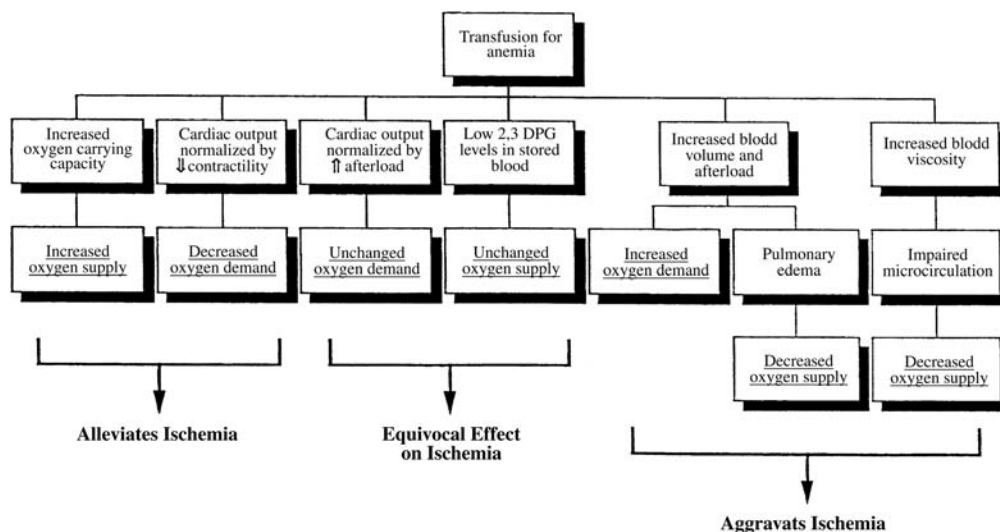

**Table 4** Critical Limit Global O<sub>2</sub> Delivery by Various Authors

Study	DO <sub>2</sub> limit	Comments
Shinbutani et al. (115)	330 mL/min/M <sup>2</sup>	In anesthetized man
Komatsu et al. (116)	300 mL/min/M <sup>2</sup>	After CPB

Abbreviation: CPB, cardiopulmonary bypass; DO<sub>2</sub>, oxygen delivery.

methods of hemostasis at the sites of injury; pharmacological and physical means for restricting blood flow to hemorrhage sites; increased tolerance of organs and tissues for hypoxia; and improved fluid and blood flow distribution to conserve function of vital organs, such as the brain and heart. The future of blood and component transfusion includes prolongation of storage of red cells, improved uptake and release of oxygen, and avoidance of allogeneic and other transfusion reactions. On the horizon, ongoing work will reduce ABO incompatibility issues by changing all blood to universal donor group O. Major advances are being made in blood safety and these will continue in the future with special emphasis on problems related to human error and the improved culture of patient safety for blood transfusion. Screening tests for West Nile Virus will be developed and earlier detection of HIV will occur. Hepatitis and other blood borne infections will continue to decline in frequency because of better detection tools and viral inactivation methods.

O<sub>2</sub> carrying solutions will eventually receive FDA approval and may be used as substitutes for the O<sub>2</sub> carrying capacity of blood. Because they are acellular, these solutions may be used like a drug to facilitate O<sub>2</sub> diffusion into the mitochondria for many purposes including ischemia, and trauma resuscitation, and to enhance the effectiveness of radiation therapy. Control of O<sub>2</sub> affinity for these O<sub>2</sub> carrying solutions may enable better tissue oxygenation with hemoglobinopathies such as sickle cell anemia. Endothelial interactions and binding of nitric oxide by free hemoglobin O<sub>2</sub> carrying solutions will be mitigated.

The indications for RBCs, platelets, FFP, and cryoprecipitate transfusions will become more individualized than the current numerical transfusion triggers. Evidence-based practices will minimize overtransfusion and identify a constellation of indications for red cell and component therapy. Monitoring of ischemia and quantification of the results of increased O<sub>2</sub> carriage will better indicate the circumstances in which red cell transfusion may be beneficial. The brain and heart, as organs at risk from acute lack of oxygen, will be targets for improved monitoring during trauma patient resuscitation.

## SUMMARY

The concept of a single transfusion “trigger” is flawed. Rather, comorbidities should be taken into consideration in erring on the side of Hct >28%. These comorbidities include cardiac risk (unstable angina, myocardial infarction), age >55, and the acuteness of ongoing hemorrhage and expectations for future blood loss. Blood loss in excess of one blood volume in six hours indicates a need to monitor Hb levels frequently. Clinicians should be aware that in 75% of patients receiving 20 units of blood, thrombocytopenia will occur; FFP may be needed should microvascular bleeding occur, or PT and PTT may need to be prolonged 1.5 times or more. Cryoprecipitate is indicated in trauma patients whose fibrinogen is decreased below 80 to 100 mg/dL with massive transfusion. Transfusion trends in many trauma centers have changed with much less O universal donor uncross-matched blood being administered, as well as less type-specific blood, indicating that clinicians have increased anemia tolerance in this patient population.

Noninfectious hazards of blood transfusion—including ABO/Rh incompatibility due to human error and TRALI that have become relatively more important complications of blood transfusion than infectious complications—have diminished in frequency (75–78). Errors occur in one out of 37,000 transfusions and cause 1 fatality/1.8 million transfusions (79–81). Generally, these noninfectious complications of transfusion are thought to be under-reported by 30%. It is estimated that circulatory overload may occur in 30,000 to 40,000 patients/yr (77). Base deficit, serum lactate, arterio-venous pH, and pCO<sub>2</sub> differences appear to be the

simplest and most practical measures for quantifying the shock state and blood loss in hemorrhaging trauma patients (26). Sublingual pCO<sub>2</sub> monitoring may be a useful real-time monitor to assess the progress of resuscitation from shock. Real-time identification of lack of DO<sub>2</sub> to the brain and heart needs more sophisticated monitors than are currently routinely in use (22). Blood collection of about 12.5 million units in 1997 was 12.6% lower/1000 population than in 1994, yet blood transfusion rates remain the same, raising concerns about progressive supply shortfalls (58). Tolerance for acute anemia is considerable in otherwise healthy individuals. Data from Jehovah’s Witness patients indicate that mortality rates are 20% when Hb is around 5 g/dL, increasing to 90% to 95% when the Hb falls below 3.5 g/dL. Brain oxygenation becomes critical in normo-volemic animals at 2.4 g/dL (109,126). Hemodiluted anesthetized human children at Hb of 2.1 g/dL showed evidence of myocardial ischemia (114). Critical DO<sub>2</sub> in anesthetized humans and animals varies between 330 mL/min/m<sup>2</sup> and 184 mL/min/m<sup>2</sup> (115–117).

Compensatory mechanisms to anemia include increased O<sub>2</sub> extraction (up to 70%), reduced O<sub>2</sub> affinity, increased cardiac output, and more O<sub>2</sub> dissolved in plasma with supplementary oxygen. Blood transfusion, although increasing O<sub>2</sub> carriage, does not necessarily increase tissue VO<sub>2</sub>. Particularly in sepsis, and maybe even in other shock states, O<sub>2</sub> extraction does not increase with increased hemoglobin (119–123,127). Red cell transfusion in critically ill patients with no cardiac or cerebrovascular disease, when hemoglobin is 7 g/dL or above, increases mortality and prolongs hospital stay (128–130). The therapeutic threshold for platelets is 50 × 10<sup>9</sup>/L for most elective surgical settings. For emergency surgery or for acutely traumatized patients with many potential bleeding sites, platelet counts of 100 × 10<sup>9</sup>/L or even higher may indicate the need for platelets when associated with clinically apparent microvascular bleeding. Dilutional thrombocytopenia is less common than may be suspected. In 75% of patients receiving more than 20 units of blood, platelet transfusion will be required. The usual platelet dose is one platelet concentrate/10 kg body weight. Thrombocytopenia may be prevented in massive transfusion by prostaglandin E<sub>1</sub> infusion. FFP is administered in a dose of 10 to 15 mL/kg for PT and PTT values more than 1.5 times the normal. One single-donor apheresis platelet, four to five

platelet concentrates, or one unit of whole blood provides one unit of FFP. Cryoprecipitate is indicated in massively transfused patients with fibrinogen concentrations of below 80 to 100 mg/dL or to correct microvascular bleeding. Factor VIIa appears to have a potential benefit for emergency use, in patients bleeding uncontrollably.

## KEY POINTS

- ✦ The requirement for blood in military and disaster situations is largely determined by the number of injured that survive long enough to present for care.
- ✦ The concept of a single transfusion trigger is flawed. Comorbidities, especially cardiac, age, injury severity, and magnitude of hemorrhage should all be considered.
- ✦ One platelet concentrate increases the platelet count by 5 to  $10 \times 10^9/L$ . In vivo platelet activity is decreased 75% from collected activity. Transfused platelets have a half-life of about two days.
- ✦ Single-donor platelets have a lower rate of alloimmunization, transmitted infections, and transfusion reactions.
- ✦ Transfusion of greater than 20 units of blood will reduce platelets to less than  $50 \times 10^9/L$  in 75% of patients. The decision to transfuse platelets is usually based on evidence of microvascular bleeding or in a patient judged to be at high risk of bleeding, rather than on the level of the platelet count per se.
- ✦ In the setting of acute intracranial bleeding, platelet counts greater than  $100 \times 10^9/L$  should be maintained.
- ✦ An FFP dose of 10 to 15 mL/kg will usually increase plasma coagulation factor concentration by 30% (the minimum level required for hemostasis for most coagulation factors).
- ✦ One unit cryoprecipitate per 10 kg body weight increases fibrinogen 50 mg/dL in stable patients, and is indicated for massively bleeding or transfused patients with fibrinogen 80 to 100 mg/dL.
- ✦ Inadvertent transfusion of ABO incompatible blood and transfusion-associated acute lung injury (TRALI) are life-threatening, noninfectious hazards of blood transfusion.
- ✦ Noninfectious transfusion risk exceeds infectious hazard by 100- to 1000-fold.
- ✦ Transfusion-associated GVHD has high mortality (>90%), but is extremely rare; irradiating blood components can prevent this complication, but is not practical in the acute trauma setting.
- ✦ Blood transfusion does not reduce mortality in stable critically ill patients with Hb 8 to 10 g/dL (except for a subset with coronary artery disease).
- ✦ Blood collection in 1997 fell 12.6%, but the rate of transfusion remained the same as in 1994.
- ✦ In bleeding, otherwise healthy trauma patients, cardiovascular compensation may be adequate to a Hb as low as 5 g/dL. However, any further compensation is inadequate with mortality 50% to 95% at Hb <3.5 g/dL.

## Glucose and Insulin Management in Critical Care

Dieter Mesotten, Ilse Vanhorebeek, and Greet Van den Berghe

Department of Intensive Care Medicine, University Hospital Gasthuisberg, Catholic University of Leuven, Leuven, Belgium

### INTRODUCTION

The discovery of insulin by Banting and Best in 1922 was a revolutionary breakthrough in the treatment and outcome of patients with Type 1 diabetes mellitus, a previously lethal disorder due to the development of ketoacidosis. In the late 19th century, Claude Bernard described the association of acute trauma with the occurrence of hyperglycemia, which was considered to be an adaptive stress response proceeding irrespective of underlying diabetes. In addition to trauma, hyperglycemia also commonly develops during other types of critical illness. Whereas hyperglycemia in critical illness was treated conventionally only when blood glucose levels became excessively elevated, the beneficial effects of treating even moderate hyperglycemia in critically ill patients have recently been established (1).

### ALTERED GLUCOSE REGULATION IN TRAUMA AND CRITICAL ILLNESS

The concept “stress diabetes” or “diabetes of injury” has been in the literature for almost 150 years. ⚡ **The stress-induced hyperglycemia, seen following severe trauma, burns and critical illness results from the combined action of hormonal, cytokine, and nervous “counter-regulatory” signals on glucose metabolic pathways.** ⚡ In the acute stage of the disease, both hepatic gluconeogenesis and glycogenolysis are enhanced in the critically ill patient. Hepatic gluconeogenesis is assumed to be upregulated by increased levels of glucagon (2), cortisol (3), and growth hormone. Hepatic glycogenolysis is stimulated by the catecholamines epinephrine and norepinephrine, which are released in response to acute injury (4). In addition, both these hyperglycemic responses may be enhanced directly or indirectly by the cytokines interleukin-1, interleukin-6, and tumor necrosis factor (5–7). The evolution of intensive care medicine during the last three to four decades has fostered a dramatic increase in the survival of patients under conditions of multiple trauma, extensive burns, and severe sepsis, among others. Hence, patients now frequently enter a chronic phase of critical illness (8). How maintenance of hyperglycemia is regulated during protracted critical illness remains less clear. In comparison to the acute phase, growth

hormone, cortisol, catecholamine, and cytokine levels are usually decreased in the more chronic phase of critical illness, but the changes in glucagon levels are not well documented (9,10). In addition to the increased synthesis of glucose, its uptake mechanisms are also affected during critical illness. In the first place, the immobilization of the patient leads to complete loss of the important exercise-stimulated glucose uptake in skeletal muscle. In addition, the insulin-stimulated glucose uptake by glucose transporter-4 (GLUT-4) as well as glycogen synthase activity are inhibited, together compromising the insulin-stimulated glucose uptake (11,12). Conflicting data have been reported on glucose oxidation through pyruvate produced in the glycolytic pathway, with some studies showing decreased oxidation rates (13), whereas the opposite effect was found by others (14). However, the decrease in insulin-stimulated glucose uptake in skeletal muscle and adipose tissue is completely offset by a massive increase in total body glucose uptake, of which the mononuclear phagocyte system in liver, spleen, and ileum is the main receiver (15). The overall increased peripheral glucose uptake (16) in light of hyperglycemia only underscores the pivotal role of increased hepatic glucose production during critical illness, which cannot be suppressed by exogenous glucose (17). Under normal circumstances, hepatic synthesis of glucose by gluconeogenesis and glycogenolysis is inhibited by insulin. ⚡ **The combined picture of increased serum insulin levels, impaired peripheral glucose uptake, and elevated hepatic glucose production indicates the development of insulin resistance during critical illness (18).** ⚡

### HISTORICAL RATIONALE FOR HYPERGLYCEMIC INTENSIVE CARE UNIT MANAGEMENT

In normal individuals, blood glucose levels are tightly regulated within the narrow range of 60–140 mg/dL (3.3–7.7 mmol/L) both in fed and fasted states. According to the definition given by the World Health Organization, fasting and fed blood glucose levels rise to, respectively, 110 mg/dL (6.1 mmol/L) or higher and 147 mg/dL (8.1 mmol/L) or higher in patients with diabetic hyperglycemia. The reported prevalence of hyperglycemia in

critically ill patients ranges from 3% to 71% (19). This large variation results from the divergent diagnostic criteria to define hyperglycemia in critically ill patients, in contrast to the clear guidelines set for diabetes mellitus. Until recently, it was considered state of the art to tolerate blood glucose levels up to 220 mg/dL (12 mmol/L) in fed critically ill patients (20), and treatment of hyperglycemia was only initiated when glucose levels exceeded this value. The primary motivation for this treatment was the occurrence of hyperglycemia-induced osmotic diuresis and fluid shifts, once glycemia exceeds that threshold. Secondly, it was known that uncontrolled and pronounced hyperglycemia predisposes to infectious complications, as shown by data regarding diabetic hyperglycemia (21,22). A third argument for tolerating glucose levels up to 220 mg/dL (12 mmol/L) was found in the commonly accepted view that moderate hyperglycemia in critically ill patients is “beneficial” for organs such as the brain and the blood cells that largely rely on glucose for their energy supply but do not require insulin for glucose uptake. Finally, many clinicians feared that tight glucose management might occasionally cause hypoglycemia and brain injury; moderate hyperglycemia was viewed as a buffer against this occurrence.

### STRICT MAINTENANCE OF NORMOGLYCEMIA DEMONSTRATED TO IMPROVE OUTCOME IN CRITICALLY ILL PATIENTS

Recently, the classical dogma that stress-induced hyperglycemia is beneficial to the critically ill patient has been challenged by an extended prospective, randomized, controlled clinical trial, studying the effects of strict glycemic control on mortality and morbidity of these patients (1). A total of 1548 mechanically ventilated patients who were admitted to the ICU, predominantly after extensive or complicated surgery or trauma, were enrolled in the study and randomly subdivided into two groups. In the intensive insulin therapy, group blood glucose levels were kept tightly between 80–110 mg/dL (4.4–6.1 mmol/L) by exogenous insulin infusion, while in the conventional treatment group insulin was only administered if blood glucose levels exceeded 220 mg/dL (12 mmol/L). **Strict maintenance of normoglycemia by intensive insulin therapy markedly reduced intensive care mortality of critically ill patients (Fig. 1), particularly in the patient population with prolonged critical illness where mortality was reduced from 20.2% to 10.6% ( $P = 0.005$ ).** The superiority of intensive insulin therapy was also demonstrated by the higher mortality even of patients with only moderate hyperglycemia of 110–150 mg/dL (6.1–8.3 mmol/L) in the conventional treatment group, compared to the patients receiving the intensive insulin therapy and having blood glucose levels below 110 mg/dL (6.1 mmol/L) (23). The extreme importance of this observation is illustrated by the lack of any intervention with such a pronounced beneficial effect on intensive care mortality since the introduction of mechanical ventilation. Intensive insulin therapy also improved several morbidity-related factors, including a reduction in the need for prolonged ventilatory support, the duration of intensive care stay, and the number of blood transfusions. In addition, a lower incidence of blood stream infections, extreme inflammation and, even more strikingly, of acute renal failure and critical illness polyneuropathy was observed. Insulin therapy also protected the central and peripheral nervous

**Figure 1** Kaplan–Meier cumulative survival plots for intensive care and in-hospital survival, showing the effect of intensive insulin treatment in a study of 1548 critically ill patients. Patients discharged alive from intensive care (*left panel*) and hospital (*right panel*), respectively, were considered survivors.  $P$ -values were obtained by log rank (Mantel-Cox) significance testing. The difference between the intensive insulin group and the conventional group was significant for intensive care survival (unadjusted  $P = 0.005$ ; adjusted  $P < 0.04$ ) and for hospital survival (unadjusted  $P = 0.01$ ). *Source:* Reproduced, From Ref. 1.

system from secondary insults and improved long-term rehabilitation of patients with isolated brain injury (24). Importantly, in a large randomized controlled trial, the Leuven protocol of glycemetic control in a predominantly surgical patient population (1) was recently proven to be similarly effective in a strictly medical ICU patient population (25).

In the intention-to-treat population of 1200 patients, in-hospital mortality was reduced from 40.0% to 37.3%. The difference did not reach statistical significance, but this was not surprising as the study was not powered for this mortality endpoint. However, in the target group of long-stay patients needing at least a third day of intensive care, for which the study had been powered based on the results of the surgical study, tight glycemetic control with insulin significantly reduced in-hospital mortality from 52.5% to 43.0%. Morbidity was significantly reduced in the intention-to-treat group of patients receiving intensive insulin therapy. New development of kidney injury occurred less frequently, the therapy allowed earlier weaning from mechanical ventilation and earlier discharge from the ICU and from the hospital, and the patients less frequently developed hyperbilirubinemia. The reduction in morbidity was even more striking in the target group of patients remaining in ICU for at least a third day. These patients were discharged from the hospital on average 10 days earlier than on conventional insulin therapy. In contrast to the surgical patients, there was no difference in bacteremia or prolonged antibiotic therapy requirement, but the number of long-stay patients with hyperinflammation was also reduced.

An earlier observational study also largely confirmed the clinical benefits of the surgical ICU trial (1) in “real life” intensive care of a heterogeneous medical/surgical population with glucose levels targeted below 7.8 mmol/L with insulin (26). A small prospective, randomized, controlled trial that aimed to control glucose levels below 120 mg/dL (6.7 mmol/L) showed a decreased

incidence of nosocomial infections in a predominantly general surgical ICU patient population (27).

### **SPECIFIC MORBIDITIES ASSOCIATED WITH HYPERGLYCEMIA**

#### **Diabetic Patients Have Improved Outcomes with Tight Glycemic Control**

The question whether tight glycemic control is beneficial for subjects with Type 1 diabetes was the subject of vigorous debate until this issue was resolved in 1993 by the results of the diabetes control and complications trial (DCCT). The study demonstrated a highly significant decrease not only of the progression rates of diabetic retinopathy, the most prevalent complication in Type 1 diabetes, but also of the development of nephropathy and peripheral and autonomic neuropathy (28). Like for Type 1 diabetes, evidence for the importance of tight glycemic control in patients with Type 2 diabetes was provided by a large clinical trial. In the late 1990s, the United Kingdom Prospective Diabetes Study (UKPDS) showed that a 0.7% decrease in glycated hemoglobin (HbA1c) lowered the incidence of retinopathy by 21%, microalbuminuria by 33%, cataracts by 24%, myocardial infarction by 16%, and resulted in a nonsignificant 5% decrease in the incidence of cerebrovascular accident (29). In addition, a tendency toward a lower death-rate was observed when blood glucose levels were tightly controlled. However, neither the UKPDS nor the DCCT was appropriately powered to detect a significant decrease in diabetes-related mortality.

A history of diabetes strongly increases the risk for fatal outcome following acute myocardial infarction (AMI). More specifically, the risk of mortality is 1.5 to two times higher in this patient group than in nondiabetic patients (30). Moreover, in AMI patients without previously diagnosed diabetes, hyperglycemia on admission has been associated with larger infarct size, a higher incidence of cardiac failure, and decreased one-year survival (31). These findings suggested that strict glycemic control might improve the prognosis for diabetic patients with myocardial infarction. This has been investigated by a number of studies, of which the Diabetes and Insulin-Glucose infusion in Acute Myocardial Infarction (DIGAMI) Study was the largest and also covered the longest follow-up period (32). In that study, diabetic patients admitted to the hospital with an AMI were randomly assigned to standard treatment (at the physician's discretion), or to "intensive insulin therapy." The latter comprised an infusion of glucose and insulin, started as soon as possible and continued for 48 hours. Thereafter, the intensive insulin therapy patients were submitted to a "stricter" blood glucose control regimen (below 215 mg/dL [12 mmol/L]) with subcutaneous insulin continued for at least three months after discharge. Thirty day and long-term survival significantly improved under the intensive insulin treatment (29% relative risk reduction at one year) (33,34) and also, the risk for re-infarction and new cardiac failure was remarkably reduced (35). An observational study of patients with diabetes undergoing cardiac surgery showed that elimination of hyperglycemia with intravenous insulin infusion lowered in-hospital mortality compared to the historical control group and reduced the occurrence of deep sternal wound infections and length of hospital stay (36).

A significant correlation between on-admission hyperglycemia and adverse outcome has also been demonstrated for other clinical conditions. Thus, high blood glucose

levels were associated with increased mortality and poorer neurological recovery after cerebrovascular ischemic insults (37,38). Similarly, hyperglycemia predicted increased morbidity and mortality after severe brain injury (39,40), trauma (41,42), and severe burn injury (43), as well as in critically ill children with widely varying pathology (44). Retrospective analysis of a heterogeneous population of critically ill patients revealed that even a modest degree of hyperglycemia was associated with substantially increased hospital mortality (45).

Although data from different studies appear controversial, administration of insulin in a glucose-insulin-potassium (GIK) regimen has shown to improve myocardial function and to protect the myocardium during AMI, open heart surgery, endotoxic shock, and other critical conditions (46,47). Lack of glucose control might explain the controversy surrounding GIK using different protocols (48–50). Indeed, direct anti-apoptotic properties of insulin, independent of glucose uptake and involving insulin signalling, have been shown to play a role in the cardio-protective action of insulin (46,51,52), but such effects may be counteracted by elevated levels of blood glucose (46). This is in line with the lack of tight glucose control and the disappointing results of the recent DIGAMI-2 trial in patients with diabetes and AMI (48), and the large randomized CREATE-ECLA trial on GIK infusion in patients with AMI (49). These studies failed to show an effect of this intervention on survival, cardiac arrest, and cardiogenic shock. Likewise, GIK infusion for 24 hours after acute stroke failed to realize a significant reduction in glycemia or mortality, as examined in the glucose-insulin in stroke trial (GIST) (53).

#### **Critical Illness—Associated Renal Failure: Role of Hyperglycemia**

The pathophysiology of diabetic and critical illness-associated nephropathy is presumably different. While in diabetic nephropathy the glomerulus is mainly affected, in the critically ill renal failure mostly results from acute tubular necrosis. Taking measures to prevent deterioration of renal function in critically ill patients is of crucial importance. This is illustrated by the lack of any therapeutic option besides bridging time to spontaneous recovery by extracorporeal hemofiltration or dialysis, with the continuous veno-venous mode being the preferred method for unstable critically ill patients (54). These preventive strategies include maintaining or optimizing renal perfusion, diligence with monitoring of nephrotoxic therapies such as aminoglycosides, and limiting the use of nonionic radiocontrast materials. Intensive insulin therapy has emerged as a specific preventive measure for acute renal failure in critical illness, with the demonstration of a 42% reduction in the number of patients that required extracorporeal replacement therapy to compensate for loss of renal function (1).

#### **Critical Illness—Associated Neuropathy: Role of Hyperglycemia**

In the diabetic patient, distal sensory neuropathy with the classic stocking distribution is the most frequent presentation of neuropathies (55). Protracted critically ill patients often suffer from a diffuse axonal polyneuropathy (56), which presents as a tetraparesis with muscle atrophy, but requires confirmation by electromyography (EMG). Although the course of critical illness neuropathy usually is self-limited and a good recovery should be expected once the underlying critical illness is overcome, it severely

delays weaning from the ventilator and mobilization of the patient (57). Several factors, including sepsis, the use of high dose corticosteroids, and the use of neuromuscular blocking agents, have been implicated in the etiology of critical illness polyneuropathy (see Volume 2, Chapter 6). However, the exact pathogenesis of critical illness polyneuropathy is still not understood (58). This lack of knowledge for a long time hampered specific prevention of, or treatment for, this complication.

However, **strong indications recently became available that underscore the importance of blood glucose levels in relation to the development of critical illness polyneuropathy.** In that regard, Bolton described a strong link between, on one hand, the risk of critical illness polyneuropathy and, on the other hand, increased blood glucose and decreased serum albumin levels, which are both metabolic manifestations of multiple organ failure and sepsis. Sepsis, and the accompanying release of cytokines, was considered to be the causal factor (59). Cytokines may indeed induce microangiopathy, which may play a role, as in diabetic polyneuropathy. In addition, the Leuven study on intensive insulin therapy in the ICU convincingly demonstrated that strict glycemic control with insulin infusion has an important preventive effect on the occurrence of critical illness polyneuropathy, which was associated with a decrease in duration of mechanical ventilation of protracted critically ill patients (1).

### Infectious Disease/Immune System Impairment by Hyperglycemia

It has long been known that hyperglycemia of diabetes predisposes to infection (21). Several mechanisms could account for this phenomenon. **Hyperglycemia inhibits the release of interleukin-1 by macrophages and oxygen radicals by neutrophils (60). In addition, phagocytosis by macrophages is impaired under hyperglycemic conditions (61,62).** Importantly, tight glycemic control was able to ameliorate the leukocyte oxidative burst and phagocytotic activity (63,64). In diabetic critically ill patients, such as those after open-heart surgery, an association between higher risk of infectious complications (65), and blood glucose levels higher than 200 mg/dL (11 mmol/L) has been documented. A follow-up study demonstrated that continuous intravenous insulin infusion reduced the incidence of postcardiac surgery deep sternal wounds (0.8% vs. 2% for subcutaneous insulin injections) (66). Also in patients with severe burn injuries, failure of skin graft take and outcome seemed to be related to uncontrolled hyperglycemia (43). Again, the causal link between hyperglycemia and higher risk of serious infections, regardless of a previous history of diabetes, was provided only recently by the Leuven insulin in ICU study (1). Indeed, the incidence of bacteremia was reduced by almost 50% and sepsis-associated mortality was largely prevented when critically ill patients were intensively treated with exogenous insulin to maintain normoglycemia. Hence, these observations suggest that insulin-titrated blood glucose control enhances the immune system. Improved capacity to clear bacterial invaders was recently shown to mediate this benefit in a novel rabbit model of prolonged critical illness (67,68).

### Lipid Metabolism—Impairment by Critical Illness and Hyperglycemia

Parallel to what is observed in diabetic patients (69), lipid metabolism is severely disturbed during critical illness, in addition to the presence of abnormally high glucose levels

(70–72). The most characteristic abnormalities are elevated triglyceride levels, due to an increase in very-low-density lipoprotein (VLDL) and low circulating high-density lipoprotein (HDL) cholesterol (73). The levels of low-density lipoprotein (LDL) cholesterol are also decreased (73), but this is offset by an increase in circulating small dense LDL particles (74) that presumably are more proatherogenic than the medium and large LDL particles (75). **The derangement in serum lipid profiles seen during critical illness is partially counteracted by intensive insulin therapy; specifically, the hypertriglyceridemia is completely eliminated, and serum levels of HDL and LDL are substantially increased, though not fully normalized (76).** The role of triglycerides in energy provision and the coordinating position of the lipoproteins in transportation of lipid components (cholesterol, triglycerides, phospholipids, lipid-soluble vitamins) are well established (77). In addition, lipoproteins have recently been shown to possess endotoxin-scavenging potential, and in that way are able to prevent death in animal models (78,79). For that reason, intensive insulin therapy may improve the overall endotoxin scavenging function. Considering these data, intensive insulin therapy would be a more integrated approach to correct the abnormal serum lipid profile when compared to the proposed infusions of lipoproteins (73,80). This was indeed demonstrated by the multivariate logistic regression analysis in which the improvement of the deranged lipidemia explained a significant part of its beneficial effect on mortality and organ failure and, surprisingly, surpassed the effect of glycemic control and insulin dose. Likewise, the effect of intensive insulin therapy on inflammation, reflected by a lowering of the serum C-reactive protein (CRP) concentrations (81), was no longer independently related to the outcome benefit when the changes in lipid metabolism were taken into account. In that way, a link may be put forward between the anti-inflammatory effect of intensive insulin therapy and its amelioration of the lipid profile. However, a mechanistic explanation for the dominant effect of serum lipid correction still needs to be delineated.

### Inflammation, Endothelium, and Coagulation Effects of Critical Illness and Insulin

Critical illness also resembles diabetes mellitus in the activation of the inflammatory cascade. Here too, intensive insulin therapy has been proved beneficial, as it prevented excessive inflammation in critically ill patients subjected to this treatment (1,81), a finding that was confirmed in an experimental rabbit model of prolonged critical illness (68). **Although the anti-inflammatory effect of insulin has clearly been established, the exact underlying mechanisms have not yet elucidated been (82).** However, several factors can be considered, such as suppression of the secretion and antagonism of the harmful actions of tumor necrosis factor- $\alpha$  (83,84), macrophage migration-inhibitory factor (85), and superoxide (86).

As in patients with diabetes mellitus, endothelial dysfunction is present in critically ill patients (87–91). Importantly, maintaining normoglycemia with intensive insulin therapy protected the endothelium, likely in part via inhibition of excessive inducible nitric oxide synthase (iNOS)-induced nitric oxide release and hereby contributed to prevention of organ failure and death with this intervention (92).

Furthermore, diabetes mellitus and critical illness both are hyper-coagulable states (93,94). Putative causes in diabetes include vascular endothelium dysfunction (95),

increased blood levels of several clotting factors (96,97), elevated platelet activation (98,99), and inhibition of the fibrinolytic system (97). Levels of the anticoagulant protein C are also decreased (100). Considering the similarities with critical illness (101,102) and the powerful preventive effect of intensive insulin therapy on septicemia, multiple organ failure, and mortality (1), investigating the influence of this simple and cheap metabolic intervention on the balance between coagulation and fibrinolysis in the critically ill is strongly recommended.

### HYPER-, NORMO-, OR HYPOCALORIC NUTRITION?

When hypercaloric nutrition (35–40 kcal/kg) is administered to critically ill patients, this “hyperalimentation” leads to a higher incidence of infections and severe metabolic complications, ranging from hyperglycemia, hypertriglyceridemia, and azotemia to hepatic steatosis, fat-overload syndrome, and hypertonic dehydration (103,104). Nowadays, serious complications of feeding have been drastically reduced thanks to the introduction of more accurate means to estimate energy expenditure and a cautious approach toward obese or highly oedematous patients.

McCowen et al. (105) compared the efficacy of hypocaloric total parenteral nutrition (TPN) feeding (14 kcal/kg) with a standard weight-based regimen (18 kcal/kg) in relation to the occurrence of hyperglycemia or infections. Surprisingly, hypocaloric nutrition did not lower these parameters. In fact, caloric restriction only seems to be effective in conjunction with a hyperproteinic approach (about 1.8 g protein per kg ideal body weight (IBW), compared to 1.2 g/kg IBW) (106). Similar results were obtained with a hypocaloric parenteral regimen with 2 g protein/kg IBW in patients with morbid obesity (107). However, a clear-cut benefit of hypocaloric over normocaloric nutrition was not consistently present. This might be attributed to the ineffectiveness of hypocaloric nutrition to lower blood glucose levels.

In view of the described morbidities associated with hyperglycemia, the importance of glycemic control is becoming increasingly clear. As indicated, hypercaloric feeding in combination with insulin infusion (GIK) should simultaneously target normoglycemia, in order to result in clinical benefits for the patients (see section “Specific Morbidities associated with Hyperglycemia”).

Recently, interest in preoperative carbohydrate loading has been rekindled through the studies of Ljungqvist et al. which revealed that carbohydrate treatment instead of overnight fasting before surgery reduces postoperative insulin resistance and length of hospital stay (108).

### INTENSIVE INSULIN THERAPY METHOD: TARGET GLUCOSE <110 MG/DL FOR ALL CRITICALLY ILL PATIENTS

Since the effect of intensive insulin therapy on morbidity and mortality of critically ill patients was equally present among those with and without previously diagnosed diabetes (1), the authors believe that strict normoglycemia below 110 mg/dL (6.1 mmol/L) should be the therapeutic goal, irrespective of diabetic condition. ⚡ **The best way to achieve blood glucose control during intensive care is by continuous insulin infusion for both diabetic and nondiabetic**

**critically ill patients. In addition, oral antidiabetic agents should be discontinued during critical illness.** ⚡

Nutrition of critically ill patients, either with enteral nutrition, TPN or with a combination of parenteral and enteral feeding, is typically administered as a continuous process. Consequently, it is intuitive that insulin should be administered in a continuous way as well. In addition, intravenous administration is more reliable and consistent than subcutaneous injections. Titrating of a continuous insulin infusion is preferred to sliding scales as the former not only provides a baseline insulin level but also can be more easily and precisely titrated in response to the actual blood glucose levels. Because of its short intravenous half-life, insulin administration via infusion also allows rapid cessation of insulin action in case the patient develops hypoglycemia.

This risk of hypoglycemia is a major concern on intensive insulin therapy during critical illness. Clinical symptoms of the autonomic response (sweating, tachycardia, tremor) and central nervous symptoms like dizziness, blurred vision, altered mental acuity, confusion, and eventually convulsions may be masked by concomitant diseases and by inherent intensive care treatments such as sedation, analgesia, and mechanical ventilation. Severe (<30 mg/dL) (<1.67 mmol/L) or prolonged hypoglycemia can lead to irreversible brain damage. Another insidious complication of hypoglycemia is the induction of cardiac dysrhythmias ranging from abnormal QT-intervals (109) and sinus bradycardias (110) to ventricular tachycardias (111).

Measures taken to prevent hypoglycemia in the critically ill are the administration of insulin together with carbohydrates, either intravenous dextrose or tube feeds, and close monitoring of blood glucose levels. Specifically in the Leuven insulin in ICU study (1), blood glucose levels were measured every one or two hours during the first 12–24 hours after the patient’s admission to the ICU. Once the targeted blood glucose level was reached on a stable insulin dose, measurements were scaled down to every four hours. In case hypoglycemia did develop, this usually took place after the first week of ICU stay, at a time when blood glucose levels were stable. The precipitating factor of this complication was often found in inadequate insulin dose reduction during interruption of enteral feeding. Clearly, the hazard of hypoglycemia warrants a strict and detailed insulin titration protocol, combined with sufficient training of the nursing and medical staff.

### EYE TO THE FUTURE

Future studies will help elucidate whether the beneficial effects of intensive insulin therapy during critical illness (1) derive from the maintenance of normoglycemia or rather result directly from the insulin infusion itself. There are data supporting the notion that both effects provide benefit (23,112,113).

Insulin may have played a direct role in the functional improvement of the insulin-sensitive organs. In a normal individual, the heart and skeletal muscles are responsible for the majority of the insulin-stimulated glucose uptake. In addition, muscle catabolism is aggravated in hyperglycemic conditions. This could partially explain the beneficial effects of intensive insulin therapy on duration of mechanical ventilation of the critically ill patients in the

intensive insulin therapy trial. At the molecular level, the higher steady-state mRNA levels of GLUT-4 and hexokinase II (HXK-II) found in skeletal muscle after intensive insulin therapy suggests that peripheral glucose uptake is stimulated in these patients, in comparison to the conventional treatment group (76).

The liver, the major site for gluconeogenesis, is another important insulin-sensitive organ that could be involved in the improved outcome of the patients intensively treated with insulin. However, a recent study showed that serum and gene expression levels of insulin-like growth factor binding protein-1 (IGFBP-1) and gene expression levels of phosphoenolpyruvate carboxykinase (PEPCK), the rate-limiting enzyme in the gluconeogenesis, are not regulated by insulin in critically ill patients. This may indicate that controlling gluconeogenesis was not the major factor in the normalization of blood glucose levels with exogenous insulin in the critically ill (114), although true glucose kinetics can only be estimated by glucose turn-over studies.

Nevertheless, such a study, using a well-designed canine model of critical illness, recently endorsed our findings to a great extent (115). After induction of a sublethal hypermetabolic infection in the dogs, hepatic glucose uptake was decreased and unresponsive to insulin administration. In contrast, peripheral glucose uptake did respond to insulin infusion. Contrary to our findings, insulin therapy suppressed hepatic glucose production. This occurred apparently by inhibition of glycogenolysis rather than diminished hepatic uptake of gluconeogenic amino acids and gluconeogenesis. The lack of insulin responsiveness in liver suggests that beneficial effects of insulin therapy in the this organ are mediated by avoiding hyperglycemia. In this regard, we recently demonstrated a protective effect of intensive insulin therapy on hepatocytic mitochondria of critically ill patients, where no effect was seen on the mitochondrial compartment in skeletal muscle (116). The tissue-specific effect combined with different glucose uptake mechanisms in these tissues is consistent with the direct effect of avoiding glucose toxicity on the hepatocytic mitochondria rather than of insulin.

Another major insulin-responsive organ is the adipose tissue. The increased serum free fatty acid and triglyceride levels present during critical illness and the relative accretion of adipose tissue as compared with lean body mass (muscle and bone tissue) with feeding in the protracted critically ill patient both point to a deranged lipid metabolism. This imbalance in serum lipids was partially restored by intensive insulin therapy, which significantly contributed to the reduced ICU mortality. However, its direct effects on the adipocytes remain to be investigated (76).

On the other hand, Finney et al. (117) recently published results showing that increased insulin administration is positively associated with death in the ICU regardless of the prevailing blood glucose level. Although this was an observational study mainly confirming the association of insulin resistance and risk of death, the data are in line with the previous interpretation (23) that metabolic control, rather than the absolute amount of exogenous insulin, explains the mortality benefit associated with intensive insulin therapy demonstrated by others in a randomized study (1).

Intensive insulin therapy is beneficial to kidney function and also decreases the incidence of critical illness polyneuropathy. This may in part be explained by maintenance of normoglycemia, as both organs are supposedly, at least in part, insulin-insensitive. Here, although on a totally

different time scale, a parallel with Type 2 diabetes emerges. Long-term studies have indeed demonstrated that meticulous blood glucose control reduces the incidence and the severity of diabetic nephropathy—and the onset of diabetic neuropathy, and that “glucose-toxicity” may be the underlying mechanism. However, the rapid onset of critical illness polyneuropathy and of acute renal failure suggest that other factors, which predispose the critically ill to the toxic effects of hyperglycemia on neurons and kidneys, must play a role.

In a similar fashion, avoiding hyperglycemia may be important for prevention of bloodstream infections. The suppression of the immune system conceivably results in increased risk of postoperative infections, as discussed precedingly. However, the exact underlying mechanisms of the clinical benefits of intensive insulin therapy in critically ill patients remain incompletely understood at this stage (112,113).

Other areas of intensive insulin therapy that have been studied with direct relevance to the critically ill trauma patient are those who undergo cardiopulmonary bypass (CPB) for myocardial revascularization, as numerous stresses in trauma critical illness can lead to myocardial ischemia. It is already known that hyperglycemia is an independent risk factor for perioperative morbidity and mortality in both diabetic and nondiabetic patients undergoing CPB (118).

In a recent prospective trial, 280 nondiabetic adult patients undergoing first-time coronary artery bypass grafting at a single university hospital were randomized to receive GIK infusion or placebo (dextrose 5%) before, during, and for six hours after surgical intervention (119). The GIK group experienced higher cardiac indices ( $P < 0.001$ ) throughout infusion, but also a decreased systemic vascular resistance (thus, the effect on contractility is unclear). However, of particular note is that the incidence of low cardiac output episodes was 16% (22/138) in the GIK group and 28% (39/142) in the placebo group ( $P = 0.021$ ). Furthermore, inotropes were required in only 18.8% (26/138) of the GIK and 40.8% (58/142) of the placebo group ( $P < 0.001$ ). Of greatest interest to the general trauma critical care population, patients in the GIK group had approximately half the rate of significant perioperative myocardial injury (16/133) versus the placebo group (32/137) ( $P = 0.017$ ) (119).

Additional clinical and laboratory studies are required to explain the underlying molecular basis for these improved outcomes associated with aggressive insulin administration and tight blood glucose control. In addition, the benefit of aggressive insulin and tight glucose during the initial prehospital and resuscitation stages is yet to be determined.

Finally, finding the best method for maintaining tight glucose control while avoiding episodes of hypoglycemia remains an important goal. Ultimately, computerized algorithms will likely perform better than insulin sliding scales administered by the bedside nurse, who can be occupied with other important patient care duties (120).

## SUMMARY

In summary, hyperglycemia is a well-known accompaniment of trauma, burns, and critical illness resulting from the combined action of “counter-regulatory” hormones,

cytokines, and nervous signals on glucose metabolic pathways. In addition, insulin resistance develops during critical illness, and is manifested by increased serum insulin levels, impaired peripheral glucose uptake, and elevated hepatic glucose production (18).

Recently, Van den Berghe, et al. (1) demonstrated that strict maintenance of normoglycemia by intensive insulin therapy markedly reduces mortality of ICU patients, particularly those with prolonged critical illness (mortality was reduced by half). Furthermore, the intensive insulin therapy was protective against acute renal failure, with a 42% reduction in dialytic therapy for loss of renal function (1). They also documented a decrease in the development of critical illness polyneuropathy.

Hyperglycemia has also been shown to impair immunity, and is known to inhibit the release of interleukin-1 by macrophages and oxygen radicals by neutrophils (60), and to impair phagocytosis by the macrophages (61,62). Hyperglycemia is also associated with a deranged serum lipid profile of critically ill patients. This can be partially counteracted by intensive insulin therapy, totally eliminating hypertriglyceridemia and substantially increasing the serum levels of HDL and LDL (76). Insulin is also known to have an anti-inflammatory effect; however, the exact mechanism has yet to be elucidated (82).

The authors believe blood glucose should be tightly controlled between 80 and 110 mg/dL, by continuous insulin infusion for both diabetic and nondiabetic critically ill patients. Blood sugars should be measured every one hour until stable, then weaned to sampling every four hours. Although most agree that continuous insulin infusion is superior to intermittent subcutaneous dosing, the perfect method for titrating of the insulin therapy may involve computerized protocols (120). Ultimately, bedside testing coupled with servo-controlled insulin administration devices coordinated by computer derived protocols will likely be utilized in the near future.

Caution must be observed when infusing intravenous insulin to eliminate the possibility of hypoglycemic complications. In particular, insulin must be weaned down or off whenever discontinuing enteral nutrition or peripheral glucose-containing solutions. In addition, oral anti-diabetic agents should be discontinued during critical illness.

## KEY POINTS

- ✎ The stress-induced hyperglycemia, seen following severe trauma, burns, and critical illness results from the combined action of hormonal, cytokine, and nervous "counter-regulatory" signals on glucose metabolic pathways.
- ✎ The combined picture of increased serum insulin levels, impaired peripheral glucose uptake, and elevated hepatic glucose production indicates the development of insulin resistance during critical illness (18).
- ✎ Strict maintenance of normoglycemia by intensive insulin therapy markedly reduced intensive care mortality of critically ill patients (Fig. 1), particularly in the patient population with prolonged critical illness where mortality was reduced from 20.2% to 10.6% ( $P = 0.005$ ).
- ✎ Intensive insulin therapy has emerged as a specific preventive measure for acute renal failure in critical illness, with the demonstration of a 42% reduction in the number of patients that required extracorporeal

replacement therapy to compensate for loss of renal function (1).

- ✎ Strong indications recently became available that underscore the importance of blood glucose levels in relation to the development of critical illness polyneuropathy.
- ✎ Hyperglycemia inhibits the release of interleukin-1 by macrophages and oxygen radicals by neutrophils (60). In addition, phagocytosis by macrophages is impaired under hyperglycaemic conditions (61,62).
- ✎ The derangement in serum lipid profiles seen during critical illness is partially counteracted by intensive insulin therapy; specifically, hypertriglyceridemia is completely eliminated, and serum levels of HDL and LDL are substantially increased, though not fully normalized (76).
- ✎ Although the anti-inflammatory effect of insulin has clearly been established, the exact underlying mechanisms have not yet been elucidated (82).
- ✎ The best way to achieve blood glucose control for both diabetic and nondiabetic critically ill patients. during intensive care is by continuous insulin infusion. In addition, oral anti-diabetic agents should be discontinued during critical illness.

### INTRODUCTION

Most patients in intensive care units (ICU) with thyroid or parathyroid disorders do not have an endocrine abnormality as their primary problem. Indeed, most endocrine hormonal derangements observed in the ICU may be attributed to primary, nonendocrine illness(es) that promote a secondary adaptation in hormonal levels. The converse is also true; primary endocrine problems modulate a patient's response to nonendocrine illness. Trauma, in particular, is a global disorder, and the clinical course of individuals recovering from trauma is directly related to their pretraumatic state. Because the endocrine system plays such an important role in a patient's premonitory homeostasis, endocrine dysfunction places the trauma victim at greater risk for morbidity and mortality.

Usually the status of the endocrine system is assessed by measurement of hormone levels. In critical illness, however, these levels are frequently deranged as the endocrine system undergoes an adaptive response to reestablish homeostasis. Thus, a primary objective of this chapter is to provide guidance for determining whether abnormal thyroid or parathyroid hormone levels occur as a result of primary endocrine disorders or due to adaptive responses of the endocrine system to nonendocrine illness.

The endocrine system is made up of glands that produce and secrete hormones, which are transported by the bloodstream to act on specific target organs. These hormones are usually measured while in transit in the systemic circulation, where their levels are influenced, and are indicative of disordered physiological states. Serum levels of these hormones can be used for diagnosing both endocrine and nonendocrine illness. Either administration or blockade of these hormones may be used for therapeutic purposes. The thyroid and the parathyroid glands are representative of the endocrine system insofar as their hormone products have been used for both diagnosis and therapy. This chapter will first address problems related to thyroid dysfunction in the ICU (Section II) and then review the clinical manifestations of parathyroid dysfunction in critically ill patients (Section III). Future directions in the diagnosis and treatment of thyroid and parathyroid disorders are discussed in Section IV. Key points and important concepts presented in this chapter are summarized in Section V.

### THYROID DYSFUNCTION IN THE ICU

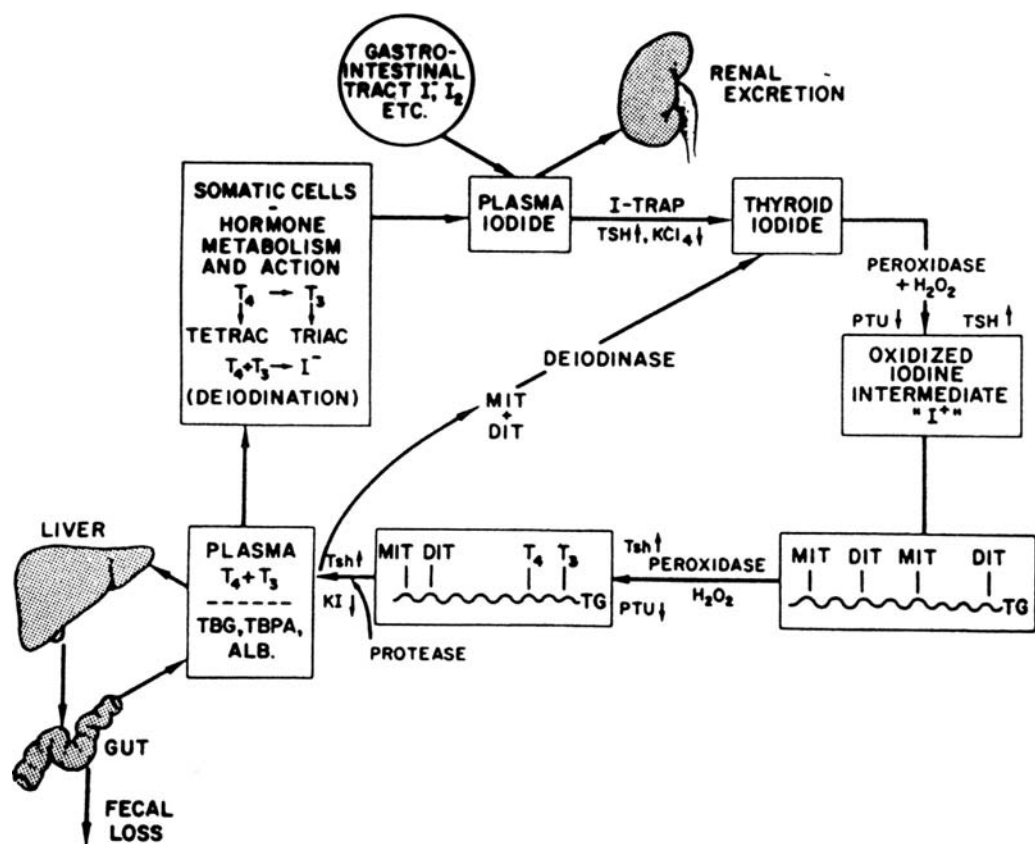

Thyroid disorders in critically ill patients may present as "euthyroid sick syndrome," as myxedema in patients with pre-existing hypothyroidism, or as thyrotoxicosis in patients with pre-existing hyperthyroid states. The signs and symptoms of all three conditions are easy to confuse with the signs of other systemic illnesses. Thus, it is important to ascertain each patient's premonitory thyroid state and to understand the perturbations that the thyroid axis causes to patients with severe illness, if these thyroid disorders are going to be properly diagnosed and managed.

### Anatomy and Physiology of the Thyroid Gland

#### Anatomy

The thyroid gland is a 15 to 20 gm, bilobed gland that lies directly anterior to the tracheal rings and cephalad to the thyroid cartilage. This position has clinical relevance insofar as thyroid enlargement may cause embarrassment to the aerodigestive tract and block emergent access to the trachea. The blood supply to the thyroid is abundant with paired inferior thyroid arteries, paired upper thyroid arteries, and occasionally a central thyroidea in an artery. The vascularity of the gland, plus its location adjacent to the parathyroid glands and next to the paired recurrent laryngeal nerves and paired superior laryngeal nerves (nerves of Galli-Curci), make surgical approaches to the gland challenging. The thyroid parenchyma is comprised mainly of follicular cells, which are arranged in acini and are responsible for the secretion of thyroid hormone. The less abundant parafollicular cells (C cells) are neuroendocrine cells, which are part of the APUD system (amine containing, precursor uptake, and decarboxylase). These cells secrete calcitonin (1), whose precursor molecule, procalcitonin, has recently been recognized as an important marker for a number of inflammatory states, often seen in critically ill patients (e.g., sepsis (1), pancreatitis (2), pneumonitis (3), smoke inhalation (4), and heat stroke (5)).

The production, storage, and secretion of thyroid hormone (Fig. 1) are the most important functions of the thyroid gland (the designation of thyroid hormone in this section will refer to thyroxine and triiodothyronine rather than calcitonin). This is accomplished by concentrating

**Figure 1** A diagram detailing the iodine cycle. Iodine from the gastrointestinal tract is trapped in the thyroid where it is bound to tyrosine to form either monoiodothyrosine (MIT) or diiodothyrosine (DIT). MIT and DIT are then coupled to form triiodothyronine (T3) or thyroxine (T4). Some T4 is deiodinated outside of the gland to form T3, the more active hormone. After T3 and T4 are utilized, they are deiodinated and the iodine is returned to the plasma where it is recycled.

plasma iodide in the gland via a specific and rate-limiting, ATP-dependent, sodium-iodide symporter protein, which can also transport monovalent anions and chemicals such as lithium. Following transport, the iodine is stored in thyroglobulin. Organification, performed by the enzyme thyroid peroxidase, occurs by iodinating tyrosine molecules to make monoiodotyrosine (MIT) and diiodotyrosine (DIT), and then combining these molecules to make the physiologically active hormones, triiodothyronine (T3), and thyroxine (T4). This entire process is stimulated by the pituitary peptide, thyrotropin, or thyroid-stimulating hormone (TSH). The hormonally active T3 and T4 are stored in the thyroid gland, bound to thyroglobulin and, in this state, form intrafollicular colloid. **Thyroxine, the prohormone, is the predominately released species upon TSH stimulation; most of the triiodothyronine, the bioactive hormone, is produced by extrathyroidal conversion.** The thyroid stores an enormous amount of thyroid hormone in colloid and can maintain a euthyroid state for several months without synthesis.

The mechanisms and regulations of thyroid secretion are complex, with the cerebral cortex stimulating thyrotropin-releasing hormone (TRH) from the hypothalamus, which in turn stimulates TSH release from the anterior pituitary. The feedback loops are both positive and negative, resulting in a very carefully regulated secretion of thyroid hormone from the thyroid gland (Fig. 2). The levels of iodide in the blood also influence the production of thyroid hormone; an important fact to keep in mind in

critically ill patients who may be administered medications high in iodine (e.g., amiodarone).

**Figure 2** The mechanism of thyroid hormone regulation. The unbound fraction of thyroxine (T4) in the blood influences the secretion of thyroid stimulating hormone from the pituitary using a negative feedback mechanism. Although the control of thyroid releasing hormone secretion from the hypothalamus is unknown, it may also be subject to the same negative feedback mechanism by unbound T4 levels.

**Metabolic Effects**

The metabolic effects of thyroid hormone are considerable and affect most tissues in the body. In general, thyroid hormone promotes growth and maturation by increasing protein turnover, oxygen consumption, heat production, and oxidative phosphorylation. These anabolic functions, however, are of secondary importance during stress when most bodily functions are focused on responding to injury-related problems such as inflammation, hypotension, or shock. For this reason, the decreased level of thyroid hormone during stress may be a teleologically programmed adaptive response. ⚡ **Levels of thyroid hormone should not necessarily be normalized during critical illness.** ⚡

**Pharmacology**

Medications commonly used to treat hyperthyroidism block the synthesis of thyroid hormone, its release from the thyroid, or its peripheral conversion. Other medications used for hyperthyroidism treat the symptoms (Table 1).

As noted above, iodide (and its oxidized form iodine) influence the production of thyroid hormone. Small amounts increase the production of hormone while larger, pharmacological doses (e.g., potassium iodide or Lugol’s solution) decrease the release of active hormone from the thyroid gland and can be used to treat thyrotoxicosis. ⚡ **This biphasic response to iodide is important insofar as iodide administration can precipitate either hyperthyroidism or hypothyroidism.** ⚡

There are multiple antithyroid medications. Potassium perchlorate interferes with the uptake of iodine by the thyroid, although it is used less often than the thionamides due to its unacceptable side effects. The thionamide derivatives propylthiouracil (PTU) and methyl-mercaptoimidazole (MMI) prevent oxidation of iodide to iodine and block the synthesis of the hormone. PTU also interferes with the peripheral conversion of T4 to T3, an important distinction between the two drugs. Lithium carbonate is a second-line antithyroid drug that decreases thyroidal secretion. Although lithium is not often used therapeutically for hyperthyroidism, its effect on thyroid hormone should be kept in mind when it is being used for nonthyroidal illnesses (discussed below). Beta-adrenergic blockers (e.g.,

propranolol) and, less commonly, alpha-adrenergic blockers (e.g., reserpine) are used to control the symptoms of thyrotoxicosis while waiting for other drugs to decrease hormone levels or for rapid control of symptoms prior to surgery.

**Studies of Thyroid Function**

**Thyroid Function Tests**

Thyroid function tests measure serum levels of T4, T3, and TSH (Table 2). As previously mentioned, T4 is considered a prohormone of T3. Although it is less potent, there is usually more T4 than T3 present. There are important circulating thyroid binding proteins, which can alter the measured total T4 or T3 levels. ⚡ **Many problems seen in the ICU cause either increased or decreased binding of thyroid hormone to its binding proteins, which may make the total hormone levels abnormal while the free, active hormone levels are normal or vice versa.** ⚡ Most laboratories now use two-step analog methods to establish the free (unbound) and hormonally active fraction of T4, thereby avoiding but not eliminating prior methods of protein binding. The more accurate equilibrium dialysis method of measuring the free T4 is cumbersome but more precise (6).

Due to the negative feedback by T4 on TSH, measurements of TSH have become the most useful tests in diagnosing hyper- and hypo-thyroid states as well as determining whether T4 administration is sufficient for suppression. Two-site noncompetitive immunometric monoclonal assays for TSH have now reached third-generation capability; i.e., the functional sensitivity is 0.01–0.02 μU/mL which can reliably separate euthyroid conditions from hyperthyroidism and subclinical hyperthyroidism, as well as nonthyroidal illness (NTI). This refinement in TSH measurement has resulted in this test becoming the initial and often the sole test to evaluate all thyroid abnormalities. Note, however, that the TSH test is not accurate in patients with pituitary insufficiency, due to either the pituitary pathology or the concurrent use of dopamine, dobutamine, or glucocorticoids.

**Table 1** Drugs Used to Treat Hyperthyroidism and the Steps Blocked

Step blocked	TH synthesis	Thyroid secretion	Peripheral conversion of T4 to T3	Symptoms
Drugs used (dose, route, interval)	PTU <sup>a</sup> (100–150 mg, po, tid, acutely) MMI <sup>b</sup> (10–15 mg/day, po, tid, acutely) Potassium perchlorate (0.6–1 g, po, qd)	Iodides <sup>c</sup> (5 drops Lugols, po, qd) Iodate sodium (0.5 g, po, qd) Lithium (300 mg, po, tid) Corticosteroids (see next column)	PTU <sup>a</sup> (100–300 mg, po, tid) Beta blockers (see next column) Iodate sodium (0.5 g, po, qd) Lithium (300 mg, po, tid) Corticosteroids (see next column)	Beta-blockers (e.g., propranolol, 10–80 mg, po qid or 1–2 mg, q15 min, iv) Alpha-blockers (e.g., reserpine or guanethidine for gradual control) Corticosteroids (e.g., hydrocortisone, 100–500 mg, iv, bid)

<sup>a</sup>100–200 mg/day for maintenance.

<sup>b</sup>5–15 mg/day for maintenance.

<sup>c</sup>In thyroid storm a loading dose of PTU or MMI should be given before iodides are started.

Abbreviations: PTU, polythiouracil; MMI, mercapto-imidazole; po, by mouth; qd, once a day; tid, three times a day; qid, four times a day.

**Table 2** Thyroid Assays

Peptide measured	Range of normal values conventional (SI units)	Assay, limitations
Total T4 (bound and free T4)	4.5–12.5 µg/dL (58–161 nmol/L)	RIA, hemolysis may cause a false decrease
Total T3	80–220 ng/dL (1.23–3.39 nmol/L)	RIA, no interference
Free T4	0.7–1.5 ng/dL (9.0–19.4 pmol/L)	Labeled antibody immunoassays (TS and AM). TS is comparable to ED, while AM often disagrees with ED in acute illness and other conditions, including NTI
Free T3	230–420 pg/dL (3.5–6.5 pmol/L)	RIA, heparin causes false low values
Reverse T3	80–350 ng/L (123–539 pmol/L)	RIA, no interference
TSH	0.3–5.0 µIU/mL (0.3–5.0 mIU/L)	The second-generation assay detects levels as low as 0.1–0.5 µIU/mL, so the range of subnormal values is limited. The third-generation assay measures levels as low as 0.01–0.05 µIU/mL which is more reliable for hyperthyroid states

Abbreviations: RIA, radioimmunoassay; TS, two-step; AM, analog method; ED, equilibrium dialysis; NTI, nonthyroidal illness.

### Radioiodine

Radioactive isotopes ( $I^{131}$ ,  $I^{123}$ , technetium<sup>99</sup>) given orally or intravenously are concentrated in the thyroid and read by a gamma camera. Small amounts of these radioisotopes are used as tests to assess the function of the gland or localize ectopic thyroid tissue (e.g., thyroid cancer metastases), while administration of higher amounts of radioactivity can be used to ablate thyroid tissue. Although this is not a modality commonly used in the ICUs, patients who have been treated with radioactive iodine should be evaluated carefully for hypothyroidism.

### Drugs that Interfere with Thyroid Studies

Patients in intensive care units often receive multiple medications. These medications may interfere with thyroid function itself, measurement of thyroid hormone, peripheral conversion of T4 to T3, or measurement of TSH. Drugs commonly used in the ICU that affect thyroid hormone status are shown on Table 3. In addition, phenytoin and carbamazepine both increase T4 metabolism and decrease T4 binding. Certain nonsteroidal anti-inflammatory drugs (and aspirin) displace T4 from binding proteins. Furosemide, at high doses used in renal insufficiency, lowers T4 levels. Several medications, such as dobutamine, dopamine, and glucocorticoids, decrease TSH levels, whereas propranolol and other  $\beta$ -blockers decrease the peripheral conversion of T4 to T3 (and are therapeutically useful in managing thyroid storm). These many drug interactions must be kept in mind when interpreting thyroid function tests in critically ill patients. Other commonly used medications, which affect thyroid function, are listed on Table 3.

**Table 3** Effects of Drugs on Thyroid Function

Inhibit thyroid function	Increase binding protein	Decrease binding protein	Inhibit T4 to T3 conversion	Decrease TSH	Increase TSH
Iodine Sulfonylureas Interleukin-2	Lithium Estrogens Clofibrate Opiates 5-fluorouracil	Androgens Glucocorticoids Danazol L-asparaginase Salicylates	Glucocorticoids Ipodate Propranolol Amiodarone Propylthiouracil	Glucocorticoids Dopamine agonists Dobutamine Somatostatin	Iodine Lithium Dopamine agonists Cimetidine

Abbreviation: TSH, thyroid-stimulating hormone.

### Hypothyroid Disorders in Critically Ill Patients

Hypothyroidism is clinically expressed as lack of energy, intolerance to cold, weight gain, lethargy, dry skin, and prolongation of the relaxation phase of deep tendon reflexes (Table 4). When these symptoms are present and TSH levels are elevated (i.e.,  $>20 \mu\text{U/mL}$ ), the diagnosis is easy to make. When subclinical hypothyroidism exists, there are scant signs and symptoms, the free T4 level is normal, and the TSH is mildly elevated but usually less than  $20 \mu\text{U/mL}$ . When overt hypothyroidism is recognized, it is easily treated with thyroid hormone replacement (approximately 1.2–1.6 µg/kg/d of levothyroxine). Subclinical hypothyroidism may also necessitate treatment. There are a number of conditions that cause hypothyroidism (Table 5). Importantly, some of these conditions may also cause hyperthyroidism.

### Euthyroid Sick Syndrome

The euthyroid sick syndrome (ESS) is the most frequently encountered thyroid condition in the ICU. In this condition, abnormal thyroid function indices develop in otherwise euthyroid patients who have a variety of illnesses such as infections, renal failure, liver disease, stress, starvation, surgery, acute myocardial infarction, stroke, poorly-controlled diabetes, cancer, and burns (7,8). Although the etiology of ESS is unclear, other neuroendocrine systems, such as the hypothalamic-pituitary-gonadal and somatotrophic axes, undergo parallel changes, which are thought to minimize the catabolic impact of severe illness and malnutrition. ⚡ **In ESS, there are perturbations in the entire hypothalamic-pituitary-thyroid hormone system and it is unclear if these patients are truly euthyroid or**

**Table 4** Common Manifestations of Hyperthyroidism and Hypothyroidism

Organ system affected	Hyperthyroidism	Hypothyroidism
Central nervous system	Poor concentration, headache, confusion (with thyroid storm: agitated, delirious, tremulous)	Lethargy, may progress to myxedema coma
Cardiac rhythm	Palpitations, atrial fibrillation	Bradycardia
Cardiac musculature	Myopathy, heart failure	Nonpitting edema (myxedema)
Cardiopulmonary symptoms	Shortness of breath, (as GI fluid losses progresses, may develop hypotension and vascular collapse)	Hypotension, hypoventilation
Thyroid size	Goiter	Sometimes thyroid not palpable
Integumentary	Warm, moist, flushed skin (due to vasodilation)	Dry skin, brittle nails, puffy skin, palor, periorbital edema, patchy hair loss
Metabolism	Hyperactivity, weight loss, fever	Decreased activity, obesity, hypothermia
Musculo-skeletal system	Tetany, spasms, seizure	Malaise, fatigue, weakness, tremor, slow relaxation of deep tendon reflexes
Eyes	Lid retraction, exophthalmos	Cataracts
Gastrointestinal	Diarrhea	Mild constipation to severe obstipation
Menstruation	Decreased menstrual bleeding	Increased menstrual bleeding

perhaps have central hypothyroidism (9). For this reason, the term NTI may be more appropriate than ESS. ♂ The clinical expression in NTI follows a certain pattern, which is shown in Figure 3. In the early (or mild) phase, the T3 level is low with a parallel increase in reverse T3, the inert metabolite of T4 (low T3 syndrome). This is thought to be due to both inhibition of the enzyme 5'-iodinase and alternate metabolism of T4. These changes occur in the majority of hospitalized patients. With increased gravity of illness or disease progression, total T4 levels decrease (low T4 syndrome), despite normal or slightly elevated free T4 (measured by equilibrium dialysis). These changes occur due to increased T4 clearance, which is the result of abnormal production and binding of thyroid-binding protein. Low measured levels of both T3 and T4 portend a poor

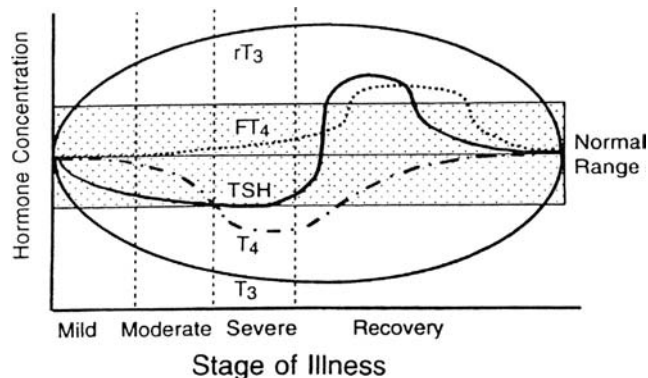

prognosis and parallel (inversely) APACHE II scores. In one study 84% of patients who had T4 levels  $<3 \mu\text{g/dL}$  died, although it is not clear whether these decreased levels of T4 contributed to morbidity or were only indicators of the severity of illness (10). Low T4 levels that persist for greater than one week also correlate with higher mortality. In NTI, the TSH is usually normal or slightly low which is detectable with the third-generation TSH assay. TSH may surge with recovery from the illness and reach levels seen in mild hypothyroidism, but usually stays  $<20 \mu\text{g/dL}$  (11).

Thus, there are several issues that must be kept in when caring for these challenging patients: (i) Serum thyroid hormone levels are fraught with interpretive problems making it difficult to determine which patients with hypothyroidism need urgent treatment. (ii) The NTI

<sup>a</sup>Also causes hyperthyroidism.

**Figure 3** Serum levels of T3, T4, rT3, FT4, and TSH during euthyroid sick syndrome, also known as nonthyroidal illness (NTI). Early in the illness, levels of the active hormone (T3) are depressed while levels of the inactive metabolite (rT3) are high. This trend reverses as NTI resolves. TSH decreases as the illness worsens, but is transiently elevated during the recovery phase. T4 levels stay within the normal range unless NTI gets very severe, when they drop below the lower level of normal. Free T4 (FT4) also stays within the normal range except for a transient elevation during recovery.

response by the thyroïdal axis may be an adaptive mechanism. (iii) Most importantly, attempts to treat routine NTI have not been successful and, in some circumstances, have been harmful (12). Considering the difficulty making this diagnosis, the clinician should not rely too heavily on laboratory measurements. Instead the focus of the evaluation should be on the physical examination and historical information relevant to thyroid disease. ⚡ **The presence of a surgical scar, a goiter, unexplained atrial fibrillation, hyponatremia, or constipation may be important clues to NTI.** ⚡ Although hormone levels appear to be predictive when NTI in the ICU is diagnosed, routine measurement of thyroid function tests in patients upon admission to the ICU does not predict outcome (13). Indeed, there is a great deal of controversy regarding whether thyroid hormones should be routinely measured or treated in the ICU. It also seems most prudent to withhold thyroid supplementation in the critical care setting in the absence of strong clinical or laboratory evidence for hypothyroidism (14).

### Amiodarone

Amiodarone is an iodine-rich medication used frequently in the intensive care setting for controlling cardiac tachyarrhythmias. ⚡ **Approximately 15% to 20% of patients on long-term treatment with amiodarone develop thyroid abnormalities, especially if there is underlying thyroid pathology (15).** ⚡ Because of its iodine content, amiodarone may prevent the oxidation of organic iodide, the first step in producing thyroid hormone (the Wolff-Chaikoff effect). This decrease in thyroid hormone production produces clinical hypothyroidism. On the other hand, the increased iodine may escape the Wolff-Chaikoff effect and cause increased synthesis of thyroid hormone and hyperthyroidism. Patients being treated with amiodarone may also develop an increase in T4 and a decrease in T3 due to the inhibition of 5'-iodinase. Less frequently, amiodarone induces thyroiditis which is associated with hyperthyroidism.

The treatment for amiodarone-induced hypothyroidism is thyroid hormone replacement. Treatment of amiodarone-induced thyrotoxicosis is more difficult, however, and often requires the use of antithyroid medications and potassium perchlorate (1 g/day) (16). Amiodarone may be continued in thyrotoxicosis or myxedema if the symptoms are mild and medically controlled. Amiodarone-induced thyrotoxicosis, however, can be life-threatening and may require aggressive treatment including ablative surgery (17).

### Lithium

Lithium carbonate is a second-line medication when used to treat thyrotoxicosis and, when used for this purpose, it works by decreasing the release of iodothyronines. It is more commonly used in clinical practice to treat bipolar affective disorder. In either case, when high levels of lithium are being used, myxedema and goiter usually result. Less often, lithium therapy can cause hyperthyroidism, which may cause decreased renal clearance of lithium and increased lithium toxicity (18). Other symptoms of lithium toxicity include blurred vision, slurred speech, hand tremor and hypercalcemia. These symptoms are easy to miss in the ICU setting so thyroid function tests must be followed carefully in all ICU patients undergoing treatment with lithium for thyroïdal or nonthyroïdal illnesses.

### Hashimoto Thyroiditis

Hashimoto thyroiditis is an autoimmune disease of the thyroid gland that is the most common cause of hypothyroidism, although rare patients with this disease have hyperthyroidism (i.e., Hashitoxicosis). Although its occurrence is not related to critical illness and its appearance in the ICU is not common, it should be identified as a premorbid condition. Critical illness, as noted above, may precipitate severe myxedema in patients who have pre-existing, poorly controlled hypothyroidism.

Patients with Hashimoto thyroiditis typically have firm goiters, although the glands can be almost normal in size. The diagnosis may be made immunologically with demonstration of TPO (thyroid peroxidase) antibodies in the serum. As with other causes of hypothyroidism in the ICU, establishing the diagnosis of Hashimoto thyroiditis is less important than recognition of the hypothyroidism (or hyperthyroidism) and instituting treatment for either condition before severe myxedema (or thyroid storm) develops.

### Ablation

Two common causes of hypothyroidism include the administration of ablative radioactive iodine to control Grave's disease and total thyroidectomy. These are both circumstances where the ablation of all functional thyroid tissue was planned. In these cases, hypothyroidism should be anticipated and adequately treated before patients develop critical illness.

### Myxedema Coma

The term "myxedema coma" does not connote a unique condition, but is simply the clinical expression of severe, uncompensated hypothyroidism. ⚡ **When hypothyroidism is severe, it will result in hypothermia, hypo-ventilation, severe metabolic derangements, cardiovascular collapse, and eventually, coma.** ⚡ It occurs most often in the elderly who have long-term, untreated hypothyroidism, but it may be seen in younger patients as well who have untreated hypothyroidism and are then subjected to severe physiological stresses, such as infection and invasive surgical procedures.

Historically, myxedema coma was associated with as high as 50% mortality. More recently, survival has increased with improved critical care and more successful treatment of the underlying disorders, although myxedema coma is still an ominous clinical entity. Treatment, as with other hypothyroid states, is mainly thyroid hormone supplementation. The hormone should probably be given intravenously to obviate the problems of uncertain enteric absorption. In severe uncomplicated hypothyroidism, the most common initial treatment is to give T4 (200–500 µg), to allow tissue conversion to the more active hormone, T3. (Some clinicians advocate an initial combination of T4 and T3, although high doses of T3 should be avoided.) It is also prudent to preadminister stress doses of glucocorticoids to patients who have other endocrine abnormalities (i.e., hormone deficiencies) and are at high risk for developing multiple hormone failure. After the initial dose, T4 is administered at about 50 µg daily.

### Hyperthyroid Disorders in Critically Ill Patients

Hyperthyroidism is easier to identify than hypothyroidism. The signs and symptoms of hypothyroidism are usually subtle whereas those of hyperthyroidism are often more flagrant (Table 4). However, either condition may be difficult to identify in critically ill patients.

**Table 6** Conditions Causing Hyperthyroidism

Drugs
Amiodarone
Lithium
Iodide containing drugs
Thyroxine (factitious)
Thyroid Neoplasia
Single toxic adenoma (Plummer disease)
Multi-toxic adenoma
Metastatic thyroid carcinoma
Autoimmunity
Toxic goiter (Graves disease)
Hashimoto disease (Hashitoxicosis)
Thyroiditis
Silent
Postpartum
Granulomatous
Endocrine
Familial nonautoimmune hyperthyroidism
Over-production of TRH
Over production of TSH (pituitary and other sources)
Pituitary resistance to thyroid hormone
TSH resistance
Ectopic
Trophoblastic tumors (high hCG)
Struma ovarii

*Abbreviations:* TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

There are multiple causes of thyrotoxicosis, which may be broken down into those caused primarily by thyroid tissue and those caused by nonthyroidal problems (19). In the first group are toxic goiter (Graves Disease), toxic adenoma (Plummer Disease), metastatic thyroid carcinoma, and thyroiditis. In the second group are factitious ingestion of thyroid hormone, administration of iodine-containing drugs, overproduction of TRH, and trophoblastic tumors that stimulate the thyroid and struma ovarii (Table 6).

### Graves Disease

Graves disease is the most common cause of thyrotoxicosis. It is an autoimmune disorder that presents with symptoms of thyrotoxicosis and others not related to hyperthyroidism. The diagnosis is usually made by noting these nonthyroidal signs and symptoms (e.g., orbitopathy) in a patient with thyrotoxicosis and a symmetrically enlarged thyroid gland. In the critical care setting, establishing the diagnosis of Graves may not be as important as controlling the acute symptoms of thyrotoxicosis. Acutely controlling symptoms, such as tachycardia, atrial fibrillation, and heart failure, with adrenergic blockade is important (see thyroid storm, below). Controlling the production and release of more thyroid hormone may be achieved in the acute or chronic setting with the use of iodine (preceded by one to two doses of PTU) and prednisone (to decrease T4 to T3 conversion). In the chronic setting, antithyroid medications, such as PTU, play a more important role. After the initial stabilization of a patient with thyrotoxicosis, more permanent remission with radioactive iodine or surgery may be considered.

☞ **Although subtotal or total thyroidectomy immediately**

**controls symptoms of Graves Disease, surgery should not be attempted unless chemical control of symptoms, and optimally, thyroid hormone levels have been achieved with antithyroid drugs.** ☞

### Iodinated Contrast Dyes and Other Agents

Critically ill patients are often given radiographic contrast material containing iodine. Although these radiographic contrast dyes have been reported to cause hyperthyroidism (i.e., jodbasedow phenomenon), the actual incidence is low. The practice of treating these patients with perchlorate or thionamide prophylactically is no longer recommended (20). It should be recognized that other iodine-containing drugs (amiodarone, betadine, iodo-niacin), which can cause hypothyroidism through mechanisms elucidated above, can also produce hyperthyroidism. This usually happens in iodine-deficient patients who may have pre-existing goiters, although this phenomenon has been reported in euthyroid patients as well (21).

### Toxic Nodular Goiter and Thyroiditis

These conditions present with findings similar to those seen in Graves disease without the autoimmune features. When they affect the elderly, these patients may present with masked (i.e., apathetic) hyperthyroidism, in which the signs and symptoms are not obvious and the clinical picture is often dominated by cardiovascular compromise such as new onset atrial fibrillation.

In thyroiditis, hyperthyroidism may be due to a spontaneously resolving inflammation with a variable clinical course. Characteristically, there is associated thyroid tenderness, jaw pain, myalgias, and an enlarged, firm, tender thyroid. The thyroid uptake of radioactive iodine is decreased and these patients need supportive care with prednisone and aspirin.

### Treatment of Hyperthyroidism

The other hyperthyroid states noted above may require different diagnostic tests to make the diagnosis (e.g., thyroid scans, sonography, CT scans, MRI); however, the treatment of these states is similar to that for Graves Disease. Treatment of life-threatening physiological derangements should be accomplished first. After the symptoms are controlled, efforts should be focused on controlling thyroid hormone production, release, and peripheral conversion. Finally, an attempt to control the source (e.g., thyroid lobectomy, excision of a diseased ovary, treatment of thyroid cancer metastases) may be appropriate if the patient is physiologically stable.

### Thyroid Storm

Similar to what was stated above about myxedema coma, the term “thyroid storm” does not connote a unique disease process different from the other conditions causing thyrotoxicosis. Rather it suggests that the disease process causing thyrotoxicosis is severe. Severe thyrotoxicosis may be seen in patients who are undergoing thyroid surgery for hyperthyroidism or patients who are undergoing nonthyroid surgery and have coexisting hyperthyroidism that is either unrecognized or poorly controlled. It is also seen frequently in hyperthyroid patients with systemic illnesses, especially infections (22). Relatively minor trauma may trigger thyroid storm in a hyperthyroid patient (23). The syndrome is therefore part of the differential diagnosis of

hyperpyrexia and tachycardia in the emergency department, where it must be distinguished from heat stroke, neuroleptic malignant syndrome, malignant hyperthermia, and serotonin syndrome (24). Thyroid storm is difficult to diagnose in patients who present to the hospital following trauma and have other reasons for hyperthermia, tachycardia, and mental obtundation.

The symptoms of thyroid storm, i.e., tachycardia, hyperthermia, sweating, and irritability, are not different from those of Graves Disease, but are much more pronounced. The tachycardia may become as severe as to precipitate congestive heart failure and pulmonary edema. These symptoms may be attributed to other systemic illnesses seen in the ICU, and if not recognized, may lead to hypotension, coma and, ultimately, death. Thus, an index of suspicion must always be maintained when these common symptoms occur if this important entity is to be recognized in critically ill ICU patients.

☞ **The symptoms of thyroid storm are believed to be the result of the precipitous release or enhanced action of catecholamines by thyroid hormone. Thus, the immediate treatment is adrenergic blockade with agents such as propranolol, reserpine, and guanethidine.** ☞ Supportive measures such as antipyretics, sedation, oxygen, glucose, sodium, and steroids should also be started early. Treatment of the thyroid hormone excess with antithyroid medications and iodine [iodine preferably after the antithyroid medications (19)] is secondary, but is also important. The best treatment however is prophylactic. Patients who are known to be hyperthyroid should be well-controlled on antithyroid medications before elective surgery or pregnancy.

## Thyroid Axis in Critical Illness

### Assessment

Disordered thyroid function can cause or contribute to critical illness, and critical illness can affect thyroid function. Although most critical illness, including burns (25), are associated with a low T3, hypothyroid state, there is evidence that there may be a biphasic response to acute traumatic injury with an immediate but short-lived "fight-or-flight" hyperthyroid response and a later adaptive, hypothyroid phase (26). Often, the cause and effect relationship between thyroid and nonthyroid disease is difficult to sort out. Nonetheless, the approach to both the problems is the same. Thyroid parameters must be evaluated to determine if treatment of the thyroid axis is appropriate. It must be kept in mind that the only hormonally active fragments are free T3 and, to a lesser extent, free T4. Determining if the levels of these hormones are appropriate requires an understanding of the measurement of these fractions, their protein binding, and the peripheral conversion of T4 to T3.

### Treatment

It should also be recognized that the endocrine response to critical illness is different for acute and chronic diseases. ☞ **When there is an acute metabolic or physiologic insult associated with trauma, sepsis, surgery, etc., the endocrine response can be characterized as actively secreting pituitary hormones with peripheral inactivation of the target organ hormones.** ☞ For the thyroid, this is seen as normal or slightly high TSH levels but decreased conversion of T4 to T3 with a low T3 state. This is most likely a protective mechanism and should not be treated with supplemental hormone. On the other hand, chronic illness is associated

with a different endocrine picture characterized by a depression of anterior pituitary secretion with a resultant depression of target organ secretion. In this scenario, there may be a role for intervention. Use of the hypothalamic peptides is optimal, allowing the normal feedback inhibition to regulate hormone levels. Studies with infusion of TRH have been able to restore T3 levels, but its ultimate effect on survival is unknown (27). Administration of the active hormone itself should be considered dangerous, based on the adverse outcomes reported when patients were treated with other active hormones (e.g., growth hormone) in the ICU (28).

## Neuroendocrine Function

### Parafollicular Cells

The parafollicular cells (C cells) of the thyroid produce calcitonin, a 33 amino acid hormone that functions to maintain calcium homeostasis (discussed in greater detail below) and to protect the skeleton in times of increased need such as growth and pregnancy. As noted above, these cells are neuroendocrine cells and are a part of the APUD system. Calcitonin acts by inhibiting bone osteoclastic activity and decreasing serum levels of calcium. Salmon calcitonin is given to patients therapeutically to treat the hypercalcemia of malignancy and conditions such as Paget's disease. Most of the body's calcitonin is made by the C cells of the thyroid, but small amounts are made by other neuroendocrine cells located in the lungs, adrenal gland, hypothalamus, pituitary, etc.

### Calcitonin and Procalcitonin

Calcitonin is made as a 116 amino acid prohormone, procalcitonin, which has recently been recognized as an important marker for inflammatory states (2–5). Furthermore, it is believed to be a mediator of inflammation (29). During inflammatory states, levels of procalcitonin increase as much as a 1000-fold and have prognostic significance (1,30). It has been determined, however, that most of this procalcitonin comes from nonthyroidal, nonneuroendocrine cells (31). Thus, although procalcitonin has become a marker (and perhaps mediator) that is measured often in ICU patients, the thyroid does not play a prominent role in the massive outpouring of procalcitonin seen during inflammation.

## Postoperative Complications in the ICU

For many years, surgeons have been reporting almost no operative mortality in large series of patients undergoing thyroid surgery (32). Postoperative complications following thyroid surgery, however, are still a significant problem and include neck swelling, bleeding, thyroid storm, nerve injury, and hypocalcemia. The thyroid gland is vascular and, in many pathological states, becomes enlarged, engorged, and extremely friable. Good operative technique dictates a careful dissection with meticulous hemostasis. Nonetheless, bleeding and airway compromise in the postoperative period does occur, mandating careful monitoring of the airway in the post anesthesia care unit. ☞ **Post thyroid surgery stridor is an airway emergency, most frequently due to bleeding into the wound or injury to the recurrent laryngeal nerves.** ☞ In the case of post surgical bleeding, opening the neck wound and decompressing the expanding hematoma may be life saving.

Thyroid lobectomy or total thyroidectomy may result in damage to one or both of the recurrent laryngeal nerves

(RLN) or the superior laryngeal nerves (nerves of Galli-Curci). Superior laryngeal nerve injuries may impair the patient's ability to phonate or sing at high pitch, but is not an emergency. In contrast, bilateral RLN injuries can be life threatening as the patient's airway may become obstructed, requiring intubation or an emergent surgical airway, if unable to intubate. Obviously, a bilateral operation puts both nerves at risk. Recently, there has been a trend toward performing unilateral or minimally invasive operations to minimize injury to surrounding structures, including the RLNs. The risk for permanent unilateral injury to the RLN is often reported as less than 1% in first operations and as much as 5% in reoperations. Therefore, reoperative surgery and aggressive operations for undifferentiated thyroid malignancy are more often associated with nerve injuries.

Thyroid surgery can also precipitate thyroid storm in a patient with untreated or uncontrolled hyperthyroidism. This condition is usually recognized in the operating room and should be managed postoperatively in a critical care setting according to guidelines outlined in the section on thyroid storm.

Unlike hypocalcemia resulting from parathyroid surgery (see below), hypocalcemia related to thyroid surgery is usually transient and is more often an outpatient problem.

## PARATHYROID DYSFUNCTION IN THE ICU

### Anatomy and Physiology of the Parathyroid Glands

#### Anatomy

The parathyroid glands are 35 mg, flat, ovoid glands that lie posterior to the thyroid. The most important features of their anatomy are the variability in numbers of glands and the variability in their locations. In a large autopsy series, 80% of patients had four glands, 13% had three and 6% had five (33). The upper glands are more consistent in location with 75% occurring immediately above the inferior thyroid artery. The locations of the inferior glands are more variable and only 50% are found immediately below the inferior thyroid artery with some extending as low as the mediastinum (33).

The blood supply to the lower glands is usually from the inferior thyroid artery. The blood supply to the upper glands may be from the inferior or the superior thyroid artery. Since the glands are small, hypertrophy rarely causes obstruction and the only significance of their anatomic position relates to finding them during surgical exploration.

### Calcium and Phosphate Homeostasis

The primary physiological role of the parathyroid glands is to maintain calcium levels. Calcium homeostasis is a complicated process which requires the participation of parathyroid hormone (PTH) and the metabolically active form of vitamin D [1,25(OH)<sub>2</sub>D], as noted in Figure 4. Calcium is an important constituent of all cells and serves as a major intracellular messenger. It is critically important for such vital functions as muscle contraction, membrane repolarization, bone mineralization, and clotting. Calcium homeostasis is characterized by: (i) multi-hormonal regulation, including PTH and vitamin D, (ii) a rapid response to changes in ambient calcium (e.g., a 1% to 2% reduction in ionized calcium leads to an increase in PTH within a few seconds), (iii) tight control of the extracellular calcium concentration, and (iv) an intracellular calcium concentration which is 10,000-fold lower than the extracellular calcium concentration. It should be noted that, while the intracellular calcium levels may be the most important for cell health, it is the extracellular levels that are tightly regulated. Intracellular calcium, on the other hand, varies widely.

Extracellular, circulating calcium levels are controlled by the interaction with a calcium sensing receptor on parathyroid cells. This cell surface protein binds extracellular calcium and is coupled to a G protein signaling system. The response of the calcium sensing receptor is coupled to PTH secretion so that a lowering of ambient calcium increases the synthesis and release of PTH. Both gain-of-function mutations (e.g., autosomal dominant hypocalcemia), which result in lower extracellular calcium, and loss-of-function mutations (e.g., familial hypocalciuric hypercalcemia), which result in increased extracellular calcium, have been identified. In addition, there are several

**Figure 4** Calcium homeostasis. Calcium enters the extracellular fluid (ECF) compartment from the bone, kidney, and GI tract. Calcium levels are increased by the stimulatory effects of vitamin D, which is converted to its active form [1,25(OH)<sub>2</sub>D] by the liver and kidney. Parathyroid hormone (PTH) stimulates bone to release calcium and the liver to produce 1,25(OH)<sub>2</sub>D. When ECF calcium levels are low, PTH is stimulated, and calcium levels increase.

acquired conditions in which the calcium-sensing receptor activity is altered (e.g., parathyroid adenomas, autoimmune hypoparathyroidism). PTH bioactivity involves mobilization of calcium from the skeleton via direct effects on osteoblasts and indirect effects on osteoclasts. PTH also acts on the kidney to reabsorb calcium and enhance excretion of phosphate. PTH also stimulates 1,25-(OH)<sub>2</sub>D hydroxylase, which converts 25-OHD to 1,25-(OH)<sub>2</sub>D, the active form of vitamin D. Interestingly, 1,25-(OH)<sub>2</sub>D imparts negative feedback control on the secretion of PTH itself.

Another peptide, PTHrp (PTH-related protein), is a nonparathyroid peptide made by certain tumor cells and, via the PTH/PTHrp receptor, increases calcium levels in malignancy. It is also involved in calcium homeostasis in multiple tissues such as placenta, mammary gland, smooth muscle, skin, uterus, and cartilage, especially during neonatal life.

### Measurement of Parathyroid Function and Calcium Homeostasis

#### Free and Total Calcium Levels

Ionized free bioactive calcium constitutes 45% of the total extracellular calcium pool, whereas albumin-bound calcium contributes 45%, and calcium complexed to anions accounts for another 10%. Therefore in patients with hypoalbuminemia, the total calcium levels will decrease without changing the ionized or active fraction. Thus, in hypoalbuminemia, a corrected total calcium level can be estimated by adding 0.8 mg/dL to the measured total calcium for every 1 g/dL decrease in the albumin below the normal 4 g/dL. However, changes in protein binding, pH, fatty acids, or other ions may also affect the levels of total, estimated, and ionized calcium. These changes often occur in the ICU, making measurement of ionized calcium necessary in circumstances where accurate calcium levels are important. ⚡ **Acidosis increases the ionized calcium levels, and alkalosis reduces these levels (i.e., an increase of pH change by 0.1 decreases ionized calcium by 0.1 mg/dL and vice versa).** ⚡ Also important in the ICU are sudden increases in phosphates, citrate, and bicarbonate, which significantly reduce the bioactive ionized calcium levels. For example, an acidotic hypotensive patient may receive several amps of sodium bicarbonate in an effort to improve pH and myocardial contractility. Unfortunately, the acute alkalosis may initially impair contractility (due to the decreased ionized calcium) to a greater extent than it restores contractility, and the patient can arrest in some situations. Accordingly, the clinician must be keenly aware of these effects, and consider supplementing the sodium bicarbonate with small (e.g., 250 mg) doses of calcium chloride or calcium gluconate (use separate syringes and I.V. lines to prevent calcium carbonate precipitation).

The most accurate ionized calcium levels are obtained in the fasting state and at a time when the patient is not hemoconcentrated. The use of a tourniquet should be avoided if possible. Drugs used often in the ICU which decrease total and ionized calcium measurements include carbamazepine, phenytoin, foscarnet, furosemide, glucocorticoids, and tetracycline.

#### Magnesium

Magnesium has important effects on calcium homeostasis. Modest magnesium deficiency increases levels of PTH, while severe magnesium deficiency causes a decrease in PTH. The resulting hypocalcemia may be severe (34). Similar to calcium, magnesium circulates in free, bound,

and chelated forms. It is now possible to measure ionized magnesium and, although not universally available, ionized magnesium levels are available and being utilized in many critical care units. Unfortunately, serum magnesium does not adequately reflect tissue magnesium levels and the assays commonly employed can detect only severe hypermagnesemia. ⚡ **Digitalis, cyclosporin, cis-platinum, diuretics, aminoglycosides, amphoterecin B, and citrate (in blood transfusions) will lower measured magnesium levels.** ⚡

#### Intact Circulating Parathyroid Hormone

The majority of PTH circulates as fragments of the parent molecule. However the two-site, immunometric measurement of the intact (bioactive) PTH (1–84) molecule is now the standard by which parathyroid activity is assessed. The level of intact PTH typically increases up to two-fold in primary hyperparathyroidism and as much as 10-fold in acute hyperparathyroidism (also called parathyroid poisoning) and secondary hyperparathyroidism. PTHrp (parathyroid hormone-related protein) is a protein that is structurally related to PTH and is found in patients with certain malignancies. It has PTH-like properties, which are responsible for malignancy-related hypercalcemia. Similar to PTH, it is measured by a two-site, immunometric assay, but there is no cross-reactivity between the two peptides. PTHrp is very labile at room temperature.

#### Vitamin D

The measurement of vitamin D is important in assessing calcium homeostasis. Liver produces 25-OHD (25-hydroxyvitamin D), which is the precursor molecule for mature vitamin D. Phenytoin, carbamazepine, rifampin, and glucocorticoids decrease liver production of 25-OHD. 25-OHD is further hydroxylated in the kidney to form 1,25 (OH)<sub>2</sub>D (1,25-dihydroxy Vitamin D), the bioactive hormone, which rises sharply with pregnancy, lactation, and obesity. Isoretonin and ketoconazole decrease renal production of the mature hormone.

#### Imaging

Ultrasound and technetium Tc 99 m sestamibi scanning both image the parathyroid glands. Although they are both used to assess parathyroid function, they have limited utility other than localizing parathyroid glands for surgical treatment.

#### Hypocalcemic Disorders

There are many causes for hypocalcemia, which may be divided into those related to hypoparathyroidism and those caused by other conditions (Table 7). Hypocalcemia in the ICU is more often caused by conditions not related to parathyroid deficiency. ⚡ **Both the absolute level and the rate of fall of calcium influence the clinical manifestations of hypocalcemia.** ⚡

As many as 70% to 80% in the ICU experience hypocalcemia at some time during their hospital course, whether calcium levels are measured by a total calcium assay or are estimated using various formulae to calculate total calcium. Hypocalcemia appears to be particularly prevalent in patients with sepsis, but its etiology in this group is often multifactorial. Hypocalcemic signs and symptoms, which are related to disturbances of the neuromuscular, gastrointestinal (GI), central nervous system (CNS), and cardiovascular systems, may be present yet masked by the severity of the concurrent illness. The diagnosis may rely

**Table 7** Conditions Causing Hypocalcemia

Parathyroid-related	Nonparathyroid
Postoperative	SIRS
Parathyroid	Pancreatitis
Thyroid	Malignancy
Other head and neck	Hypoproteinemia
Magnesium Deficiency	Hyperphosphatemia
PTH Failure	Necrotizing fasciitis
Genetic-DiGeorge,	Enteric fistulas
APECED	Vitamin D deficiency
Sporadic	Malabsorption
Hungry Bone Syndrome	Liver failure
PTH Resistance	Renal failure
Infiltrative	Vitamin D resistance
Hemochromatosis	Chelation
Wilson Disease	Hyperphosphatemia
Metastatic tumor	Hypoproteinemia (pseudohypocalcemia)
	Renal failure (acute and chronic)
	Rhabdomyolysis

*Abbreviations:* APECED, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; SIRS, systemic inflammatory response syndrome.

on a careful physical exam and performance of confirmatory tests (Table 8).

**Systemic Inflammatory Response Syndrome**

Hypocalcemia is commonly associated with critical illness and the systemic inflammatory response syndrome (SIRS). Indeed, hypocalcemia is a prognostic factor in ICU patients with or without SIRS. Their hypocalcemia is thought to be due to multiple abnormalities such as hypomagnesemia, impaired vitamin D synthesis, impaired vitamin D action, calcium chelation, or calcium precipitation. Prior evidence implicating parathyroid insufficiency as the main causative factor for hypocalcemia in SIRS patients appears not to be correct. Indeed, PTH is frequently elevated during hypocalcemia and its levels often correlate to both the APACHE II scores and mortality.

**Table 8** Signs and Symptoms of Hypocalcemia

Symptoms	Physical Finding	Tests
Circumoral numbness	Carpopedal spasm	Serum
Tingling in extremities	Laryngospasm	hypocalcemia
Abdominal cramps	Hyperactive tendon reflexes	Increased ICP
Muscle cramping	Chvostek sign	Somatosensory EP changes
Fatigue	Trousseau sign	EKG changes
Anxiety	Papilledema	QT prolongation
Irritability	Dry skin	EEG
Depression	Coarse hair	
Seizures (grand mal and petit mal)	Brittle nails (transverse grooves)	
Dementia	Hypotension	
Steatorrhea	CHF	

*Abbreviations:* ICP, intracranial pressure; EKG, electrocardiogram; CHF, congestive heart failure; EEG, electroencephalogram.

Endotoxin causes ionized hypocalcemia, suggesting that proximal cytokines, stimulated by gram negative sepsis, may be involved. Another group of peptides, which are involved in the inflammatory response and may also influence calcium levels, are the so-called calcitonin precursors (CTpr). These are the peptide fragments derived from the procalcitonin molecule, including procalcitonin itself, which are released by both endotoxin and TNF. Levels of CTpr, but not PTH, correlate inversely to ionized hypocalcemia (35). As noted above, CTpr levels are valuable markers of the severity of stress and correlate with the severity of SIRS, sepsis, and septic shock state (1). The studies demonstrating that CTpr levels correlate with the degree of hypocalcemia provide further evidence that CTpr are mediators as well as markers of the inflammatory response (see calcitonin and procalcitonin above).

✎ **Administration of calcium in systemic inflammation has not been useful. In this regard, the hypocalcemia seen with SIRS may be part of the inflammatory response process and may be protective.** ✎ Extracellular hypocalcemia might even be a response to intracellular hypercalcemia, which is toxic to the cells.

**Postsurgical**

Hypocalcemia may result from surgery of the thyroid gland, parathyroid glands, or other head and neck structures (e.g., lymph nodes being dissected for oropharyngeal malignancy). When a parathyroid adenoma is removed, the resulting hypocalcemia is usually transient (about one week) and related to the preoperative atrophy of the remaining parathyroid glands. Occasionally, in cases of severe, preoperative osteoblastic overactivity, the hypocalcemia may be more profound due to the “hungry bone syndrome” (described below). Permanent hypocalcemia, which is rare, is usually due to the deliberate removal of all parathyroid tissues for hyperplasia or the inadvertent removal of all parathyroid tissues in very extensive head and neck operations.

✎ **Hypocalcemia from the hungry bone syndrome occurs following surgical resection of large adenomas, which had caused severe primary hyperparathyroidism.** ✎ Removal of the exuberant PTH elaboration (from the resected adenoma) results in disappearance of the osteoclasts in the bone and thus promotes rapid calcium deposition into the skeleton (along with phosphate and magnesium). The subsequent hypocalcemia can be severe, causing symptoms in the first 24 hours and reaching a nadir two to three days postoperatively. This effect may persist for as long as three months. Tetany, seizures, and CHF may accompany the hypocalcemia from hungry bone syndrome. Hypophosphatemia and hypomagnesemia may also manifest as concomitant electrolyte disturbances in the hungry bone syndrome. Risk factors for this form of hypocalcemia include the volume of the resected adenoma, the blood urea nitrogen level, the alkaline phosphatase level, and the patient’s age. Interestingly, preoperative PTH level is not a risk factor.

Patients undergoing subtotal thyroid resection due to thyrotoxicosis may also experience transient hypocalcemia. The etiology of this phenomenon is unclear, although the hyperthyroid state is associated with increased bone turnover as well as elevated serum calcium.

**Malignancy**

Although malignancy is more often associated with hypercalcemia, osteoblastic metastases from prostate and breast cancer may also cause hypocalcemia. In addition, about

10% of cancer patients experience hypocalcemia due to hypoproteinemia. For others with malignancy, chemotherapy-induced rhabdomyolysis and tumor lysis precipitate a sudden influx of phosphate into the intravascular space, which lowers calcium. Oliguria may contribute to this occurrence, exacerbating the hypocalcemia. Although this cause for hypocalcemia is not specific for ICU patients, a similar drop in calcium is seen more often in the ICU with phosphate infusion.

### **Magnesium**

Magnesium deficiency occurs in a variety of conditions and can cause reversible hypocalcemia. Severe hypomagnesemia decreases PTH secretion. Hypomagnesemia is also associated with abnormal PTH receptor action. Finally, hypomagnesemia can lower the production of 1,25-(OH)<sub>2</sub>D. Alternatively, hypermagnesemia, as seen in the obstetric use of high-dose magnesium infusions, can also cause hypocalcemia. For these reasons, magnesium levels, which may be high or low in the intensive care unit, must be considered in the differential diagnosis of hypocalcemia in critically ill patients.

### **Vitamin D**

Hypovitaminosis is common in hospitalized patients and especially those in the ICU who may have compromised nutrition. This is especially true for vitamin D, because of the restricted exposure to sunlight for patients residing in the ICU. In one study, 57% of 164 hospitalized patients had a 25-OHD level < 15 ng/mL while 22% had levels < 8 ng/mL (nl. Level > 25 ng/mL) (36). These numbers are probably larger for ICU patients.

Deficiencies or impaired activity of vitamin D result in poor intestinal absorption of calcium and subnormal mobilization of calcium from bone. The resulting hypocalcemia may cause an adaptive elevation of PTH and low phosphate, which may be helpful in making the diagnosis. Malabsorption syndromes are associated with the lack of the parent vitamin D compound. In addition, liver disease is associated with the inability to form 25-OHD, while renal abnormalities are associated with inability to form 1,25-(OH)<sub>2</sub>D. Renal disease is also associated with decreased calcium due to the elevated concentration of phosphate, resulting from decreased glomerular filtration rate. Elevated phosphate decreases renal-associated hydroxylation of 25-OHD, resulting in decreased GI absorption of calcium. Similarly, hepatobiliary disease is associated with a specific deficiency in 25-OHD.

### **Pancreatitis**

In acute pancreatitis, the destruction of pancreatic exocrine tissue leads to release of fatty acids with the precipitation and deposition of calcium salts in the damaged pancreatic tissue and surrounding fat. The resulting hypocalcemia correlates with the severity of pancreatitis and is a clinically useful indicator [Ranson criterion (37)] for predicting morbidity and mortality in patients with acute pancreatitis.

### **Idiopathic (Autoimmune, Genetic, Sporadic)**

There are several other causes of hypocalcemia that may not be associated with the ICU illness per se but may be contributing factors. Idiopathic hypoparathyroidism may be sporadic or occur in a familial syndrome, which may involve multiple glands and be associated with other developmental abnormalities. For example, type 1 polyglandular

syndrome, which has been given the acronym APECED for autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy typically occurs in early childhood followed by hypoparathyroidism and subsequent adrenal failure (38). Mutations in the AIRE (autoimmune regulator) gene, located on chromosome 21, have been reported in patients with APECED.

Idiopathic hypoparathyroidism may also occur as an isolated deficiency, not related to other endocrine disorders. These disorders, like APECED, usually involve antibodies that inhibit parathyroid secretion or destroy parathyroid tissue. They may occur at any time in life, but are most often seen before the age of 10 years.

Hypoparathyroidism may also occur due to agenesis or dysgenesis of the parathyroid glands. In the DiGeorge syndrome, under-developed third and fourth branchial pouches are associated with congenital absence of the parathyroid glands and thymus and characteristic facial anomalies (e.g., hypertelorism, antimongoloid slant of the eyes, asymmetric malformed ears). Children with the DiGeorge syndrome are susceptible to infections and cardiac failure and do not often survive into adulthood. This is not often a problem seen in adult ICUs, however it may be seen on pediatric wards or in pediatric ICUs.

### **Other**

Rarely, infiltrative parathyroid conditions, including hemochromatosis, Wilson's disease, and metastatic tumors, may cause hypoparathyroidism. Even more rarely, exposure to I<sup>131</sup> can cause postirradiation hypoparathyroidism. These conditions result in PTH-related hypocalcemia.

Hypocalcemia has also been associated with massive blood transfusions as well as volume expansion with associated hypoalbuminemia. These last two causes for hypocalcemia are seen frequently in ICU patients. Indeed, hypoalbuminemia for any reason is the most common cause for hypocalcemia in hospitalized patients. For these patients an ionized calcium determination or a calculated total calcium level is more clinically relevant than measured serum calcium levels. In addition, many of the drugs associated with hypocalcemia are used in the ICU.

There are several disorders that cause PTH receptor resistance and result in hypocalcemia with high PTH (39). These include the pseudohypoparathyroidism syndromes (1a, 1b, 1c, 2) as well as several hypomagnesemic conditions.

### **Treatment**

Correction of hypocalcemia in sepsis and during the acute phase response is not always recommended. Although normalizing calcium levels may increase blood pressure regardless of the level of ionized calcium, it does not change cardiac index or oxygen delivery and may be associated with catecholamine resistance (40). Thus, treatment of mild to moderate ionized hypocalcemia (0.7–1.05 mmol/L) is generally not recommended. Instead, reducing aggravating conditions, such as loop diuretic administration, should be the clinical focus in caring for patients with moderately depressed levels of calcium. ⚡ **Aggressive therapy should be reserved for severe ionized hypocalcemia, (<0.7 mmol/L), severe symptoms (Table 8), or antagonism of specific conditions such as hyperkalemia, hypermagnesemia, and calcium channel blocker toxicity.** ⚡ If a patient with hypocalcemia is symptomatic, treatment may require intravenous calcium gluconate [initially 1–2 amps (90 mg Ca/amp) in

50 mL of D5 infused over 10–20 min until symptoms stabilize, followed by a maintenance infusion of five to six amps in 1L D5 infused at 100–125 mL/hr]. When the hungry bone syndrome is expected, such as in surgery for hyperparathyroidism and renal dysfunction, the patients need preoperative calcitriol (2 µg for about five days) along with oral calcium (2–3 g/day for about five days) to prevent the expected decline in calcium. Calcium levels can also be raised in renal failure patients by dialysis using a high calcium bath. Preoperative use of bisphosphonates appears to inhibit calcium mobilization from bone and thus decreases the impact of the acute PTH withdrawal that precipitates the hungry bone syndrome.

Routine administration of calcium with massive blood transfusions is controversial, however calcium is frequently useful if blood is administered rapidly and when ten or more units are administered (41). Measuring ionized calcium levels and electrocardiogram monitoring of QT intervals may be done and calcium administered only when hypocalcemia has been documented.

Because of the various effects of magnesium on calcium homeostasis, magnesium levels should be monitored and corrected in all hypocalcemic patients.

**Osteoporosis**

Although osteoporosis is not invariably associated with hypocalcemia, it is often seen in critically ill patients. **Severe illness, prolonged immobilization, low vitamin D levels, and aging all conspire to increase bone resorption.** These conditions usually respond to combined calcitriol and pamidronate treatment (42). Other factors that adversely impact the health of the skeleton include the use of glucocorticoids and anticonvulsants. In both the conditions, the prompt use of vitamin D and calcium may ameliorate the effects on the bone. In the case of glucocorticoids, the use of bisphosphonates or calcitonin should also be considered.

**Table 9** Conditions Causing Hypercalcemia

Common	Rare
Hyperparathyroidism	Immobilization <sup>a</sup>
Primary	Familial hypocalciuric hypercalcemia
Secondary	Thyrotoxicosis
Tertiary	Hypophosphatemia <sup>a</sup>
Ectopic	Addison disease
Drug-induced	Vipoma
Vitamins A and D	Parathyroid cysts
Thiazides	Milk-alkali syndrome
Lithium	Paget disease
Malignancy	Pheochromocytoma
Osteolytic lesions	
PTHrp	
Lymphoma	
Multiple myeloma	
Granulomatous disease	
Sarcoid	
Tuberculosis	

<sup>a</sup>Although immobilization and hypophosphatemia are often seen in critically ill patients and may contribute to the hypercalcemia caused primarily by other conditions, they are not often the sole cause of hypercalcemia. *Abbreviation:* PTHrp, PTH-related protein.

**Table 10** Signs and Symptoms of Hypercalcemia

Early	Late
Apathy	Obtundation
Lassitude	Severe weakness
Drowsiness	Coma
Headache	Stupor
Confusion	Depression
QT shortening	Death
Bowel hypomotility	Constipation
Nephrogenic diabetes	Dehydration
Polyuria	Obstructive uropathy
Polydipsia	Band keratopathy
Nephrocalcinosis	Pancreatitis, PUD
Calcium phosphate precipitation	Weight loss
Nausea, vomiting	Chondrocalcinosis
Anorexia	
Gout, pseudogout	

*Abbreviation:* PUD, peptic ulcer disease.

Other drugs used in the ICU which effect bones include long-term, high dose heparin (>15,000 IU/day) and possibly catecholamines. Acidosis and vitamin D deficiency predispose to osteomalacia characterized by bone pain, elevated alkaline phosphatase, and radiological abnormalities.

**Hypercalcemic Disorders**

Hypercalcemia may be caused by a multitude of conditions often seen in the ICU (Table 9). Hypercalcemia from any cause can be severe when renal elimination of calcium is impaired. In ICU patients, renal function is often compromised for a multitude of reasons, including dehydration, vomiting, drug toxicity, and multiple organ dysfunction syndrome. Immobilization, which is another problem for critically ill patients, also contributes to hypercalcemia.

The signs and symptoms of hypercalcemia start in ICU patients with nonspecific findings such as apathy, drowsiness, confusion, bowel hypomotility, and anorexia. As the hypercalcemia becomes more severe, these signs develop into more ominous conditions such as obtundation, coma, dehydration and death (Table 10).

**Primary Hyperparathyroidism**

Primary hyperparathyroidism, with elevated PTH levels, is most commonly due to a single adenoma or, less commonly, multiple adenomas. Primary hyperparathyroidism related to either single or multiple adenomas is more common than primary hyperparathyroidism caused by multiple gland hyperplasia. Hyperparathyroidism associated with a genetic syndrome (e.g., a MEN syndrome) is less common than sporadic cases. On the other hand, when hyperparathyroidism is part of a genetic syndrome, hyperplasia is the usual pathology. Secondary hyperparathyroidism is invariably caused by hyperplasia. Very rarely, hypercalcemia is due to parathyroid carcinoma.

Most patients with hyperparathyroidism are asymptomatic with modest elevations of serum calcium. The PTH levels in these patients are usually less than twice normal. Any patient, however, may decompensate to a life-threatening hypercalcemic crisis with PTH levels reaching 10–20 times normal. Almost 25% of these patients in crisis have chronic stable hypercalcemia characteristic of primary

hyperthyroidism, prior to their decompensation. On the other hand, only 1% of patients with mild hyperparathyroidism develop crisis.

In patients with pre-existing hyperparathyroidism, the crisis may be precipitated by spontaneous hemorrhage and rupture of an adenoma (43). Another consequence of rupture of an adenoma is mediastinal hemorrhage with superior vena cava obstruction, mimicking a dissecting aortic aneurysm. Partial necrosis of parathyroid cysts accounts for another small percentage of patients experiencing hyperparathyroid crisis.

### **Malignancy**

Malignant tumors, including lung cancer, breast cancer, lymphomas, and multiple myeloma, are associated with malignancy-related hypercalcemia. Some of these tumors produce PTHrp (see above), while others stimulate local osteolytic humoral factors. Approximately 80% of patients with solid tumors and hypercalcemia produce PTHrp (44), making this the most common cause for hypercalcemia in these patients. Those patients with concurrently elevated PTHrp have PTH levels which are suppressed, a finding which helps with the diagnosis. In addition, patients with malignancy-associated hypercalcemic crisis are often more debilitated and immobile, exacerbating their hypercalcemia. Although almost any cancer can be associated with life-threatening hypercalcemia, lung cancer, breast cancer, lymphoma (especially HTLV-1), and multiple myeloma are most commonly involved.

### **Disorders of Vitamin D**

There are several conditions associated with endogenously-generated, excessive levels of vitamin D [1,25(OH)<sub>2</sub>D]. In general, these are granulomatous disorders, such as sarcoidosis, tuberculosis, histoplasmosis, and coccidiomycosis, which have amplified macrophage-derived 1,25 (OH)<sub>2</sub>D activity. In lymphoma, the lymphomatous tissue generates enhanced 1,25 (OH)<sub>2</sub>D hydroxylase activity. HTLV-1 is associated with severe hypercalcemia, related to elevated levels of vitamin D. These conditions respond to glucocorticoid or hydroxychloroquin treatment, which impairs the hydroxylase enzyme activity.

### **Endocrine**

Other endocrine conditions result in hypercalcemia. In thyrotoxicosis, hypercalciuria is commonly present and 20% also have transient hypercalcemia due to excessive bone remodeling by thyroxine. Pheochromocytoma and VIPomas can generate PTHrp and cause hypercalcemia through mechanisms outlined above. Severe Addison disease has been associated with hypercalcemia, perhaps mainly due to hemoconcentration. Familial hypocalciuric hypercalcemia is a loss-of-function mutation in the calcium-sensing receptor with resultant hypercalcemia, mildly elevated PTH, and hypermagnesemia. These patients typically are asymptomatic and, although the PTH levels may be high, the hypercalcemia does not respond to parathyroid surgery.

### **Drugs and Ingestion**

As was the case with hypocalcemia, many drugs used in the ICU can lead to hypercalcemia. The thiazide diuretics reduce distal tubule reabsorption of calcium and may cause hypercalcemia. This condition may be exacerbated by diuretic-induced dehydration. Hypercalcemia develops in 10% to

15% of patients treated with lithium, which appears to reset the set point for PTH release, shifting the response curve to the right (45). These patients may also have hypocalciuria and hypermagnesemia. Recently, the milk-alkali syndrome is being seen more often, due to public health efforts to get people to increase dietary calcium or use antiosteoporotic calcium supplementation. Excessive vitamin A may also cause calcium toxicity related to increased osteoclastic activity. This is a problem of intoxication and is not a problem when recommended daily allowances are observed.

### **Immobilization**

Immobilization caused by a medical condition or a sedentary lifestyle is well known to exacerbate underlying positive calcium balance by increasing bone resorption. This is an under-appreciated yet important cause of hypercalcemia in the ICU that is usually masked by the hypocalcemia more often associated with critical illness. The resulting osteoporosis, however, is a significant clinical problem, which is often manifested by pathologic fractures following falls.

### **Treatment**

The cornerstone for treatment in mild to moderate hypercalcemia involves rehydration, preferably using normal saline, sometimes supplemented with diuretics. For more rapid control, albeit with modest reductions, subcutaneous calcitonin injection may be administered twice per day at a dose range of 100–200 IU. Pamidronate inhibits bone resorption without inhibiting bone formation. It is useful for treatment for hypercalcemia due to malignancy, Paget disease, and osteoporosis. Bisphosphonates can also be very effective for osteoporosis and Paget disease, but take two to three days to act. Bisphosphonates must be used carefully in patients with renal failure and high phosphate levels.

♣ The patient with “hypercalcemic crisis” often presents with signs and symptoms of severe hypercalcemia including severe fatigue, oliguria, anuria, somnolence, and coma. ♣ In extreme cases, either emergency surgery or hemodialysis may be needed for a successful outcome. In cases with parathyroid carcinoma, there are often associated bone and kidney diseases and a palpable neck mass. Some of these patients need urgent surgery.

### **Postoperative Complications in the ICU**

The postoperative complications in the ICU following parathyroid surgery are similar to those noted above for thyroid surgery and include neck swelling, bleeding, nerve injury, and hypocalcemia. Because the parathyroid glands are smaller than the thyroid, neck swelling and bleeding are not common problems following surgical exploration and excision. The parathyroid glands are more variable in location and an extensive exploration is sometimes necessary in the retro-thyroid space, making injury to the one or both of the recurrent laryngeal nerves more likely. Damage to a superior laryngeal nerve (nerve of Galli-Curci) is less common in parathyroid surgery because these nerves lie in close apposition to the superior thyroid artery, which does not have to be routinely divided as it does in thyroid surgery. Because the inferior parathyroid glands may be found in the mediastinum, parathyroid surgery may involve retrosternal or mediastinal exploration. These extended operations are certainly more complicated and carry increased risks of bleeding and aerodigestive tract compromise.

Hypocalcemia following thyroid surgery may occur, if all of the parathyroid glands are removed, injured, or devascularized. The hypocalcemia in these cases may take weeks to develop and is often transient. When a patient is being operated on for hyperparathyroidism, the responsible adenoma is removed or the hyperplastic tissue is reduced in volume. In these circumstances, the bones, which were previously decalcified by hyperparathyroidism, avidly take up calcium (hungry bone syndrome, discussed above). The serum calcium levels may plummet rapidly in these patients and require extremely aggressive intravenous calcium replacement with cardiac and hemodynamic monitoring in an ICU.

The trend toward minimally invasive procedures is revolutionizing parathyroid surgery. Adenomas can be localized with preoperative sestamibi scintigraphy, allowing a unilateral exploration through a minimal incision. Occasionally, a hand-held gamma camera is also used to further localize the adenoma. A rapid PTH assay is then used to document intraoperatively that the PTH levels normalize after removal of the adenoma. Minimally invasive parathyroid surgery is too recent to have long-term follow-up data, but initial results suggest that this approach has a 93% success rate in the 64% of patients who have hyperparathyroidism caused by sporadic adenomas (46).

## EYE TO THE FUTURE

### Thyroid

New, highly sensitive TSH assays have become the cornerstone of diagnostic testing used to evaluate the thyroid axis. Tests with the highest sensitivity can differentiate normal from hyperthyroid levels in virtually all cases, including acutely ill patients. Improved TSH sensitivity has also contracted the upper range of normal values. The majority (>95%) of euthyroid individuals have a serum TSH between 0.4 and 2.5 mU/L. Individuals with a TSH value above 2.5 mU/L may have the early stages of thyroid failure (47).

The isolation and genetic cloning of the sodium iodide symporter protein (NIS), which is important in iodide transport, has opened a new field in thyroid research. These ongoing studies involving the molecular mechanism of iodide transport have important implications for nuclear medicine evaluation and treatment of both benign and malignant thyroid diseases. Reduced NIS expression accounts for reduced iodide uptake in thyroid cancer cells. These cancer cells can be targeted to increase NIS expression and thereby enhance the effectiveness and scope of radioiodine therapy. Interestingly, it also appears that radioiodine could have a similar diagnostic and therapeutic role in breast cancer, as these cells also express NIS.

Another important advance in thyroid disease management has been the development and use of recombinant human thyrogen (i.e., TSH). The indications for thyrogen should increase depending on the results of several ongoing trials. Already, it has a role in assessing metastatic disease in lieu of the standard practice of body scanning following induced hypothyroidism. Combined with ultrasonography of the neck, it has the highest sensitivity for monitoring differentiated thyroid carcinoma (48). Future uses will most likely include therapeutic preparation of patients for radioiodine treatment.

Interventional radiology is being used more for the evaluation and treatment of endocrine disorders.

Minimally-invasive techniques for treating Graves disease are being developed using selective arteriography and arterial embolization of thyroid arteries using the Seldinger technique. These techniques are especially valuable in patients who have significant comorbidity, making their risk for surgery prohibitively high.

Following thyroidectomy for Graves disease, some investigators have advocated the combined administration of T4 and T3. To demonstrate the efficacy of thyroid hormone replacement in this situation, however, will require additional trials. Although surgery is no longer considered primary treatment for hyperthyroid Graves disease, thyroidectomy is still indicated in circumstances when patients cannot tolerate medical treatment or when rapid control of hyperthyroidism is deemed necessary. In these situations, rapid control of hyperthyroidism can be achieved with a combination of iopanoic acid and dexamethasone (49). Another area of controversy involves the use of thyroid hormone replacement in the so-called euthyroid sick syndrome. Thus, the data does not support such an approach. It appears, however, that better powered trials might be able to discern a potential role of thyroid hormones and/or thyroid hormone-like agents in this hypothyroid state.

### Parathyroid

Hyperparathyroidism with normal calcium but elevated parathyroid hormone levels (without secondary hyperparathyroidism) is now more commonly recognized, due to more routine PTH screening. This probably represents detection of hyperparathyroidism at an early stage, before hypercalcemia develops. Because it may be associated with clinical problems such as osteoporosis, treatment of this early stage of hyperparathyroidism may be appropriate.

Parathyroid scintigraphy for the diagnosis and surgical location of hyperparathyroidism is evolving rapidly. Dual-tracer (subtraction) techniques using technetium-99 m sestamibi has become the standard mode of localizing parathyroid adenomas. Refinements, including the use of 99 m-tetrofosmin, single-photon emission tomography, and PET scanning are currently being evaluated. The availability of improved precision in the localization of a single adenoma has already changed the scope of surgery to include minimally invasive techniques utilizing a radio-guided surgical approach.

Another area of development involves the use of allosteric activators of the calcium sensing receptor, that is, calcimimetic agents. These small organic molecules lower the threshold for receptor activation by extracellular calcium and thereby diminish parathyroid hormone secretion. Their effectiveness in controlling parathyroid hormone levels has been shown in both primary and secondary hyperparathyroidism. These agents are alternatives to vitamin D and calcium therapy to treat the secondary hyperparathyroidism of renal failure. Notably they have also been reported to decrease the calcium-phosphorus product (50).

Other agents that control parathyroid hormone secretion are the modified vitamin D compounds. Although these agents are already important in secondary hyperparathyroidism due to end-stage renal disease, newer compounds with more potent effects on the secretion of parathyroid hormone are being developed.

Finally, the availability of parathyroid hormone itself, administered as a once-daily injection, will potentially revolutionize the anabolic approach to osteoporosis. Completed

phase III trials demonstrate an impressive increase in bone mineral density as well as a decrease in bone fractures using PTH supplementation.

## SUMMARY

### Thyroid Dysfunction

The signs and symptoms of thyroid dysfunction may be confused with those caused by critical illness, and an understanding of thyroid hormone secretion and action is important in order to recognize thyroidal illness in ICU patients. The most important aspect of thyroid hormone physiology is the recognition that most of the biologically active hormone T<sub>3</sub> is not secreted directly from the thyroid, but is produced by extrathyroidal conversion of T<sub>4</sub>. TSH, in general, relates inversely to the levels of T<sub>4</sub>, the inactive species, due to the negative feedback mechanism. When T<sub>4</sub> is not converted to active T<sub>3</sub>, it may be converted to the inactive hormone, reverse T<sub>3</sub> (rT<sub>3</sub>), therefore levels of T<sub>4</sub> only bear an indirect relationship to levels of T<sub>3</sub>, the active hormone. Although the measurement of TSH is usually sufficient to determine whether thyroid hormone levels are adequate, because of the confusing metabolism and feedback of T<sub>3</sub> and T<sub>4</sub>, it may be necessary to measure the levels of other hormones to assess the thyroidal axis in these challenging patients. When thyroid hormone levels are determined to be high or low, it is not necessarily beneficial to normalize these levels.

The most common thyroid problem seen in the ICU is "euthyroid sick syndrome," which represents abnormal laboratory tests that don't reflect primary thyroidal problems. Although some clinicians consider that patients with ESS may have clinical hypothyroidism, there is no role for therapeutic thyroid hormone supplementation in these patients. Several medications used in the ICU are commonly associated with hypothyroidism, including amiodarone and lithium. Other conditions encountered in ICU patients that may lead to hypothyroidism include Hashimoto thyroiditis and conditions requiring thyroid ablation by radioactive iodine or surgery. When hypothyroidism is severe it may lead to "myxedema coma" with cardiovascular collapse, severe metabolic derangements, and eventually, coma.

The signs and symptoms of hypothyroidism are usually subtle whereas those of hyperthyroidism are more flagrant and easy to recognize. The main cause of hyperthyroidism in the ICU as well as in the general population is Graves Disease. Although symptoms in Graves Disease may be severe, surgery, which controls the disease immediately, should not be attempted unless chemical control of the symptoms has been achieved with antithyroid drugs. Other less common but important causes of hyperthyroidism are use of iodinated contrast dyes, toxic nodular goiter, and thyroiditis. When hyperthyroidism is extreme, thyroid storm may be precipitated, which, if not recognized in critically ill patients, may lead to death. The symptoms of thyroid storm are believed to be related to the precipitous release of catecholamines. Thus the immediate treatment of this life-threatening condition is adrenergic blockade.

In general, there is an endocrine response to acute physiologic derangements seen in the ICU. This response is characterized by actively secreting pituitary hormones (e.g., TSH) with peripheral inactivation of the target organ hormones (e.g., T<sub>3</sub>). It is unclear whether this mechanism is harmful or protective. Treatment of these low hormone

states with hormone supplementation has not been successful to date.

The parafollicular cells of the thyroid produce calcitonin and its prohormone, procalcitonin. Procalcitonin has become increasingly recognized as an important marker for inflammatory states such as sepsis. Most of the procalcitonin produced in these states are not produced in the thyroid, but originates in extrathyroidal, nonneuroendocrine cells.

### Parathyroid Dysfunction

The parathyroid glands vary in number and in position for all patients, thus, an understanding of these variations is important before one embarks upon surgical exploration and removal of parathyroid tissue. The principal action of these glands is the regulation of calcium levels. It should be noted that although the intracellular levels of calcium may be most important for cell health, it is the extracellular levels that are tightly regulated by the parathyroid glands. Extracellular calcium exists as free active calcium, calcium bound to albumin and calcium complexed to anions. Because of changes in albumin and electrolytes in the ICU, measurement of ionized calcium is important to understand how much free bioactive calcium is present. Measurements of other serum levels such as magnesium, PTH, and Vitamin D are important to get a complete picture of calcium homeostasis and the role that the parathyroid glands play.

The rate at which calcium levels fall as well as the levels of hypocalcemia influence the clinical manifestations of hypocalcemia. There are many clinically-encountered conditions which lead to low serum levels of calcium, among which are postsurgery (parathyroidectomy), malignancy, hypomagnesemia, hypovitaminosis (Vitamin D), pancreatitis, autoimmune diseases (e.g., APECED), genetic diseases (e.g., diGeorge syndrome), infiltrative diseases (e.g., hemochromatosis), massive blood loss, and hypoalbuminemia. Some of these conditions, such as malignancy, can also be associated with hypercalcemia. Some, such as massive blood transfusion and hypoalbuminemia, are seen often in the ICU.

Calcium administration should be reserved for ionized levels less than 0.7 mmol/L, whereas mild hypocalcemia should be treated by measures such as withholding loop diuretics. Although massive blood transfusion may lead to hypocalcemia, calcium supplementation is usually not necessary unless ten or more units of banked blood have been transfused.

Hypercalcemia initially presents with nonspecific findings such as drowsiness, confusion, and anorexia, which are difficult to identify in ICU patients. Unrecognized hypercalcemia may become severe leading to more serious conditions such as obtundation, coma, and death. There are multiple etiologies for hypercalcemia including primary hyperparathyroidism, malignancy, hypervitaminosis (D and A), granulomatous disease, thyrotoxicosis, pheochromocytoma, thiazide diuretics, milk-alkali syndrome, and immobilization. Treatment of hypercalcemia usually requires only hydration and diuresis (saline diuresis). For severe hypercalcemia and hypercalcemia caused by specific disease processes, pamidronate, calcitonin, biphosphonates, and, in rare circumstances, surgery (parathyroidectomy) may be required. Surgery for both parathyroid and thyroidal illnesses relies on careful, meticulous technique and, when done correctly, is not associated with much morbidity or mortality. Nonetheless, recent advances in minimally invasive surgery have given surgeons more options for performing

these delicate operations. The most commonly recognized problem for parathyroid (and less commonly, thyroid) surgery is hypocalcemia secondary to hypoparathyroidism. Significant acute hypocalcemia that might require ICU monitoring occurs only following removal of hyperactive parathyroid tissue causing "hungry bone syndrome."

## KEY POINTS

- ✂ Thyroxine, the prohormone, is the predominately released species upon TSH stimulation; most of the triiodothyronine, the bioactive hormone, is produced by extrathyroidal conversion.
- ✂ Levels of thyroid hormone should not necessarily be normalized during critical illness.
- ✂ This biphasic response to iodide is important insofar as iodide administration can precipitate either hyperthyroidism or hypothyroidism.
- ✂ Many problems seen in the ICU cause either increased or decreased binding of thyroid hormone to its binding proteins, which may make the total hormone levels abnormal while the free, active hormone levels are normal or vice versa.
- ✂ In ESS, there are perturbations in the entire hypothalamic-pituitary-thyroid hormone system and it is unclear if these patients are truly euthyroid or perhaps have central hypothyroidism (9). For this reason, the term nonthyroidal illness (NTI) may be more appropriate than ESS.
- ✂ The presence of a surgical scar, a goiter, unexplained atrial fibrillation, hyponatremia, or constipation may be important clues to NTI.
- ✂ Approximately 15% to 20% of patients on long-term treatment with amiodarone develop thyroid abnormalities, especially if there is underlying thyroid pathology (15).
- ✂ When hypothyroidism is severe, it will result in hypothermia, hypo-ventilation, severe metabolic derangements, cardiovascular collapse, and eventually, coma.
- ✂ Although subtotal or total thyroidectomy immediately controls symptoms of Graves Disease, surgery should not be attempted unless chemical control of symptoms and, optimally, thyroid hormone levels have been achieved with antithyroid drugs.
- ✂ The symptoms of thyroid storm are believed to be the result of the precipitous release or enhanced action of catecholamines by thyroid hormone. Thus, the immediate treatment is adrenergic blockade with agents such as propranolol, reserpine, and guanethidine.
- ✂ When there is an acute metabolic or physiologic insult associated with trauma, sepsis, surgery, etc., the endocrine response can be characterized as actively secreting pituitary hormones with peripheral inactivation of the target organ hormones.
- ✂ Post thyroid surgery stridor is an airway emergency, most frequently due to bleeding into the wound or injury to the recurrent laryngeal nerves.
- ✂ Acidosis increases the ionized calcium levels, and alkalosis reduces these levels (i.e., an increase of pH change by 0.1 decreases ionized calcium 0.1 mg/dL and vice versa).
- ✂ Digitalis, cyclosporin, *cis*-platinum, diuretics, aminoglycosides, amphoterecin B, and citrate (in blood transfusions) will lower measured magnesium levels.
- ✂ Both the absolute level and the rate of fall of calcium influence the clinical manifestations of hypocalcemia.
- ✂ Administration of calcium in systemic inflammation has not been useful. In this regard, the hypocalcemia seen with SIRS may be part of the inflammatory response process and may be protective.
- ✂ Hypocalcemia from the "hungry bone syndrome" occurs following surgical resection of large adenomas, which had caused severe primary hyperparathyroidism.
- ✂ More aggressive therapy should be reserved for severe ionized hypocalcemia (<0.7 mmol/L), severe symptoms (Table 8), or antagonism of specific conditions such as hyperkalemia, hypermagnesemia, and calcium channel blocker toxicity.
- ✂ Routine administration of calcium with massive blood transfusions is controversial; however, calcium is frequently useful if blood is administered rapidly and when ten or more units are administered (41).
- ✂ Severe illness, prolonged immobilization, low vitamin D levels, and aging all conspire to increase bone resorption.
- ✂ The patient with "hypercalcemic crisis" often presents with signs and symptoms of severe hypercalcemia including severe fatigue, oliguria, anuria, somnolence, and coma.

### INTRODUCTION

The adrenal cortex produces steroids of three different types: glucocorticoids, mineralocorticoids, and steroidal sex hormones. The adrenal medulla produces the catecholamines adrenaline (aka epinephrine) and noradrenaline (aka norepinephrine). In the case of adrenal injury, failure of production or secretion of the glucocorticosteroid cortisol bears the most serious consequences (1–3). Hypocorticism is a rather rare disease and is, therefore, more difficult to diagnose. The absence of hydrocortisone in the critically ill patient can have catastrophic consequences (4).

✂ **Adrenal crisis, also known as Addisonian crisis, in a critically ill patient is a medical emergency.** ✂ Fatalities have been described following inadequate hydrocortisone administration in patients severely stressed by acute illness and in those undergoing major surgery (1–4). The intensivist should be familiar with the classic presentation of adrenal crisis and be prepared to supplement the ill patient with adequate amounts of glucocorticoids. ✂ **Because adrenal crisis is a rare event, the diagnosis may be missed, unless the traumatologist/intensivist has a high index of suspicion.** ✂ Often empiric therapy is warranted due to the lack of history and time constraints, especially in the unconscious patient.

This chapter reviews the physiology of normal adrenal function and the associated hormones, the classic clinical presentation, and diagnostic and treatment options of adrenal crisis in the setting of the operating room and the intensive care unit (ICU). In addition, the effects of various exogenous steroids are provided, along with perioperative guidelines for exogenous steroid use in patients with presumed adrenal suppression.

### ADRENAL GLAND ANATOMY

The adrenal glands are located in the retroperitoneal space above the superior pole of the kidneys. The adrenal glands are extremely well vascularized and consist of two distinct but interconnected endocrine organs of embryologically distinct origins: the adrenal cortex (derived from mesoderm), which produces three major categories of steroid hormones; and the adrenal medulla, derived from ectoderm (neural crest cells), which produces the catecholamines epinephrine and norepinephrine.

The medulla is perfused by a portal venous system that drains the cortex, providing a rich flow of glucocorticoids that induce enzymes responsible for catecholamine synthesis. The chromaffin cell is the principle cell type that synthesizes catecholamines from cholesterol. The medulla is richly innervated by preganglionic sympathetic nerve fibers, serving in essence as an extension of the sympathetic nervous system.

The adrenal cortex is divided into three layers: the outer zona glomerulosa, which produces and secretes the mineralocorticoid aldosterone; the middle zona fasciculata, which produces the glucocorticoid cortisol; and the inner zona reticularis, which produces androgens.

### HYPOTHALAMIC-PITUITARY-ADRENAL AXIS PHYSIOLOGY

The production and release of glucocorticoids and androgens is regulated by the hypothalamic-pituitary-adrenal (HPA) axis (5). The hypothalamus is responsible for the production of corticotropin-releasing hormone (CRH). CRH, in turn, acts upon the anterior pituitary gland by signaling the release of adrenocorticotropic hormone (ACTH). ACTH regulates the synthesis and release of glucocorticoids and androgens in the adrenal cortex (6). The glucocorticoid cortisol is life maintaining, and its deficiency plays a central role in hypoadrenal crisis. In contrast, the androgens do not play a significant role. Both CRH and ACTH receive negative feedback regulation from cortisol (Fig. 1) (7).

ACTH and cortisol secretion have a diurnal pattern of variation, with maximum secretion between 2 a.m. and 8 a.m., and minimum availability around midnight. Normally, in the absence of any physical or psychological stressors, the body produces 15 to 20 mg of cortisol per day (8).

An abnormally flattened circadian cortisol cycle has been linked with chronic fatigue syndrome (9), insomnia (10), and “burnout” (11). Critically ill patients often manifest a slightly elevated but flattened curve as well (particularly when chronically stressed) (3–8).

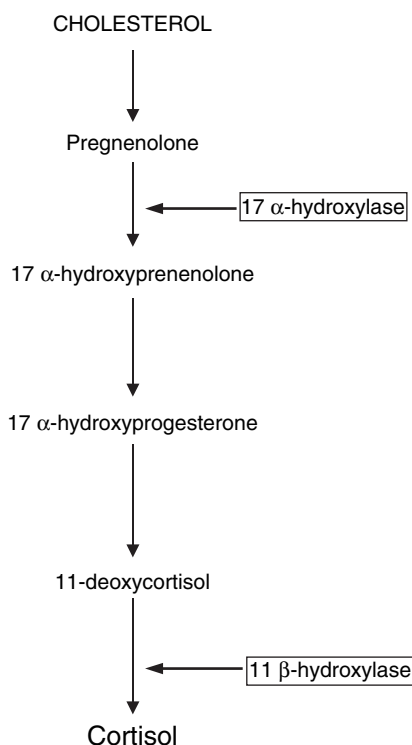

### Cortisol Production and Actions

Cortisol, like many other steroidal hormones, is an end product of cholesterol. Cholesterol is first metabolized in the adrenal gland to pregnenolone, which serves as a precursor for both cortisol and aldosterone, in two separate biochemical pathways. The last step of the synthesis of cortisol is the

**Figure 1** Hypothalamic-pituitary-adrenal axis. Hypothalamus releases corticotropin-releasing factor, stimulating the pituitary gland. The pituitary gland releases adrenocorticotropic hormone which stimulates the adrenal gland to produce cortisol. Cortisol exerts a negative feedback to the pituitary gland and the hypothalamus, and thus inhibits both their activity. *Abbreviations:* ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone. *Source:* From Ref. 5.

conversion of 11-desoxycortisol to cortisol, under the influence of the enzyme  $11\beta$ -hydroxylase (Fig. 2) (12). If one of the rate-limiting steps in the cortisol production is

**Figure 2** Etomidate inhibits in a dose-dependent fashion the enzyme  $11\beta$ -hydroxylase, and to a lesser extent the enzyme  $17\alpha$ -hydroxylase. This leads to an excess of 11-deoxycortisol and a lack of cortisol. *Source:* From Ref. 12.

inhibited (as can occur with the drug etomidate), then the production and homeostasis of glucocorticoids is severely disturbed (13).

### Cardiovascular Effects of Cortisol

✎ Cortisol is essential in maintaining vascular tone and thus sustaining blood pressure; indeed, in the absence of cortisol, smooth muscle cells become unresponsive to catecholamines. ✎ Cortisol both facilitates the vasoconstrictor actions of catecholamines, and has a permissive role on catecholamine synthesis (14,15). Classic mediators of septic shock, like interleukin-1 (IL-1) and interleukin-6 (IL-6), have been shown to stimulate the HPA axis and raise plasma cortisol levels by inducing the release of CRH (16).

### Stress Hormone Role of Cortisol

Cortisol is considered a stress hormone and has a positive effect on mood, providing a sense of well being. Stress-mediated neuronal stimulation of the hypothalamus causes CRH release, which induces ACTH release and a subsequent raise in cortisol; this mechanism overrides the body's usual circadian rhythm of ACTH and cortisol secretion (17). Patients with an intact HPA axis are found to have elevated cortisol levels during periods of stress and illness (16). Serum cortisol increases by two to 10 times that of normal, depending on the nature of the stressor (1,8–19). For example, with the stress of surgery, cortisol requirements usually increase from 75 to 150 mg/day (6). The maximum release of cortisol does not exceed 300 mg. Even major surgery does not lead to more than 200 to 300 mg of cortisol secretion in the first 24 hours (6,18). Patients with adrenal insufficiency, by definition, fail to reach the normal increased physiologic levels in a stressed state (1,8).

Anatomical connections between the amygdala, hippocampus, and hypothalamus facilitate activation of the HPA axis (20). Sensory information arriving at the lateral aspect of the amygdala is processed and conveyed to the central nucleus, which hosts projections to several parts of the brain involved in the fear responses. At the hypothalamus, fear-signaling impulses activate both the sympathetic nervous system and the HPA axis (20–22). These neuroendocrinological connections involving the HPA axis are now thought to be integrally related to the development of post-traumatic stress disorder (PTSD), which is fully reviewed in Volume 2, Chapter 65 (20–22).

Glucocorticoids serve important functions, including modulation of stress reactions, but they can be damaging with chronic stimulation. ✎ **Atrophy of the hippocampus is seen in humans and animals exposed to severe stress, and believed to result from excessive stress-induced glucocorticoid levels.** ✎ Deficiencies of the hippocampus are believed to reduce the memory resources available to help a body formulate appropriate reactions to stress (23).

### Metabolic Properties of Cortisol

Cortisol has metabolic and catabolic properties as well. It promotes glucose production through gluconeogenesis and antagonism of insulin action (1,8). It also promotes the breakdown of lipids and proteins, mobilizing these energy stores as substrate for gluconeogenesis.

Cortisol and other glucocorticoids affect bone and calcium homeostasis. Cortisol increases calcium reabsorption from bone and in excess can cause osteoporosis (1,2). Cortisol also inhibits intestinal calcium absorption and

drives extracellular calcium into intracellular space. Cortisol and other glucocorticoids also inhibit ADH, and when in high concentrations, bind to mineralocorticoid receptors, providing an aldosterone-like effect (sodium reabsorption and potassium secretion).

## ALDOSTERONE PRODUCTION REGULATION AND ACTION

The secretion of aldosterone is mainly under the control of the rennin-angiotensin-aldosterone system (RAAS). Aldosterone is the principle mineralocorticoid, although cortisol is said to have weak mineralocorticoid effects in nonrodent mammals. Aldosterone causes sodium reabsorption in conjunction with potassium and hydrogen ion excretion at the renal tubules, and serves as the primary controller of extracellular fluid and plasma volume (24,25). Also see Volume 2, Chapter 44.

A decrease in intravascular volume leads to increased secretion of renin by the juxtaglomerular apparatus (JGA), leading to increased conversion of angiotensinogen to angiotensin I, and then to angiotensin II. Angiotensin II acts on the adrenal zona glomerulosa to increase the activity of aldosterone synthase, and therefore, the secretion of aldosterone. Hyperkalemia also increases the activity of aldosterone synthase.

✎ **Aldosterone deficiency leads to hyponatremia, decreased plasma volume, hyperkalemia, and metabolic acidosis. In primary adrenal crisis, these effects exacerbate those due to cortisol deficiency and lead to profound cardiovascular collapse (24,25).** ✎

## ADRENAL INSUFFICIENCY DEFINITIONS AND ETIOLOGIES

“Primary” adrenal insufficiency is defined as a deficiency of aldosterone, cortisol, and other adrenal hormones due to disease of, or direct trauma to, the adrenal glands themselves, or due to drugs that block the adrenal synthesis of cortisol. “Secondary” adrenal insufficiency is defined as a decrease in secretion of ACTH by the pituitary gland either due to direct pituitary pathology, or because of hypothalamic pathology resulting in decreased elaboration of CRH (though some term the hypothalamic causes as “Tertiary” adrenal insufficiency) (3). “Tertiary” adrenal insufficiency is generally referred to as that resulting from peripheral resistance to cortisol, and is by far the least common variety of adrenal insufficiency. The pathological entities that can result in primary and secondary adrenal insufficiency are extensive. Only the most common causes will be reviewed here.

### Primary

Primary adrenal insufficiency, dysfunction of the adrenal glands themselves, is commonly referred to as Addison’s disease. Though this term is probably best reserved for the autoimmune variety (the most common type), Addison’s disease is reported to occur in 39 to 177 individuals per million population (26,27). The mean age at which it is diagnosed in adult patients is 40 years (range, 17–72 years old) (28). The estimates of occult adrenal insufficiency in critically ill patients and in the general population depend partly upon the criteria chosen and the tools used to diagnose the disease. Therefore, it is difficult to compare older with newer literature (29).

In one survey, over 80% of patients with adrenal insufficiency and who belonged to the National Adrenal Disease Foundation (NADF) had seen two or more physicians before the correct diagnosis was considered (30). The NADF estimates that approximately 10,000 individuals in the United States suffer with Addison’s disease (30). The NADF points out that this figure most likely underestimates the prevalence of Addison’s disease in the United States. The number of people who have subclinical secondary adrenal insufficiency that can be uncovered by stressful events is not included.

### Autoimmune

Primary adrenal insufficiency, also known as Addison’s disease, most commonly results from an autoimmune adrenitis, accounting for about 70% to 90% of all cases of adrenal insufficiency in the United States (1–3,31,32). Autoimmune adrenitis may present alone or along with other autoimmune endocrine diseases, and may be found as a component of type I or II polyglandular syndrome (1–3,31,32). The primary autoimmune etiology is the formation of autoantibodies against the 21-hydroxylase enzyme producing cells. Also, see Volume 2, Chapter 52 for a discussion of autoimmune disease in trauma and critical care.

### Granulomatous Disease

Tuberculosis (TB) was once the most common cause of primary adrenal insufficiency (1). Granulomatous diseases (including TB), along with some fungal diseases (i.e., histoplasmosis, blastomycosis), can cause complete adrenal destruction (1). Other causes of primary adrenal insufficiency include acquired immunodeficiency syndrome (AIDS), metastatic carcinoma, and sepsis-related adrenal hemorrhage.

### Trauma-Related Adrenal Hemorrhage

Adrenal hemorrhage can also result from abdominal trauma (33), and the risk is likely elevated in patients taking anticoagulants (33,34). Porter et al. (33) describe in a case series of blunt trauma deaths (mainly caused by motor vehicle accidents) with an adrenal hemorrhage incidence of 8% (21 of 269 patients). The authors suggest in this study that adrenal hemorrhage can result from direct injury itself, rather than as a terminal event involving the HPA axis, and that some patients with severe abdominal trauma may benefit from exogenous steroid administration (33).

In a case series of 14 patients with adrenal gland trauma by Gomez et al. (35), 12 patients required surgical exploration of the adrenal gland. In seven of the 12 patients, repair, rather than removal of the gland, was possible and no patient required adrenal corticosteroid replacement therapy (35). Webster and Bell (36) describe a young patient who developed primary adrenal insufficiency in a rehabilitation center one month after an isolated serious head injury and a complex ICU course. The patient’s symptoms improved markedly under corticosteroid therapy (36).

Both blunt and penetrating abdominal trauma, as well as prolonged critical illness and stressful operations, have led to bleeding or dysfunction of the adrenal gland resulting in relative hypoadrenalism or adrenal insufficiency (so-called “Addisonian crisis”) (1–3). However, primary injury to the adrenal glands is a far less common cause of adrenal insufficiency in critically ill trauma patients.

### Human Immunodeficiency Virus and Miscellaneous Causes

Adrenal insufficiency is also the most serious endocrine complication that occurs in persons with human immunodeficiency virus (HIV) infection (37). In AIDS, the adrenal gland may be destroyed by opportunistic infections. Adrenal insufficiency develops in 30% of patients with advanced AIDS (1,31). Metastases to the adrenal gland most often originate from the lung, but also from other primary sites including the breast, kidney, stomach, pancreas, and colon.

### Secondary Adrenal Insufficiency

Secondary adrenal insufficiency can result from any lesion to the pituitary (decreasing ACTH production) or the hypothalamus (impairing CRH). The most common cause is the abrupt discontinuation of exogenous glucocorticoid administration following long-term glucocorticoid therapy (38). Chronic glucocorticoid use results in prolonged suppression of CRH production and release. In the long-term glucocorticoid user, adrenal insufficiency clinically manifests itself in two circumstances: (i) when maintenance steroids are not increased in response to stress, or (ii) when chronic steroids are tapered too abruptly (1–3).

## ADRENAL SUPPRESSION AND CRISIS IN CRITICAL ILLNESS

✎ **Secondary adrenal insufficiency is most commonly seen with long-term use of glucocorticoid usage. However, in critically ill patients, prolonged periods of elevated stress are also associated.** ✎

The patient postcessation of steroid therapy may be asymptomatic unless there is an acute stress. If the patient undergoes surgery or sustains an infection, it is critical to provide replacement steroids, otherwise circulatory collapse may result (5,16–19).

It may only take a few weeks of glucocorticoid administration to develop suppression of the HPA axis and relative adrenal insufficiency to occur (2). However, it can take six to 12 months postsuppression by exogenous steroids for the HPA axis to fully recover its function (39). Lamberts et al. (19) emphasize that the duration of recovery of the HPA can range from days to one year. Less common causes of secondary adrenal insufficiency include pituitary or metastatic tumors, hypothalamic tumors, craniopharyngioma, sarcoidosis, pituitary surgery or radiation, traumatic brain injury (TBI), and postpartum pituitary necrosis (Table 1) (1).

Glucocorticoids administered in equivalent doses of up to 5 mg of prednisone, for any given period of time, generally do not cause secondary adrenal insufficiency once the steroid is withdrawn (19,40). However, doses greater than 10 mg prednisone for extended periods may cause HPA suppression.

Trauma patients are prone to adrenal hemorrhage. Porter (33) describes a 7% incidence of adrenal hemorrhage in ultimately fatal motor vehicle accident victims. Adrenal injuries should also be considered in blunt and penetrating trauma (35). The incidence and response to treatment of adrenal insufficiency in high-risk postoperative patients was studied in a prospective observational case series by Rivers et al. (17). They found that 33% of patients, amongst 104 critically ill surgical patients over the age of 55, have abnormally low adrenal function. Although the study design did not test prospectively against a noncortisol treatment group, it appears that there was a trend toward earlier

**Table 1** Factors Contributing to the Development of Relative Hypoadrenalism in Critically Ill Patients

Pre-existing or previously undiagnosed asymptomatic diseases of the adrenal gland
Partial destruction of the adrenal cortex
Autoimmune adrenalitis
Tuberculosis
Metastasis
Acute partial destruction of the adrenal glands
Hemorrhage
Massive retroperitoneal bleeding
Thrombocytopenia
Anticoagulant therapy
Bacterial infection (meningococemia), viral, or fungal infections
Previously unknown hypothalamic-pituitary disease resulting in undiagnosed secondary hypothalamic-pituitary-adrenal insufficiency
Cytokine-mediated inhibition of ACTH release during septic shock? (16)

*Abbreviation:* ACTH, adrenocorticotropic hormone.

*Source:* From Ref. 19. Courtesy of NEJM.

recovery from vasopressor therapy within 24 hours among the patients who received a hydrocortisone stress dose.

Critically ill patients with adrenal dysfunction and those with functional hypoadrenalism have a different response to fluid resuscitation and pressors than those with normal cortisol function (41). This is partly due to the low systemic vascular resistance (SVR) present with this condition. Seriously ill patients have a higher prevalence of adrenal insufficiency than the general population (4,41,42). Merry et al. (43) found that postoperative patients older than 55 also have a higher incidence of adrenal failure.

In critically ill patients with hemodynamic instability, a cortisol level and an ACTH test should be considered to test for the diagnosis of adrenal insufficiency (17). There is a wide variance of postoperative incidents of adrenal insufficiency and failure. One of the reasons for this wide discrepancy could be different patient populations, and different types and states of disease in various studies.

Routine screening for adrenal failure in the critically ill is therefore expensive, because with an incidence as low as 1%, it would take 99 patients without disease to find one ill patient with adrenal insufficiency. Patients with a high pretest probability such as old age, massive stress, laboratory abnormalities, and poor response to pressors and fluids should be considered as candidates for presumptive cortisol replacement and ACTH response testing.

## DIAGNOSIS OF ADRENAL SUPPRESSION IN CRITICAL ILLNESS

### Clinical Picture

In primary adrenal insufficiency, patients demonstrate depressed mentation, weakness, nausea, vomiting, diarrhea, pigmented skin, and eosinophilia. With secondary adrenal insufficiency, fluid and electrolyte disturbances are minimized, but hypoglycemia can be severe because both cortisol and (occasionally) growth hormone can be missing. These patients often lack the marked weight loss that is present in primary adrenal insufficiency and are not pigmented.

**Table 2** Laboratory Finding with Primary Adrenal Insufficiency

Hyponatremia (frequent)
Hyperkalemia
Acidosis
Slightly elevated plasma creatinine
Hypoglycemia
Hypercalcemia (rare)
Normocytic anemia
Lymphocytosis
Mild eosinophilia

Source: From Ref. 25.

Fever, tachycardia, low SVR, and orthostatic hypotension are seen with both varieties.

Biochemical profiles usually show a prerenal azotemia, an abnormal hyponatremia, increased potassium levels initially, and hypoglycemia (Table 2). **The cardiovascular exam in adrenal-suppressed patients usually reveals tachycardia, a weak thready pulse, a small cardiac silhouette on chest X-ray (CXR), and an empty heart by transesophageal echocardiography (TEE); Swan-Ganz would show a low cardiac output (due to low stroke volume) despite a low SVR.**

### Baseline Laboratory Abnormalities

Adrenal insufficiency typically causes classic electrolyte abnormalities, which include hyponatremia, hyperkalemia, and hypercalcemia. Hypoglycemia is also common and a mild metabolic acidosis and azotemia may also occur (Table 1) (1). However, serum electrolyte levels may all be initially normal in the adrenal insufficient patient, particularly if the onset of adrenal insufficiency is abrupt.

The hyponatremia that may occur with Addison's disease is rarely less than 120 mEq/L. Hyperkalemia is rarely greater than 7 mEq/L. Hyponatremia results from both aldosterone and cortisol deficiency in primary adrenal insufficiency. Cortisol deficiency results in increased levels of antidiuretic hormone (ADH, also known as vasopressin), which prevents the excretion of free water. **Hyponatremia is less profound in secondary adrenal insufficiency because both RAASs are still typically intact.** Aldosterone deficiency, seen in primary adrenal insufficiency, results in sodium depletion with retention of potassium and hydrogen ions. In secondary adrenal insufficiency, the reasons for hyponatremia are due to cortisol deficiency, increased vasopressin secretion, and water retention (25).

**Table 3** Considerations During Cortisol and Cosyntropin<sup>a</sup> Laboratory Testing in Critically Ill Patients

Basal cortisol level between 8 and 9 AM	Lower than 3 mcg/dL = primary adrenal insufficiency Higher than 18 mcg/dL = no primary adrenal insufficiency
Standard cosyntropin stimulation testing with 250 mcg i.v	Response of more than 18 mcg/dL cortisol is considered to be a normal test and should exclude primary adrenal insufficiency Problems 250 mcg cosyntropin is unphysiologically high and it can miss ACTH resistance and partial secondary adrenal insufficiency Current data suggest that the cortisol response to the ACTH stimulation test in critical illness should exceed 25–30 mcg/dL
The standard dose of 250 mcg cosyntropin for the ACTH stimulation test should be replaced by 1–2 mcg by IV	1–2 mcg of cosyntropin is more physiologic and sensitive in critically ill patients

<sup>a</sup>Cosyntropin is synthetic adrenocorticotropic hormone (ACTH).  
Abbreviation: ACTH, adrenocorticotropic hormone.

Recognition of the above described laboratory/electrolyte abnormalities may be very helpful in establishing the diagnosis of adrenal insufficiency. However, it is important that the diagnosis of adrenal insufficiency not be excluded on the basis of normal electrolytes, because they may be relatively normal initially. In addition, electrolyte abnormalities alone do not constitute a basis for diagnosis.

### Measurement of Cortisol Levels

A first step to evaluate a patient for adrenal insufficiency is to obtain a basal plasma cortisol level at 8 AM to 9 AM. If the basal cortisol level is less than 3 mcg/dL (83 nmol/L), the patient has primary adrenal insufficiency and no further testing is needed. A basal morning cortisol level of more than 19 mcg/dL (525 nmol/L) rules out a primary adrenal insufficiency (1–3,18,44). All other patients need dynamic testing with cosyntropin (synthetic ACTH) induced cortisol stimulation. For the critically ill patient, it is very important to recognize adrenal insufficiency. Acute adrenal insufficiency is now more commonly recognized in patients with sepsis and septic shock (17,42).

In the standard cosyntropin stimulation test, the plasma cortisol levels are measured before and after cosyntropin is administered. In this test, a high dose of 250 mcg is given intravenously before 10 AM, and plasma cortisol levels are measured prior to injection, as well as 30 and 60 minutes after injection (1). A response of more than 18 mcg/dL of cortisol is considered to be a normal test and should exclude primary adrenal insufficiency (Table 3) (44).

Because of erratic absorption via intramuscular injections in critically ill patients, this test should only be performed with intravenous administration of cosyntropin. Zaloga and Shenker believe that a high-dose cosyntropin ACTH stimulation test (250 mcg), normally used for noncritically ill patients, may not be appropriate for critically ill patients in an ICU (5,18).

Current data suggests that the cortisol response to critical illness should exceed 25 to 30 mcg/dL, which is higher than the 18 mcg/dL proposed by Grinspoon (5,44). Additionally, in critically ill patients with an acute onset of stress and illness, a normal response to exogenous ACTH can occur due to acute adrenal insufficiency, partial secondary adrenal insufficiency, and ACTH resistance. Furthermore, the standard ACTH stimulation test uses nonphysiologic high doses of cosyntropin, and should be replaced by lower doses of 1 to 2 mcg of cosyntropin since critically ill patients can develop ACTH resistance, which can be overcome with nonphysiologic high doses of cosyntropin (5,18).

The insulin hypoglycemia or the metapyron test are better for testing for secondary adrenal insufficiency, but they are cumbersome and difficult to perform with an ICU patient (18). The considerations and potential pitfalls with the cortisol and cosyntropin laboratory testing in critically ill patients is reviewed in Table 3.

## DRUG INTERACTIONS CAUSING ADRENAL SUPPRESSION

☞ **Certain drugs like etomidate or rifampin can cause adrenal insufficiency and potentially trigger or exacerbate an Addisonian crisis in a critically ill patient with pre-existing adrenal insufficiency.** ☞

Numerous drugs can interfere with the release, biosynthesis, metabolism, and receptor effects of glucocorticoids, which precipitate drug-induced adrenal insufficiency or adrenal crisis. Another factor can be an unrecognized use of steroids. The patient and the physician might not always be aware of previous steroid use. Intra-articular injections of corticosteroids have seldom caused HAA suppression and been associated with subsequent adrenal crisis, which rapidly improved with hydrocortisone therapy (45). Systemic glucocorticoid therapy is more likely to suppress the HPA axis than intra-articular, inhalation, or topical steroid use (46).

The most common cause of secondary adrenal insufficiency in the ICU is the withdrawal of exogenous glucocorticoids (47). Many surgical and medical patients enter the ICU because of an emergency without a detailed medical history and with the immediate need for critical and life-saving interventions like endotracheal intubation. In these cases, the health care personnel (physicians and nurses) have to investigate the patient's prior medication history. Adrenal insufficiency should always be a differential diagnosis in critically ill patients with a recent use of steroids and therapy-refractory hypotension. Classic examples for steroid use are asthma bronchiale, rheumatologic disease, and chronic inflammatory conditions.

There are many drugs which can lead to relative hypoadrenalism. Several drugs and medications interfere with corticosteroid homeostasis and therapy. Adrenal insufficiency under stress may simply be due to previously unknown glucocorticosteroid therapy. Patients with obvious Cushing syndrome should be considered at risk for relative adrenal insufficiency under medical or surgical stress. Relative deficiency of endogenous glucocorticosteroids or current steroid therapy can be a result of a drug–drug interaction, change in cortisol synthesis, glucocorticoid-receptor blockade or interference with ACTH action at the adrenal gland (1–4,19). Patients who are treated with phenytoin, rifampin, barbiturates, mitotane, and aminoglutethimide have increased steroid metabolism (Table 4) (19).

Rifampin is a good example for such a drug–drug interaction. Rifampin is a potent inducer of both gut and hepatic cytochrome P450 (CYP3A4) (31,47). The induction of this enzyme leads to a significant increase in the clearance of steroids and other drugs (47). Ketoconazole is an effective inhibitor of endogenous steroid production. Ketoconazole inhibits the synthesis of glucocorticoids by blocking the 17 $\alpha$ -hydroxylase cytochrome P450 (CYP-17 $\alpha$ ), which is an important enzyme in steroidogenesis (48).

Mefipristone (RU 486), or the abortion pill as it is known, acts by blocking glucocorticoid receptors and was approved by the Food and Drug Administration (FDA) in

**Table 4** Drug-Related Factors Contributing to the Development of Relative Hypoadrenalism in Critically Ill Patients

Previously unknown corticosteroid therapy
Medroxyprogesteron, megestrol acetate
Increased metabolism of cortisol: phenytoin, phenobarbital, rifampin
Changes in cortisol synthesis: ketoconazol, etomidate, aminoglutethimite, metapyron, mitotane, trilostane
Interference with ACTH action: suramin
Peripheral glucocorticoid-receptor blockade

*Abbreviation:* ACTH, adrenocorticotrophic hormone.

*Source:* From Ref. 19. Courtesy of NEJM.

2000 as an option for first-trimester abortions (49). Replacement therapy with glucocorticoids in patients with adrenal insufficiency receiving RU 486 may be insufficient, due to the steroid receptor blockade of this drug. Also, megestrol acetate, a synthetic pro-gestational agent used to increase appetite in cachexia-inducing illnesses, can suppress ACTH secretion at doses of >160 mg/day, leading to secondary adrenal insufficiency.

Etomidate is another example where a therapeutic drug interferes with steroidogenesis, and can lead to problems with the stress response of critically ill or injured patients in the perioperative period, or the ICU setting. Etomidate is a carboxylated imidazole-containing compound that is chemically unrelated to any other drug used for the induction of anesthesia. Following an induction dose of 0.3 mg/kg intravenously, the onset of unconsciousness occurs within one arm-to-brain circulation time. It is used in trauma because of its hemodynamic stability. Etomidate inhibits the 11 $\beta$ -hydroxylase and (to a lesser extent) the 17 $\alpha$ -hydroxylase enzymes (Fig. 1) (12). After a single dose, adrenal suppression lasts only six to eight hours (13). However, with a prolonged infusion in critically ill trauma patients, Ledingham et al. (50) found an increased mortality compared to patients sedated with morphine and benzodiazepines. Fellows et al. (13) confirmed this observation in a small prospective study with six multiply injured patients in an ICU. All had in common a low adrenocortical function, and all received etomidate infusions for sedation. Another ICU study with similar patients, also receiving steroid replacement, did not experience increased mortality. Vitamin C restores the plasma cortisol level after etomidate (51,52).

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for adrenal insufficiency, especially under medical or surgical stress, is broad. Often the patients are unconscious and cannot give a history of previous steroid use. This is true in patients with head injuries or other intracranial pathology such as subarachnoid bleed. Mental status changes should be investigated for other structural-anatomic or toxic metabolic causes. Patients with an unknown change of mentation should undergo advanced head imaging studies, such as computed tomography, as well as a full laboratory work-up including cultures of all body fluids in the febrile patient. A lumbar puncture should be performed in the absence of a classic contraindication.

New psychiatric changes, especially after the third life decade, should receive a full medical work-up, including an

endocrine evaluation, since adrenal insufficiency can present as depression or apathy. Anytime a patient shows mental status or psychiatric changes accompanied with fluid and electrolyte imbalance and cardiovascular instability, adrenal insufficiency should be included in the differential diagnosis.

High fever without apparent cause and negative cultures that do not respond to antibiotics should generate a differential diagnosis of adrenal insufficiency (19). Unexplained circulatory instability (including low SVR) should raise suspicion for sepsis, unrecognized hypovolemia, unknown drug ingestion or medications, adrenal insufficiency, and other endocrinopathies. Hypoglycemia, hyponatremia, hyperkalemia, neutropenia, and eosinophilia can all be caused by adrenal insufficiency (Table 2). However, these symptoms can also be seen with diabetes mellitus, hypotonic dehydration, renal failure, chemo- and radiotherapy, and parasitic disease.

Skin changes like vitiligo, altered pigmentation, or cushingoid appearance with striae can be helpful in establishing a diagnosis of adrenal insufficiency, especially in the patient who cannot communicate. Physicians caring for seriously injured and unconscious patients should perform a careful inspection to look for a Medical-Alert (“Med-Alert”) bracelet or necklace, which could warn of pre-existing medical conditions such as adrenal insufficiency.

**TREATMENT**

**Adrenal Insufficiency/Crisis**

Empiric steroid administration should be considered in the patient who is hemodynamically unstable despite adequate fluid resuscitation and the use of high dose vasopressors. Administration of glucocorticoids should not be delayed for testing in a crisis situation. However, moderately stable or “metastable” patients can generally tolerate a brief time delay (for testing) between corticosteroid administration. If the patient is dwindling, then dexamethasone (a corticosteroid that does not interfere with the cosyntropin test) can be immediately administered.

☞ **The diagnosis and treatment of adrenal insufficiency in the “metastable” patient involves administration of dexamethasone sodium phosphate as the glucocorticoid of choice so as not to interfere with the cosyntropin stimulation test.** ☞

A lack of cortisol response following the administration of cosyntropin (synthetic ACTH) confirms hypoadrenocorticism. The intravenous administration 0.9% sodium chloride will help repair the hyponatremia and hypovolemia.

Although there is no strict biochemical criteria for relative adrenal insufficiency (19), Lamberts et al. (19) emphasize that the diagnosis of adrenal insufficiency should be entertained if administration of hydrocortisone to severely ill patients is followed by a period of diminished or absent requirement for exogenous vasopressor administration. In addition, as Zaloga and Marik (7) point out, a therapeutic trail with hydrocortisone should not be withheld in patients with suspected adrenal insufficiency who have pending results of a diagnostic stress cortisol level or cosyntropin stimulation test.

☞ **Emergency treatment for Addisonian crisis involves prompt intravenous administration of hydrocortisone, glucose, and 0.9% sodium chloride for shock and maintenance fluid volumes. Glucose and steroids will help to correct hypoglycemia.** ☞ Fever etiologies should be

thoroughly evaluated with appropriate cultures. However, fever is an important element in the constellation of Addisonian crisis and will resolve with glucocorticoid replacement and rehydration.

Baldwin and Allo (41) report that the administration of 100 to 300 mg hydrocortisone in a 24-hour period decreased or eliminated the need for vasopressors in critically ill patients. This suggests the occurrence of previously unrecognized occult hypoadrenalism, which under conditions of stress manifests as adrenal crisis.

**Perioperative Glucocorticoids for Suspected Hypothalamic-Pituitary-Adrenal Axis Suppression**

Classically, a bolus of 100 mg hydrocortisone is administered intravenously immediately prior to a major operation, and again after eight and 16 hours (approximately 300 mg hydrocortisone) on the first perioperative day in patients with suspected HPA axis depression, with continued high dose therapy for an additional one to two days, and a taper over the subsequent five days. However, this aggressive approach may not be required in patients who are undergoing minimally invasive procedures.

A consensus paper by Salem et al. (6) provides less aggressive recommendations for the substitution and supplementation of hydrocortisone depending upon both the previous dose and the magnitude of the operation. For minor stress, 25 mg is considered sufficient, and for moderate stress, 50 to 75 mg is recommended. If the patient is subjected to major operative and perioperative stress, a dose of 100 to 150 mg hydrocortisone per day over a period of one to three days should be administered. Since the more seriously ill patients remain intubated postoperatively and cannot eat, the hydrocortisone should be administered intravenously (Table 5).

Jabbar (8) recommends tapering the corticosteroid pulse over a five-day period. It is emphasized that the patient has to be stable and stressors such as fever or vomiting have been resolved, otherwise the taper is extended over a longer duration (Table 6).

For children undergoing major surgery, Tan (53) recommends the administration of hydrocortisone 100 mg/m<sup>2</sup>/day for 24 hours peri- and postoperatively before tapering over several days to a maintenance dose. After tapering, the patient needs to receive the regular maintenance dose. The authors point out that it is unnecessary to give mineralocorticoids over such periods if the patient starts

**Table 5** Dosage Recommendations for Hydrocortisone Supplementation Based upon the Magnitude of the Surgical Stress

Magnitude of stress	Amount of hydrocortisone per day
Minor stress	25 mg
Moderate stress	50–75 mg
Major stress	100–150 mg

The recommended glucocorticoid dose should be given for one to three days depending on the clinical course. The glucocorticoids are administered in three divided doses over each 24-hour span. See Table 6 for recommendations on tapering. Topical steroid users: In patients who use topical steroids (like inhaled beclomethasone), hypothalamic-pituitary-adrenal axis suppression is very rare. They usually do not need glucocorticoid supplementation with minor or moderate stress if they are clinically asymptomatic.

Source: From Refs. 6, 31.

**Table 6** Tapering Recommendations for Hydrocortisone Dosage Following Major Surgical Stress<sup>a</sup> in the Preoperative Phase for Patients with Hypothalamic-Pituitary-Adrenal Axis Suppression

Day of surgery	Dose of IV hydrocortisone per injection	Frequency of IV application
1	100 mg	Every 8 hr or tid
2	50 mg	Every 8 hr or tid
3	25 mg	Every 8 hr or tid
4	25 mg	Every 12 hr or bid
5	15–20 mg (AM) and 5–10 mg (PM)	Morning and evening dose

<sup>a</sup>Major surgical stress includes large scale tissue manipulation, cardiopulmonary bypass, major burns, massive trauma. Once fever and hemodynamic instability have resolved, the taper can be started.

Abbreviation: bid, twice a day; IV, intravenous; tid, three times a day.

Source: From Ref. 8.

the operation with adequate salt balance (43). This is in support of common practice in most hospitals, in that all patients with fluid and electrolyte imbalance, including those with adrenal insufficiency, should have their physiological status optimized before major surgery takes place.

Some controversy appears in the animal experimental literature: whether supraphysiologic doses of glucocorticoids, which are ten times the normal cortisol production rate, are really necessary to treat adrenal insufficiency during operative procedures to prevent hemodynamic instability (54).

## EYE TO THE FUTURE

Newer methods of diagnosis and treatment of glucocorticoid deficiency are on the horizon. Diagnosis requires measurement of the serum cortisol levels and the response of cortisol to ACTH. Currently, these tests to measure mcg levels of hormones at specific times are time-consuming and expensive. Often, patients require a series of hormonal testing panels performed in different settings before a definitive diagnosis can be established. In the future, easier and less expensive testing will help to establish adrenal insufficiency in the perioperative trauma patient. Treatment depends upon the degree of adrenocortical dysfunction, response to stimulating hormones, and clinical presentation.

Testing of therapeutic drugs on their propensity to disrupt cortisol synthesis should be intensified in the future, prior to release by the FDA. Etomidate is a commonly used anesthetic drug that can significantly impair adrenal function, especially in compromised patients in stressful situations. Vitamin C has been shown to attenuate this response in laboratory animals, and should be administered to trauma patients requiring etomidate for induction.

Ongoing studies are currently evaluating the role of high dose glucocorticoids in the context of hemorrhagic shock and septic shock. No conclusive data currently justify the routine prophylactic use of high dose corticosteroids in adrenally noncompromised patients to improve outcome. However, this role of steroids and other

inflammation inhibitors will continue to be the subject of future clinical investigation.

One of the most common errors in diagnosing adrenal insufficiency, especially in the unconscious or mentally impaired patient, is failure to consider the pre-existing condition, or failure to recognize the disease stigmata amongst other life-threatening injuries. Beyond the obvious benefit of reviewing a Med-Alert bracelet or necklace, future selected patients might have a microchip implanted under their skin on a voluntary basis (55). Implanted microchips could store vital information including: allergies, medical history, and current therapy for pre-existing conditions. In the case of important allergic predispositions or pre-existing adrenal insufficiency, this information could be life saving.

## SUMMARY

Glucocorticoids are life-sustaining steroids. Lack or relative lack of glucocorticoids can lead to therapy-refractory hypotension, imbalance of glucose, fluids, and electrolyte homeostasis in critically ill patients.

Life-threatening hypotension due to adrenal insufficiency constitutes adrenal (“Addisonian”) crisis (1–3). In many cases patients with chronic steroid use cannot produce enough endogenous glucocorticoids to combat the stress of severe illness, surgery, or massive trauma.

A common reason for adrenal suppression is the chronic use of steroids (secondary adrenal insufficiency) (38). Other causes of adrenal insufficiency are destruction of the adrenal glands by infection (e.g., tuberculosis), metastasis, or hemorrhage (e.g., trauma) (31). It is crucial to identify patients with true adrenal insufficiency. A medical history and clinical awareness are important to make the correct diagnosis.

Often, the diagnosis of adrenal insufficiency or adrenal crisis in the ICU or in the operating room can only be made empirically by treating therapy-refractory hypotension with glucocorticoids. A full work-up in search of the precipitating illness has to be performed. Supportive care, fluid administration, and hydrocortisone of up to 300 mg intravenously are the mainstay of therapy to treat adrenal crisis.

## KEY POINTS

- ✎ Adrenal crisis, also known as Addisonian crisis, in a critically ill patient is a medical emergency.
- ✎ Because adrenal crisis is a rare event, the diagnosis may be missed unless the traumatologist/intensivist has a high index of suspicion.
- ✎ Cortisol is essential in maintaining vascular tone and thus sustaining blood pressure; indeed in the absence of cortisol, smooth muscle cells become unresponsive to catecholamines.
- ✎ Atrophy of the hippocampus is seen in humans and animals exposed to severe stress and believed to result from excessive stress-induced glucocorticoid levels.
- ✎ Aldosterone deficiency leads to hyponatremia, decreased plasma volume, hyperkalemia, and metabolic acidosis. In primary adrenal crisis, these effects exacerbate those due to cortisol deficiency and lead to profound cardiovascular collapse.
- ✎ Secondary adrenal insufficiency is most commonly seen with long-term glucocorticoid usage. However, in

critically ill patients, prolonged periods of elevated stress is also associated.

- ✎ The cardiovascular exam in adrenal-suppressed patients usually reveals tachycardia, a weak thready pulse, a small cardiac silhouette on CXR, and an empty heart by TEE Swan-Ganz would show a low cardiac output (due to low stroke volume) despite a low SVR.
- ✎ Hyponatremia is less profound in secondary adrenal insufficiency because both RAASs are still typically intact.
- ✎ Certain drugs like etomidate or rifampin can cause adrenal insufficiency and potentially trigger or exacerbate an Addisonian crisis in a critically ill patient with pre-existing adrenal insufficiency.
- ✎ The diagnosis and treatment of adrenal insufficiency in the “metastable” patient involves administration of dexamethasone sodium phosphate as the glucocorticoid of choice, so as not to interfere with the cosyntropin stimulation test.
- ✎ Emergency treatment for Addisonian crisis involves prompt intravenous administration of hydrocortisone, glucose, and 0.9% sodium chloride for shock and maintenance fluid volumes. Glucose and steroids will help to correct hypoglycemia.

### INTRODUCTION

Systemic inflammation characterizes the nonspecific constitutional disturbance resulting from numerous insults including trauma, burns, major surgery, sepsis, and a variety of disease processes including pancreatitis. The cause of this postinjury systemic inflammatory response remains incompletely understood. The currently known inflammatory mediators involved in the systemic derangement involve multiple normally protective systems (including the immune and coagulation systems). The name given to this systemic maladaptive disturbance is the systemic inflammatory response syndrome (SIRS).

Whereas Volume 2, Chapter 47 (Sepsis) focuses mainly upon the infectious disease-related triggers and considerations for SIRS, this chapter highlights the fact that a variety of non-infective triggers can cause SIRS and reviews the many inter-related, cellular, and humoral (paracrine, autocrine, and endocrine) processes known to be involved. The chapter begins by reviewing the definition of SIRS, followed by a survey of the known contributors to SIRS, including in the immune system, cytokines, various markers of inflammation, the neuroendocrine system, and hormones. The increasingly appreciated interaction between inflammation and the coagulation system is reviewed subsequently. A theoretical construction is provided to incorporate the factors involved in the progression of SIRS to compensatory anti-inflammatory response syndrome (CARS) and multiple organ dysfunction syndrome (MODS). The presentation and progression of SIRS within specific populations (including trauma and critical care) is next examined, following which the effects of resuscitation, the gut, immunomodulation, and immunonutrition on SIRS are reviewed. Finally, the eye to the future section provides new definitions, improved diagnostic techniques, and emerging therapies still on the clinical horizon.

### THE 1992 DEFINITION OF SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND ITS REVISION IN 2001

SIRS is a systemic response to nonspecific insults, which may include infections (Volume 2, Chapter 47), pancreatitis

(Volume 2, Chapter 39), trauma, and burns (Volume 1, Chapter 34). SIRS, as a constitutional disturbance frequently associated with sepsis and trauma, has been recognized clinically for over a century. However, operational definitions and descriptions were extremely variable. A consensus conference of the American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM) was convened in 1991 and developed a uniform definition in an effort to provide standardization of definitions for both SIRS and sepsis for use in clinical research (1,2). According to the 1991 ACCP/SCCM Consensus Conference Committee, SIRS is defined as a widespread inflammatory response to a variety of clinical insults (infectious and non-infectious). The 1991 ACCP/SCCM scoring system for SIRS has a range from 0 to 4, with 1 point for each variable present (Table 1). SIRS is diagnosed if two or more of the following criteria are present: fever or hypothermia ( $T > 38^{\circ}\text{C}$  or  $T < 36^{\circ}\text{C}$ ), tachycardia ( $\text{HR} > 90$ ), tachypnea respiratory rate ( $\text{RR} > 20/\text{min}$  or  $\text{PaCO}_2 < 32$ ], and abnormal white blood cell count ( $\text{WBC} > 12,000/\text{mm}^3$  or  $< 4000/\text{mm}^3$ , or 10% bands).

✎ SIRS has been classified as an early component of the sepsis syndrome. SIRS and sepsis commonly present as a continuum of disease states, with progression of SIRS to sepsis, severe sepsis, and septic shock. ✎ "Sepsis" is defined as SIRS with a presumed or confirmed infectious process (see Volume 2, Chapter 47) (1). Sepsis can progress to "Severe Sepsis" that is defined as sepsis with evidence of organ dysfunction, hypoperfusion, or hypotension. "Septic shock" is defined as sepsis-induced hypotension persisting despite adequate fluid resuscitation, along with the presence of hypoperfusion abnormalities or organ dysfunction. The presence of altered organ function in an acutely ill patient with SIRS, often progresses to MODS (3).

In 2001, an international consensus was convened to review the 1991 definitions (4). The 2001 conference consensus included delegates from the SCCM, European Society of Intensive Care Medicine (ESICM), ACCP, American Thoracic Society (ATS), and the Surgical Infection Society (SIS) (4). They concluded that the current concepts of sepsis, severe sepsis, and septic shock seem robust and should remain as described 10 years prior. However, they also concluded that the diagnostic criteria for SIRS were overly sensitive

**Table 1** American College of Chest Physicians/Society of Critical Care Medicine Scoring System for Systemic Inflammatory Response Syndrome (SIRS). SIRS Is Diagnosed if Two or More of the Following Criteria Are Present (SIRS Score  $\geq 2$ )

SIRS score variables	Points
Fever or hypothermia ( $T \geq 38^\circ\text{C}$ or $\leq 36^\circ\text{C}$ )	1
Tachycardia (HR $>90$ )	1
Tachypnea (RR $>20/\text{min}$ , $\text{PaCO}_2 <32$ )	1
Abnormal WBC (WBC $>12,000/\text{mm}^3$ , or $<4000/\text{mm}^3$ , or 10% bands)	1
Maximum total SIRS score	4

Abbreviations: RR, respiratory rate; SIRS, systemic inflammatory response syndrome; WBC, white blood cell count, HR, heart rate.

Source: From Ref. 1.

and not specific (4). They proposed an expanded list of signs and symptoms of sepsis (provided in Volume 2, Chapter 47) and a staging system called PIRO (Predisposition, Infection, Response, and Organ dysfunction) (also provided in Volume 2, Chapter 47) (4). However, they do not provide any new guidance regarding noninfectious etiologies of SIRS. The 2001, SCCM/ESICM/ACCP/ATS/SIS summary recommendations are provided in Table 2 (4).

## IMMUNE SYSTEM REVIEW AND ROLE IN THE SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

The immune system is a complex network of diverse cells and proteins that continuously evolves in response to both innate and environmental stimuli. The individual cells communicate and collaborate with each other to modulate their own proliferation, and to coordinate the complex

elaboration of compounds, which aid in the identification and destruction of foreign invaders and other compounds associated with survival, repair, and recovery after critical illness, surgery or trauma.

### Initial Immune Response

The immune response is triggered when an antigen encounters antigen-presenting cells (APCs). APCs process a protein component of the antigen and present it to antigen-specific helper T lymphocytes. These helper T lymphocytes become activated and initiate an immune cascade (Fig. 1). This process involves the self-proliferation of helper T cells that then carry out their specific effector functions. These helper T cells subsequently activate other immune effector cells (B cells, cytotoxic T cells) as well as other systemic cascades (complement, kinin, fibrinolysis), which are described below. These interactions lead to phagocytosis, thrombosis, and ultimately structural repair under normal conditions. However, in certain individuals, and following certain major insults, these processes lead to an increased inflammatory state (which may be dysfunctional).

Lymphocytes, immunoglobulins, and APCs are considered the key components of the immune system in regards to finding and destroying "foreign" cells. However, the elaboration of certain humoral factors (e.g., cytokines) represents the most important immune system mediators of SIRS. Some cytokines are proinflammatory, whereas others are anti-inflammatory. Typically the proinflammatory mediators predominate during the acute phase, whereas the anti-inflammatory cytokines predominate in the later "chronic" phase of SIRS.

### Inflammatory Response

The inflammatory response involves a complex network of interactions that proceeds along specific pathways delineated by distinct physiological and biochemical events. These events are controlled by cytokines and other regulatory molecules, known collectively as inflammatory

**Table 2** 2001 International Systemic Inflammatory Response Syndrome/Sepsis Conference Conclusions<sup>a</sup>

Consensus point	Conclusion/comments/examples
Current concepts of sepsis, severe sepsis, and septic shock are robust.	Should remain as described 10 years ago (1991 ACCP/SCCM definitions), until further evidence arises justifying alteration.
Current definitions do not allow precise staging of the host response to infection.	Staging system called PIRO proposed (see below), involves host response.
Signs and symptoms of sepsis are more varied than the initial criteria established in 1991.	In contrast to SIRS (which may be triggered by a variety of noninfectious processes), sepsis must be diagnosed promptly, because there are specific treatments (antibiotics, activated protein C, etc).
An expanded list of the signs and symptoms for the diagnosis of sepsis is presented.	See Chapter 47, Table 2
The future lies in developing a staging system that characterizes the progression of sepsis.	Staging system called PIRO proposed definition involves progression and the extent of the resultant organ dysfunction
SIRS remains a useful concept, but the diagnostic criteria published in 1992 are overly sensitive and nonspecific.	Biomarkers (e.g., IL-6, procalcitonins, and C-reactive protein) among others, should be used to document the degree of SIRS.

<sup>a</sup>The conference included delegates from the following organizations: SCCM, ESICM, ACCP, ATS, and SIS.

Abbreviations: ACCP, American College of Chest Physicians; ATS, American Thoracic Society; ESICM, European Society of Intensive Care Medicine; PIRO, stratifies patients on the basis of their Predisposing conditions, the nature and extent of the Insult (in the case of sepsis, infection), the nature and magnitude of the host Response, and the degree of concomitant Organ dysfunction; SCCM, Society of Critical Care Medicine; SIRS, systemic inflammatory response syndrome; SIS, Surgical Infection Society.

**Figure 1** The response to pathogens in sepsis, involving “cross-talk” among many immune cells, including macrophages, dendritic cells, and CD4 T cells. Macrophages and dendritic cells are activated by the ingestion of bacteria, and by stimulation through cytokines (e.g., interferon) secreted by CD4 T cells. Alternatively, CD4 T cells that have an anti-inflammatory profile (type 2 helper T cells [Th2]) secrete interleukin-10, which suppresses macrophage activation. Macrophages and dendritic cells secrete interleukin-12, which activates CD4 T cells to secrete inflammatory (type 1 helper T-cell [Th1]) cytokines. Depending on numerous factors (e.g., the type of organism and the site of infection), macrophages and dendritic cells will respond by inducing either inflammatory or anti-inflammatory cytokines, or causing a global reduction in cytokine production (anergy). Other processes that release inflammatory cytokines (e.g., trauma/burns) may trigger some of these systems causing SIRS in the absence of infection. Macrophages or dendritic cells that have previously ingested necrotic cells will induce an inflammatory cytokine profile (Th1). Ingestion of apoptotic cells can induce either an anti-inflammatory cytokine profile, or anergy. A plus sign indicates upregulation, and a minus sign indicates downregulation; in cases where both a plus sign and a minus sign appear, either upregulation or downregulation may occur, depending on a variety of factors. *Abbreviations:* Th1, type 1 helper T cells; Th2, type 2 helper T cells. *Source:* From Ref. 187.

mediators. The inflammatory mediators include molecules operating as paracrine, autocrine, and endocrine effectors. ⚡ **The outcome of inflammation may be beneficial (inactivation of injurious substances, initiation of repair) or deleterious (injury to tissue, interference with normal functions) to the host.** ⚡

Inflammation may proceed along different pathways based upon the specific inciting event and, therefore, may present clinically with different signs and symptoms. When activation of the innate immune system is severe

enough, the host response may propel the patient into SIRS, shock, and/or MODS (5). The mortality of patients with MODS increases linearly with the SIRS score (Table 3). SIRS and multiple organ failure (MOF) are observed in as many as 30% of all trauma patients and can result in a mortality rate as high as 80% (6). Most patients do survive the initial SIRS insult, but remain at risk for developing secondary or opportunistic infections because of a CARS, typically occurring later in the “chronic” phase.

**Table 3** Mortality and Multiple Organ Dysfunction Syndrome are Significantly Correlated with Day 2 Systemic Inflammatory Response Syndrome Score in Surgical Intensive Care Unit Patients

SIRS score	APACHE III score	ICU stay (days)	MOD score	Mortality (%)
0	47.6	4.0	3.6	3.8
1	51.8	7.0	4.5	8.2
2	60.3	11.3	7.0	18.4
3	58.0	12.6	7.5	24.2
4	78.5	9.8	8.5	40.0

*Abbreviations:* APACHE III, Acute Physiologic and Chronic Health Evaluation; ICU, intensive care unit; MOD, multiple organ dysfunction; SIRS, systemic inflammatory response syndrome.

### Acute Phase Response

Most soluble mediators of inflammation are present in minute concentrations under normal conditions. Elaboration of these mediators may dramatically increase when the body is exposed to infecting organisms, trauma, surgery, and/or critical illness. With these insults, the liver responds by immediately increasing synthesis of key proteins, referred to as acute phase proteins. This process is designed to augment immune defense against invading organisms in the case of infection, and initiate the processes of stabilization and repair after surgery and trauma. Exposure to cytokines [primarily interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- $\alpha$ ], released via both paracrine and endocrine mechanisms, incites hepatocytes to initiate the acute phase response.

Lipopolysaccharide (LPS) is a potent stimulant for release of the above mentioned cytokines. The acute phase proteins as well as complement factors (particularly C3), mannan-binding lectin, LPS-binding protein, and C-reactive protein (CRP) are directly involved in antimicrobial activity and are also released. Other proteins involved in antimicrobial defense include coagulation factors (primarily fibrinogen), granulocyte colony-stimulating factor (GCSF), antioxidants, and metal-binding proteins. The cytokines involved in this process react systemically in concert with hormonal and neural factors to cause systemic symptoms including fever (mediated by the hypothalamus via induction of endogenous pyrogens), lethargy, malaise, and anorexia. Increased glucocorticoid release by the adrenals results from cytokine stimulation of the hypothalamus, which in turn increases the secretion of corticotropin-releasing factor, and adrenocorticotrophic hormone from the pituitary. Prolongation of this response can lead to cachexia and anemia. The presence of the acute phase response can be determined by measurement of serum fibrinogen, CRP, procalcitonin (PCT), or the time-honored erythrocyte sedimentation rate.

### Endothelial Activation

The endothelium contained within the human body covers approximately 4000 to 7000 m<sup>2</sup> of surface area (7). Endothelial cell properties vary widely depending upon the specific organ or blood vessel type and size. For example, hypoxia and/or acidosis in the systemic arterioles causes vasodilation, whereas the presence of these factors in the pulmonary vasculature leads to vasoconstriction. When surrounding tissue is stressed, endothelial cells (in particular, cells lining postcapillary venules) express high levels of

specific adhesion molecules. This stress results from exposure to inflammatory mediators including cytokines, complement, histamines, LPS, or components of the coagulation system (7).

A recent study demonstrated that activated protein C (APC) signals through protease-activated receptor-1 (PAR-1), an endothelial cell protein required for the cytoprotective antiapoptotic effect (8). Two of the most commonly studied adhesion molecules include intercellular adhesion molecule 1 (ICAM-1, CD54) and vascular cell adhesion molecule 1 (VCAM-1) (see Volume 2, Chapter 47, Fig. 1). E-selectin and P-selectin (in the selectin family of carbohydrate-binding proteins) are also widely expressed on activated endothelium (discussed later in the section on adhesion molecules). These adhesion molecules have an affinity for surface molecules expressed by different leukocytes.

**The selectin-phase is the first component of endothelial activation promoting neutrophil migration. In this phase, passing neutrophils or other leukocytes attach to P-selectin and E-Selectin molecules on the activated endothelium.** Leukocytes come into contact with inflammatory mediators (referred to as leukocyte chemotactic factors) elicited both locally and systemically. When these mediators bind to the leukocytes, the surface adhesion properties of the leukocytes change. One example is that L-selectin (typically present on neutrophils and all other leukocytes) is shed. At the same time, integrins located on the surface of leukocytes transform their molecular shape, enabling them to bind to specific endothelial glycoproteins. This endothelial surface interaction with integrin creates a stable bond that effectively stops neutrophil rolling, allowing the neutrophils to migrate out of vessels into adjacent tissue. Then, through the process of chemotaxis, neutrophils travel to the site of infection or injury.

The integrins are heterodimeric proteins, composed of  $\alpha$  and  $\beta$  chain polypeptides, that can associate in different combinations to produce dimers with distinct binding properties that are expressed on different cell types. The integrins bind extracellular matrix proteins as well as nonintegrin adhesion molecules such as VCAM-1.

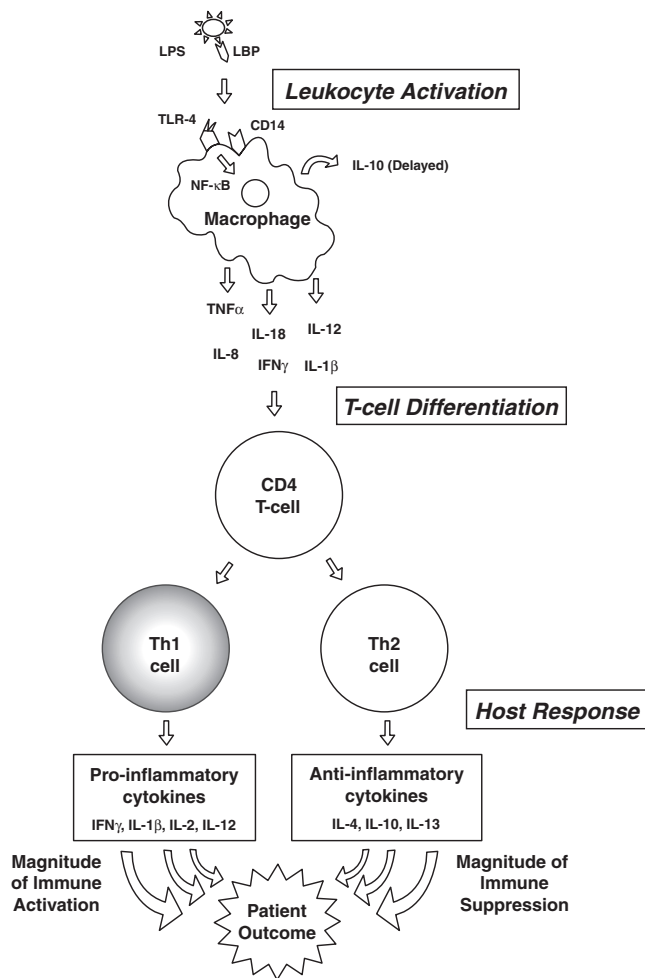

## CYTOKINES

### Cytokine Structure and Physiology

Cytokines are the soluble mediators involved in coordinating the immune inflammatory response. They are potent glycoproteins (MW 6000–60,000), involved in intercellular signaling. Acting in concentrations of 10<sup>-9</sup> to 10<sup>-15</sup> M, they bind to specific cell membrane receptors and influence intracellular processes ultimately leading to gene transcription and translation, creating the mediators (including other cytokines) that produce the biochemical/molecular cascade of events known as the inflammatory response.

It was initially believed that, unlike hormones which are preformed and secreted into the circulation to act systemically, cytokines were produced locally, and had their effect primarily in an autocrine or paracrine manner. However, recently, new cytokine assays have detected large concentrations of cytokines in serum under certain inflammatory conditions, suggesting that cytokines may play a key endocrine role as well (9).

Some cytokines cause cellular chemoattraction (these are known as chemokines). Others cause cellular proliferation or apoptosis. Others cause the release of bioactive substances (e.g., histamine from mast cells or basophils). The

**Figure 2** Balance of pro-inflammatory and anti-inflammatory cytokines. Simplified schematic, depicting initiation of host response to lipopolysaccharide (LPS) challenge by macrophages. Beyond this stage, the interaction and redundancy of host inflammatory and anti-inflammatory response is dependent on factors such as infectious cause, coexisting conditions, and genetics. *Abbreviations:* IFN, interferon; IL, interleukin; LBP, lipopolysaccharide-binding protein; Th1, type 1 helper T cells; Th2, type 2 helper T cells; TLR, Toll-like receptors; TNF, tumor necrosis factor. *Source:* From Ref. 73.

cytokines involved in systemic inflammation are considered either pro- or anti-inflammatory (Fig. 2). “Cross-talk” among many immune cells, including macrophages, lymphocytes, and endothelial and dendritic cells, is vitally important for a functional inflammatory response. ⚡ **Pro-inflammatory cytokines are responsible for initiation and augmentation of inflammation and its sequelae, whereas anti-inflammatory cytokines are associated with moderation of the inflammatory response.** ⚡ Recent studies have demonstrated that an imbalance between pro- and anti-inflammatory cytokines leads to worse outcome in these patients (10). An exuberant inflammatory response may cause SIRS, acute respiratory distress syndrome (ARDS), or MODS. Whereas an exaggerated anti-inflammatory response may lead to immune suppression and infection. TNF- $\alpha$ , IL-1 $\alpha$ , IL-1- $\beta$ , IL-2, IL-4, IL-6, IL-8, IL-10, IL-18, and transforming growth factor (TGF) $\beta$  are the most frequently studied cytokines associated with trauma, surgery, and critical illness (Table 4). These and

other cytokines mediate the biological cascades associated with the inflammatory response.

### Cytokine Receptors

Cytokine receptors and receptor antagonists have been studied extensively in recent years. Both membrane-bound and soluble receptors play key roles. It is apparent that acute utilization of membrane receptors and the release of soluble receptors and their receptor antagonists occur in specific sequences based on time-specific physiological cascades. It is therefore theorized that the receptors regulate the inflammatory response and that the balance between receptors for the pro- and anti-inflammatory cytokines more so than the serum level of these cytokines defines the immune response. Measurement of soluble receptors may be utilized to characterize the immune response and may serve as markers for SIRS and MODS (11).

### Cytokine Measurements in Systemic Inflammatory Response Syndrome Patients

Cytokines signal the normal processes of inflammation and repair in all organs. Therefore, adequate measurement of cytokines is critical to adequately assess their role in this process. Plasma cytokine concentrations are at times difficult to detect, perhaps due to the methods of measurement. Enzyme-linked immunosorbent assay (ELISA) is the method utilized most often in research studies. It requires binding at two sites in order to detect the cytokines and, therefore, measures only free cytokines.

Most cytokines are bound to carrier proteins, frequently present in 10 to 1000 times the cytokine concentration, that block detection by two-site ELISAs. Therefore, a bound cytokine is 1000 times more apt to exist on the cellular receptor than the soluble species. Although bound cytokines are not measurable by ELISA, they are present in the circulation and have the potential to be active at the cellular level.

Recent evidence suggests that the total cytokine assay (a competitive immunoassay) has the highest detectability for cytokines in biological samples such as serum and plasma, since only one antibody site is required for capture and detection, thereby detecting essentially all the cytokine in the sample. Malone et al. (9) compared this new assay to ELISA in a study evaluating serum cytokine concentrations in trauma patients, and determined that no significant differences in mean serum cytokine concentrations were noted between trauma patients and normal controls for IL-1, IL-6, and IL-10 using ELISA. In contrast, trauma patients had significantly higher serum concentration of these cytokines on admission compared to normals using the “Total” cytokine immunoassay. Competitive immunoassays may be the method of choice when measuring cytokines in biological fluids, and new normal ranges for cytokines need to be established for future accurate research in systemic inflammation.

### OTHER MARKERS OF INFLAMMATION

#### Procalcitonin (PCT) and C-Reactive Protein (CRP)

PCT and CRP can be utilized to determine the presence and severity of inflammation. These mediators differ in sensitivity and specificity, as related to the ability to differentiate between infectious versus noninfectious causes of SIRS, sepsis, and MODS. Both PCT and CRP are included in the

**Table 4** Inflammatory and Anti-inflammatory Cytokines

	Principal source	Target cells	Function
IL-1 $\alpha$ and $\beta$	Monocytes, macrophages, APCs, endothelial cells	T and B cells, hematopoietic cells	APCs and T cell stimulation B-cell proliferation Immunoglobulin production Phagocyte activation Inflammation
IL-2	Activated T cells, NK cells	T and B cells, NK cells	Activated T cell proliferation T cell growth factor T cell apoptosis (after repeated activation) NK cell activation B cell proliferation
IL-4	T cells (Th2), mast cells	T and B cells, mast cells	B cell activation and growth factor Class II MHC expression Th2 and CTL proliferation Mast cell and eosinophil proliferation Inhibition of monocyte proliferation
IL-6	Monocytes, macrophages, T cells (Th2), APCs, endo- thelial cells	T and B cells, fibroblasts, hematopoietic cells	B cell stimulation, proliferation and differentiation Synergism with IL-1 and TNF- $\alpha$ Acute phase response
IL-8	Monocytes, macrophages, endothelial cells	Neutrophils, basophils	Neutrophil activation and chemoattraction T cell chemoattraction Angiogenesis
IL-10	T (Th2, CD8) and B cells, macrophages	Monocytes, mast cells, T cells	Inhibition of cytokine production B cell proliferation Suppression of cell-mediated immunity
IL-18	Macrophages, keratinocytes, intestinal epithelial cells	T cells, NK cells	T cell (Th1) activation NK cell activation and proliferation IFN $\gamma$ production Pro-inflammatory cytokine production
TNF- $\alpha$	Macrophages, endothelial cells	T and B cells, monocytes, macrophages, neutrophils, endothelial cells, hemato- poietic cells	T cell activation B cell proliferation Monocyte and macrophage chemoattraction Neutrophil activation and cytokine production Angiogenesis
TGF- $\beta$	Macrophages, T lympho- cytes, platelets	Macrophages, T and B cells, endothelial cells, hemato- poietic cells	Suppression of cytokine production Antiproliferation of T and B cells Neutrophil and monocyte chemoattraction

*Abbreviations:* APC, antigen presenting cell; IFN, interferon; MHC, major histocompatibility complex; NK, natural killer cell; TGF, transforming growth factor; TNF, tumor necrosis factor.

PIRO system of response assessment for sepsis (see Volume 2, Chapter 47, Table 3).

Elevated levels of PCT are associated with both systemic inflammation and sepsis. Experiments have demonstrated that serum levels are predictive of injury severity and mortality in clinical studies; however, no studies to date have elucidated the source of PCT and its mechanism of action in these inflammatory states. Indeed, some studies have actually suggested an anti-inflammatory role for this molecule. Some investigators have demonstrated that PCT may be a modulator that augments the inflammatory response, initiated by other mediators, to include LPS and cytokines (12).

Serum concentrations of PCT, compliment C3a, CRP, and elastase were evaluated for their ability to predict SIRS versus sepsis in medical intensive care unit (ICU) patients (13). In this study, serum PCT and C3a levels were shown to discriminate between sepsis and SIRS, whereas CRP and

elastase (measured in some ICUs to evaluate systemic inflammation) did not.

Serum levels of PCT, cytokines, and acute phase proteins were measured in patients with postoperative SIRS, sepsis, limited wound infections, or pneumonia in another clinical study to determine if any of these inflammatory indices were more predictive of infection (14). PCT, when compared to these other markers, was more sensitive to systemic stimuli accompanying bacterial infection, most notably endotoxin. It was found to have much less sensitivity to nonbacterial stimuli after surgery or localized bacterial inflammation. Molter et al. (15) cautioned, however, that postoperative PCT plasma concentrations in patients without signs of infection are largely influenced by the type of surgical procedure. These investigators report that on postoperative days 1 and 2, PCT concentrations are more frequently elevated in patients after major abdominal, vascular, or thoracic surgery compared to patients

undergoing minor procedures. Therefore, the “infection monitoring” capacity of PCT may be impeded during the first two postoperative days.

Furthermore, PCT may only be a useful marker in patients without leukopenia. Indeed, a recent study showed that PCT was not a sensitive marker for sepsis in leukopenic patients with WBC  $<1.0 \times 10^9$  leukocytes/L (16). These authors determined that PCT had both high positive and negative predictive values in patients with WBC  $>1.0 \times 10^9$ /L.

PCT and CRP were assessed as markers for noninfectious SIRS versus sepsis, and as predictors of the severity of organ failure in critically ill patients (17). CRP levels were not found to be significantly different between the three groups. PCT levels differed significantly between the three groups and were determined to be a good indicator of severity of sepsis and organ failure in patients with severe SIRS. PCT was also found to be more predictive than CRP and WBCs in emergency department patients suspected of sepsis (18).

CRP, SIRS, temperature, and WBC were prospectively evaluated as predictors for infection in 74 medical ICU patients at admission and every four days thereafter (19). Multivariate analysis determined that CRP and SIRS were the only variables independently associated with the presence of infection. The combination of CRP and SIRS was significantly more predictive than any of the other indices. A decrease in CRP between admission and day 4 was the best predictor of recovery.

Preoperative elevations of serum CRP, without other indications of infection, were associated with worse outcome after cardiac surgery with CPB (20). Fifty patients with isolated preoperative CRP elevation were compared with matched (age, gender, and disease) patients who did not have preoperative elevations of CRP. Septic complications, prolonged catecholamine support, increased duration of respiratory support, and increased ICU length of stay were more frequently demonstrated in patients with preoperative elevations in CRP. **It appears that patients without apparent infection who have increased CRP values preoperatively are at increased risk for infectious complications postoperatively.**

### Nitric Oxide

Although nitric oxide (NO) does not itself cause inflammation, NO is increased in many SIRS and shock states, and has been shown to be the primary effector of vasodilation in endotoxin LPS-induced hypotension during sepsis (21). NO is an inhibitor of mitochondrial electron transport, an inducer of vascular leak, and a mediator of LPS-induced cytokine release. NO has also been shown to directly increase ileal mucosal membrane and enterocyte monolayer permeability, and bacterial translocation (22). These investigators demonstrated that increased NO production and inducible nitric oxide synthase (iNOS) mRNA expression is associated with endotoxin and/or cytokine-induced loss of enterocyte monolayer barrier function.

The mechanism of action in sepsis-induced NO elaboration may be due to an increased expression of mRNA, for the production of iNOS in vascular tissue as well as activated neutrophils. Although a recent study indicates that iNOS activity may be compartmentalized at the site of infection in patients in septic shock (23), most studies demonstrate systemic release. Circulating peripheral neutrophils in post-surgical septic patients were compared to those from healthy

controls after stimulation with LPS and/or TNF $\alpha$ , to determine if there were differences in iNOS expression and constitutive NO production (24). These authors demonstrated that neutrophils from septic patients expressed higher levels of iNOS mRNA than those patients with SIRS alone. Neutrophils from healthy controls did not express iNOS mRNA and did not produce NO. After in vitro stimulation with LPS and TNF- $\alpha$ , these neutrophils did produce iNOS mRNA and NO, indicating that activated neutrophils might be a source of NO in sepsis.

NO is also elevated in hemorrhagic shock with concurrent induction of iNOS along with cyclo-oxygenase (COX)-2 and CD14. This promotes inflammation by the immediate production of NO and prostaglandins. However, hemorrhagic shock patients do not manifest vasodilation during hemorrhagic shock, because more powerful vasoconstrictive forces are at play (centrally-mediated catecholamine elaboration from volume depletion). Another transcription factor, hypoxia-inducible factor-1 is thought to regulate the induction of iNOS during the ischemic phase of shock (25). NO acts as a signaling molecule involved in redox reactions to include activation of nuclear factor- $\kappa$ B (NF- $\kappa$ B) (25). This activation of NF- $\kappa$ B can also promote inflammatory cytokine expression during reperfusion, further contributing to organ injury after hemorrhagic shock.

Sepsis-induced hypotension is also related to impaired angiotensin II (AII)-mediated adrenal catecholamine release, despite the strong systemic activation of the renin-angiotensin system. This may be due to the down-regulation of the adrenal AII receptors (26).

### Lipopolysaccharide-Binding Protein

Lipopolysaccharide-binding protein (LBP) is a humoral protein that recognizes and forms complexes with LPS, the macromolecule on the outer lipid layer of gram-negative bacteria. LBP activity has been historically associated with gram-negative bacterial sepsis. Specialized CD14 cell surface receptors on numerous cells (including human monocytes, neutrophils, and endothelial cells) bind with the LBP-LPS complex. This bond initiates the immunological steps that destroy these bacteria. CD14 is a 55 kD glycoprotein originally thought to promote differentiation of monocytes. CD14 is now known to have a glycosylphosphatidylinositol anchor in the cell membrane, and requires interaction with transmembrane receptors (necessary for cell membrane signal transduction), including Toll-like receptors (TLRs) and certain integrins (e.g., CD18, CD55) to transmit signals into the cell. Recently, Trianafilou et al. (27) proposed a new model of LPS recognition upon discovery of a signaling complex of receptors involving heat shock proteins.

LBP, PCT, CRP, and IL-6 were studied as markers of inflammation in the first four postoperative days, in 12 adult male patients with SIRS, and at least two dysfunctional organs (MODS) following coronary artery bypass graft (CABG) surgery (28). Plasma PCT and IL-6 concentrations were significantly elevated in all MODS patients. PCT and LBP were markedly elevated in MODS patients with positive microbial findings. The authors concluded that LBP may be a marker for differentiation between noninfectious SIRS and ongoing bacterial sepsis in the early postoperative course following CABG while microbiological results are still pending.

In another study of 24 patients with severe sepsis, LBP serum levels from patients with gram-positive or fungal infections did not differ from those with gram-negative infections (29). When compared to LBP levels in healthy

volunteers, levels were significantly increased in patients with sepsis regardless of bacterial etiology. In patients with multiple bouts of sepsis, the LBP response was of lesser magnitude with each subsequent episode. These data suggest that LBP may be a nonspecific marker of sepsis. An ongoing clinical study at our institution is examining the time-dependent changes LBP following trauma (29a).

### Intestinal Fatty Acid Binding Protein

The intestinal fatty acid binding protein (IFABP) is a small protein uniquely located in the small intestine enterocyte, and is believed to be important for fatty acid transport and storage (6). IFABP is not typically detectable in serum and/or urine of healthy individuals. It is, however, detectable after episodes of acute intestinal ischemia and inflammation, occurring most often at a time when the insult was still reversible. Urinary levels of IFABP were significantly elevated in critically ill patients with SIRS, and peaked 1.4 days before SIRS was diagnosed, suggesting that urinary levels of IFABP could be used to predict patients at risk for SIRS (30).

### Adhesion Molecules

Adhesion molecules play a critical role in SIRS, sepsis, and MODS as described above in the section on endothelial activation. Figure 3 shows the sequential activation and engagement of various families of adhesion molecules (including L, P, and E-selectins). These adhesion molecules have been utilized as markers for ongoing systemic inflammation following injury. L-selectin (CD62L) surface expression on neutrophils, monocytes, and lymphocytes and soluble CD62L (sCD62L) plasma concentrations were measured in trauma patients at different time points after injury (31). Severe organ dysfunction in these patients was associated with altered CD62L expression on leukocytes and circulating sCD62L plasma concentrations. Nonsurvivors had decreased sCD62L on admission and T-cell CD62L expression after four hours. E-selectin (principle ligands are surface proteins on cutaneous lymphocytes)

and P-selectin (principle ligand is P-selectin glycoprotein ligand 1) activity was measured in ICU patients who had experienced cardiopulmonary resuscitation (CPR) to determine if there was an association between CPR, SIRS, and elaboration of these molecules (32). SIRS was a common occurrence after CPR (66% of all patients). Soluble P-selectin (sP-selectin) levels were higher in patients with SIRS compared to those without SIRS or with noncritically ill control patients. Soluble E-selectin (sE-selectin) levels were higher in patients with and without SIRS compared to noncritically ill patients, and were higher in nonsurvivors than in survivors. P-selectin was higher in patients who developed sepsis within one week after CPR. These authors concluded that SIRS was a nonspecific finding after CPR, and the determination of sP- and sE-selectin early after CPR might be utilized to identify patients at a high risk for sepsis or adverse outcome. E-selectin is so strongly expressed in sepsis states that its identification on intravascular, interstitial, or intra-alveolar leukocytes in postmortem exams is diagnostic of sepsis-induced fatalities (33). These authors determined that ICAM-1 is strongly expressed on endothelial cells of pulmonary vasculature, macrophages, and lymphocytes, and may be considered a marker for death due to sepsis. Most recently, a prospective, double-blind, randomized, placebo-controlled clinical trial evaluated the safety and efficacy of the humanized monoclonal anti-L-selectin antibody aselizumab in severely injured patients. Aselizumab was associated with a higher rate of infections and leukopenia, however, this difference was not significantly different compared with placebo (34).

### NEUROENDOCRINE RESPONSE

Neurological and endocrine functions interact intimately with inflammatory mediators after injury or onset of illness. Together, these systems modulate the immune system via release of neurotransmitters, neuropeptides, and endocrine hormones (6). The immunological response to the release of hormones associated with the hypothalamic-pituitary-adrenal axis after trauma-hemorrhage has been

**Figure 3** Adhesion molecules-sequential engagement. Sequential activation and engagement of all the families of adhesion molecules, resulting in neutrophil migration onto tissue. *Source:* From Ref. 188.

studied. The administration of prolactin augmented splenocyte proliferation and splenocyte elaboration of IL-2 and IL-3 in mice, after trauma-hemorrhage (35). Prolactin also significantly improved macrophage IL-1 and IL-6 release after trauma hemorrhage, and demonstrated better survival after sepsis [cecal ligation and puncture (CLP) model] (36). These same investigators demonstrated that administration of metoclopramide, to augment circulating prolactin levels, exerted a beneficial cell-mediated immune response following hemorrhagic shock (37). Melatonin, the major hormone released by the pineal gland, maintains immune function in mice subjected to severe hemorrhage and soft tissue injury (6). Glucocorticoids, released by the adrenal glands, have demonstrated anti-inflammatory effects by interfering with leukocyte proliferation, and release of cytokines and other inflammatory mediators. These steroids have also been shown to limit TNF $\alpha$  production and enhance IL-10 synthesis in septic states (38).

Cells of both the central and peripheral nervous systems, as well as endocrine organs, are capable of producing cytokines. Cytokines released under conditions of stress by these cells act in an autocrine or paracrine manner to stimulate organ-specific responses within the involved organ. This is evidenced by the adrenal expression of mRNA for IL-6 in cells of the cortex and the medulla in juxtaposition to cells responsible for catecholamine secretion (39). Furthermore, IL-6 and its receptors are expressed in adrenal cell cultures in the presence or absence of macrophages (40). Under conditions of stress, these cytokines are also released systemically, eliciting an endocrine response.

Cells of the central nervous system (CNS) respond in similar fashion, demonstrating both the ability to release cytokines and express cytokine receptors, as well as react to systemically released cytokines. Cytokines play an important role in normal development of the brain (neurotrophic) and the response to traumatic brain injury (TBI) (41). Levels of IL-6 in the CNS compared to measurement in other organs or plasma, after either local (into CSF) or systemic injection of cytokines to include IL-1 $\alpha$ , IL-1 $\beta$ , and IL-6, indicate that the brain may be a significant source of this cytokine elaboration (42,43). Whether released locally or systemically, the cytokines act in an afferent manner, eliciting an efferent response to the stimulus. This efferent response is the brain-directed physiological sequelae to injury or illness.

Peripheral nerves are affected by the inflammatory response as well. Inflammatory mediators have been shown to alter neuronal phenotypes affecting growth and functional and electrical properties (44). IL-6 and IL-6 receptor expression, after neuronal injury has been associated with initiation of neural tissue repair (45).

Neurogenic inflammation is thought to originate from the release of substance P and other neurokinins encoded by the preprotachykinin A gene, from unmyelinated nerve fibers following noxious stimuli (46). This mechanism may account for respiratory distress in response to CNS injury. The airways have a complex network of sensory nerve fibers just below the epithelial surface. Conceivably, any change in the bronchial environment could stimulate the release of substance P (47). Piedimonte demonstrated this phenomenon in an animal study wherein the respiratory syncytial virus (RSV) caused a marked increase in airway vascular permeability, resulting in an increase in overall inflammation (47). He demonstrated that these changes were mediated by the high affinity receptor for substance P (neurokinin [NK-1]). T lymphocyte subpopulations within bronchial-associated lymphoid tissue in the lungs of

RSV-infected rats also expressed high levels of the NK-1 receptor. This upregulation presumably occurs at the gene expression level, as NK-1 receptor mRNA levels were noted to increase significantly during RSV infection.

The neurological and endocrine systems work in collaboration after either systemic or end-organ release of inflammatory mediators. Cytokines released by neurological cells act on those cells and others in the nervous system, but also on the endocrine organs. These endocrine organs secrete cytokines as well as hormones that act within the endocrine system, but also act as afferent stimuli for the nervous system. Recent evidence suggests that there is a specific afferent system directly connecting endocrine and CNS cells (48). This creates an intricate immunological cycle incorporating the CNS and the hypothalamic-pituitary-adrenal hormonal axis, wherein the systemic functional physiological outcome after trauma or illness may be orchestrated.

## HORMONAL INVOLVEMENT

Animal studies utilizing trauma-hemorrhagic shock models have demonstrated gender differences in outcome. Females demonstrated enhanced immune function and better outcome compared with males following hemorrhagic shock and sepsis, whereas males demonstrated better outcomes following major burn injury. Clinical studies have been inconsistent in regard to outcome associated with gender. However, basic science studies have demonstrated sex hormonal differences that may explain the observed gender based survival variation.

IL-10 therapy has been shown to have a potential role in treatment of the early inflammatory state after hemorrhagic shock in some animal studies. To determine whether gender impacted these results, male and female mice were subjected to hemorrhage or sham operation, and then received either recombinant murine IL-10 (rmIL-10) or placebo during the resuscitation phase (49). At 48 hours after resuscitation, peritoneal macrophages and splenocytes were harvested. IL-1 $\beta$  and IL-12 released by the macrophages, and splenocyte proliferation, interferon (IFN) $\gamma$ , and IL-2 release capacity was measured. IL-10 plasma levels were not increased after treatment. In males, the treatment with IL-10 restored the depressed immune response as evidenced by depressed splenocyte proliferation, IFN $\gamma$ , and IL-1 $\beta$ . Only depression of splenocyte proliferation was demonstrated in female mice. Furthermore, sham-operated male mice treated with rmIL-10 demonstrated depressed immune responses compared with the placebo group.

Another recent study demonstrated female gender protection from sepsis following hemorrhage (50). In this study, both male and female mice were subjected to hemorrhage or sham operation. All mice were then subjected to sepsis by CLP, and survival was assessed over 10 days. Male mice subjected to hemorrhage prior to CLP had higher mortality than shams. In contrast, mortality in female mice after CLP was comparable in both the hemorrhage and sham groups. Plasma levels of the inflammatory mediators, IL-6 and TNF- $\alpha$  after CLP were increased in males subjected to hemorrhage, whereas these mediators were not increased in hemorrhaged females.

In contrast, Wichmann et al. (51) did not demonstrate gender differences regarding death from severe sepsis in almost 4000 human patients in a surgical ICU. In a smaller

critical care population, female gender was associated with a lower mortality rate after severe sepsis (52). When patients were stratified by age and injury severity score (ISS), there were no gender differences in mortality in 18,892 blunt trauma patients (53). In this study, male gender was associated with an increased incidence of pneumonia after injury; however, females with pneumonia had higher mortality. Gannon et al. (54) studied 22,332 patients from 26 trauma centers. These researchers demonstrated that age, ISS, non-Caucasian race, blunt injury, revised trauma score, and pre-existing diseases were associated with increased risk for mortality. Gender was not associated with increased risk for mortality. Female patients represented 27% of the 17,589 trauma patients stratified by age, ISS, mechanism of injury, and gender in another study that evaluated outcome to include mortality (55). Females  $\leq 40$  years old had a survival advantage in the ISS 16 to 24 group; however, these patients had significantly less severe injury. Males had more infectious complications, and females with pneumonia had higher mortality. Interestingly, burn trauma shows an opposite gender dimorphic outcome response. With burn trauma, premenopausal women demonstrate worse outcome compared with age-matched males (see Volume 1, Chapter 34).

### Estradiol

♂ The hormone 17-beta-estradiol has been associated with female gender-specific protective effects from SIRS following trauma and hemorrhage in animal studies. ♂ The Kupffer cell is a major source of inflammatory cytokine release following trauma. Estradiol appears to directly attenuate Kupffer cell release of inflammatory mediators. To study this effect in an injury model, male mice were subjected to laparotomy and hemorrhage or sham operation (56). Two hours later, Kupffer cells were harvested and cultured with 17beta-estradiol, in the presence or absence of LPS stimulation. Kupffer cell production of IL-6 and TNF- $\alpha$  were increased following trauma and hemorrhage. Production of IL-6 was attenuated in all animals after incubation with 17-beta-estradiol in a dose-dependent manner. In contrast, the down-regulation of TNF- $\alpha$  was minimal. Continued synthesis of 17-beta-estradiol, in proestrus female mice, appears to be responsible for maintenance of T lymphocyte cytokine release associated with protection after trauma and hemorrhage (57). Specifically, it may be that estradiol in females may maintain type 1 helper T cells (Th1) cytokine release (e.g., IL-2, IFN- $\gamma$ ) after trauma and hemorrhage, whereas androgens are responsible for depressed Th1 cytokine release (58).

### Testosterone

♂ In contrast to the female sex hormone estradiol, increased levels of the male sex hormone testosterone are associated with decreased cell mediated immune response following trauma in animal studies. However, testosterone decreases muscle catabolism following burns. ♂ In multiple animal studies male mice exhibited significantly decreased levels of cytokine release from inflammatory cells after trauma and during severe sepsis (CLP) (6). Castration, leading to undetectable serum testosterone levels, was associated with conservation of cell-mediated immunity in these studies. To determine whether castration and testosterone inhibition was the causative factor in this immune response, flutamide, a testosterone receptor antagonist, was administered to male mice after trauma-hemorrhage (59). At 72 hours

postinjury and hemorrhagic shock, protection of cell-mediated immunity was observed in the flutamide treated males.

Studies have also demonstrated that flutamide was protective against the lethal effects of CLP after hemorrhagic shock (60). Yokoyama et al. (56) also demonstrated that castration or androgen receptor blockade with flutamide after trauma-hemorrhage in male mice presented beneficial effect. This group also demonstrated that administration of 17-beta estradiol or prolactin to male animals significantly improved immune function.

Some clinical studies have demonstrated abnormally low testosterone levels in males after trauma. Severely burned male mice were found to have abnormally low testosterone levels after injury (61). These mice were then treated with testosterone enanthate (1 dose/wk) for two weeks. Serum testosterone levels increased from baseline to low normal in one week, and to high normal range after two weeks. These investigators also measured protein synthesis over this time period, and found that protein synthetic efficiency increased two-fold, demonstrating that restoration of serum testosterone can ameliorate the muscle catabolism of severe burn injury. Abnormally low levels of testosterone were elaborated in male patients after traumatic injury, in a study that evaluated time-dependent changes in serum hormones (62). In this study, serum estradiol, progesterone, and testosterone were measured at admission and at 24 hours in male and female trauma patients. Estradiol levels were not significantly different at admission, but females had significantly higher levels at 24 hours. Progesterone levels were not different between the genders at admission or at 24 hours; however, male levels were noted to be abnormally high at admission. Males had significantly higher testosterone levels than females at admission, but not at 24 hours. Interestingly, testosterone levels were at a low normal value for males at admission and were below normal at 24 hours. There were no differences in outcome based on gender. Future studies must examine time-dependent changes in sex hormone concentrations at later time points, to further elucidate their role in gender-related outcome differences in human SIRS and sepsis following trauma.

### Progesterone

To date, progesterone has not been studied as extensively as estradiol or testosterone. The main focus of some of the studies is modulation of the immune system. In one study, progesterone administration in a trauma-hemorrhage animal model was found to ameliorate the pro-inflammatory response (decreased IL-6 and TNF- $\alpha$ ), and subsequently hepatocellular injury (decreased transaminases and reduced myeloperoxidase activity), compared to controls that received resuscitation fluid alone (63). Shear et al. (64) studied progesterone as a treatment for cerebral edema after TBI. These investigators determined that a single dose of progesterone can attenuate cerebral edema after TBI in rats, but didn't always lead to functional improvement. Regimens continued for three to five days reduced the size of injury-induced necrosis and cell loss, and a five-day regimen improved behavioral outcome.

### Leptin

Leptin is an adipocyte-derived hormone whose serum levels are influenced by cytokines. It is thought to regulate immune function, food intake, and energy expenditure. Recent studies have demonstrated that hypercatabolism and immune dysfunction are closely associated with SIRS and

MODS. Papathanassoglou et al. studied leptin levels, nutritional indices, and outcome in critically ill patients (65). Critically ill patients exhibited higher serum levels of leptin, as well as IL-6, TNF- $\alpha$ , and cortisol than controls. The authors concluded that cytokines and cortisol up-regulate leptin levels that in turn may predispose the patients to hypercatabolism, wasting, and immune dysfunction. Serum leptin levels alone were not independently associated with severity of SIRS or MODS, or with mortality. Gender specific changes in leptin levels also require further elucidation.

### SYSTEMIC INFLAMMATORY RESPIRATORY SYNDROME—COAGULATION SYSTEM INTERACTION

The increasingly appreciated molecular linkage between the procoagulant and inflammatory systems is one of the critical discoveries of the last 25 years (66). The coagulation system evolved as a mechanism to limit the loss of vital elements from the internal milieu following mechanical injury to the circulatory system. Whereas the innate immune system was developed as a rapid response mechanism for detection and clearance of microbial invaders that breach the integument, the coagulation and innate immunity systems co-evolved from a common ancestral substrate early in eukaryotic development, and these two systems retain a highly integrated and co-regulated circuitry of signals and control elements that defend the host following tissue injury and microbial invasion. Indeed, the ancestry may predate eukaryotic development, as primitive microorganisms, lacking a circulatory system and thus without need for coagulation to stop bleeding, possess a coagulation system that is used to protect against microbial invasion (66).

Coagulopathy and systemic inflammation are almost universal findings in patients with sepsis. Septic patients are also known to have diminished concentrations of circulating antithrombin III (AT III), tissue plasminogen activator, and activated protein C (APC) (67).

In the landmark Protein C Worldwide Evaluation in Sepsis (PROWESS) trial, Bernard et al. (68) showed a significant decrease in mortality for septic patients treated with recombinant human APC compared to placebo. The PROWESS trial was very well conducted with a large sample number (1690 patients), demographic factors were similar in the treatment and placebo groups, and protein C deficiency was detected in 90% of the patients in which it was measured (68). The relative risk of death in the treated group was reduced by 20%. Furthermore, APC reduced mortality in almost every subgroup examined in the phase III trial. The only significant side effect of the drug is bleeding, and the treatment patients had a higher rate of bleeding episodes compared to placebo (3.5% vs. 2.0%), but this difference was not clinically or statistically significant ( $p = 0.06$ ).

The administration of APC was associated with a reduction in plasma D-dimer levels, demonstrating that the procoagulant effects of sepsis were diminished by this therapy. A concomitant reduction in the serum levels of IL-6 and TNF- $\alpha$  indicated that treatment also attenuated the inflammatory cascade. The reduced TNF- $\alpha$  results are in concert with the evidence that APC reduces the production of TNF- $\alpha$  monocytes by inhibiting the coupling of endotoxin and CD14, without affecting the antimicrobial properties of monocytes (69).

Additionally, APC inhibits factors Va and VIIIa resulting in decreased thrombin generation, and increases the fibrinolytic response by reducing the levels of plasminogen activator inhibitor-1 and by preventing activation of thrombin-activatable fibrinolysis inhibitor (TAFI) (70). APC is also known to reduce interactions between neutrophils and endothelial cells, and to decrease tissue ischemia (71), in part by reducing the endothelial expression of E-selectin (72).

At present, no clinical studies have evaluated the use of agents that alter both coagulation and inflammation (such as APC) in patients with noninfectious causes of SIRS. Additionally, studies involving patients who are at increased risk of bleeding (omitted from the PROWESS trial) must be studied to better define the potential morbidity of APC therapy. Real-time protein detection technologies, which monitor a panel of sepsis-related bio-markers (including APC levels) will likely improve the targeting of this promising therapy (73). Optimal use of APC and other anticoagulant agents in sepsis and SIRS requires additional basic research into the critical linkage between coagulation and innate immunity (73).

### PROGRESSION OF SYSTEMIC INFLAMMATORY RESPONSE SYNDROME TO COMPENSATORY ANTI-INFLAMMATORY RESPONSE SYNDROME AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

It is unclear whether SIRS serves a purposeful function, or merely represents an epiphenomenon resulting from severe tissue injury, induced by trauma, shock, and infection. However, we do know that the severity and intensity of the inflammatory response affects outcome, and appears to be determined by the balance between inflammatory and CARS. Bone was the first to propose the five-stage progression from SIRS to MODS (Fig. 4), in 1996 (74). At that time, considerable new evidence indicated that, in addition to a massive pro-inflammatory reaction, a compensatory anti-inflammatory response contributes to the onset of these disorders. The five stages summarized in Figure 4 are as follows: (i) local inflammatory response, (ii) systemic inflammatory response, (iii) massive systemic inflammatory response, (iv) immunologic paralysis, and (v) immune dissonance. If the last three phases do not quickly resolve, cell damage can be amplified thus perpetuating the inflammatory process and promoting infectious complications, resulting in MODS.

At a local site of injury or infection, and during the initial appearance of pro- and anti-inflammatory mediators in the circulation, the beneficial effects of these mediators typically outweigh their harmful effects. However, when the balance between these two forces is lost, widespread inflammation occurs and these mediators become harmful. Sequelae of an unbalanced systemic pro-inflammatory reaction include shock, organ dysfunction, and coagulation defects. An unbalanced systemic compensatory anti-inflammatory response can result in anergy and immunosuppression. This late immunosuppressive phase was termed the “CARS”—by Bone (Fig. 4). The pro- and anti-inflammatory forces may ultimately reinforce each other, creating a state of increasingly destructive immunologic dissonance. SIRS continues to be recognized as an ubiquitous early harbinger of MODS. Although these acronyms are clever and provide simplified understanding of the pathophysiology, they do not fully explain the complexity of the human response to injury.

**Figure 4** Progression from systemic inflammatory response syndrome (SIRS) to compensatory anti-inflammatory response syndrome (CARS) to multiple organ dysfunction syndrome (MODS). The five stages in the development of multiple organ dysfunction as postulated by Roger Bone. Stage 1 begins at a site of local injury or infection. Pro-inflammatory mediators are released locally to promote wound healing and to combat foreign organisms or antigens. Anti-inflammatory mediators are then released to downregulate this process. If the original insult is small and the patient is healthy, homeostasis will be quickly restored. Stage 2 occurs if local defense mechanisms are insufficient to correct the local injury, or eliminate the local infection. Through various mechanisms, pro-inflammatory mediators are released into the systemic circulation; these recruit additional cells to the local area of injury. Systemic release of anti-inflammatory mediators follows soon thereafter; under normal circumstances, these mediators ameliorate the pro-inflammatory reaction and restore homeostasis. Stage 3 occurs if the systemic release of pro-inflammatory mediators is too massive, or if the anti-inflammatory reaction is insufficient to permit downregulation. It is at this stage that most patients have symptoms of the SIRS, as well as incipient evidence of the MODS. Stage 4 can be represented by excessive systemic levels of anti-inflammatory mediators that develop as a response to a massive pro-inflammatory response; however, these levels can also develop de novo. Patients with a stage 4 CARS have marked immunosuppression and, thus, are at increased risk for infection. The body can re-establish homeostasis after stage 3 or 4 and improve. Others will advance to stage 5—the final phase of MODS. At this stage of immunologic dissonance, the balance between pro- and anti-inflammatory mediators has been lost, and many of these patients currently go on to die. Some patients may have persistent, massive inflammation; others may have ongoing immunosuppression and secondary infections. Still others may oscillate between periods of inflammation and immunosuppression.

Source: From Ref. 74.

The human immune response is regulated by a highly complex and intricate network of control elements (many still unknown). Prominent among the known regulatory components are the anti-inflammatory cytokines and specific cytokine inhibitors (75). Under physiologic conditions, these cytokine inhibitors serve as immunomodulators limiting the potentially injurious effects of sustained or excess inflammatory reactions. Under pathologic conditions, these anti-inflammatory mediators may either: (i) provide insufficient control over pro-inflammatory activities in immune-mediated diseases; or (ii) overcompensate and inhibit the immune response, rendering the host at risk from systemic infection. A dynamic and ever-shifting balance exists between pro-inflammatory cytokines and anti-inflammatory components of the human immune system. The regulation of inflammation by these cytokines and cytokine inhibitors is further complicated by the fact that the immune system has redundant pathways with multiple elements having similar physiological effects.

## SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND SPECIFIC PATIENT POPULATIONS

### Trauma and Critical Illness

Traumatic injury immediately stimulates inflammation in order to save the individual and initiate repair. This inflammatory response is a cascading process involving a delicate balance between pro- and anti-inflammatory mediators, and components of all bodily systems. If the injured person does not die immediately, his morbidity and/or mortality may depend in large part on the degree to which systemic inflammation influences his clinical course. Basic and clinical science studies have demonstrated an intricate relationship between trauma, shock, SIRS, and sepsis (6). ⚡ **Trauma, especially when complicated by hemorrhagic shock, may induce SIRS, potentially resulting in immunodepression, MODS, severe sepsis, or septic shock.** ⚡ If severe enough, this inflammatory response may adversely affect organ systems not involved in the original traumatic injury. In this scenario, MODS typically follows a specific pattern affecting the lungs first, followed by the liver, gut, and kidneys (6). The presence of SIRS may provide insight into patients at risk, for progression to MODS.

A SIRS score of  $\geq 2$  at the time of admission has been shown to be an independent predictor of increased mortality and length of stay in trauma patients, suggesting that admission SIRS score may be used as a predictor of outcome and resource utilization (76). These findings were confirmed in 9539 trauma patients admitted to a level-one trauma center over a 30-month period (77). This study demonstrated that the SIRS score was an independent predictor of mortality and ICU length of stay, hypothermia (temperature  $< 36^{\circ}\text{C}$ ) was the most significant predictor of mortality, and leukocytosis (neutrophil count  $> 12,000/\text{mm}^3$ ) was the most significant predictor of total hospital length of stay (LOS). Another study of 4887 blunt trauma patients admitted to a level one trauma center determined that admission SIRS score, independent of age and ISS, was an independent predictor of infection (78). Infected patients had statistically longer hospital lengths of stay and increased risk for mortality.

The predictive capability of daily SIRS scores and outcome in trauma patients admitted to an ICU has been evaluated (79). SIRS on hospital days 3 to 7 was a significant predictor of nosocomial infection and hospital length of stay. Persistent SIRS to hospital day 7 was associated with a

significant risk for increased mortality. In another study, SIRS for  $\geq 3$  days in trauma patients was associated with an increased incidence of disseminated intravascular coagulation (DIC), the adult respiratory distress syndrome (ARDS), and MODS (80).

A review of published cohort studies, examining the septic syndromes with an emphasis on ICU patients revealed that the prevalence of SIRS is very high, affecting one-third of all in-hospital patients and  $> 50\%$  of all ICU patients (81). SIRS occurs in 80% of all surgical ICU patients. In this patient population, the prevalence of infection and bacteremia increases with the number of SIRS criteria met, as well as with increasing severity of the septic syndromes. Approximately one-third of patients with SIRS has, or evolves to, sepsis. Sepsis may occur in 25% of ICU patients, progressing to severe sepsis in  $> 50\%$  of the cases. Mortality rates increase with progression from SIRS to septic shock, and are similar within each stage whether infection is documented or not. Most deaths (3/4) occur during the first few months after sepsis, but there is also a 50% reduction of life expectancy over the following five years. When SIRS progresses to MODS and MOF, mortality rates increase substantially (30–80%), depending on the number of failed organs (82).

A prospective study evaluating daily SIRS scores and outcomes in 2300 surgical ICU admissions demonstrated that SIRS on postoperative day 2 (compared to the score on day 1) was a more accurate predictor of mortality and correlated better with Acute Physiologic and Chronic Health Evaluation III (APACHE III) and MODS scores (Table 3) (83). It was hypothesized that the effects of surgery, surgical stress, anesthesia, and ICU resuscitation in the first 24 hours may overestimate the pro-inflammatory response itself, making quantitation of the SIRS within that time period too sensitive.

The degree of metabolic stress among critically ill patients may be variable, and dependent upon whether or not SIRS is related to infection and/or sepsis (84). Moriyama et al. (84) demonstrated that oxygen consumption and resting energy expenditure were higher in SIRS patients with sepsis, compared to SIRS patients without sepsis.

### Surgery

⚡ **Surgical procedures are known to elicit systemic inflammation. The magnitude and duration of the procedure, comorbid diseases, and reperfusion injury are just a few of the variables that affect the inflammatory response.** ⚡ Some operations are associated with specific procedures that directly affect the immune response. Knowledge of these potential inflammatory insults may lead to modification of certain surgical procedures and/or re-evaluation of their indications.

Cardiopulmonary bypass (CPB) and extracorporeal circulation have been associated with SIRS and MODS due to inflammatory mediator release. Survival in patients with MODS after CPB may be affected by the degree of inflammatory mediator release. A recent study determined that levels of IL-8, IL-18, and PCT could be used as parameters for the prognosis of patients with organ dysfunctions after cardiac surgery (85).

The inflammatory response associated with hepatic ischemia/reperfusion during liver resection and transplantation has been studied, though the clinical implications remain to be clarified. These findings may also be applicable to hepatic surgery associated with traumatic injury. The

inflammatory cytokines TNF- $\alpha$ , IL-1 $\beta$ , IL-6, and IL-8 were measured in serial samples of portal and systemic blood before hepatic inflow clamping, at the end of clamping, one hour, and one day after continuous inflow occlusion in 25 patients undergoing elective hepatectomy (86). These investigators demonstrated that portal IL-6 levels during resection and at one hour after cessation of clamping significantly correlated with duration of hepatic inflow occlusion, portal venous pressure, and increase in postoperative serum transaminases and bilirubin. Increased levels of systemic IL-8 demonstrated increases in these same parameters, whereas portal IL-8 levels showed no such correlation. The one patient who died had elevated cytokine levels in the presence of elevated portal venous pressure. The authors proposed that hepatectomy that would require prolonged inflow occlusion be reconsidered when an enhanced acute generation of cytokines is anticipated, especially in the presence of markedly increased portal pressure.

Instrumentation is frequently utilized in orthopedic trauma surgery. The effects of instrumentation on postoperative inflammation in patients undergoing spinal injury were investigated by Takahashi et al. (87). The pro-inflammatory cytokines IL-6 and IL-8, the anti-inflammatory cytokines IL-10 and IL-1RA, and the soluble TNF- $\alpha$  receptors I and II were assayed in seven patients who underwent lumbar spinal posterior decompression, six patients with spinal decompression and posterolateral fusion without instrumentation, and seven patients with spinal decompression and posterolateral fusion with instrumentation. All cytokines increased significantly after spinal instrumentation on postoperative days 0 and 1. Seven days later, the inflammatory cytokines had normalized, but the anti-inflammatory cytokines remained elevated in this group. These findings suggest that patients undergoing instrumentation may be at higher risk for infection and/or SIRS and MODS, due to an exaggeration of the inflammatory response.

Extremity ischemia/reperfusion injury is frequently encountered in trauma and vascular surgery. Free radical release following ischemia/reperfusion leads to inflammation, and the patient's innate antioxidant system [total antioxidant capacity (TAC)] is the mode of defense. TAC was evaluated in patients with chronic leg ischemia who underwent femoral-distal bypass (88). Patients who developed SIRS following revascularization had a significantly reduced TAC, and increased lipid peroxidation and vascular permeability (measured by changes in the urinary albumin to creatinine ratio). TAC may represent a marker for patients at risk for SIRS, and the authors thought that augmentation with antioxidants may be utilized to augment their defense.

Levels of postoperative inflammatory cytokine levels have been shown to reflect the magnitude of surgical stress. Laparoscopically performed intra-abdominal surgery has been demonstrated to elicit lower postoperative levels of inflammatory cytokines (specifically IL-6 and IL-8) compared with open procedures, lending support to the use of this modality when technically and/or surgically feasible (89). Indications for the use of laparoscopic surgery in trauma are presently under investigation.

## Anesthesia

☞ With the exception of anaphylaxis and allergy (see Volume 1, Chapter 33), anesthetics and analgesics by themselves are not initiators of SIRS. However, several anesthetics and analgesics have shown immunomodulatory effects, and may therefore have some effects on SIRS. ☞

Different anesthetic agents have different effects on the inflammatory response. The inflammatory response associated with Total Intravenous Anesthesia (TIVA) and Balanced Inhalation Anesthesia (BIA) was compared in patients undergoing elective lumbar discectomies (90). In the BIA group, the IL-6 plasma concentration was significantly elevated, but IL-2R $\alpha$  and IL-1RA were reduced compared with the TIVA group. There was also a relatively greater increase in postoperative cortisol, epinephrine, and norepinephrine concentrations under BIA, perhaps representing an enhanced activation of the hypothalamic-pituitary-adrenal axis and the sympathetic nervous system. Ketamine reduced the CPB-induced IL-6 and IL-8 response in patients undergoing cardiac valve replacement (91). Anesthesia with ketamine/acepromazine/zylazine significantly blunted the LPS-induced plasma TNF- $\alpha$  release in an animal study (92). Preoperative administration of clonidine decreased both plasma and CSF concentrations of TNF- $\alpha$  (93). A large dose of clonidine resulted in no detectable TNF- $\alpha$  in the CSF. Clonidine also led to decreased catecholamine release in the periphery and CNS. Furthermore, patients who received clonidine preoperatively had lower pain scale scores and required less postoperative pain medications. Propofol inhibited IL-6 and IL-10 production by LPS-stimulated peripheral blood mononuclear cells and thiopental induced IL-10 production, when different IV anesthetics were compared (94). General anesthesia with propofol and fentanyl led to a decrease in circulating lymphocytes, characterized by a significant increase in the percentage of T lymphocytes in favor of CD4+ cells, increased B lymphocytes and a significant decrease in NK cells, suggesting promotion of a pro-inflammatory immune response in patients undergoing elective orthopedic surgery (95). These investigators also studied the immune response to whole blood stimulated with LPS in these patients. There was a significant enhancement of TNF- $\alpha$  and IL-1 $\beta$  release in these samples after induction of anesthesia. Synthesis of IL-10 decreased significantly in these LPS-stimulated cultures.

Inhalational (volatile) anesthetics utilized during GA have been studied for their effect on systemic inflammation and for effects on pulmonary tissue. Alveolar epithelial type II (AT II) cells are known to elicit cytokines when stressed and are exposed to volatile anesthetics when patients are under GA. Giraud et al. (96) studied the effects of halothane, enflurane, and isoflurane on rat AT II cells after stimulation with recombinant murine IL-1 $\beta$  (rmIL-1 $\beta$ ). The volatile anesthetics decreased AT II secretions of inflammatory cytokines, but did not modify total protein secretion. Halothane exposure decreased the inflammatory response in a dose- and time-dependent manner. This inhibition was reversed between 4 and 24 hours postoperatively.

Thoracic epidural anesthesia utilized during cardiac surgery has been associated with a reduction in ischemia/reperfusion injury, which may in turn decrease the elaboration of pro-inflammatory cytokines (97). Epidural anesthesia with bupivacaine administered during CPB surgery led to an attenuated inflammatory response compared to patients who had GA alone (98).

Inflammatory mediators, when present in patients preoperatively, may adversely affect anesthesia. An animal study demonstrated that both central (via intracerebroventricular placement) and peripheral (via intraperitoneal placement) administration of TNF- $\alpha$  decreased anesthesia time induced by ketamine or propofol (99).

### Cardiopulmonary Bypass

CPB has been the traditional methodology for providing oxygenated blood for tissue perfusion during cardiac surgery. CPB is associated with augmentation of the systemic inflammatory response. Okubo et al. (100) studied the immunological effect of CABG, with and without CPB. In this study, 10 patients who had CABG on pump, and 10 patients who underwent CABG without CPB, had peripheral blood sampled before and 6 hours after surgery. This blood was then evaluated for gene expression of cytokines, adhesion molecules, and vasoactive substances in the leukocytes. Postoperative expression of mRNA for IL-1, IL-8, IL-10, TNF- $\alpha$ , heme oxygenase-1, platelet endothelial cellular adhesion molecule, and Mac-1 increased significantly in the on-pump group, but not in the off-pump group.

☞ **Direct contact between patient blood and the synthetic surfaces of the CPB system, along with released intracellular elements of destroyed cells, are the most likely reasons for the increased inflammatory mediators seen with CPB.** ☞

In a review of alternatives to CPB, Ganapathy et al. (97) reported that beating heart surgery (without CPB) significantly attenuates the pro-inflammatory cytokine stress response. They reported that there is reduced renal dysfunction associated with beating heart surgery as well.

Dexamethasone given to patients prior to CABG surgery led to a relative decrease in inflammatory mediator release and an increase in anti-inflammatory mediators (101). Patients who had dexamethasone also had better outcome immediately postop, and shorter ICU lengths of stay. Dopexamine administered intravenously during cardiac surgery, and up to 18 hours postoperatively, led to a decrease in the pro-inflammatory immune response when compared to controls [normal saline (NS) infusion instead of dopexamine] (98).

### EFFECTS OF RESUSCITATION ON INFLAMMATION

☞ **Resuscitation for trauma and surgery may affect an individual's innate immune response, as a result of the type, quantity, and timing of fluid resuscitation.** ☞ Controversy presently exists regarding the timing and titration of fluid resuscitation, as related to goal mean arterial pressure (MAP) and end-points of resuscitation (e.g., measurement of base deficit and/or lactate vs. other). There is also concern that certain IV fluids may be more efficacious and less immunogenic than others (see Volume 1, Chapter 11). As with all decisions in medicine, one must balance risks of fluid resuscitation with the benefits (102).

One of the concerns regarding fluid resuscitation in hemorrhagic shock is the potential to disrupt efficacious vascular clot. Animal studies have demonstrated that increasing IV rates/blood pressure in the presence of uncontrolled bleeding is accompanied by increased bleeding (102). Using a rat model of uncontrolled hemorrhage, Burris et al. (103) demonstrated that the group that had no fluids had the lowest survival rate. Groups resuscitated with lactated ringers (LR) to a MAP of 100 mmHg also had low survival rates. The highest survival rates were seen in rats resuscitated to a MAP of 80 mm Hg with LR or 40 mm Hg with 7.5% hypertonic saline (HS) and 6% hetastarch. Timing and volume of fluid resuscitation, cytokine elaboration, and mortality were evaluated in an animal model of hemorrhagic shock (104). Sprague-Dawley rats were hemorrhaged 35% of their total blood

volume and then resuscitated with varying volumes of crystalloid either early (15 minutes), delayed (60 minutes), or not at all. These investigators determined that rats resuscitated early had decreased cytokine elaboration and decreased mortality. Interestingly, the delayed resuscitation group had increased mortality compared to both the early resuscitation and no resuscitation groups. Excessive fluid resuscitation in both early and late resuscitation groups resulted in increased inflammatory cytokine elaboration and increased mortality. The authors concluded that perhaps volume of fluid, rather than timing of initiation, is a more important determinant of outcome after hemorrhagic trauma.

The first study to evaluate low MAP resuscitation in humans was published in 1994 (105). These investigators randomized hypotensive penetrating trauma victims to routine fluid resuscitation or no fluid resuscitation, until surgical control of bleeding had been achieved. The results demonstrated a survival advantage in the group that had resuscitation withheld initially. However, when the data included those patients who "died in the field" on an intent-to-treat basis, no survival advantage was demonstrated when fluid was withheld. No survival advantage was demonstrated in a more recent study when 110 trauma patients presenting with hemorrhagic shock were randomized to receive resuscitation to either systolic blood pressure (SBP) > 100 mmHg (conventional) or SBP of 70 mmHg (low) (106). These investigators determined that the imprecision of SBP as a marker for tissue oxygen delivery might have accounted for these results. Clearly, large, multicenter prospective randomized studies need to be done to evaluate this more closely.

Resuscitation studies have also focused recently on the type of fluid used. Presently, isotonic fluids are given preferentially in resuscitation protocols. Normal saline (NS) or LR are the crystalloids most frequently utilized. Isotonic fluids are quickly distributed throughout the entire extracellular space, as unfortunately there is no predilection for the intravascular space. This results in fluid retention with an increased ratio of extracellular to plasma space; only 10% to 20% or less of infused isotonic fluids remain in circulation (107). Colloid solutions elicit an oncotic pressure similar to plasma (20–30 mmHg). Commonly used colloids include: albumin (20–25 mmHg), hetastarch (30–35 mmHg), and dextran 70 (60–75 mmHg) (107). Albumin expands plasma volume by 80% of infused volume, hetastarch expands plasma volume equal to the infused volume, and dextran expands plasma volume 20% to 50% more than the infused volume.

HS has been investigated extensively as both a fluid medium for resuscitation and as an anti-inflammatory agent in trauma and critical illness. It has demonstrated efficacy in the restoration of hemodynamic stability and microcirculatory support, in patients who are hypovolemic due to hemorrhagic shock (6). HS has been associated with decreased blood viscosity and improved microcirculation, when utilized as a resuscitation fluid. HS mobilizes an amount of cellular water proportional to osmotic load, and tends to reduce overall volume needs in perioperative patients (107). Cells become edematous during shock and surgical stress, and HS has been shown to normalize cell volume rather than reduce it below normal (107). HS resuscitation was associated with improvement in microcirculatory perfusion to the kidney and small bowel (108). Coimbra et al. (109) demonstrated decreased bacterial translocation and decreased incidence of lung

injury associated with HS resuscitation. Resuscitation with HS was also associated with restoration of intestinal nutrient blood flow, prevention of gut barrier breakdown and bacterial translocation, and prevention of organ failure (110). Gurfinkel et al. (111) demonstrated improved tissue oxygenation and perfusion, and reduced SIRS when HS [compared with isotonic saline (IS)] was utilized for resuscitation in an animal model of hemorrhage/shock. These authors demonstrated that animals that received HS had higher oxygenation and perfusion indices, and lower arterial lactate, TNF- $\alpha$ , and IL-6 levels. These animals also demonstrated less pulmonary edema, polymorphonuclear cell (PMN) sequestration, and lower mortality compared with animals that received IS. HS (7.5%) was added to dextran 70 (HSD), by Kramer et al. (107), with the theory that HS would expand the vascular space by mobilizing cellular water and that a hyperoncotic colloid might selectively retain more of this water in the vascular space. Their work demonstrated significantly higher and more sustained cardiac output and MAP, and a lower total peripheral resistance compared with either compound alone. These results were repeated in multiple animal studies, some of which also demonstrated decreased mortality.

HS has demonstrated immune-enhancing properties when utilized for fluid resuscitation. Increasing sodium-chloride concentrations in resuscitation fluid was associated with increased T-cell proliferation and decreased levels of immunosuppressive mediators [e.g., prostaglandin E<sub>2</sub> (PGE<sub>2</sub>)] (6). Neutrophil activation and associated release of oxygen radicals and proteases is associated with worse outcome after trauma-hemorrhage. Resuscitation with LR was associated with neutrophil activation and release of these harmful reactants, whereas resuscitation with HS was not in an awake-swine model of hemorrhagic shock (112). Junger et al. (113) demonstrated that increasing the tonicity of the saline resuscitation fluid led to a dose-dependent (saline concentration) decrease in N-formyl-methionyl-leucyl-phenylalanine activated human neutrophil release of proteases and oxygen radicals. When compared with LR in an animal model of trauma-hemorrhage, then sepsis (CLP), HS resuscitation was associated with decreased mortality (14.3%) compared to LR (76.9%) (108). These investigators also demonstrated less severe lung injury in animals resuscitated with HS. In another study, these same investigators demonstrated that pentoxifylline added to HS reduced bacterial translocation and lung injury in an animal model of hemorrhagic shock, compared to resuscitation with LR (114).

HS can reverse the immunosuppressive effects of trauma, and the mechanism may in part be due to altered neutrophil adhesion properties in the microcirculation (102). Preliminary human studies have demonstrated many of the same immunological benefits, but not all studies demonstrate clear-cut differences in the immune response to different fluids. Isotonic and hypertonic fluids were evaluated, to determine whether or not the differential effects elicited by these compounds were due to different cytokine gene elaboration profiles (115). All of the resuscitation fluids analyzed led to increased pro-inflammatory mediator gene expression (to include TNF- $\alpha$ , IL-1 $\alpha$ , IL-6, and IL-10). There was no difference in the cytokine expression profile between isotonic and hypertonic fluids in this study. Likewise, multicenter trials that have studied the efficacy of HSD, compared to other crystalloids (e.g., LR), have not demonstrated an overall survival benefit, although a subgroup of patients who received HSD

and required surgery had a survival advantage (102). Clearly, human studies need to be undertaken to study this more in depth.

A recent clinical study, designed to determine if HSD was detrimental when administered to hypotensive patients after penetrating trauma to the torso, demonstrated that HSD resuscitation improved survival in the patients who required surgery (116). The study evaluated 230 patients. Overall survival in the 120 patients who received HSD was 82.5%, whereas survival was 75.5% in those who received an equivalent amount of NS ( $p = 0.19$ ). Surgery was required in 157 patients (68%). Of these patients, 84 were resuscitated with HSD and 73 with NS. Survival was 84.5% in those patients who received HSD, compared with 67.1% in those resuscitated with NS ( $p = 0.01$ ).

HS has become a mainstay of therapy for intracranial hypertension associated with TBI. HS decreases intracranial pressure, due to changes that primarily occur in areas of the brain that maintain intact blood-brain barriers (102). Different saline tonicities are also being investigated regarding efficacy in this scenario. A 7.5% saline solution in doses of 2 mL/kg per treatment was as (or more) efficacious than mannitol, for intracranial hypertension refractory to other standard methods of treatment (117). Other strategies most recently utilized along with HS for intracranial hypertension include mild hypothermia, and decompressive craniotomy (118).

## THE ROLE OF THE GUT IN SYSTEMIC INFLAMMATORY RESPONSE SYNDROME AND SEPSIS

Under nonstressed conditions, gut integrity is well protected. Intraluminal contents (containing large quantities of bacteria) are kept within the confines of the bowel in multiple ways. An intact gastrointestinal (GI) mucosa via maintenance of tight intracellular junctions is one important method. Additionally, the GI tract has immunological tissue referred to as gut-associated lymphoid tissue (GALT). GALT includes Peyer's patches, mesenteric lymph nodes, and intraepithelial and lamina propria lymphocytes. These immunological cells represent the first line of defense against foreign proteins. Furthermore, surface immunoglobulin A is found in high concentrations amongst these cells. If foreign antigens transfer across the bowel wall, clearance through the portal system (including the mesenteric veins and lymphatics, liver, and spleen) should eliminate the toxic threat (Fig. 5). **A breakdown in any component of this GI defense system may contribute to bacteremia and sepsis, following injury or illness.** The transfer of bacteria across the bowel wall and into surrounding tissue and/or circulation is known as "bacterial translocation." When normal mesenteric processes tasked with controlling this bacterial load fail, overwhelming levels of local, and then circulating, endotoxin levels lead to SIRS, sepsis, and MODS. The pathophysiology of intestinal bacterial translocation is not entirely understood, but it is probably due in part to a breakdown at the local intestinal mucosal barrier from an imbalanced local inflammatory response, ischemia, malnutrition, or a combination of these. Gut associated immune cells release both pro- and anti-inflammatory cytokines when stressed (119). Animal studies have demonstrated significant changes in GALT after hemorrhagic shock and soft tissue trauma. Buzdon et al. (120) utilized a murine femur fracture model to demonstrate a significant

**Figure 5** Gut–liver–lung axis in response to shock and hemorrhage. The gut–liver–lung axis in response to hemorrhagic shock injury. These organs (gut, liver, and lung) seem to be the major target organs of systemic inflammatory response syndrome. Initiation of the inflammatory state can occur in any of these organs following trauma or shock. The gut can leak inflammatory mediators into the portal circulation, which will cause a response in the liver. Inflammatory mediators then travel in the hepatic vein to the inferior vena cava and to the lungs. The lungs may become injured, may inactivate some substances (not shown), or can release inflammatory substances themselves, which travel systemically to distant organs (including the gut). *Abbreviation:* LPS, lipopolysaccharide. *Source:* From Ref. 188.

increase in Peyer's patch lymphocyte CD3, CD4, and TCR $\alpha\beta$  expression, as well as a significant decrease in Peyer's patch IL-10 protein expression. Secretion of the inflammatory cytokines TNF- $\alpha$ , IL-6, and IFN $\gamma$  occurs in the small bowel and levels of IL-6 are increased in states of bacterial overgrowth (38). Ischemia/reperfusion may contribute to this insult. In ex vivo human intestine, ischemia/reperfusion was associated with increased pro-inflammatory cytokine levels in venous effluent (38).

Basic science and clinical research have demonstrated that the GI tract plays a pivotal pathogenic role in the development of postinjury SIRS and MODS (121). These and other investigators have demonstrated the following findings: (i) shock with resulting gut hypoperfusion is an important inciting event; (ii) upon reperfusion, the gut is a source of pro-inflammatory mediators capable of amplifying SIRS and contributing to early MODS; (iii) early gut hypoperfusion causes an ileus in the stomach and small bowel that sets the stage for progressive gut dysfunction, so that the proximal gut becomes a reservoir for pathogens and toxins that contribute to late sepsis-associated MODS; and (iv) Late infections then cause worsening of the gut dysfunction. These findings elucidate the gut's role as both an initiator of inflammation and as a "victim" of SIRS/MODS.

The exact role of malnutrition in this scenario is unknown. Malnutrition has not been directly associated with bacterial translocation; however, there is evidence to suggest that it may make the gut more sensitive to inflammatory mediator release. Maintenance of bowel mucosal integrity in the setting of SIRS is a target of ongoing scientific investigation.

Selective decontamination of the digestive tract (SDD) is a process through which the intraluminal bacterial load is

decreased. A decreased bacterial load is theorized to modulate the inflammatory response to gut hypoperfusion after trauma or critical illness.

Male Wistar rats were divided into four groups in a study to determine the influence of SDD on the pro-inflammatory immune response of the gut (122). The rats were given either SDD or conventional rat chow, and underwent hemorrhage with withdrawal/reinfusion of shed blood or not. TNF- $\alpha$  and IL-6 were measured in portal and caval blood, splenic macrophages, and gut mononuclear cells. Mesenteric lymph nodes were harvested to determine bacterial translocation and a histological specimen was taken from the distal ileum. Feces were also examined to evaluate the effect of SDD. SDD eliminated gram-negative enteric bacteria, but had no influence on mucosal damage or on bacterial translocation in control animals and animals after hemorrhage. There was a significantly elevated LPS-induced pro-inflammatory cytokine release in portal blood, splenic macrophages, and gut mononuclear cells in animals subjected to hemorrhagic shock that were fed rat chow. Hemorrhagic shock after SDD led to suppressed or unchanged cytokine release in these organs, compared to unmanipulated animals receiving SDD. In unmanipulated animals, SDD itself induced a significant inflammatory response. Plasma concentrations of cytokines were significantly elevated in animals after hemorrhage and SDD, compared with animals after hemorrhage alone. The authors warn that SDD may induce an increased inflammatory response in some patients that can be augmented after an insult such as hemorrhagic shock.

Clinical trials have not demonstrated improved outcome after SDD. In a study of 78 consecutive cardiac surgery patients, Bouter et al. (123) demonstrated that SDD

effectively reduced the percentage of gram-negative flora, but did not affect the incidence of postoperative endotoxemia and cytokine activation. SDD did not decrease bacterial colonization, nor did it decrease subsequent infectious episodes when severely burned pediatric patients were studied (124).

## IMMUNOMODULATION: MODERATING THE INFLAMMATORY RESPONSE

✂ **Manipulation of immune pathway mediators may become a tool for modulating the balance between the pro-inflammatory and anti-inflammatory conditions.** ✂ The key is to balance the exuberant pro-inflammatory response (which may lead to SIRS) with selected anti-inflammatory modulators that decrease systemic inflammation, but do not decrease the necessary local antibacterial or inflammatory processes needed to control infection and promote healing. The ideal modulator would be effective when given after injury or onset of illness to regulate SIRS, and it would be readily available and economical.

### Tumor Necrosis Factor $\alpha$ and Interleukin-1

TNF- $\alpha$  is a target of immunological research, as it initiates the pro-inflammatory response and is a key mediator in the development of sepsis. Despite continued investigation into the role of TNF- $\alpha$  in injury and sepsis and therapies designed to control its role in adverse physiological outcome, little progress has been achieved over the last decade.

Antibodies to TNF- $\alpha$  and IL-1 have been investigated as potential therapeutic agents, with encouraging results in preliminary studies but disappointing results in clinical trials, due to lack of efficacy and the occurrence of unwanted side-effects (125). Large clinical trials of anti-TNF- $\alpha$  monoclonal antibodies and soluble TNF- $\alpha$  receptors produced only small, insignificant beneficial trends in patients with sepsis (6). Furthermore, when investigated for its effects on cytokine release and physiological responses in patients with severe sepsis, there was no difference in overall pattern of cytokine activation or the physiological derangements associated with sepsis.

Pentoxifylline, a methyl-xanthine derivative, best known for successful treatment of atherosclerotic disease, inhibits the formation of TNF- $\alpha$  and has demonstrated efficacy in attenuating the inflammatory response in clinical trials (6). In a multitude of studies, it has been demonstrated to decrease the release of inflammatory cytokines that lead to neutrophil activation and superoxide radical release (6). It has been shown to improve erythrocyte flow and increase tissue oxygenation when added to resuscitation fluids (126–128). It has also been shown to restore effective hepatic blood flow after shock and resuscitation, perhaps by reducing neutrophil-endothelial cell interaction and activation (129).

TGF $\beta$  and corticosteroids as antagonists to these two agents have also been investigated. TGF $\beta$  does reduce IL-1 production, but it also induces production of IL-1RA (competitively binds to IL-1 receptors), making the immunosuppression overly toxic. Likewise, corticosteroids amplify immunosuppression by reducing production of IL-1 and TNF- $\alpha$ , but they also increase IL-1RII. This receptor preferentially binds IL-1 $\beta$  and inhibits it.

GCSF, a growth factor, has been shown to modulate these two cytokines. GCSF supplementation suppresses the LPS-induced release of TNF- $\alpha$  and IL1 $\beta$ , and increases sTNF-R p75 and IL-1ra, thus enhancing anti-inflammatory activity (6). Growth factor was evaluated by Zhang et al. (130), who used rat acute necrotizing pancreatitis (ANP) models and measured serum levels of IL-6, IL-8, IL-10, and TNF- $\alpha$ . They also observed TNF- $\alpha$  mRNA in the liver, lung, kidney, and heart after ANP. Serum levels of these inflammatory cytokines were elevated in response to ANP, and this elevation led to the development of MODS. The administration of Somatostatin and growth hormone inhibited these inflammatory mediators and TNF- $\alpha$  mRNA over-expressions, reduced the risk of the MODS, and markedly increased survival.

Exciting work by Wang et al. (131) has demonstrated a key link between inflammation and the involuntary nervous system that may lead to new therapeutic options. These researchers discovered that the vagus nerve has receptors for inflammatory cytokines and, once stimulated, can suppress ongoing inflammation. In an animal study, this group electrically stimulated the vagus nerve after injecting LPS into rats (132). This stimulation prevented the release of TNF- $\alpha$  from macrophages and death. They characterized the macrophage nicotinic receptor that binds to the acetylcholine released by the vagus nerve, leading to suppression of TNF- $\alpha$  release. This receptor is comprised of five copies of the monomer  $\alpha 7$ . When this receptor was blocked, acetylcholine and nicotine were no longer able to prevent the release of TNF- $\alpha$ . This was confirmed by studying  $\alpha 7$  deficient mice. These mice actually exhibited an exaggerated inflammatory response to LPS. Therapies involving vagus nerve and/or  $\alpha 7$  stimulation should undergo further investigation.

### Interleukin-2

Preoperative pretreatment with IL-2 has been shown to abrogate the immunosuppression associated with surgery. The cytokine mechanisms responsible for this effect were studied in colorectal cancer patients (133). Operable colorectal cancer patients ( $n = 12$ ) pretreated with IL-2 were compared to 21 age- and disease-matched patients (controls) who underwent surgery without IL-2 pretreatment. Serum levels of IL-6 were measured before surgery, and then at days 3 and 7 in the postoperative period. A significant increase in mean serum levels of IL-6 occurred in the postoperative period in the control patients, whereas no significant difference was seen between presurgical and postsurgical IL-6 mean concentrations in the IL-2 pretreated groups, suggesting that the neutralization of surgery induced immunosuppression by IL-2 may, in part, be due to inhibition of IL-6.

Preoperative administration of IL-2 was also associated with attenuation of immunodysfunction after nephrectomy for renal cell carcinoma (134). In this study, postoperative levels of IL-6 and IL-10 were lower in the pretreated patients. T cell and activation markers were also decreased.

### Cyclo-oxygenase Inhibitors

PGE<sub>2</sub> is known to disrupt cell-mediated immunity after severe trauma or hemorrhage (6). PGE<sub>2</sub> acts on the phosphokinase-A-phosphokinase-C pathway by cAMP. Prostaglandin inhibitors would therefore block this pathway or enhance cyclic guanosine monophosphate, which is protective.

Diclofenac, a COX inhibitor (and thus prostaglandin inhibitor), has been studied as a modulator of inflammatory cytokine release. In a double blind, placebo-controlled study, the administration of diclofenac in the perioperative period (of patients undergoing major urological surgery) was associated with lower IL-6 and IL-10 concentrations, lower leukocyte count, and CRP (135). It was concluded that Diclofenac might play an anti-inflammatory role in surgery.

Prostacyclin has been theorized as an anti-inflammatory option for patients undergoing CABG (136). In a randomized prospective double-blind study, 40 patients undergoing CABG were divided into four groups. One group served as a control, another group received prostacyclin, another group was given high-dose aprotinin, and the last group was treated with prostacyclin and aprotinin. Plasma elastase, PCT, C1-esterase inhibitor (CEI), and coagulation and fibrinolysis parameters were measured in the perioperative period. Levels of elastase increased significantly in the peri- and postoperative period in all patients, and were most pronounced in the control and aprotinin groups. The duration of myocardial ischemia could be directly correlated to elastase levels at the end of CPB. Elastase levels were significantly higher in patients who developed SIRS. These patients developed a hypercoagulatory state. PCT and CEI levels did not change significantly during and after CPB. These authors speculated that prostacyclin controlled the inflammatory effects of increased elastase release associated with CPB and myocardial ischemia.

Thymopentin stimulates cyclic guanosine monophosphate, and has been shown to result in improved in vitro lymphocyte proliferation compared to placebo-treated cardiac surgery patients (137). When combined with indomethacin, cardiac surgery patients who received this therapy demonstrated improved cell-mediated immunity (i.e., IL-1, IL-2, and IFN $\gamma$  production and IL-2 receptor expression) and lymphocyte proliferation (138).

### Nitric Oxide Inhibitors

Due to the extensive involvement of NO in the augmentation of inflammation following hemorrhagic shock and sepsis, it is a target for therapeutic intervention. Animal studies have demonstrated that NO scavengers may suppress pro-inflammatory signaling. Hierholzer et al. (139) studied NOX, an inhibitor of induced NO (iNO), in rats subjected to hemorrhagic shock. These rats were resuscitated and then examined 24 hours later for histological evidence of inflammatory lung injury. Nontreated animals demonstrated IL-6 localized to luminal sides of bronchial cells, and increased activation of NF- $\kappa$ B and Stat3 (IL-6 signaling intermediary). Administration of NOX beginning at 60 minutes of shock reduced all measured inflammatory parameters within lung tissue, and the authors concluded that NOX might prevent lung injury in this hemorrhagic shock model.

In contrast to short-term animal studies, long-term human studies have shown nonselective NO inhibition to increase mortality (140). A recent multicenter, randomized, two-stage, double-blind, placebo-controlled safety and efficacy study was performed to assess the safety and efficacy of the nonselective NO synthase inhibitor 546C88, in patients with septic shock in a total of 124 ICUs in Europe, North America, South America, South Africa, and Australia. A total of 797 patients with septic shock diagnosed for <24 hours were enrolled. Patients with septic shock were allocated to receive 546C88 or placebo (5% dextrose) for up to seven days (stage 1) or 14 days (stage 2) in addition to

conventional therapy. Study drug (546C88) was initiated at 2.5 mg/kg/hr and titrated up to a maximum rate of 20 mg/kg/hr to maintain MAP between 70 mmHg and 90 mmHg, while attempting to withdraw concurrent vasopressors.

The trial was stopped early, after review by the independent data safety monitoring board detected an increased mortality in the NO synthase inhibitor group (140). The day-28 mortality was 59% (259/439) in the 546C88 group, compared to 49% (174/358) in the placebo group ( $p < 0.001$ ). The overall incidence of adverse events was similar in both groups, although a higher proportion of the adverse events were attributed to the study drug in the 546C88 group (140). Most of the events accounting for the disparity between the groups were associated with the cardiovascular system (e.g., decreased cardiac output, increased pulmonary and systemic hypertension, and increased heart failure). The causes of death in the study were consistent with those expected in patients with septic shock, although there was a higher proportion of cardiovascular deaths and a lower incidence of deaths caused by MOF in the 546C88 group (140).

Interestingly, sub-group analysis of the 312 patients with vasopressor-dependent septic shock treated with the NO synthase inhibitor 546C88 showed slightly improved resolution of shock, and an acceptable overall safety profile. Indeed, administration of 546C88 was associated with resolution of shock at 72 hours in 40% and 24% of the patients in the 546C88 and placebo cohorts, respectively ( $p = 0.004$ ). There was no evidence that treatment with 546C88 had any major adverse effect on pulmonary, hepatic, or renal function. A decrease in cardiac index occurred, but stroke index was maintained. Day 28 survival was similar for both groups (141).

### Antithrombin III

Experimental data and clinical observations suggest a therapeutic role for Antithrombin III (AT III) in sepsis, as its plasma concentration is commonly decreased in patients with sepsis or septic shock, and the degree of decrease of AT III is correlated with the severity of the clinical status (142).

AT III, a serine protease inhibitor, has been demonstrated to prevent the development of DIC, decrease the incidence of organ dysfunction during sepsis, and lower the mortality rate in septic animals (143). AT III may incur this effect by inhibiting the induction of iNOS, by inhibiting production of TNF- $\alpha$  (144). This effect may be mediated by the endothelial release of prostacyclin. In another animal study, Mizutani et al. (145) observed that AT III reduced ischemia/reperfusion renal injury by inhibiting leukocyte activation, and concluded that these therapeutic effects may be mediated by prostacyclin as well. AT III limited renal cellular injury by inhibiting LPS-induced iNOS expression in an obstructive jaundice model in rats (146). When recombinant human AT III was administered to baboons, the baboons demonstrated less severe coagulopathic pathology, and a significantly attenuated inflammatory response, compared to baboons that did not receive rhAT III after challenge with *Escherichia coli* (147). However, the rhAT III was given one hour before *E. coli* challenge.

AT III dosage may be the key determinant to its efficacy. AT III inhibited LPS-induced production of inflammatory cytokines when given at high concentrations (5 or 10 U/mL), and actually enhanced production of these cytokines at lower doses in a study utilizing vascular smooth muscle as

a monoculture model (148). This effect of high dosage was demonstrated in CBA mice given different doses of AT III just prior to heart transplantation (149). A 50 U/kg dose induced a moderate increase in graft survival, whereas with a 500 U/kg dose, all grafts survived indefinitely and regulatory cells were generated. In vitro, the AT III suppressed the proliferation of mixed leukocyte responses and generation of IL-2.

The same results could not be duplicated in human studies. In the human studies, however, the dosages were much lower proportionally than those in the animals, and were started several hours after the onset of sepsis. In these patients, AT III was shown to improve laboratory values associated with DIC, but did not decrease mortality. A recent study of high-dose AT III (30,000 intravenously over 7 days in 2,314 patients with severe sepsis documented increased 90-day survival in the AT III group ( $p = 0.04$ ) (150). Presently, AT III is indicated to treat AT III hereditary disorders, DIC, and lack of heparin effect due to low AT III levels. The potential therapeutic effects of AT III in patients with SIRS have yet to be demonstrated.

### Protease Inhibitors

Because intestinal ischemia and mucosal injury are thought to be contributors to shock induced MODS, researchers hypothesized that pancreatic proteases may cause mucosal stress, or incite inflammatory mediators within ischemic intestine leading to SIRS, and that inhibition of pancreatic proteases may attenuate that response. In an animal study utilizing male Wistar rats, Fitzal et al. (151) demonstrated that intestinal ischemia and reperfusion-induced hypotension was accompanied by a significant increase in leukocyte-endothelium interactions, suggesting neutrophil cell activation. Lavage with the protease inhibitor gabexate mesilate resulted in a stable blood pressure throughout the experiment and essentially abolished cell activation, leukocyte-endothelial interactions, and cell death. The researchers concluded that pancreatic protease inhibition significantly attenuates intestinal ischemia-induced shock by reducing SIRS and gut injury. Much additional work needs to be done in this area prior to initiating human studies.

### Platelet-Activating Factor

Platelet-activating factor (PAF) is a potent phospholipid autocoid with a major role in priming, amplification, and regulation of inflammatory mediator release in septic patients. PAF is thought to amplify the inflammatory response associated with SIRS, sepsis, and MODS. This may in part be due to acetylhydrolase, a lipoprotein-associated enzyme, that hydrolyzes PAF to an inactive form. Depressed activity of this enzyme has been correlated with death due to sepsis, suggesting that prolongation of the half-life of PAF contributes to the pathophysiology of fatal sepsis (6). Early studies of the PAF receptor antagonists failed to demonstrate a therapeutic benefit. Recently the PAF antagonist, TCV-309 was studied in a double-blind, randomized, placebo controlled multicenter trial to determine if this antagonist could reduce morbidity and mortality associated with septic shock (152). Though the overall survival was similar in treated versus placebo groups, the mean percentage of failed organs per patient and mean APACHE II scores were significantly lower in the treatment group. The number of patients who recovered from shock after 14 days was significantly higher in the TCV-309 treated group. The number of adverse events was not different between the groups. These findings led the investigators to

conclude that TCV-309 can substantially reduce the organ dysfunction and morbidity associated with septic shock, without an increase in adverse events.

Opal et al. (153) recently reported the results of their phase III clinical trial of a recombinant human platelet-activating factor acetylhydrolase, in sepsis. No significant difference in 28-day mortality was identified. Of note, however, is that the anti-PAF agent used by Opal was not studied in a population with a mortality risk as high as in the APC trial. This is the seventh clinical sepsis trial studying the inhibition of the PAF inflammatory pathway. Analysis of the combined treatment effect from these seven trials of anti-PAF agents reveals a small, but nonsignificant improvement in survival rate (odds ratio of survival 1.10; 95% confidence interval, 0.93–1.30,  $p = 0.28$ ) (154). These data stress the importance of the need for adequately powered clinical trials in high-risk patient populations to definitively determine efficacy.

### Leukodepletion

As described previously, the interaction between PMNs and vascular endothelial cells is considered the stimulus for the development of SIRS and MODS. This concept is supported by the increased elaboration of PMN cell surface receptors and adhesion to endothelium in patients with SIRS. Leukodepletion filters have been evaluated as a means of removing activated PMNs from the blood of patients with SIRS. In a laboratory-designed extracorporeal circuit, passage of SIRS blood through leukodepletion filters resulted in a marked depletion of PMNs (155). Of the cells that remained in the blood, far fewer cells were adherent to cultured endothelial cells, compared with PMNs prior to leukofiltration (LF). LF was evaluated in a clinical study by Treacher et al. (156), who examined patients who developed SIRS after CPB. Patients randomized to receive LF underwent LF for 60 minutes every 12 hours while SIRS criteria were met. LF patients demonstrated improvement in respiratory and renal function, while demonstrating no improvement in mortality rate or ICU length of stay compared with controls.

### Hypertonic Preconditioning

As a potential therapeutic agent, hypertonic preconditioning was hypothesized to impair subsequent inflammatory mediator signaling through a reduction in stress fiber polymerization and mitogen-activated protein kinase activity after LPS stimulation, in a study utilizing rabbit alveolar macrophages (157). Rabbit alveolar cells were stimulated with LPS. Selected cells were preconditioned with NaCl, mannitol, or urea and then returned to isotonic medium prior to LPS stimulation. Preconditioning of macrophages with NaCl or mannitol resulted in a dose dependent decrease in extracellular signal-related kinase, a dose-dependent attenuation of TNF- $\alpha$  production, and a failure of LPS-induced stress fiber polymerization. Urea (intracellular hypertonic condition) had no significant effect. These investigators concluded that HS or mannitol resuscitation might protect against MODS due to reduced pro-inflammatory responsiveness.

### Anti-lipopolysaccharide Compounds

Different classes of compounds that bind directly to LPS, thereby neutralizing its effects, have been examined (158). These consist primarily of antiLPS monoclonal antibodies, naturally occurring proteins and their derivatives, including Limulus antiLPS factor (LALF), and antibiotics including

polymyxin B and taurolidine. The LPS monoclonal antibodies failed to demonstrate clinical efficacy, but investigation of these compounds led to a better understanding of the biochemical interactions associated with LPS-induced inflammation and endotoxin antagonism.

### Pituitary Adenylate Cyclase-Activating Polypeptide and Vasoactive Intestinal Peptide

Pituitary adenylate cyclase-activating polypeptide (PACAP) is a neuropeptide in the vasoactive intestinal peptide (VIP)/secretin/glucagon family of peptides. Recent research has demonstrated that this molecule is a potent anti-inflammatory mediator, functioning by regulating the production of both pro- and anti-inflammatory mediators. Delgado et al. (159) demonstrated that PACAP prevented the deleterious effects of arthritis by downregulating both the inflammatory and autoimmune components of the disease. These authors suggest that PACAP may be used as treatment for acute and chronic inflammatory and autoimmune diseases, including septic shock.

VIP and PACAP have been shown to have inhibitory effects on the production of pro-inflammatory mediators associated with microglia (160). Microglia have a central role in the regulation of immune processes, inflammation, and tissue remodeling in the CNS. Pathological activation of microglia is thought to contribute to progressive damage in neurodegenerative diseases, via the release of pro-inflammatory and cytotoxic factors. VIP and PACAP may, therefore, have therapeutic potential in the treatment of inflammatory or degenerative brain disorders.

## IMMUNONUTRITION IN TRAUMA AND CRITICAL ILLNESS

Immunological dysregulation due to trauma and critical illness may complicate a patient's clinical course and result in sepsis and MOF. Immunomodulatory interventions aim to ameliorate the pro-inflammatory component of systemic inflammation. ⚡ **Immunonutrition is a modulatory intervention intensively investigated over the past two decades (also see Volume 2, Chapters 31–33).** ⚡ It is theorized that changes in the GALT may contribute to gut-derived sepsis, and enteral feeding supplemented with key nutrients may prevent that change. Bastian et al. (161) utilized a prospective, randomized, double-blind, controlled study to demonstrate that immunonutrition to include arginine, n-3 fatty acids, and nucleotides significantly reduced the number of SIRS days per patient and lowered MOF scores. Other studies have demonstrated reduction in septic complications, decreased antibiotic usage, decreases in hospital length of stay, and reduction in hospital costs when patients were randomized to receive immuno-enhancing diets (IED). The mechanism for the gut-protective effect of IED may be augmentation of blood flow to the GALT in the terminal ileum (162). This protection is in contrast to TPN, which has been associated with increased release of pro-inflammatory cytokines when compared to an enteral diet (163).

The amino acid L-glycine has demonstrated anti-inflammatory, immunomodulatory, and cytoprotective effects in recent immunonutrition research (164). Glycine protects against shock due to hemorrhage, endotoxin, and sepsis, and prevents multi-organ ischemia/reperfusion injury. It suppresses inflammatory cytokine release from inflammatory cells to include macrophages. In the plasma

membrane, it activates a chloride channel that stabilizes membrane potential. This suppresses the agonist-induced opening of calcium channels, thus preventing cellular calcium influx (believed to be an important component of the onset of inflammation).

Glutathione (GSH), an endogenous antioxidant believed to be an important defense against oxygen metabolites, was measured along with TNF- $\alpha$  and IL-6 in 28 trauma patients and 14 normal controls who were treated with recombinant human growth factor (rhGH) (165). All patients received total parenteral nutrition (TPN) starting after 48 hours. Plasma levels of GSH were not altered in the early catabolic phase, but TNF- $\alpha$  and IL-6 were elevated compared to controls. After seven days, GSH levels were enhanced with TPN alone, but these levels were two times higher in patients who also received rhGH. These patients also had higher levels of TNF- $\alpha$ , but no change in IL-6. These authors concluded that modification of plasma GSH and TNF- $\alpha$ , by adequate nutritional support with adjuvant rhGH, has a beneficial role in enhancing antioxidant defenses.

Zinc is essential for the proper functioning of all cells in the human immune system. These cells demonstrate decreased function in states of zinc depletion. Zinc depletion impairs all monocyte functions, decreases cytotoxicity in NK cells, reduces phagocytosis in neutrophils, and impairs T cell function (166). Autoreactivity and alloreactivity of T cells is increased, and B cells undergo apoptosis. These impaired immune functions can be reversed by adequate supplementation. However, overtreatment can induce negative effects on immune cells similar to those seen in zinc deficiency.

Animal studies have demonstrated the benefit of zinc therapy in inflammation. Zinc depletion sensitized mice to the deleterious effects of TNF- $\alpha$ , whereas pretreatment with zinc conferred protection against these deleterious effects in a study evaluating the role of metallothionein as a mediator in TNF-induced SIRS (167). Furthermore, co-treatment with zinc led to complete regression of inoculated tumors with TNF- $\alpha$  and INF $\gamma$ , leading to significantly increased survival.

Selenium is an essential micronutrient associated with improvement in T cell function and reduced apoptosis in animal studies (166). It may enhance resistance to infections through modulation of IL-1, and the Th1/Th2 response. It upregulates IL-2 and increases the activation, proliferation, differentiation, and programmed cell death of T helper cells. Baum et al. (168) report that selenium supplementation may down-regulate the abnormally high levels of IL-8 and TNF- $\alpha$  in human immunodeficiency virus type 1 disease that has been associated with disease progression and increased viral replication.

Selenium has been shown to modulate cytokine-induced expression of the adhesion molecules ICAM-1, VCAM-1, and E-selectin, thus hindering the endothelial pro-inflammatory state (169). Selenium at physiological levels mediates the inhibition of the activation of NF- $\kappa$ B (the transcription factor that regulates the genes that encode for inflammatory cytokines), and the reduction of selenium induces the synthesis of CRP by hepatocytes during the acute phase response (170).

Selenium was investigated as an adjunct to treatment in children suffering from inflammatory surgical diseases and extended scalded skin, in an age and diagnosis-matched cohort study (169). All of the patients in the study had SIRS. Inflammatory mediators and acute phase reactants

were measured on the first, second, third, sixth, and last treatment day. Levels of IL-6 and the acute phase reactants CRP and fibrinogen were similar in both groups. Plasma glutathione peroxidase activity increased significantly (representing cell membrane protection) in patients who received selenium, in comparison to those who did not. Malondialdehyde was initially elevated in all patients (representing raised lipid peroxidation), and then decreased to normal levels in the selenium treated group, thus supporting selenium as supportive therapy in children with SIRS.

## EYE TO THE FUTURE

The concept of SIRS has been evolving for decades. The operational definition has recently come under great scrutiny (172–175). Bossink et al. (174) documented that SIRS is present in 95% of patients with fever, despite the fact that only 44% of patients had sepsis with a microbiologically confirmed infection. Earlier sections in this chapter described some of the recent research which has begun to elucidate the pathophysiology of SIRS. In this section, we would like to focus the interested reader on a few additional topics, which will play an increasing role in management of patients with SIRS in the near future, and also describe some promising areas of investigation, which may allow manipulation of SIRS in future patients. We will review the new PIRO staging system proposed for SIRS, the role of accurate ICD-9 coding, important advances in the pathophysiology of SIRS, and an area of potential treatment not discussed above, based upon vitamin supplementation.

### New Predisposition, Infection, Response, and Organ Dysfunction Staging System for Systemic Inflammatory Response Syndrome and Sepsis

In 2001, an International Sepsis Definitions Conference was convened to review the strengths and weaknesses of the current definitions of sepsis and related conditions, identify ways to improve the current definitions, and identify methodologies for increasing the accuracy, reliability, and/or clinical utility of the diagnosis of sepsis (4). The primary consensus points of this conference are reviewed in Volume 2, Chapter 47. A new system, PIRO (Volume 2, Chapter 47, Table 3), has recently been proposed for characterizing and staging the host response to infection.

This newly developed conceptual framework for understanding sepsis, called the PIRO concept, is a classification scheme that could stratify patients on the basis of their predisposing conditions, the nature and extent of the insult (in the case of sepsis, infection), the nature and magnitude of the host response, and the degree of concomitant organ dysfunction (Volume 2, Chapter 47, Table 3). The PIRO system has been conceptually modeled from the TNM classification (tumor size, nodal spread, metastases) that has been successfully used in defining treatment and prognostic indicators in clinical oncology. PIRO was introduced as a hypothesis-generating model for future research and extensive testing will be necessary before it can be considered ready for routine application in clinical practice. It should be noted, however, that SIRS remains a prominent feature in the new PIRO paradigm as one of the earliest “Response” markers of sepsis. Furthermore, SIRS continues to be utilized as an excellent screening tool to enroll patients in clinical studies on SIRS and sepsis.

### New ICD-9 Codes for Systemic Inflammatory Response Syndrome and Sepsis

In October 2002, the Centers for Medicare and Medicaid Services established new ICD-9 codes for SIRS and sepsis (Table 5). Prior to this, there were no ICD-9 codes for SIRS, and the only code for sepsis was “septicemia.” As medical practitioners caring for critically ill trauma patients with SIRS and sepsis, it is important to utilize these codes. By so doing, additional information will be captured regarding the accurate incidence and outcome of patients with SIRS, sepsis, and severe sepsis that have sustained traumatic injury. Although these ICD-9 codes do not themselves shed light on the pathophysiology of SIRS, their correct application is mandatory for accurate epidemiological data and outcome studies in humans.

### Advances in Pathophysiology of Systemic Inflammatory Response Syndrome

Additional advances continue to be made in understanding the pathophysiology of SIRS (176). The resemblance between SIRS and sepsis has long been recognized. In the case of sepsis, exogenous macromolecules such as LPS acting on TLRs trigger the SIRS response. What triggers SIRS in the absence of infection, however, has not been fully elucidated. A recent study reported that a SIRS-like response could be induced in mice by the administration of a soluble heparan sulfate and by elastase, both of which were dependent on functional TLR 4, because mutant mice lacking that receptor or its function do not develop SIRS (177). These important results provide an additional molecular explanation for the initiation of noninfectious SIRS.

Resolution of inflammation and infection involves removal of neutrophils and other inflammatory cells by the induction of apoptosis. Fas/Apo-1 is a widely occurring apoptotic signal receptor molecule expressed by almost any type of cell, which is also released in a soluble circulating form. A recent study investigated the role of circulating Fas/Apo-1 in patients with systemic SIRS. They evaluated 57 critically ill patients, 34 with infectious SIRS (sepsis and septic shock), and 23 patients with noninfectious SIRS (178). Levels of Fas/Apo-1 were significantly elevated in patients with infectious and noninfectious SIRS (10.4 +/- 8.1 pg/mL, controls: 5.0 +/- 0.7 pg/mL;  $p < 0.0001$ ). In this small study, Fas/Apo-1 levels were not predictive of poor outcome of patients with SIRS. Importantly, these results show that increased levels of Fas/Apo-1 from patients with SIRS is a mechanism that contributes to

**Table 5** New ICD-9 Codes for Systemic Inflammatory Response Syndrome and Sepsis

ICD-9 code	Diagnosis
995.90	SIRS, unspecified
995.91	SIRS due to infectious process without organ dysfunction
995.92	SIRS due to infectious process with organ dysfunction (severe sepsis)
995.93	SIRS due to noninfectious process without organ dysfunction
995.94	SIRS due to noninfectious process with organ dysfunction

Abbreviation: SIRS, systemic inflammatory response syndrome.

inflammatory response, through accumulation of neutrophils at sites of inflammation/infection.

Interestingly, two recent studies in septic rodents demonstrated significant survival benefit by inhibiting apoptosis (179,180). The first utilized the antiretroviral protease inhibitor nelfinavir<sup>®</sup> (Agouron Pharmaceuticals, La Jolla, California, U.S.A.), in a mouse cecal perforation and ligation sepsis model (179). Mice pretreated with nelfinavir<sup>®</sup> demonstrated improved survival (67%;  $p < 0.0005$ ) compared with controls (17%), and a significant ( $p < 0.05$ ) reduction in lymphocyte apoptosis.

The second study demonstrated that Akt (a serine/threonine kinase, and a key regulator of cell proliferation and death) overexpression in lymphocytes prevents sepsis-induced apoptosis, causes a Th1 cytokine propensity, and improves survival (180). Findings from this study strengthen the concept that a major defect in sepsis is impairment of the adaptive immune system, and further bolsters the concept that strategies to prevent lymphocyte apoptosis represents an important new strategy of sepsis therapy. Furthermore, it may turn out that in late SIRS (from sepsis or other sources), triggering apoptosis to occur may be actually beneficial. Much additional animal work needs to be done before apoptotic control is studied in humans with SIRS.

### Antioxidant Strategies: Vitamin Supplementation

We currently have few efficacious strategies to prevent the progression from SIRS to MODS. Early enteral nutrition and the use of immunonutrition have been discussed as an early preventive strategy in trauma. Two recent studies examined the use of antioxidant vitamin E and C supplementation as an additional preventive strategy to consider.

A recent prospective, randomized study compared outcomes in patients receiving early antioxidant supplementation versus those receiving standard care, with a cohort of 595 patients, 91% of whom were trauma victims (181). The treatment regimen included  $\alpha$ -tocopherol (Aquasol-E 1000 IU q8 h via NGT) and ascorbate (1000 mg IV in 100 ml D5W q8 h) for the shorter duration of ICU stay or 28 days. Patients randomized to antioxidant supplementation had significantly decreased risk for pulmonary morbidity, including ARDS and pneumonia (RR 0.81, CI 0.60–1.1), and MOF (RR 0.43, CI 0.19–0.96). Patients randomized to antioxidant supplementation also had a shorter duration of mechanical ventilation and length of ICU stay. This important study documented that the early administration of antioxidant supplementation reduced the incidence of organ failure and shortened ICU length of stay in a cohort of critically ill surgical patients. Significant limitations of this study included lack of a placebo and lack of investigator blinding.

Oxidant stress has been implicated in SIRS both as a mechanism for direct cellular injury, as well as activation of intracellular signaling cascades within inflammatory cells, resulting in progression of the inflammatory response. Vitamin E is an inexpensive, nontoxic, chain-breaking antioxidant that has therapeutic potential in regulating this process. A recent review evaluated the current literature regarding the use of Vitamin E in controlling the excessive inflammation seen in SIRS and argued for further study of its therapeutic potential for critically ill and injured patients (182). Additional studies in this important area of investigation are clearly warranted.

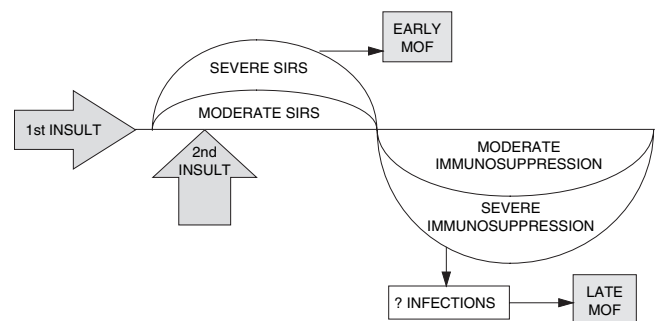

### Genetic Influences

Genetic epidemiologic studies suggest a strong genetic influence on the outcome from sepsis, and genetics may explain the wide variation in the individual response to infection that has long puzzled clinicians (176). Several candidate genes have been identified as important in the inflammatory response and investigated in case-controlled studies, including the TNF- $\alpha$  and TNF- $\beta$  genes, positioned next to each other within the cluster of human leukocyte antigen class III genes on chromosome 6. Other candidate genes for sepsis and septic shock include the IL-1 receptor antagonist gene, the heat shock protein gene, the IL-6 gene, the IL-10 gene, the CD-14 gene, the TLR-4 gene, and the TLR-2 gene, to name a few. A number of recent comprehensive reviews have summarized the evidence for a genetic susceptibility to development of sepsis and death from sepsis (183–185). These reviews discuss candidate genes likely to be involved in the pathogenesis of sepsis, and review the potential for gene targeted therapy and prophylaxis against sepsis and septic shock (183–185). Few studies have examined genetic polymorphisms and genetic susceptibility for SIRS, and additional research in this area is also warranted (186).

### SUMMARY

The systemic response to trauma, surgery, and critical illness is extremely complex and is a major factor affecting morbidity and mortality in trauma. The pathogenesis of SIRS and sepsis is becoming increasingly understood. When tissue injury is severe, a maladaptive dysregulation of the immune response occurs, which may lead to SIRS, and later to CARS and MODS.

Early in the course of severe injury, patients demonstrate an increase in inflammatory mediators, which may lead to complications (e.g., SIRS or ARDS). However, later in the course of severe illness following trauma, the immune system may become impaired (i.e., CARS), leading to other complications such as infections from organisms not normally encountered by immuno-competent individuals (Fig. 6). Research focusing upon manipulating the

**Figure 6** Progression from systemic inflammatory response syndrome (SIRS) to multiple organ dysfunction syndrome (MODS). Following major trauma, patients develop an early physiologic state of hyperinflammation (i.e., SIRS) due to a dysfunctional inflammatory response. This can lead to early multiple organ dysfunction or failure (MODS, MOF). Subsequently, the compensatory anti-inflammatory response is associated with significant immunosuppression and risk for infectious complications that is the most common cause of late MODS and MOF. Source: From Ref. 189.

immune system is ongoing. Decreasing the initial exuberant inflammatory state (SIRS), and/or increasing immunocompetence during the (later) immuno-impaired state (CARS) may result in significant improvement in morbidity and mortality.

Researchers and clinicians have made great strides in determining many of the key facets of the immunological system related to SIRS over the past few decades. Perhaps the most astounding finding is that systems previously believed to be entirely separate are now known to be intricately related (e.g., inflammation and coagulation). Furthermore, SIRS is not merely the result of a single dysfunctional cytokine, autocrine, paracrine, or endocrine response. Rather, it is now recognized as a complex phenomenon, involving all of the above mediators and perhaps many others (some still unrecognized).

Although numerous prior attempts to foil specific steps in the inflammatory response failed to improve patient outcomes, the PROWESS study has recently shown that mortality can be affected by inhibition of coagulation with APC therapy in severe sepsis. The benefit in SIRS patients without a septic etiology has not yet been studied. Additionally, the benefit of APC treatment in patients with various coagulation disorders is unclear. Answers to these questions, and review of numerous other novel treatments, are now being contemplated. Some of the newer potential remedies have been reviewed earlier in the Eye to the Future section (e.g., apoptosis manipulation, antioxidant administration, and genetic manipulations). As the frontiers of research push our knowledge forward, SIRS, sepsis, and organ failure are becoming increasingly understood.

## KEY POINTS

- ✂ SIRS has been classified as an early component of the sepsis syndrome. SIRS and sepsis commonly present as a continuum of disease states, with progression of SIRS to sepsis, severe sepsis and septic shock.
- ✂ The outcome of inflammation may be beneficial (inactivation of injurious substances, initiation of repair) or deleterious (injury to tissue, interference with normal functions) to the host.
- ✂ Most soluble mediators of inflammation are present in minute concentrations under normal conditions. Elaboration of these mediators may dramatically increase when the body is exposed to infecting organisms, trauma, surgery, and/or critical illness.
- ✂ The selectin-phase is the first component of endothelial activation, promoting neutrophil migration. In this phase, passing neutrophils or other leukocytes attach to P-selectin and E-Selectin molecules on the activated endothelium.
- ✂ Pro-inflammatory cytokines are responsible for initiation and augmentation of inflammation and its sequelae, whereas anti-inflammatory cytokines are associated with moderation of the inflammatory response.
- ✂ It appears that patients without apparent infection who have increased CRP values preoperatively are at increased risk for infectious complications postoperatively.
- ✂ Neurological and endocrine functions interact intimately with inflammatory mediators after injury or onset of illness.

- ✂ The hormone 17-beta estradiol has been associated with female gender-specific protective effects from SIRS, following trauma and hemorrhage in animal studies.
- ✂ In contrast to the female sex hormone estradiol, increased levels of the male sex hormone testosterone are associated with decreased cell mediated immune response following trauma in animal studies. Testosterone also decreases muscle catabolism following burns.
- ✂ Trauma, especially when complicated by hemorrhagic shock, may induce SIRS, potentially resulting in immunodepression, MODS, severe sepsis, or septic shock.
- ✂ Surgical procedures are known to elicit systemic inflammation. The magnitude and duration of the procedure, comorbid diseases, and reperfusion injury are just a few of the variables that affect the inflammatory response.
- ✂ With the exception of anaphylaxis and allergy (see Volume 1, Chapter 33), anesthetics and analgesics by themselves are not initiators of SIRS. However, several anesthetics and analgesics have shown immunomodulatory effects, and may therefore have some effects on SIRS.
- ✂ Direct contact between patient blood and the synthetic surfaces of the CPB system, along with released intracellular elements of destroyed cells, are the most likely reasons for the increased inflammatory mediators seen with CPB.
- ✂ Resuscitation for trauma and surgery may affect an individual's innate immune response, as a result of the type, quantity, and timing of fluid resuscitation.
- ✂ A breakdown in any component of this GI defense system may contribute to gut-derived bacteremia and sepsis, after injury or illness.
- ✂ Key mediators in the immune pathways continue to be studied extensively in an effort to control or modulate the pro-inflammatory/anti-inflammatory response.
- ✂ Immunonutrition is a modulatory intervention intensively investigated over the past two decades (also see Volume 2, Chapters 31–33).

## Providing Family-Centered Care

Catherine McCoy-Hill

School of Nursing, Azusa Pacific University, Azusa, California, U.S.A.

William C. Wilson

Department of Anesthesiology and Critical Care, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

A family-centered approach to critical care is characterized by collaboration between the patient, family (or loved ones), and the health care providers. The important elements of family-centered care include: (i) respect for patient's values, beliefs, including their cultural and spiritual backgrounds; (ii) frequent communication and information sharing; and (iii) physician encouraged collaboration in the decision-making process (Table 1) (1). Caring for the needs of families is an important component of comprehensive trauma care and likely facilitates improved outcomes (1–3).

The American College of Surgeons Committee on Trauma (ACS-COT) has identified the provision of family services as an important measure for trauma programs process improvement (4). Providing family-centered care in trauma settings requires multidisciplinary support, including education of providers, and is facilitated when a dedicated case manager can oversee the process. Institutional guidelines that address family support, information sharing, and utilization of supportive resources can be developed and implemented from evidence-based models (1).

### IMPACT OF TRAUMA AND CRITICAL ILLNESS ON FAMILY MEMBERS

☞ **Because the nature of trauma is sudden and unexpected and includes the potential for loss of life or significant disability, family systems are often stressed to their emotional limits.** ☞ Typical responses evoked by observing one's family member in a life-threatening situation include: shock, disbelief, helplessness, fear, and anxiety, as loved ones seek understanding of what has happened. Fears about death often predominate. Anxiety centers on concerns about the seriousness of the patient's condition as well as the quality of medical care being received.

Additional burdens impacting family members include financial hardships, loss of work, and concerns about the future. Often the family's entire lifestyle is disrupted, with resultant changes in roles, relationships, and usual routines. Lifelong goals and dreams may be shattered (5–7).

The circumstances surrounding the trauma as well as the nature and severity of the injury impact the family's ability to cope with the crisis. The nature of the trauma [e.g., unanticipated, violent, or stigmatizing (suicide attempts)] can provoke high degrees of stress on families.

Tragic insults such as spinal cord injury (SCI) and traumatic brain injury (TBI) are emotionally overwhelming, as they represent lifelong debility to the patient. Severe disfigurements from major burns, craniofacial injuries, amputations, etc., are similarly devastating and result in high levels of emotional distress to patients and their loved ones (7–9).

Acute grief responses can occur as members of the family are confronted with actual or potential loss of the patient's physical status, level of function, and future capabilities. Individual family member characteristics also influence their response to the crisis. These include: age and developmental stage, relationships and family demands, past experiences with illness or trauma, social support networks, cultural and spiritual values, as well as pre-existing states of mental health and coping abilities (7,9,10). Specific family members will also react differently based upon their relationship with the patient and their own emotional condition. When extreme emotional stresses are perceived by a family member, initial anxiety and grief can develop into an Acute Stress Disorder (ASD), or, if prolonged, to Post Traumatic Stress Disorder (PTSD), as described briefly later, and extensively in Volume 2, Chapter 65 (7–9).

### FAMILY NEEDS FOLLOWING TRAUMA AND CRITICAL CARE

☞ **Evidence indicates that families exhibit a universally predictable set of needs when a loved one becomes critically ill (7–10).** ☞ Common family needs following injury or critical illness of a loved one include: (i) information, (ii) proximity (i.e., to "be with" the patient), (iii) emotional support (including reassurance that the patient is receiving optimal care), (iv) cultural sensitivity, and (v) spiritual support (Table 1) (10–16).

#### Communication and Information Sharing

The desire to obtain timely and accurate information about the patient's condition is the concern of family members most widely recognized. Informational needs are particularly important to families of trauma patients, as the unexpected injury evokes high levels of emotional distress (8,9). Sparse communication from physicians and the unfamiliar environment of the surgical intensive care unit (SICU) can intensify feelings of anxiety, uncertainty, worry, and fear.

☞ **Well-informed families report a greater sense of control, are more often able to accept the tragedy affecting their loved one, and participate more effectively in patient**

**Table 1** Universal Family Needs During the Management of Trauma and Critical Care

Family needs	Elements of care emphasized, comments, and examples
Communication and information sharing	Information should be honest and sensitively communicated; Brief daily meetings should be scheduled for information exchange; The family should always be notified promptly following a change in the patient's condition; Regular (e.g., weekly) multidisciplinary family conferences are encouraged, especially regarding major changes in patient status or treatment direction; The family should be provided access to clinicians (phone number, pager etc.); Informational booklets should be utilized (e.g., SCCM brochure: <i>When your loved one is in the ICU</i> ).
Proximity (need to be with the patient)	Liberalized, flexible visiting hours should be maintained; The family should be prepared for what to expect in terms of patient's condition and the ICU environment; Family members should be informed regarding what they can do for the patient at the bedside.
Emotional support	Reassure family optimal care is occurring; Provide anticipatory guidance re: treatment plan and expected outcomes; Assist in mobilizing family resources; Refer to social worker, clergy, mental health clinicians, etc. when indicated; Identify family members at risk for psychologic sequelae (i.e., depression, PTSD).
Cultural sensitivity	Accept and respect cultural differences; Adapt care to be congruent with cultural preferences when appropriate; Utilize translators when language barriers exist.
Spiritual support	Assessment of spiritual needs should be ongoing; Spiritual rituals should be allowed to occur whenever possible; Referrals should be made for spiritual support services whenever needs are identified (e.g., grave news, ethical dilemmas, at or near the end of life).

Abbreviations: SCCM, Society of Critical Care Medicine; PTSD, posttraumatic stress disorder.

**care decision making (2,5,8).** Understanding the patient's diagnosis, treatment plan, and likely outcome constitute essential information elements for families to develop realistic expectations regarding the patient's condition and prospects for recovery. Clinicians have an obligation not only to provide honest and timely information, but also to convey it in a sensitive and thoughtful manner. When patients are not capable of making their own decisions (e.g., coma, severe TBI), family members must be prepared to act as surrogate decision makers, regarding invasive procedures, life support, and end-of-life care (refer to Volume 2, Chapters 68 and 69).

Several studies have addressed how health care providers can best meet the informational needs of families (2,5). Findings indicate that most family members want and expect direct, specific information about the patient's condition and overall management goals to be delivered by the attending physician at least once a day. From nurses, families expect to be informed about the daily care of the patient, reasons for particular treatments, and general information regarding the critical care environment (staff roles, procedures, equipment, policies, etc.). Family members also place great importance on being promptly informed of any significant changes in the patient's condition (5-7). Many of the studies investigating family needs have used the Critical Care Family Needs Inventory (Table 2), originally developed by Molter in 1979 (12). This tool has been validated across multiple critical care and trauma settings (5,11-14).

Useful strategies to maintain communication include scheduling a specific time for daily updates, holding multidisciplinary family conferences (especially with changes in treatment direction), and providing family members with written information that outlines the communication process and lists the responsible physician and means of access (i.e., names, phone/pager numbers, etc.).

A number of hospitals have made loaner pager systems available to family members of unstable critical patients so that they can feel more comfortable in leaving the ICU, knowing they will be easily reached if the need arises. The Society of Critical Care Medicine (SCCM) and The American Association of Critical Care Nurses (AACN) have published brochures that provide useful information for families of critically ill patients, advising them of their rights and responsibilities along with a list of questions they should consider asking the doctors and nurses (15,16).

More recently, critical care family/visitor centers have been developed. These spaces often equipped with web-enabled computers providing access to informations (e.g., medical conditions, treatments, tests, drugs, etc.) (17). This concept has been implemented in a number of ICUs and is

**Table 2** The Critical Care Family Needs Inventory<sup>a</sup>

Do you feel that the best possible care is being given to the patient?
Do you feel that the hospital personnel are courteous and care about the patient?
Have explanations about the patient's condition been in terms you can understand?
Do you feel that you have been given honest information about the patient's condition?
Do you believe that someone will notify you following a significant change in the patient's condition?
Have the staff members shown interest in how you are coping?
Have the hospital personnel explained the equipment being used?
Do you feel comfortable visiting with the patient in the intensive care unit?
Is the waiting room welcoming and comfortable?

<sup>a</sup>The listed questions are asked of the family members by the staff. Source: Adapted from Refs. 12, 13.

expanding as individuals want access to knowledge sources and desire to be well informed. The reader is referred to Ref. 17 for an excellent resource sponsored by the SCCM, detailing implementation of a consumer medical information system in ICU settings (17). Ideally, the environment of waiting rooms should also be welcoming and comforting (furnishings, noise, lighting, refreshments, etc.) to visitors.

Communication is an ongoing process among the critical care team, the patient, and the patient's family members. Open exchange of information and regular access to the physician are vital to this process. **Although the physician's time is limited due to the complex demands of the trauma and critical care environment, consistent communication with the family and open access to informational resources are essential in meeting family needs.**

When communicating with families, information should be presented at a level the family members can easily understand. The family's emotional status must also be considered, since denial or severe anxiety limits the amount of information that can be assimilated. **During serious discussions, family members may be intimidated or ashamed to admit that they do not fully understand what has been said. To avoid confusion, medical information should be clearly explained, and repeated as necessary. Technical language and euphemisms should be avoided, whereas clarifying questions should be encouraged.** Initial attention should be focused on listening to and addressing the most pressing concerns of the family. These discussions ideally occur in a comfortable, private place protected from the noise and chaos of the Trauma Resuscitation Suite (TRS), emergency department (ED), or SICU. Conflicts may arise when information given to families is inadequate, inconsistent, or is not clearly understood. Examples of inadequate communication include using phrases such as the patient is "stable" without further explanation of clinical status, or stating that certain physical findings have improved when, in fact, the patient's overall condition may be worsening. Inconsistencies occur when physicians from different specialties give contradictory information, or when there is a lack of consensus in the clinical management plan.

### Proximity: Open Visitation Policy

The need for proximity (to be with the patient) reflects the desire of the family to be physically near the patient to maintain family relationships and provide emotional support to their loved one (10). Not long ago, critical care units maintained rigid visiting hours that limited family access to the patient and restricted visits by children or those beyond the immediate family. In most critical care units these traditions have given way to more liberalized visitation policies. **A flexible visitation policy has psychological benefits for both the patient and the family members, with a resultant positive influence on their overall satisfaction with care.**

For family members, being physically present enables them to provide support to the patient and maintain family connections. Being at the bedside also provides assurance that their loved one is receiving the best possible care. Visitation policies should consider patient preferences, remain flexible to accommodate family needs, and convey the message that families are valued. Family presence is especially important in the acute phase, and whenever the family perceives the patient as being critically ill.

Prior to visiting, and especially at the initial visit, family members should be given explanations of the patient's medical status, appearance, and behavior, as well as a description of the bedside environment. Whenever possible, a nurse should remain with the family members to assess their level of distress and to provide information and emotional support. Families often require guidance regarding what they can do at the bedside, and should be encouraged to communicate with the patient even when the patient cannot respond.

### Emotional Support

Family requirements for emotional support typically center on the tragedy of the trauma, and the universal wish to be assured that their loved one is receiving the best possible care. Family members also commonly perceive strong needs to maintain personal coping strength in order to "be there" for their ill-loved one. **Although family members give priority to the welfare of their relative, their own emotional needs become increasingly significant over time, while the quest for hope remains universal (11–14).**

Other support needs emerge as family members of severely traumatized patients begin to redefine their hopes about the future, and as they begin to recognize the emotional toll that the injury experience has imposed upon them. The burden of having a traumatized family member impacts multiple domains within the family structure, including practical day-to-day concerns, financial worries, and material comfort needs. High levels of anxiety, depression, anticipatory grief, ASD, and later PTSD are frequently reported in patients with life threatening injuries (Volume 2, Chapter 65), and in their family members as well (7–9,18).

Interventions to assist family members include strengthening family-coping abilities and mobilizing resources to provide needed emotional support. Because of their 24-hour presence and close relationship with the patient, the bedside SICU nurse plays a critical role in the emotional well-being of family members by providing information, support, and encouragement. Often family members need someone to listen to them, acknowledge their feelings, and be sensitive to their concerns. Recognition by clinicians that this is an overwhelming and stressful time helps to "normalize" feelings of fear, anger, or helplessness.

Anticipatory guidance regarding the treatment plan and expected outcomes also helps relatives to better understand the nature and severity of the illness, and serves to foster more realistic expectations for recovery. When recovery is unlikely, families require the most intensive support and guidance during the difficult transition from curative to palliative care (3). Family members who are highly distressed or struggling to grasp the gravity of irrecoverable medical conditions benefit most from clear, direct explanations by the attending physician. **Occasionally, reviewing diagnostic images (e.g., brain computerized tomography scans, etc.) with family members helps to convey situations that are difficult to grasp by words alone.**

Those family members who are highly distressed or unable to cope may need the support of social workers, mental health clinicians, or visitation by their spiritual leaders. Utilizing the expertise and resources of interdisciplinary specialized support services early in the process can help identify "at-risk family members," and allow for earlier implementation of supportive interventions.

In many centers, the trauma nurse coordinator or case manager acts as a liaison between the patient/family and the trauma team to monitor patient progress, coordinate implementation of care needs, and facilitate access to needed services throughout the continuum from admission, through discharge and follow-up.

### Cultural Sensitivity

Changing demographics and the increasingly diverse cultural profiles of major city populations' worldwide (>300 languages are spoken in the US alone) mandates the provision of culturally sensitive and competent care by health providers. Culture refers to integrated patterns of behavior that include the language, beliefs, values, and customs of racial, ethnic, or social groups. **Cultural factors are recognized to have a strong influence on health practices, and to affect patient/family satisfaction with medical care, trust of healthcare providers, and adherence to treatment regimens (19,20).**

In 2001, the Department of Health and Human Services published national standards for culturally and linguistically appropriate services (CLAS) in health care. These standards address the need for patients to receive effective, understandable, and respectful care compatible with their cultural health beliefs, practices, and preferred language. Cultural and linguistic competence refers to the ability of health care providers and their organizations to understand and respond effectively to these patient and family needs (21).

When language barriers are encountered, bilingual translators/interpreters should be utilized to obtain important clinical information and ensure accurate two-way communication. Family members or children should not be used as translators (unless requested by the patient), to avoid problems with confidentiality and impartiality.

In situations where patients or families have unique needs, it is appropriate to involve a social worker or patient advocate/ombudsperson with special expertise regarding unusual concerns. When important to the family, the patient's cultural traditions (e.g., healing rituals, ethnic customs, etc.) can often be integrated into the medical plan of care. Clinicians should also be sensitive to individual family dynamics (e.g., divorce, estrangement), as well as differences in educational and socioeconomic backgrounds amongst members within the family group. When families and their doctors have trouble agreeing, an ethics consult is often helpful in resolving conflict (Volume 2, Chapter 67).

Although difficult on a busy trauma service or critical care unit, knowledge and awareness of cultural factors not only improves diagnostic accuracy and decreases errors, but also improves therapeutic relationships by demonstrating understanding and acceptance of the unique concerns of patients and their families.

### Spiritual Support

Assessment, recognition, and support of the spiritual concerns of patients and their families are important aspects of modern critical care. Indeed, assessing and acknowledging the patient's spirituality can provide vital information and guidance throughout their critical illness, from initial resuscitation management (e.g., Jehovah's Witness), to end of life decision making, including the withholding or withdrawal of life-sustaining therapy when further treatment is futile (also refer Volume 2, Chapter 67–69) (22).

Spiritual support services have become an integral aspect of care provided in most western hospitals, and spiritually related issues can influence medical care and ethical decision-making (23). Spirituality is recognized as a universal human phenomenon that transcends biological and psychosocial realms. For many individuals, spirituality provides a sense of inner strength, meaning, and purpose in their lives (24). **Spiritual belief systems can influence a patient or family's explanation of injury causation, perceptions of severity, and acceptance of changes imposed by illness.** When faced with the crisis of critical illness, including patient suffering, fear of death or uncertain prognosis, spiritual concerns often arise. Ethical conflicts ensue when patient/family values or beliefs conflict with treatment plans, and/or with the healthcare professional's perceptions regarding quality of life (23,24).

While not endorsing any particular belief system, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has identified the provision of spiritual support services as a requisite for quality, holistic patient care (25). Hospitals are expected to anticipate, plan for, and address patient/family spiritual needs. Ideally, requests or needs for spiritual care are assessed as part of the admission assessment, and on an ongoing basis as concerns arise. Upon request or when needs are expressed or identified, clinicians have a responsibility to make appropriate referrals (with patient/family permission) for spiritual support services (22,23).

As part of the healthcare team, pastoral care professionals (priests, rabbis, mullahs, pastors, etc.) can offer valuable support and assistance in addressing the diverse spiritual needs of patients and families. Considerations for referral include situations where grave news has been received, when ethical dilemmas present, and at or near the end of life (Volume 2, Chapter 68). Changes in a patient's emotional state (e.g., hopelessness, grief, or despair) may also warrant referrals.

## COLLABORATING WITH FAMILIES

**Collaboration between clinicians and family members is fundamental in meeting the emotional needs of patients and families.** Collaboration in care transcends the ICU stay, and continues into the recovery period when family members often assume the role of care provider for the patient.

The establishment of rapport begins at the initial contact with patients and families. Distress in family members can be reduced when clinicians are perceived as knowledgeable and professional, yet approachable, understanding, and empathetic (26). The ability to convey a sense of experienced professionalism at the same time as humility, openness, and unhurried compassion, results from years of experience in counseling families in crisis situations. This is why senior members of the trauma team should speak with the family about these important considerations.

Early and effective communication provides the foundation for developing a relationship of mutual trust, and influences the efficacy of future deliberations. Conversely, inadequate attention to the interpersonal relations between the trauma team and family can generate negative emotions, and can impair the family's ability to cope and participate effectively in decision-making. Poor communication also promotes family dissatisfaction with care (26,27).

Due to their condition, patients are often unable to participate in care; family members must be educated and empowered to act as advocates, and at times, as surrogate decision makers (5). As patients recover, family members often are the patient’s most important source of support. Effective communication between family members and the healthcare team is strongly associated with empowerment and improved decision-making, yet suboptimal communication in trauma and ICU settings continues to be reported (2,26,27).

Ideally, collaborative discussions should take place with the trauma/critical care team (including house staff and nursing staff) prior to meeting with the family about major changes in patient condition or treatment plans, to ensure information consistency. The challenge for the attending physician is to synthesize all of the patient data and present it in a clear and understandable way that provides a full perspective of the patient’s condition, while showing empathy and compassion to the family (6,28). In most cases it is best to have a designated family member serve as spokesperson, and as a primary point of contact to receive and relay information to other family members.

**ACUTE GRIEF MANAGEMENT AND BEREAVEMENT SUPPORT**

**Acute Grief Management**

Family members often require considerable levels of guidance and support to facilitate coping with the psychological stress associated with injury or impending death of a loved one. Patients themselves may manifest serious feelings of grief and/or guilt, especially those who were involved in motor vehicle collisions (or other traumas) where they may have been only minimally injured, whereas another family member was severely harmed or killed. The survivor guilt can become particularly profound when the minimally injured patient was directly responsible for the accident or injury (e.g., driving while intoxicated), or otherwise derelict in his or her duty (e.g., failure to use a car seat resulting in infant death). In all of these situations professional grief management should be employed. ⚡ **Specialists trained in grief and bereavement management may not be available when most needed (e.g., in the middle of the night or on weekends). Accordingly, the physicians, and especially the nursing staff, often provide this essential supportive role.** ⚡

The most important element in grief intervention is demonstrating compassion and genuine concern for the grieving patient as well as for their family and loved ones (29,30). When patients and family members perceive that the physicians and nurses are genuinely concerned about them, an unnecessary barrier to care is removed. Providing early and open emotional support positively impacts the patient and family’s experience, and may decrease the development of ASD, and later PTSD, as discussed in Volume 2, Chapter 65 (31,32).

**Notifying the Family About Bad News**

Notifying families of trauma victims that a death has occurred is perhaps one of the most difficult challenges faced by the trauma team and minimal formal attention is typically given to this aspect of trauma management. Notification is best carried out by a senior physician on the trauma team who is experienced in handling this delicate task (3). The manner in which survivors are informed of a death in the family and the support provided at this time has an

enduring impact on their grief response, and emotional healing process (29). Grief reactions of emotionally distraught family members can be mediated by receiving skilled, sensitive, and caring support from the trauma team. Strategies for conveying unpleasant news to families are summarized in Table 3.

Jurkovich et al. (2000) published the results of one of the first studies in the trauma literature that addressed the needs of bereaved family members of trauma victims (29). The study investigated “giving bad news,” and identified characteristics valued by families whose loved one had died after a short stay in the ED or Trauma ICU. ⚡ **Family perceptions regarding the most important elements of “giving bad news” include: (i) the attitude of the news-giver, (ii) the clarity of the information conveyed; and (iii) the ability to have questions answered.** ⚡ Clinician behaviors found to be most comforting were: (i) the display of an empathetic and caring attitude, (ii) the deli-

**Table 3** Strategies for Conveying “Bad News” (e.g., Poor Prognosis or Poor Outcomes) to Family Members and Loved Ones

Strategies	Comments and explanations
General approach	Display a compassionate and caring demeanor; a sensitive and thoughtful approach can positively impact the survivor’s grief process.
Information-giving	Attending physician responsibility (delegation is discouraged); provide clear, direct, honest information in understandable terms, avoiding euphemisms; utilize translators as needed.
Anticipate grief reactions	Reactions can include: shock and disbelief, anger, extreme sadness, and occasionally violent behavior; assess coping abilities, mobilize resources as needed; identify those at risk for ASD (later PTSD) for early intervention.
Allow sufficient time	Maintain a non-hurried attitude allowing time for emotional responses and questions; allow loved ones to be with the patient before death if possible, and following death; ongoing clinician presence can provide comfort and guidance to distraught family members.
Provide emotional support	Reassure the family that the patient received the best possible care; acknowledge the sorrow of losing a loved one; respect spiritual and cultural traditions; provide privacy and physical comfort.
Follow-up and referral	Refer to interdisciplinary support services as indicated (trauma case manager, social service, pastoral care, bereavement specialist, etc); provide written informational resources; consider follow-up condolences with phone calls or correspondence.

Abbreviations: ASD, acute stress disorder; PTSD, post traumatic stress disorder.

very of a well-informed clear message, (iii) privacy of the conversation, and (iv) the allowance of sufficient time to answer questions and allow families to adjust to the emotional distress (29).

When a patient dies following trauma, the goals and efforts of the trauma team are directed toward comforting and supporting the family through the initial bereavement experience. Documented needs of families facing sudden bereavement include: (i) prompt and compassionate attention from professional staff immediately upon arrival to the hospital; (ii) notification of imminent or actual death in a sensitive and compassionate manner; (iii) opportunity to be with the patient before death, if possible, and in most cases, following death; (iv) to know the patient received the best possible care; (v) to have questions answered; (vi) to be advised on what to do next; and (vii) to be given support and follow-up resources (29,30).

Kenneth Iseron, MD in *Grave Words: Notifying Survivors About Sudden Unexpected Deaths*, outlines strategies to effectively communicate with and support survivors, emphasizing that delivering bad news with sensitivity and in the right context, including support and direction for continued assistance can attenuate the grief process (30). In most, cases, it is the responsibility of the trauma surgeon to notify the family of a death. The presence of a nurse, social worker, or clergy provides additional resources for emotional and spiritual support of the family.

When initial contact is made by phone, it is generally agreed that the relative should not be told over the phone that the patient has died. It is usually best to briefly describe the event, notify the family that the patient is "seriously injured" and ask them to come to the hospital as soon as possible, ideally with someone to drive and accompany them. In circumstances where informing of death by phone is unavoidable, the clinician should attempt to ensure that the individual receiving the news does so in the company of family or loved ones, and is not left alone. Follow-up communication should also be specifically arranged at that time. Extreme care must always be taken to accurately identify the deceased person and notify the appropriate family members (30,33).

Upon arrival to the resuscitation suite or SICU, a nurse or social worker should meet the family member(s), bring them to a private room, and remain with them. In communicating with the family, the attending physician can assess what is already known, and give a brief chronology of pre-hospital, resuscitation, and subsequent events. The deceased should always be referred to by name, and by use of clear words stating that the person has "died" rather than using terms such as "expired" or "succumbed" and so on (30,33,34).

Bereaved relatives have the right to thoughtful explanations of the circumstances surrounding their loved one's death, the efforts taken to save the person's life, and that everything possible was done by providers in both the pre-hospital and hospital settings (34,35). **Careful listening to the family's style of communication and vocabulary can help healthcare professionals develop a message that is clearly understandable.** Nonverbal communication gestures such as sitting together and speaking on the same physical level, maintaining eye contact, and a non-hurried attitude also enhance communication.

### Bereavement Support

Clinicians must be prepared for the resultant, sometimes intense, expressions of grief and sadness following notification of a patient's death. Grief-stricken survivors are known

to experience a period of severe psychic pain, which usually lasts for 10 to 20 minutes (36). During this highly stressful time, the family's emotional reactions should be acknowledged, allowing time for responses and questions. Insensitive remarks such as "we all must deal with death" do little to console, and must be avoided. The clinician's remaining presence, expression of sorrow for the family's loss, and conveyance of empathy through physical touch when appropriate, and even tears, can provide immeasurable support and comfort to suffering and distraught family members.

Following the initial grief responses, the family should be given the option of spending time with the deceased. The physical appearance of the body should be made to look as attractive as possible prior to viewing, and relatives should be informed of what to expect ahead of time. This is especially important with disfiguring injuries, and when medical equipment (e.g., endotracheal tubes, etc.) is required to remain in place for postmortem exam. When viewing the deceased, staff should allow for privacy but remain nearby to answer questions and provide emotional support. Families can be encouraged to touch the body, and in the case of young children, to hold the child. It is essential to allow unrushed time for expression of mourning, and demonstrate respect for cultural and spiritual traditions, which may help survivors accept the loss of a loved one. A concluding process in which families are given "permission" to leave and guidance regarding what to do next is often helpful (33,35,36).

Requests for organ/tissue donation and autopsy requirements are best handled after the family has acknowledged the patient's death, in order to emotionally separate the issues. Personnel (usually from the regional organ procurement agency), skilled in approaching families and knowledgeable regarding procurement protocols should be utilized. Survivor grief may be facilitated by the sense of comfort associated with the decision to donate. When handled timely and sensitively, negative reactions are minimized and donation rates are improved (refer Volume 2, Chapter 16 for a discussion of the donor procurement process) (30,33).

When autopsy is indicated, requests for permission should involve an explanation of the reasons for postmortem exam, along with a brief description of procedures to dispel any misconceptions. When the cause of death is unclear, a specific determination of cause may help the family's grief process by reassuring them that nothing else could have been done to save the patient's life (33).

In medical examiner cases where authority to perform autopsy does not require consent, clinicians must clearly communicate mandates for medico-legal examination. In cases involving criminal investigation, notification of death may be under the jurisdiction of law enforcement, and viewing the body may be temporarily prohibited. Although complex situations can arise, the clinician's role is to provide necessary information in a compassionate and consoling manner.

The nature and circumstances of the death may also place survivors at greater risk for adverse psychological sequelae. Unexpected mortality (e.g., following acute trauma) is generally more difficult to assimilate than is a death resulting from chronic illness, and traumatic deaths are associated with higher rates of psychological morbidity in loved ones, including prolonged or pathologic grief, depression, and PTSD (35). Recognized risk factors for psychological morbidity include: death of a child; death or disability of more than one family member; traumatic, mutilating, or violent death; death by homicide or suicide; and

death perceived as preventable. The bereaved may suffer from survivor guilt, believing that they could or should have done more to prevent the death; this is especially serious when the survivor was unintentionally responsible for the death. Individual characteristics such as prior mental health problems, multiple life stressors, conflicted or overly dependent relationships with the deceased, and limited social support networks increase vulnerability for psychological morbidity (31,32,37,38). Survivors who seem to be especially disturbed or those recognized to be at high-risk for pathologic grief should be identified and offered referral for early psychiatric intervention.

Bereaved survivors should be informed about the psychological impact of traumatic loss, the process of grieving, and available supportive resources. Written material for follow-up contacts, available hospital and community-based grief support systems, mental health services, and pastoral care (if indicated) should be provided in the hospital, and mailed out in the following weeks. Follow-up phone calls can also be made to express condolences (35,37). This provides families with a sense that clinicians “really care” and also affords an opportunity to assess the family’s grief status, identify needs for ongoing support, and to make referrals if warranted.

✎ **A structured approach to bereavement care that is integrated into the spectrum of trauma services has great potential to reduce the stressors of the grief-stricken family members faced with the sudden, unexpected death of a loved one.** ✎ Resources have begun to appear in the trauma literature, and much can be learned from existing models in pediatrics and palliative care where family needs in bereavement have been more thoroughly investigated (3,35,38). Multidisciplinary teams comprised of trauma surgeons, intensivists, nurses, social workers, clergy, and psychiatric clinicians committed in providing family-centered care can have a positive impact on the grief experience of those loved ones who are the “secondary victims” of trauma.

## FAMILY PRESENCE DURING RESUSCITATION

The presence of patients’ families in the trauma resuscitation suite is a topic of recent and considerable debate. Controversy on this topic centers on medico-legal issues, fear of causing psychological trauma to witnessing family members, and practitioner concerns that family needs may compete with urgent patient care demands or scarce resources (39,40). Although mostly limited to small, noncontrolled studies, a growing body of research indicates that many families would elect to be present during resuscitative and invasive procedures, and when given the option, often choose to remain. ✎ **Almost universally, studies questioning family members who have experienced resuscitations have strongly supported family-witnessed resuscitation (FWR), and most would elect to do so again (41,42).** ✎ Although “media miracles” and glorified misinformation may be influential, lay surveys indicate that the majority of the general population also favors FWR (43,44).

Several investigators have reported that witnessing resuscitation has few adverse psychological effects, and that family members may benefit from the practice. Reported benefits include seeing that everything possible was being done, feeling they were able to support the patient, and in facilitating the grief process when death was imminent

(41,42,45). In the only study to date addressing patient preferences, Benjamin et al. in 2004 studied resuscitation survivors and reported that 72% (n of 200) of patients surveyed favored the presence of their families (46).

Several professional organizations (Emergency Nurses Association; American Association of Critical Nurses) have recommended that health care providers offer families the option to be present during both adult and pediatric resuscitations (47). In 2000, the *American Heart Association Guidelines for Emergency Cardiovascular Care and CPR* advocated family-witnessed resuscitation and recommended that family members be given the option to be present during CPR attempts (48). The American College of Emergency Physicians (ACEP) has made the following statement: “When no hospital policy exists, the decision should be based on the family’s wish to remain with their loved one, the views of medical personnel, the reactions of family members and patients to the situation, and the nature of the emergency”(49). A few emergency departments and trauma centers (including Parkland Hospital in Dallas, Texas, U.S.A.) have adopted family presence protocols for FWR. The protocols generally involve pre-screening for suitability of family members (e.g., emotional stability, no hostile intent, no evidence of intoxication or drug use, etc.) and the agreement to follow all instructions and leave the resuscitation room if instructed to do so. A family facilitator is designated (usually a social worker or nurse) to prepare family members beforehand and remain present for guidance, information, and support (41)

Provider views on this issue are divergent, with nurses generally holding more favorable views of FWR than physicians, and less experienced clinicians more often preferring to avoid the practice (39). Geographic differences also exist, with Midwest professionals more likely to allow family presence, and northeastern states least likely to implement FWR (39). Pediatric providers have a longer history with FWR and are generally more supportive of family presence (40).

While opposing views are likely to remain, continued research exploring family presence is needed to evaluate outcomes of family witnessed resuscitation from patient, family, and provider perspectives (50). Not all resuscitations are amenable to family presence (e.g., resuscitative thoracotomy, open head injury, violent crime circumstances, etc.). Also, not all family members will choose this option.

Most importantly, staff resources and physical space must be available to screen, monitor, and provide support to the family. Protocols may be helpful, although their usefulness has not been well studied. Currently, research on FWR is still in early stages since the concept is relatively new. Many clinical, ethical, and legal/risk management issues surrounding FWR deserve further exploration, and research must specifically address outcomes in trauma settings. Both proponents and critics of FWR agree that an individualized rather than a prescribed approach is essential, and that multiple variables (patient needs, family characteristics, resource availability, clinician education, etc.) must be considered in decision-making and establishment of best practices.

## ROLE OF THE CASE MANAGER

Successful achievement of family-centered care not only requires a dedicated staff trained in the various elements reviewed in this chapter but also is best facilitated by the establishment of a trauma case manager (often a clinical

nurse specialist) who begins working with the family, patient, bedside nurse, and trauma/critical care team from the initiation of admission to the unit through the hospital course of stay (51).

The trauma case manager helps both to standardize and optimize care by facilitating the communication and collaboration between patients and health professionals and between the health professionals themselves. Collaboration among health care disciplines is well supported as an effective solution to many problems, particularly fragmentation among complex patient groups (52).

Indeed, a recent study showed that the introduction of a trauma case manager system resulted in several benefits including: (i) a trend toward reduced length of stay (especially in older patients and those with higher injury severity scores), (ii) improved missed injury detection rates ( $p < 0.0015$ ), (iii) more efficient coordination of allied health workers ( $p < 0.0001$ ), and (iv) staff surveys exhibiting dramatic improvement in perceived effectiveness of patient care ( $p < 0.0001$ ) (51). One criticism of the study is the absence of a survey comparing the family's perceptions before and after the program.

Despite these minor reservations, the introduction of the Trauma Case Management system provided greater continuity and familiarity for the patient and family. The unexpected benefit of improved missed injuries may have directly led to the overall trend toward decreased length of stay. Similar results have been achieved by others, particularly in terms of improving the ability to follow critical pathways in the management of critically ill patients (53). Additional randomized controlled studies are required to further validate this model.

## EYE TO THE FUTURE

As trauma systems have matured, it is now recognized that the delivery of comprehensive trauma care extends across the continuum, from the acute phase of injury through critical care and rehabilitation and beyond, to the time when patients have returned to their families and communities. Advances in the long-term management of injury are occurring with increasing recognition of the importance of optimizing psychosocial and functional outcomes following trauma from both patient and family perspectives (54–56).

Over the past several decades, trauma outcomes research by Michaels (57), Holbrook (58), Zatrack (59), Richmond (54), and others has made significant contributions to understanding the long-term physical and psychological effects of trauma. These studies have examined pre-post, and injury-related factors influencing functional recovery (e.g., return to work, school, homemaking, etc.), psychological outcomes (e.g., emotional well-being, depression, PTSD, substance abuse, etc.), and health-related quality of life in trauma survivors. Evidence indicates that functional limitations and trauma-related emotional problems, especially PTSD and post injury depressions, are common across trauma populations, and are still under-recognized and poorly treated (57–60). Pre-existing and untreated psychiatric disorders as well as problems of substance abuse/dependence are also prevalent, and contribute to the recidivistic nature of certain types of trauma (57–60).

Trauma outcomes data suggest that psychological and functional recovery from trauma is not just related to injury severity and degree of physical disability, but that psychoso-

cial factors are additional important recovery predictors (54,56,61). Evidence suggests that positive family coping and adaptation may be associated with improved patient functioning, long-term outcomes, and directly influences treatment adherence (62,63). Further research is needed to specifically examine the mediating effects of family support in trauma recovery, and greater attention should be focused on investigating the social and psychological factors surrounding injury.

With shortened hospital stays, a greater percentage of trauma recovery takes place at home; accordingly, family members frequently assume much of the responsibility for care, necessitating earlier intervention with families (56,61–63). Studies have begun to address the need to educate and adequately prepare patients and families to cope after discharge from hospitalization. These issues have been best studied in major burn victims and brain injured populations, where it has been demonstrated that patients and families benefit from education and guidance regarding the emotional, financial, and life disruptions they will likely experience. Findings indicate that patients and family caregivers frequently require more knowledge and assistance in accessing resources (e.g., counseling, financial, legal, etc.) and obtaining follow-up care than they usually receive (62,64–66). These studies suggest that educational and counseling interventions can positively impact patient and family functioning, and are most effective when begun early in rehabilitation and extended through recovery via formalized programs and services.

Research on the impact of sudden bereavement in trauma settings is also increasing. Previous literature on delivering grave news and providing bereavement support has been primarily anecdotal, with recommendations based on the experiences and opinions of experts. More recently, interventional studies in the emergency and trauma literature are contributing to a more evidence-based approach to the communication of bad news and the establishment of bereavement protocols following trauma-related deaths. Models of bereavement care, which are well established in palliative care settings, are becoming increasingly studied and implemented in trauma settings (3,29,37,67).

## SUMMARY

Trauma services continue to be challenged to deliver holistic care including complex physiological and psychosocial support for their patients. Likewise, clinicians have a responsibility to address the needs of distressed and vulnerable family members who are the "secondary victims" of trauma. There is a compelling need to humanize the critical care unit, and create a more caring and supportive environment conducive to recovery and quality end-of-life care. Equally important is the obligation to assist patients and families to adapt and cope with the many potential long-term physical, psychological, and life-quality sequelae following trauma.

Future research will focus on evidence-based approaches to caring for relatives who are suddenly bereaved by the unexpected death of a loved one. These studies will include longitudinal studies to identify psychological and socioeconomic issues affecting the health and well-being of patients and families that often emerge after hospitalization and rehabilitation. In addition, the inclusion of greater numbers of well-designed trauma outcomes studies may provide a deeper understanding of the life experiences and

perspectives of patients and their families following serious injury or death (68,69).

There are perhaps few situations in health care where the family suffers more than in trauma and critical care. As technological advances improve the ability to sustain life after critical injury, simultaneously the need to support patients and families faced with the acute and chronic burdens imposed by trauma increases (70). Recognition of the family's importance to a patient's recovery, and an understanding of the impact of critical injury on the family are essential prerequisites to establishing the systems and resources for providing comprehensive family-centered trauma care.

## KEY POINTS

- ☞ Because the nature of trauma is sudden and unexpected with the potential for loss of life or significant disability, family systems are often stressed to their emotional limits.
- ☞ Evidence indicates that families exhibit a universally predictable set of needs when a loved one becomes critically ill.
- ☞ Well informed families report a greater sense of control, are more often able to accept the tragedy affecting their loved one, and participate more effectively in patient care decision making.
- ☞ Although the physician's time is limited, due to the complex demands of the trauma and critical care environment, consistent communication with the family and open access to informational resources are essential in meeting family needs.
- ☞ During serious discussions, family members may be intimidated or ashamed to admit that they do not fully understand what has been said. To avoid confusion, medical information should be clearly explained, and repeated as necessary. Technical language and euphemisms should be avoided, whereas clarifying questions should be encouraged.
- ☞ A flexible visitation policy has psychological benefits for both the patient and the family members, with a resultant positive influence on their overall satisfaction with care.
- ☞ Although family members give priority to the welfare of their relative, their own emotional needs become increasingly significant over time while the quest for hope remains universal.
- ☞ Occasionally reviewing diagnostic images (e.g., brain computed tomography scans, etc.) with family members helps to convey situations that are difficult to grasp by words alone.
- ☞ Cultural factors are recognized to have a strong influence on health practices, and to affect patient/family satisfaction of medical care, trust of healthcare providers, and adherence to treatment regimens.
- ☞ As with culture, spiritual beliefs systems can influence a patient or family's explanation of injury causation, perceptions of severity, and acceptance of changes imposed by illness.
- ☞ Collaboration between clinicians and family members is fundamental in meeting the emotional needs of patients and families.
- ☞ Specialists trained in grief and bereavement management may not be available when most needed (e.g., in the middle of the night or on weekends). Accordingly,

the physicians, and especially the nursing staff, often provide this essential supportive role.

- ☞ Family perceptions regarding the most important elements of "giving bad news" include: (i) the attitude of the news-giver, (ii) the clarity of the information conveyed, and (iii) the ability to have questions answered.
- ☞ Careful listening to the family's style of communication and vocabulary can help healthcare professionals develop a message that is clearly understandable.
- ☞ A structured approach to bereavement care that is integrated into the spectrum of trauma services has great potential to reduce the stressors of the grief-stricken family members faced with the sudden, unexpected death of a loved one.
- ☞ Almost universally, studies questioning family members who have experienced resuscitations have strongly supported FWR, and most would elect to do so again (41,42).

### INTRODUCTION

Post-traumatic stress disorder (PTSD) is a psychiatric ailment resulting from an individual experiencing or witnessing an actual or potential life-threatening event. Symptoms include recurrent, intrusive recollections of the event (e.g., nightmares or flashbacks), avoidant behavior (e.g., emotional numbing), increased arousal (e.g., irritability, insomnia), and significant impairment in social and occupational functioning (1–8).

Both acute stress disorder (ASD) and PTSD are increasingly recognized to occur in trauma survivors, and each entity has specific Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) criteria. To achieve the diagnosis of PTSD, the aforementioned symptoms must be present for more than one month. When these manifestations combine with dissociative symptoms and persist between two days and four weeks following the traumatic event, this entity is referred to as ASD. Being affected by ASD or PTSD significantly impacts the quality of life (QoL), emotional well being, and functional recovery outcomes of these patients (1,5).

The symptoms attributable to ASD and PTSD have been most closely associated with military combatants, and have been recognized in various forms for centuries. Myers ABR (1838–1921) (9) was the first to publish a clinical description of symptoms describing ASD and PTSD in his treatise “on the etiology and prevalence of diseases of the heart among soldiers” in 1870. Da Costa JM (1833–1921), (10) an American internist working at a Philadelphia military hospital, chronicled cases of PTSD that occurred during the American Civil War in 1871; consequently, for a time this entity was known as “Da Costa’s Syndrome.” Since then, symptoms of ASD and PTSD have been called by various terms including: (i) “Soldier’s Heart” (Spanish American War), (ii) “Shell Shock” (World War I), and (iii) “Combat Fatigue” (World War II). During and after the Vietnam conflict, the recurrent nature of the reliving

experiences became popularized by the symptom terminology known as “flashbacks.” However, not until 1980 and the compilation of DSM-III was PTSD even listed as an official psychiatric disorder; it was at this time that the diagnostic criteria were initially specified. The formal diagnosis of ASD was not specified until 1994 and the publication of DSM-IV.

Post-traumatic stress symptomatology is not rare. Research on trauma survivors cared for in U.S. Trauma Centers reveals that 10% to 40% develop symptoms of ASD and PTSD (1–8). In addition, it is now recognized that ASD and PTSD can develop in loved ones or family members through “vicarious traumatization” mechanisms, when they are confronted with death or serious injury to significant others.

Fifty percent of American adults will experience a traumatic stressor significant enough to cause PTSD (11). Fifteen percent of those exposed will develop chronic symptoms of PTSD (12). Childhood trauma is also not uncommon (Volume 1, Chapter 36). Sixteen percent of women were sexually abused before the age of 18, (13) and probably half as many men. PTSD is about twice as common in women as men even after controlling for trauma rates for all causes of trauma except perhaps rape (Fig. 1A and B) (14). One million Americans were exposed to traumatic stress in Vietnam, and several hundred thousand more were exposed during the Gulf War and the antiterrorist campaigns in Afghanistan and Iraq.

Structural changes occur in the brains of patients whose PTSD symptoms have been allowed to persist untreated for too long. The connection between exposure to traumatic stressors and the development of ASD/PTSD is becoming increasingly well characterized in psychological, neuroanatomical, and evolutionary terms. The mind/brain initially reacts to trauma by increasing the elaboration of stress hormones (e.g., cortisol, epinephrine, and norepinephrine) to marshal resources, direct attention, and increase awareness. However, if the stress hormones,

**Figure 1** (A) Prevalence of trauma category according to gender. (B) Probability of developing post-traumatic stress disorder by type of trauma. *Source:* From Ref. 14.

which are beneficial during the acute trauma response, remain elevated for too long a time period, detrimental changes can occur including brain damage to memory centers and thought association loci. Chronic stress can also exacerbate the development of heart disease, gastric stress ulcers (Volume 2, Chapter 30), and immunosuppression (Volume 2, Chapter 52) (15,16).

This chapter provides a multidisciplinary approach to the pathophysiology, diagnosis, and treatment of ASD and PTSD in acutely injured trauma and critically ill patients. Post-trauma depression (PTD) is also briefly summarized. The neurobiological mechanisms underpinning ASD and PTSD are emphasized. Treatment modalities are reviewed, including the optimum timing for each type. Emphasis is placed on early recognition of risk factors and symptoms during initial hospitalization, with specific focus on interventions occurring in the Trauma Resuscitation Suite (TRS) and the surgical intensive care unit (SICU), when possible.

## NEUROBIOLOGY OF POST-TRAUMATIC STRESS DISORDER

### Anatomic Brain Regions Involved in Post-traumatic Stress Disorders

Several anatomic areas of the brain have been implicated in the pathophysiology of ASD and PTSD. ⚡ **Four integral components of the limbic system are specifically involved in the pathophysiology of ASD/PTSD.** ⚡ These include the hippocampus, the amygdala, the medial prefrontal cortex (MpfC) (cingulate gyrus), and the hypothalamus. The limbic system is an evolutionarily primitive portion of the brain involving memory, emotions and motivations, especially those involved in survival. Certain structures in the limbic system are critical for memory formation

(especially the hippocampus, the amygdala, and the hypothalamus), and likely play an important role in the pathophysiology of PTSD. The MpFC, rectifies thoughts that pass through the aforementioned structures, and also regulates the hypothalamic-pituitary-adrenal (HPA) axis under basal and stressful conditions.

The hypothalamus, like the MpFC, is involved in both the limbic system, and the neurohormonal regulation between the anterior pituitary gland and the adrenal glands (Volume 2, Chapter 62). Apart from cardiorespiratory and thermoregulation, the hypothalamus is an important attenuator of emotional output by adjusting the elaboration of hormones that cause joy, sadness, anger, and depression. Numerous studies implicate dysregulation of the HPA axis in PTSD, (17–22) along with impairments in cognitive function, (23) hippocampal tissue volume reduction, (24) and alterations in the neuronal circuitry of the limbic system (25). Recently Wang et al. (26) demonstrated axonal shrinkage, myelin deformation, and neuronal degeneration in both the hippocampal and hypothalamic structures of dogs following high-energy missile wounds to extremities, suggesting central nervous system (CNS) damage to limbic structures following distant injury.

The hippocampus is integral to learning, data acquisition, and memory of content, (27,28) and also records the emotions associated with memorized events (29–31). Structures within the hippocampal complex have access to virtually the entire brain, and create integrated records of various aspects of memory including visual, auditory, smell, and the somatosensory context. Permanent memory of any event typically takes at least 45 minutes, but final memory consolidation may take weeks or months. Hippocampal dysfunction or damage during consolidation can cause impaired memory of events surrounding and subsequent to a trauma. Furthermore, damage to the hippocampus can result in increased risk of subsequent ASD/PTSD, chronic memory loss, and a propensity to dissociate memory from experiences that occur later.

The amygdala is important in the acquisition of emotional memory experiences, but not for neutral memory. The amygdala is involved in producing an anger or fear response when a threat is detected. Its size is positively correlated with aggressiveness in humans, and shrinks by 30% following castration in men. The amygdala connects with many areas of the brain and causes the stress response by stimulating cortisol and epinephrine release (32). The amygdala also has critical functions affecting the conditioned fear response and emotional memory. Recently, Eric R Kandel's group identified the gene that codes for "stathmin," a protein highly expressed in the amygdala, which inhibits microtubule formation, and appears to be critical to the formation of the innate and acquired fear response. When knocked out in laboratory animals, fear was abolished (33).

The MpFC is important in regulating emotion and suppressing primitive brain reactions such as those emitted by the amygdala (35). Although the acute stress response following fearful situations is universal, PTSD patients fail to show remission of this response. The failure of higher brain centers to suppress amygdala activity is likely responsible for the exaggerated "startle response" that is often seen in PTSD (36–38). The suppressive function of the MpFC inhibits fear responses from the amygdala when no actual threat exists. In patients with PTSD, this suppressive response is altered, creating a tendency to respond to all threats as if they were real.

## Neuroendocrine Changes

The neurobiological mechanisms mediating the response to stress include: (i) stimulation of the sympathetic nervous system, (ii) parasympathetic nervous system suppression, and (iii) activation of the HPA axis.

Adrenergic stimulation causes adrenal medullary release of epinephrine and norepinephrine with consequent increased heart rate (HR), contractility, blood pressure (BP), respiratory rate, and tidal volume coupled with a sharpening of mental focus and memory formation. HPA axis activation results in release of corticotropin releasing hormone (CRH) from the hypothalamus and subsequent secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland, which signals cortisol release from the adrenal cortex (Volume 2, Chapter 62).

Elevated hippocampal cortisol is thought to impair the formation of new memories, while epinephrine causes stronger memory formation and increased emotional intensity associated with specific memories. Increased norepinephrine levels also stimulate brain activity; however, excessive release of these endogenous catecholamines can lead to neurotransmitter overload, inhibiting the brain's ability to process information. These factors may partially account for the chaotic memory formation commonly surrounding trauma events, as well as the intrusive memories characteristic of PTSD.

🔗 **Individuals with PTSD have dysregulation of the HPA axis (resulting in lower than normal cortisol levels), as well as an elevated basal adrenergic tone.** 🔗 These initially beneficial survival mechanisms are likely deleterious in the chronic state. Long-term alterations of these neurotransmitters may be partly responsible for the structural changes detected in the brains of ASD and PTSD patients.

Several neuroendocrine studies have shown lower than normal cortisol levels in individuals with PTSD as well as an increased cortisol response (receptor sensitivity) to subsequent trauma events (Fig. 2) (20,39). Norepinephrine under extreme stress conditions may act longer or more intensely on the hippocampus, leading to abnormally strong memory formations. Since cortisol normally limits norepinephrine activation, low cortisol levels may increase adrenergic hyperarousal mechanisms (19–22). Long-term effects of elevated adrenergic levels have adverse cardiovascular effects whereas diminished baseline cortisol may have an impact on stamina, mood, and immune-mediated disorders (see Volume 2, Chapter 52) (15–16).

Other neurotransmitter functions are altered in PTSD. Benzodiazepine receptors are reduced in the frontal cortex of humans with PTSD (40). Opioid receptors appear to be stimulated during traumatic reminders in PTSD, creating decreased pain sensitivity during re-experiencing periods (41). Frontal cortex serotonin function is also dysregulated in PTSD. Animal studies indicate that serotonin may block frontal cortex stress responses (42). Selective serotonin reuptake inhibitor (SSRI) drugs are currently first line pharmacotherapy for PTSD (discussed later).

## Structural Changes

It is now well established that structural and biochemical changes occur within the brain of trauma survivors supporting the mind/brain-integrated concept (43). Although experiencing the symptoms can be seen as psychological in origin, the neural circuitry underlying this is biological as are the consequent structural changes associated with ASD/PTSD.

The most significant structural damage that occurs after the stress of trauma is found in the hippocampus. The hippocampus is involved in recording the emotions associated with a traumatic event. Several well-controlled studies have demonstrated hippocampal volume shrinkage in PTSD populations (44,45,50–51). Hippocampal volume decrease is nearly always imageable by two years post-trauma, but has been seen as early as five to six months after trauma (46,48,52). Structural hippocampal changes including atrophy have been correlated with decreased capacity for hippocampal mediated memory tasks, indicating that the physiological damage is directly relevant to the clinical deterioration of memory functioning in PTSD patients (47,49).

Stress may also affect the expression of brain derived neurotrophic factor (BDNF), a protein necessary for neuronal survival, normal hippocampal activity, and long-term memory function. Decreased BDNF is probably associated with the cell atrophy and death seen in PTSD (53).

PET scans have identified an entire network of dysfunctional memory areas of the brain in PTSD patients including the hippocampus, amygdala, and the MpfC (38). The amygdala also exerts supernormal influence on the visual cortex, subcallosal gyrus, and anterior cingulate gyrus in PTSD compared to normal controls (54). In PTSD, the amygdala appears to be hyperreactive to trauma-related stimuli (55,56).

## IMPACT OF TRAUMA INTERVENTIONS

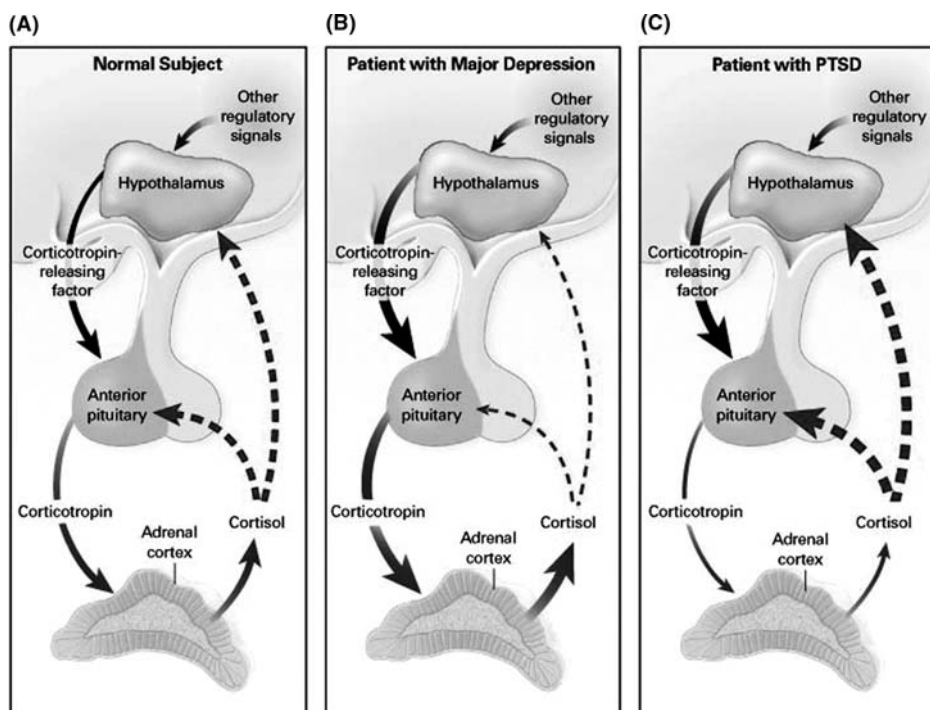

### Effect of Resuscitation, Anesthesia, and Critical Care on Acute Stress Disorder/Post-traumatic Stress Disorder

🔗 **The initial resuscitation, anesthesia, and critical care experiences may contribute (negatively or positively) to the development of ASD/PTSD.** 🔗 Because of the changing awareness of these patients (due to hypotension, anxiety, pain), their memories can become distorted. In addition, some of the drugs administered to alleviate stress and pain may contribute to memory impairment (and possibly ASD/PTSD).

Awareness under anesthesia, prolonged ICU treatment (ARDS, septic shock), and successful resuscitation after cardiac arrest are also linked to the development of PTSD. The prevalence of PTSD in these medical conditions lies around 10% to 20%; they are therefore considered important comorbidities (57,58).

Studies of former ICU patients utilizing a 10 item, the Post-traumatic Symptom Scale (PTSS), indicate 17% screen positive for probable PTSD, and just under 10% confirm positive for PTSD following rigorous clinical evaluation (58). Large level I trauma center studies have revealed higher rates of PTSD development ranging between 30% to 40% after severe injury (excluding those with moderate or severe brain injury) (1–8,59).

Treatment occurring in the critical care setting appears to further increase the risk of developing PTSD. In studies of patients undergoing treatment for myocardial infarction (MI), cardiac surgery, hemorrhage, stroke, burns, cancer, and awareness under anesthesia, the highest rates of PTSD were found in those whose course included treatment in ICUs (60). Postcardiac surgery patients show an 18% PTSD rate, which is highly correlated with the number of traumatic memories from their ICU/CCU treatment (61). Spinal cord injury (SCI) patients show a 10% to 20% PTSD rate (62), and rates of up to 51% have been seen in orthopedic trauma patients (63). ICU stays have also been shown to be

**Figure 2** Response to stress in a normal subject (A), a patient with major depressive disorder (B), and a patient with post-traumatic stress disorder (PTSD) (C). In normal subjects (A) and in patients with major depression (B), brief or sustained periods of stress are typically associated with increased levels of both cortisol and corticotropin-releasing factor. In each panel the thickness of the interconnecting arrows denotes the magnitude of the biologic response. Corticotropin-releasing factor stimulates the production of corticotropin, which in turn stimulates the production of cortisol. Cortisol inhibits the release of corticotropin from the pituitary and the release of corticotropin-releasing factor from the hypothalamus. It is also responsible for the containment of many stress-activated, biologic reactions. In patients with PTSD (C), levels of cortisol are low and levels of corticotropin-releasing factor are high. In addition, the sensitivity of the negative-feedback system of the hypothalamic–pituitary–adrenal axis is increased in patients with PTSD rather than decreased, as often occurs in patients with major depression. *Source:* from Ref. 208; Photos courtesy of Ref. 20.

extremely stressful to relatives of trauma patients, and to relatives of patients undergoing elective cardiac surgery (64).

### Duration of Mechanical Ventilation and Other Interventions

PTSD, which can develop as a result of traumatic experiences during ICU treatment, causes significant impairment, decreased QoL, and increased risk for comorbid mental health conditions (65). In a large review of long-term survivors of ICU-based ARDS treatment, 44% were found to meet criteria for PTSD upon hospital discharge. At eight year follow-up, 24% continued to suffer full-blown PTSD and an additional 20% had continuing post-traumatic symptoms (66). ⚡ **In one large study of critically ill patients the risk of PTSD was directly correlated with the duration of mechanical ventilation and inversely related to patient age (67).** ⚡ Questionnaires after discharge from ICU treatment indicated almost 40% had significant PTSD symptoms, and 14% met full diagnostic criteria for PTSD three months following discharge from the ICU (67).

Although trauma-inducing interventions during critical care treatment can increase PTSD rates, sedating patients throughout the critical care experience (using standard drugs) does not abolish it. In fact, daily sedation interruption for patients on mechanical ventilation was correlated with a lower incidence of PTSD (68).

⚡ **Trauma outcomes researchers have consistently identified PTSD as a significant factor in functional limitations and diminished QoL above and beyond the medical**

### comorbidities associated with their physical wounds (7,62–67,69,70).

During and just after critical care treatment, patients can make incorrect subjective decisions about the need for psychiatric care (71). Trauma patients are often less able to communicate due to the need for mechanical ventilation soon following trauma, and are generally not interviewed about the need for psychiatric involvement unless the patient has a pre-existing psychiatric history or was injured during a suicide attempt. Following discharge, few patients seek mental health treatment; some fail to recognize they have a problem, others believe the symptoms will resolve on their own. Patients who seek care late more often present with somatic symptoms, sleep disorders, and increased rates of comorbid depression and substance abuse (59,60,71).

In a study of almost 100 people with civilian PTSD, more than half had some form of suicidal ideation, and almost 10% had made at least one suicide attempt. While PTSD is considered a significant risk factor for suicide (72), substantial disability and suicidal risk is also associated with those experiencing subdiagnostic post-traumatic symptoms (73).

### ACUTE STRESS DISORDER (ASD)

#### Overview

Prior to 1994 (DSM-IV), severe psychological and emotional distress immediately following trauma was not a diagnostic

entity. This led to delay in diagnosis and appropriate treatment. Currently, the diagnosis of ASD is made in individuals experiencing significantly distressing symptoms of re-experiencing, avoidance, and increased arousal within two days to four weeks of the traumatic event. ⚡ **The diagnosis of ASD symptoms helps identify patients at risk for PTSD, in quantifying the severity of distress suffered by the trauma survivor during the first month following the event.** ⚡

The diagnostic criteria for ASD include the presence of dissociative symptoms (not included in the criteria for PTSD). Dissociative symptoms by themselves are strong predictors of post-traumatic symptom severity. Several studies have documented that having ASD markedly increases the risk of subsequently developing PTSD. Approximately 50% of those with ASD will go on to develop PTSD (74). However, ASD does not necessarily need to be present prior to developing PTSD. One study of severely injured hospitalized trauma survivors found only 1% with ASD at day eight, while at months 3 and 12, the PTSD rates were 9% and 10% respectively (75). However, ASD appears to be a more accurate predictor of PTSD in females than males. (76).

In one study of motor vehicle crash (MVC) survivors, 78% of those who met criteria for ASD at one month were diagnostic for PTSD at six months. Sixty percent of those who met all but the dissociative criteria for ASD were also positive for PTSD at six months (77). This study has been supported by similar studies of MVC survivors who sustained mild traumatic brain injuries, (78,79) and in studies of sexual and physical assault victims (80).

#### **Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) Diagnostic Criteria**

Since patients without ASD symptoms may later develop PTSD, it is imperative to maintain a high index of suspicion, and utilize early and follow-up symptom screening. Those who meet criteria for ASD, with or without dissociative symptoms, need definitive treatment because of their higher risk of long-term pathology. The complete DSM-IV criteria for ASD are summarized in Table 1. Each of the specific symptom criteria is discussed subsequently.

#### **Exposure (A<sub>1</sub>) and Response (A<sub>2</sub>) to Traumatic Stressor (Criterion A)**

The DSM-IV Criterion A for the diagnosis of ASD requires the person to have been exposed to a traumatic event in which both of the following has occurred: (i) The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury to self or others; and (ii) the person's response involved intense fear, helplessness, or horror. This trauma exposure criterion for ASD is the same as that required for PTSD.

#### **Dissociative Symptoms (Criterion B)**

Criterion B symptoms for ASD are dissociative in nature. Dissociation refers to an unconnectedness of things that should normally be linked. When experiences are not encoded correctly into memory, they do not contribute to the normal sense of self.

⚡ **Dissociative symptoms contribute to discontinuities in memory, identity, and perception; these are required for the diagnosis of ASD but not PTSD. Re-experiencing, avoidant, and hyperarousal symptoms are characteristic of both entities.** ⚡

A common manifestation of dissociative symptomatology is "emotional numbing" where the person may fully recall a trauma, but feels no emotions associated with it (81). Dissociative experiences are also commonly expressed in the opposite way, with strong and overwhelming emotions displayed without any obvious cognate memory. Some patients experience acting, feeling, or thinking as if "someone else" was actually carrying out their actions. Five main categories of dissociation are listed in DSM-IV Criterion B (Table 1): (i) subjective numbing, (ii) awareness reduction, (iii) derealization, (iv) depersonalization, and (v) dissociative amnesia. To meet the DSM-IV criteria for ASD, the victim must exhibit at least three of the five dissociative symptoms listed in Table 1.

The dissociative symptom load manifested by ASD patients is significant since three of the five listed symptom categories must be present for diagnosis. Subjective numbing can take several forms, including a lack of emotional response to the trauma, anhedonia (the inability to feel pleasure), or the experience of intense guilt. Reduced awareness can manifest as difficulty concentrating, missed social cues, and difficulty remembering post-trauma details. Derealization is the subjective experience that the world is not real; these patients often describe seeing things through a fog or a veil (82). Depersonalization is the subjective sense of being detached from one's own body. In extreme cases, patients may not even recognize themselves in the mirror (83). Dissociative amnesia is the inability to remember substantial details of the trauma and subsequent period. Episodes of amnesia can also occur well after the trauma, usually with a significant attempt on the part of the survivor to conceal their memory impairment from others.

#### **Re-experiencing Symptoms (Criterion C)**

Psychological re-experiencing of the traumatic event can be extremely debilitating. For the diagnosis of ASD, re-experiencing must occur in at least one of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, a sense of reliving the experience, or distress with exposure to reminders of the traumatic event (Table 1). Images, thoughts, or flashbacks about the trauma can intrude forcefully on the person's awareness or they may experience dreams and nightmares with content related to the trauma. The re-experiencing criterion is considered positive whenever the person has significant emotional distress when confronted with a trigger stimulus or reminder of the traumatic event.

#### **Avoidant Symptoms (Criterion D)**

Avoidant symptoms describe the marked abstention from stimuli that arouse recollections of the trauma (including thoughts, feelings, conversations, activities, places, or people). The trauma survivor with ASD or PTSD goes to significant lengths to avoid anything that might cause the event(s) to be remembered. Often, the nature of protracted legal or medical procedures place the survivors into situations where they are unintentionally forced to remember the event. Avoidant symptoms can drive ASD/PTSD patients away from using beneficial services in an attempt to avoid retraumatization.

#### **Hyperarousal/Anxiety Symptoms (Criterion E)**

Symptoms of anxiety or increased arousal may include difficulty sleeping, irritability, poor concentration, hypervigilance,

**Table 1** Acute Stress Disorder: Diagnostic Criteria

Criterion	Short title	Description
Criterion A	Exposure to traumatic stressor	The person has been exposed to a traumatic event where both of the following were present: The person experienced, witnessed, or was confronted with an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others The person's response involved intense fear, helplessness, or horror
Criterion B	Dissociative symptoms	Either while experiencing or after experiencing the distressing event, the individual has three (or more) of the following dissociative symptoms: A subjective sense of numbing, detachment, or absence of emotional responsiveness A reduction in awareness of his or her surroundings (e.g., "being in a daze") Derealization Depersonalization Dissociative amnesia
Criterion C	Re-experiencing symptoms	The traumatic event is persistently re-experienced in at least one of the following six ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience, or distress on exposure to reminders of the traumatic event
Criterion D	Avoidant symptoms	Marked avoidance of stimuli that arouse recollections of the trauma (e.g., thoughts, feelings, conversations, activities, places, or people)
Criterion E	Anxiety/arousal symptoms	Marked symptoms of anxiety or increased arousal (e.g., difficulty sleeping, irritability, poor concentration, hypervigilance, exaggerated startle response, motor restlessness)
Criterion F	Distress level	The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning or impairs the individual's ability to pursue some necessary task, such as obtaining necessary assistance or mobilizing personal resources by telling family members about the traumatic experience
Criterion G	Duration of symptoms	The disturbance lasts for a minimum of 2 days and a maximum of 4 wk and occurs within 4 wk of the traumatic event
Criterion H	Other etiologies	The disturbance is not due to the direct physiological effects of a substance (e.g., drug of abuse or medication) or a general medical condition, is not better accounted for by brief psychotic disorder or other Axis I or II, DSM-IV disorder

Abbreviation: DSM-IV, Diagnostic and Statistical Manual of Mental Disorders, 4th edition.

Source: Courtesy of DSM-IV.

exaggerated startle response, or motor restlessness. The criterion is specifically vague, as there are numerous ways hyperarousal can manifest in ASD.

#### **Distress Level (Criterion F)**

For diagnosis, the symptomatology disturbance must: (i) cause clinically significant distress or impairment in social, occupational, or other important areas of functioning, or (ii) impair the individual's ability to pursue some necessary task, such as obtaining assistance or mobilizing personal resources by telling family members about the traumatic experience.

#### **Duration of Symptoms (Criterion G)**

The disturbance must last for a minimum of two days to a maximum of four weeks and must occur within four weeks of the traumatic event to meet the criteria for ASD. Disturbances lasting beyond the four-week period become categorized as PTSD, providing the other criteria (see subsequently) are also present.

#### **Absence of Other Etiologies (Criterion H)**

The disturbance must not be due to the direct physiological effects of a substance (e.g., a drug of abuse or medication) or a general medical condition, and must not be better accounted for as a brief psychotic break, or an exacerbation of a pre-existing Axis I or Axis II DSM-IV disorder. Differential diagnosis can be difficult due to the high

prevalence of psychiatric comorbidities (i.e., major depressive and anxiety disorders) that may pre-exist or co-occur with PTSD.

## **POST-TRAUMATIC STRESS DISORDER (PTSD)**

### **Overview**

The factors underlying PTSD development are multiple, complex, and not entirely understood. These include pre-trauma individual differences (i.e. psychological, neurobiological, and genetic), peritrauma variables (e.g., characteristics of the trauma, responses to the event), and post-trauma factors (i.e. biological and environmental).

The DSM-IV criteria for the trauma exposure necessary for PTSD (Table 2) is identical to that required for ASD, and can usually be made based on clinical interview alone. However, if an evaluation of treatment efficacy is being conducted or prolonged therapy is contemplated, the diagnosis should be confirmed by a trained mental health professional.

### **DSM-IV Diagnostic Criteria**

#### **Exposure (A<sub>1</sub>) and Response (A<sub>2</sub>) to Traumatic Stressor (Criterion A)**

To fulfill the DSM-IV (Criterion A<sub>1</sub>) for PTSD, the person had to be exposed to a catastrophically traumatic event involving actual or threatened death or physical harm to him/herself or others (Table 2). The general injury types can be divided

**Table 2** Post-traumatic Stress Disorder: Diagnostic Criteria

Criterion	Name	Description
Criterion A1	Involvement proximity and type of trauma	The person had to see or learn about a trauma that involved: Actual or threatened: death, serious injury, or violation of the body of self or others
Criterion A2	Reaction to trauma	The person had to react to the trauma with: Intense fear, Hopelessness, or Horror
Criterion B	Re-experiencing symptoms	Five ways trauma can be relived. Only one is required for diagnosis: Recurrent, intrusive recollections of the event Recurrent, distressing dreams of the event Acting or feeling as if the trauma were recurring [i.e., dissociative hallucinations, illusions, flashbacks, (including those occurring upon awakening or when intoxicated)]. Intense psychological distress upon exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event Physiological reactivity upon exposure to such internal or external cues
Criterion C	Avoidant symptoms	At least, three of these seven avoidance symptoms must have developed since the trauma, for diagnosis: Efforts to avoid thoughts, feelings, or conversations associated with the trauma Efforts to avoid activities, places, or people that arouse recollection of the trauma Inability to recall important aspects of the trauma Markedly diminished interest or participation in significant activities Feeling of detachment or estrangement from others Restricted range of affect (e.g., unable to have loving feelings) Sense of foreshortened future (does not expect to have a career, marriage, children, or a normal life span)
Criterion D	Persistent increased arousal symptoms	At least, two of five types of persistent increased arousal must be experienced for diagnosis, with onset since the trauma: Difficulty falling or staying asleep Irritability or outbursts of anger Difficulty concentrating Hypervigilance Exaggerated startle response
Criterion E	Duration of symptoms in B, C, and D	The symptoms of PTSD from criteria B, C, and D must be experienced for one month for diagnosis. Given this, the diagnosis of PTSD cannot be made prior to 1 mo after the trauma
Criterion F	Distress level	If all the criteria above are met, for the diagnosis of PTSD to be made, the symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning

*Abbreviations:* DSM-IV, Diagnostic and Statistical Manual of Mental Disorder 4th edition; PTSD, post-traumatic stress disorder.

*Source:* Courtesy of DSM-IV.

into three groups: (i) intentional (including combat, abuse, criminal acts, and torture), (ii) unintentional human acts (e.g., industrial accidents, MVC), and (iii) surgery (the secondary harm is unintentional, though the surgery is intentional); and acts of nature, (e.g., hurricanes, tornados, floods, earthquakes, etc.). Traumas in the intentional category (especially involving interpersonal violence) are known to cause higher rates of PTSD than traumas in the other two categories.

Having been exposed to the trauma is not sufficient to meet DSM-IV criteria; the person must also have reacted to the trauma with intense fear, hopelessness, and/or horror (Criterion A<sub>2</sub>).

### **Re-experiencing Symptoms (Criterion B)**

The re-experiencing (Criterion B) symptoms associated with PTSD describes a condition where “to remember is to relive.” That is, when survivors are remembering the

trauma they are actually reliving it in their mind, complete with the full emotional impact. Indeed, PTSD is very much a derangement of memory, where recollections of the trauma intrude on the person against their will. Common re-experiencing symptoms include recurrent and intrusive recollections that involve images, thoughts, or perceptions of the trauma, as well as illusions, flashbacks, or distressing dreams of the event (as described above for ASD)(Table 2). Only one re-experiencing/reactivating symptom cluster is required to fulfill Criterion B.

☞ **Intrusive recollections are unwanted and unintentional memories of the trauma event that force themselves into awareness, and in so doing evoke panic, terror, dread, or grief.** ☞ Vivid nightmares in these patients are particularly troublesome because sleep difficulties are also specifically associated with PTSD (Criteria D), due to increased arousal symptoms. Although the subject matter is trauma-specific, these nightmares are otherwise subject

to the same distortions and characteristics associated with normal dreams. Flashbacks can be particularly devastating because the individual feels as though the traumatic event is actually occurring again.

☞ **Triggers (e.g., experiences, sounds, smells) can generalize to such an extent that what is initiating a flashback years after the event may not appear on the surface to be connected in any way to the original trauma.** ☞

In PTSD, the term “trigger” refers to anything that might initiate the recurrence of a memory or a re-experiencing symptom. These include any sensory experience, (i.e., the smell of gunpowder or fire, the sound of helicopters or gunshots). Anniversaries of previous traumas new stressful events associated with strong emotions can also trigger intrusive recollections. Initially, the triggers are obviously related to the trauma. Eventually, conditions that trigger a response become blurred and generalized (e.g., a woman may develop a fear of flying after going on a trip where she ran into someone who resembled her rapist) through a process of trigger generalization.

### **Avoidant Symptoms (Criterion C)**

The Criterion C symptoms are “avoidant” in nature. Indeed, trauma survivors with PTSD will go out of their way to avoid anyone or any thing that reminds them of the trauma. Amnesic symptoms, with inability to recall important parts of the trauma, are experienced by many. The structural alteration of biological memory centers (i.e., hippocampus, amygdala), along with HPA axis dysregulation provides the anatomic neurohumoral explanation of why memory gaps of the event occur.

In addition, individuals can lose their ability to feel strong emotions or participate in meaningful interpersonal relationships. In order to fulfill Criterion C, the trauma survivor must experience at least three of seven specific avoidant symptoms (Table 2). Since a wide range of avoidant symptoms can occur, trauma survivors can present with a variety of cognitive, affective, and behavioral symptoms as part of avoidance mechanisms.

As with ASD, depressive symptoms (including restricted affect, anhedonia, detachment from others) can be experienced. Trauma survivors with PTSD often relate a sense of foreshortened future and beliefs that the positive aspects in life are unattainable. From an interpersonal perspective, these symptoms are particularly troubling, as they contribute to a decreased social support system when it is most needed.

### **Hyperarousal Symptoms (Criterion D)**

While the individual’s effect may be flattened, arousal levels are characteristically elevated. At least two of the five types of persistent hyperarousal symptoms listed in Table 2 must be present to fulfill Criterion D. Symptoms resemble those seen in panic and generalized anxiety disorders, including emotional irritability, concentration difficulties, and sleep disturbances. An exaggerated startle response to innocuous stimuli is common and may be one of the most pathognomic symptoms of PTSD. Hypervigilance is characteristic, with a sense that once something so horrible has been experienced, “constant guard” must be maintained during surveillance for anything even remotely similar.

These increased arousal symptoms are psychobiologically mediated. The amygdala and other structures frequently send out “beware of trauma” signals, which in PTSD are not appropriately suppressed by the higher-level

brain functions of the MpFC, resulting in high levels of arousal, emotionality, and hypervigilance. This is exemplified by combat veterans who talk about “walking the perimeter” at night and rape survivors who refer to keeping watch when “things just aren’t safe.”

Hyperarousal behaviors can include anger, hostility, and self-destructive behavior (e.g., acting out, dangerous behavior, substance abuse, etc.). Emotional reactivity can escalate to the level of rage and can be misdiagnosed as bipolar disorder, antisocial behavior, or erroneously attributed to agitated depression.

### **Duration of B, C, and D Symptoms (Criterion E)**

The PTSD criteria B, C, and D symptoms must be experienced for at least one month to fulfill Criterion E of DSM-IV diagnostic requirements for PTSD. This does not mean that trauma survivors manifesting these symptoms cannot be identified or receive treatment prior to one month. Indeed, many patients can be identified early as having ASD, and with proper treatment, may not progress to full PTSD.

### **Distress (Criterion F)**

In addition to the above criteria (A–E), for the diagnosis of PTSD to be made, the symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

### **Additional DSM-IV Specifiers**

PTSD is labeled “acute,” if the symptoms are of less than three months in duration and modified as “chronic,” if persisting beyond three months. Delayed onset PTSD can occur if the symptoms do not appear until six months or more after the trauma. Finally, the symptoms of PTSD must have developed since the trauma. Pre-existing symptoms are excluded from the diagnostic criteria.

“Complex” PTSD refers to PTSD symptoms that develop after extreme traumas, including childhood sexual abuse, torture, captivity, and other prolonged horrific experiences. In addition to the typical PTSD symptoms, complex PTSD is associated with substantial risk for other psychiatric comorbidities and can cause severe emotional dysregulation, dissociative symptoms, and increased risk for suicide.

### **Instruments to Assist in Diagnosis**

In clinical studies, rigorous evaluations are time intensive and require specially trained staff. The gold standard for comprehensive evaluation is the Clinician Administered PTSD Scale (CAPS). Due to its statistical validity, intervention literature typically reports CAPS scores for diagnosis, severity, and improvement measurements (84,85).

### **The Post-traumatic Stress Disorder Checklist—Civilian**

The PTSD Checklist-Civilian (PCL-C) is the clinical assessment instrument that can be used in the process of any mental health evaluation. It has shown correlations with the CAPS of over 0.9 in diagnostic and overall severity ratings (86). The PCL-C is an instrument developed by the National Center for PTSD Behavioral Science Division (87). Patients are asked to rate the severity of impact in the last month (on a scale of 1–5) for 17 PTSD symptoms (Table 3). Questions 1 to 5 refer to re-experiencing symptoms, 6 to 12 are avoidant in nature, and 13 to 17 focuses on hyperarousal symptoms. For critically ill trauma patients, these questions can be asked as soon as the “high-risk” patient becomes capable of answering questions. Although the PCL-C is

**Table 3** The Post-traumatic Stress Disorder Checklist—Civilian

Question/symptom	1	2	3	4	5
1. Repeated, disturbing memories, thoughts, or images of a stressful experience from the past?					
2. Repeated, disturbing dreams of a stressful experience from the past?					
3. Suddenly acting or feeling as if a stressful experience were happening again (as if you were reliving it)?					
4. Feeling very upset when something reminded you of a stressful experience from the past?					
5. Having physical reactions (heart pounding, trouble breathing, sweating) when something reminded you of a stressful event of the past?					
6. Avoiding thinking about or talking about a stressful experience from the past or avoiding having feelings related to it?					
7. Avoiding activities or situations because they remind you of a stressful experience?					
8. Trouble remembering important parts of a stressful experience from the past?					
9. Loss of interest in activities that you used to enjoy?					
10. Feeling distant or cut off from other people?					
11. Feeling emotionally numb or being unable to have loving feelings for those close to you?					
12. Feeling as if your future will somehow be cut short?					
13. Trouble falling or staying asleep?					
14. Feeling irritable or having angry outbursts?					
15. Having difficulty concentrating?					
16. Being “super-alert” or watchful or on guard?					
17. Feeling jumpy or easily startled?					

Note: Rating, scale of 1 to 5.

Abbreviations: 1, not at all; 2, a little bit; 3, moderately; 4, quite a bit; 5, extremely.

specifically designed to evaluate the overall symptom burden, it has also been used as a general guide to monitor therapy in PTSD patients (88).

### Trauma History Screen

A trauma patient's prior history of ASD/PTSD is generally unknown to SICU staff. The Trauma History Screen (Table 4) was developed for patients who are not critically ill; however, the 12 questions (or selected items as appropriate) can be asked by the critical care nursing staff to determine the emotional impact of prior events on the trauma survivor. The information gathered from this screen helps to determine if a subsequent full mental health evaluation for ASD or PTSD should be conducted.

## EARLY RECOGNITION OF POST-TRAUMATIC STRESS DISORDER

Most critically ill trauma patients will by default meet ASD/PTSD Criterion A<sub>1</sub>. If the patient's response to this event included significant horror or helplessness (Criterion A<sub>2</sub>), the patient has both of the necessary prerequisites to diagnose ASD (symptoms <1 month) or PTSD (symptoms >1 month). Initially, trauma patients may not be able to convey their feelings about the event due to intubation and/or sedation. However, once the patient recovers and begins to follow commands, inquiries about the patient's emotional status should be sought.

In addition to the PCL-C and trauma history screen (mentioned above), the Impact of Events Scale (IES) can be used to measure early ASD/PTSD symptoms. Ideally this should be done at least, once prior to hospital discharge

(8,77). The IES is a well-validated 15-item symptom scale that measures subjective distress (related to intrusion and avoidance) surrounding traumatic events. The IES appears to be a very useful early screening tool in the acute care setting.

### Trauma-Associated Risk Factors for Developing Acute Stress Disorder/Post-traumatic Stress Disorder

#### Prior Traumatic Exposure

Pretrauma factors have a significant influence on which patients develop PTSD following physical trauma. A major risk factor for developing PTSD is the experience of a previous traumatic stressor. In one study of Vietnam combat veterans, 37% of those with PTSD had a history of severe childhood abuse, while only 7% of those without PTSD had such a history (89). ⚡ **When previous trauma includes interpersonal violence, either as a child or adult, the risk of developing PTSD is particularly high following exposure to subsequent trauma.** ⚡ Domestic violence is another situation where numerous prior victimization factors increase the likelihood of developing PTSD. In one urban county medical facility for survivors of domestic violence, a two-year sample revealed that nearly 70% of the population met diagnostic criteria for PTSD (91).

#### Peritrauma Factors

⚡ **Peritrauma factors increasing the risk of PTSD development fall into three categories: characteristics of the trauma, survivor reactions, and psychosocial support.** ⚡ Although the degree of trauma is difficult to quantify, in general PTSD frequency and intensity increase with greater severity, duration, and repetitions of trauma events. Factors of the trauma

**Table 4** Trauma History Screen

Instructions: These events may or may not have happened to you. Answer "Yes" if that kind of thing has happened to you and "No" if it has not

Event	Yes	No	If you answer YES, indicate the number of times something like that happened to you
1. A really bad car, boat, train, or airplane accident			
2. A really bad accident at work or home			
3. A hurricane, flood, earthquake, tornado, or fire			
4. Getting beat up or attacked—as a child			
5. Getting beat up or attacked—as an adult			
6. Forced sex—as a child			
7. Forced sex—as an adult			
8. Attack with a gun, knife, or weapon			
9. During military service, seeing something horrible or being badly scared			
10. Sudden death of close family or friend			
11. Seeing someone badly hurt or killed			
12. Some other event that scared you badly			

Answer the following questions for each event that happened to you, if it bothered you emotionally

Question	Answer	
1. When this happened, did anyone get hurt or killed?	Y	N
2. When this happened, were you afraid that you or someone else might get hurt or killed?	Y	N
3. When this happened, did you feel very afraid, helpless, or horrified?	Y	N
4. When this happened, did you feel unreal, spaced out, disoriented, or strange?	Y	N
5. After this happened, how long were you bothered by it?	a. Not at all, b. 1 wk, c. 2–3 wk, days $\geq$ 1 mo	
6. At the time, how much did it bother you emotionally?	a. Not at all b. A little c. Somewhat d. Much e. Very much	

associated with higher PTSD risk include: (i) intentional trauma, (ii) being wounded, (iii) seeing others killed (especially loved ones, particularly when the survivor is responsible for the death of another), and (iv) repetition or feared repetition of the trauma. **Perceived threat to life (92) and injury due to penetrating trauma (93) are consistently identified as major predictors for the development of PTSD.**

The presence of three or more ASD symptoms from the re-experiencing and hyperarousal categories has been found to be an accurate and strong predictor of future PTSD development (80).

Survivor reactions which include physiological hyperarousal and/or dissociation in the peritrauma period comprise the highest risk group for long-term symptoms, and are more likely to dissociate during traumatic reminders in the future (94,95).

Decreased or limited psychological and social support after a trauma is a major (underappreciated) risk factor for PTSD. This issue is further complicated in the critical care setting. The support systems and coping mechanisms that the patient relied on during the pretrauma phase can be disrupted. Characteristics of the SICU environment (e.g.,

constant noise, lights, unfamiliar people, frequent treatments, etc.) must be considered when evaluating the impact of critical care on the psychobiology of the survivor.

Other factors associated with greater risk of developing PTSD include: pre-existing mental health conditions, genetic predisposition, high levels of chronic stress, poor coping skills, lack of education, emotional immaturity, female gender, and family history of mental illness.

### Predicting Likelihood of Acute Stress Disorder/ Post-traumatic Stress Disorder

Despite a large body of literature, predicting which patients will develop ASD and PTSD remains an illusive task. Several studies have shed important light, however, on this process and certain factors are known to increase the likelihood of developing ASD in accident victims. These include: prior trauma, stay in an ICU/CCU, pre-existing psychiatric disorders, perceived threat to life, appraisal of accident severity, preventability of accident, pain, and prognosis for physical recovery (96,97).

In women who were assaulted as adults, two factors predicted greater PTSD severity even after treatment: previous

childhood trauma and sustaining physical injury during adult trauma (98). Younger age is also frequently cited as a risk factor for developing PTSD; a study of 400 adolescent trauma victims showed a long-term PTSD rate of 27% (99). Gender itself is a predictor; women develop significantly more PTSD than men, given the same trauma exposure. In a study of MVC survivors, 23% of females developed ASD compared to 8% of males, and PTSD was diagnosed in 38% of females and 15% of males. Females also had higher rates of dissociative symptoms; and, ASD like PTSD has a higher predictive value for females across all age groups (100–104).

Several studies have shown the presence of delusions in acutely traumatized patients as a significant predictor of developing ASD and PTSD. Factual memories of difficult trauma are less associated with PTSD than are delusions. In one study, well more than half of ICU patients had delusional memories of their ICU treatment and up to 10% had no factual memories of their time in the ICU/CCU (105).

In a study of burn patients, acute levels of anxiety, depression, and avoidant symptoms strongly predicted symptom levels at three months postburn. Perceived threat to life during the burn also predicted severity, but objective burn severity did not (106). In another study more than a quarter of burn patients were symptomatic in the first month, and 15% remained positive for PTSD at one year (107). Similarly, in MI survivors, perceived severity of MI predicted PTSD, while the actual severity did not (108).

In a large SCI study, perceived threat to life was a significant predictor of PTSD levels. Death awareness, pain level, and spiritual/religious coping were also significant predictors (109). In an orthopedic trauma sample, patients who answered yes to the question, “Do the emotional problems caused by the injury cause more difficulty than the physical problems?” had a very high correlation with the presence of PTSD (63). In accident victims, some evidence suggests that extended periods of trauma-induced unconsciousness actually decreases rates of PTSD (110).

Providing written information about psychological recovery from ICU stay was not shown, in one study, to be effective as a stand-alone intervention in decreasing patient or relative stress, anxiety, or PTSD rates (111). Further, studies are warranted regarding the efficacy of written educational interventions in the early post-trauma period in preventing PTSD.

### Diagnosis and Evaluation in the Trauma/Surgical Intensive Care Unit Setting

Referral for mental health evaluation in the emergency department (ED) is rare, but more common when physicians are satisfied their institution provides qualified mental health services (112). Requests for formal psychiatric evaluation is similarly rare in the critical care setting, partly because psychiatrists are perceived as not being particularly receptive to interviewing patients in the SICU. This impression should be changed, as screening and awareness of ASD, PTSD, and post-traumatic depression is very important for the patient’s ultimate recovery. **Trauma surgeons and intensivists should develop a level of expertise in counseling patients with these disorders, in addition to requesting early psychiatric consultation when appropriate.**

The successful SICU/trauma center will require education of all staff as well as advanced collaboration with mental health professionals. SICU studies show that rates

of detection for mental health conditions are far less than the actual occurrence, and when diagnoses are made by critical care clinicians, there is low correlation with objective psychiatric assessment, (113) although diagnostic accuracy improves when the case specificities are more typical (114).

For the purpose of evaluating those at risk for PTSD, evaluations within the first week are sometimes futile. However, at one-week post-trauma, most studies show that a reasonable assessment can be made, providing the patient is awake and cooperative. In one relatively large-scale study it was found that surgical ward PTSD symptoms (though too early to meet DSM-IV criteria) were strong predictors of PTSD symptoms over the course of the year after injury (7). The one-week post-trauma time frame provides some guidance for trauma providers to determine when more formal evaluation and intervention might be warranted.

### POSTINJURY DEPRESSION

Depression and PTSD are highly correlated. Depression has been found in numerous studies of trauma victims to be the most prevalent psychiatric condition occurring with PTSD (59). The associative mechanisms between PTSD and depression are not well understood. Current evidence suggests that pre-existing depression may render an individual more vulnerable to PTSD; conversely the presence of PTSD may increase the risk of depression. Studies also suggest that the PTSD/depression combination that occurs after a trauma is different from generalized depression post-injury that occurs without PTSD (115).

Some of the most in-depth studies of depression in critical care settings have been conducted on coronary artery bypass graft (CABG) patients. Typically, 20% of these patients are depressed. Depressed patients also have a higher late mortality (116–118) and a higher subsequent cardiac event rate (27% vs. 10% for nondepressed patients) (119,120). Depression one-month postsurgery was found to be a major indicator of cardiac morbidity five years later (121).

The subject of depression is of considerable clinical importance in traumatized populations, given the significance of depressive comorbidity in determining treatment options. Relationships between PTSD and postinjury depression (and other mental health sequelae) are becoming increasingly understood, but additional research is required to identify predictive patterns.

### ACUTE STRESS DISORDER/POST-TRAUMATIC STRESS DISORDER TREATMENT

**Treatment goals in PTSD are aimed at: reducing core symptoms, improving stress resilience, improving QoL, and reducing disability and comorbidity.**

Early on, patients and families should be educated about why PTSD develops, the expected responses to trauma (psychological and physical), and that treatment is available to assist in the healing process. Education should be given in a way that is practical and easily understandable. Follow-up resources should be provided, as well as how and when to access needed support services.

For the SICU patient, recognition of risk factors, early symptom identification, management of distressing symptoms [pharmacological and nonpharmacological, and

minimizing potential triggers (e.g., reducing loud noises, approaching the patients calmly)] are important initial interventions.

### Early Interventions

Though many people show early signs of distress following a trauma most will resolve their symptoms and adapt within three months. This text deals with patients mainly in their first days and weeks following trauma. Those who have not resolved their symptoms by three months are at greatest risk for developing severe, chronic PTSD; their treatment should be coordinated by a mental health professional trained in managing PTSD (122,123).

### Single Session Psychological Debriefing Is Worse Than No Debriefing

Psychological debriefing (PD) refers to the process of engaging in a single session with trauma survivors or witnesses, either individually or in groups. PD was previously advocated for stimulating emotional processing and normalizing reactions. After reviewing its implementation over many years, there is no evidence for PD effectiveness in preventing future psychopathology (124,125), and in several replicated studies, PD has been shown to actually exacerbate subsequent PTSD symptoms (126). Most experts have called for ceasing single session psychological debriefing interventions (64).

Critical Incident Stress Debriefing (CISD) is a common form of PD for families and loved ones of trauma victims. Originally intended for use with emergency medical services (EMS) personnel, its use has widened to other areas of trauma treatment. Cessation of CISD as a secondary PTSD prevention measure is supported by scientific review of the available data (128,129). Techniques for dealing with families and loved ones of trauma survivors are provided in Volume 2, Chapter 64.

### Cognitive Behavioral Therapy ≥ 4 sessions

Controlled trials of brief Cognitive Behavioral Therapy (CBT) for recently traumatized individuals has shown great promise in functioning as a secondary prevention for PTSD. The initial trial compared assault victims who completed a four-session course of CBT with evaluation only controls. The treatment patients showed significantly less PTSD and depression symptoms two months postassault and a strong signal for a similar difference at 5.5 months (130). In another trial of five session CBT versus supportive counseling for MVC and industrial accident survivors with ASD, those who completed the brief CBT showed significant benefit with lower rates of subsequent PTSD and depression (131).

### Psychological First Aid

Prior to September 11th, the American Red Cross and most other multinational relief agencies were not routinely providing psychological first aid (132). PTSD support researchers BA Hong, CS North (both from the Washington University, St. Louis, Montana, U.S.A.), were at that time developing an organized plan for the mental health needs of disaster survivors called "Project CREST"(132). Findings from studies of survivors of the September 11th 2001 terrorist attacks were coupled with those from survivors of the Oklahoma City bombing and experience of B. Pfefferbaum (University of Oklahoma) to develop a "Practical Front Line Assistance and Support for Healing<sup>®</sup>" (P-FLASH<sup>®</sup>). This is an

empirically based rapid mental health intervention program suitable for use in disaster settings.

The focus of this front-line counseling (also known as "Psychological First Aid") is current symptom reduction and/or issue resolution. There are six major elements of front-line counseling (Table 5). These symptom reduction techniques are most relevant to acute trauma treatment and are likely to be helpful in both the prehospital setting as well as the TRS.

✎ The patient and family (when appropriate) should be made aware that there is a normal biological basis for their symptoms and be reassured that treatment options are available to help them. ✎

### Symptom Management

Symptom management tools can have an immediate impact and can be taught by health care providers. The tools described below can often be implemented in the SICU as symptoms arise. The tools and skills are divided into two sets, based on the symptoms they address. The Criterion B (Re-experiencing), and D (Hyperarousal) symptoms have a specific set of treatment tools. The Criterion C (Avoidant symptoms) has a different set of management tools.

### Post-traumatic Stress Disorder Criterion B (Re-experiencing) and D (Hyperarousal) Management

Symptom management tools for Criterion B (Re-experiencing) symptoms are provided in Table 6. In general, relaxation techniques and other nonpharmacologic treatments are preferred. Muscle relaxation skills first became a tool for stress reduction in the 1920s when it was shown that stress could be maintained in muscles, and that it was nearly impossible to remain stressed or anxious and be relaxed at the same time. Relaxation skills are typically

**Table 5** Psychological First Aid: For Survivors of Trauma<sup>a</sup>

Element	Key points of psychological first aid
Supportive listening	Being present and demonstrating interest in listening to the patient is paramount.
Education and reassurance	Provide the patient with knowledge that ASD and PTSD symptoms are natural, understandable, and treatable.
Coping and stress management	Suggest nonpharmacological therapy first (e.g., sleep meditation, exercise, and relaxation training).
Problem solving	Refrain from pejorative counseling. Rather, use objective problem solving capabilities. Help them untangle their web of problems.
Finding meaning and perspective	Without imposing one's own belief-system on the patient, help them describe and find their own perspective.
Observation and reassessment	Continued observation and reassessment is required—patients may have a delayed onset of symptoms as well as intermittent set backs and exacerbations.

<sup>a</sup>Tools such as this may be most suitable for dealing with large casualty situations (e.g., Hurricane Katrina, 2005; Indian Ocean Tsunami, 2004).  
Abbreviations: ASD, acute stress disorder; PTSD, post-traumatic stress disorder.

**Table 6** Post-traumatic Stress Disorder Criterion B (Re-experiencing) and D (Hyperarousal) Symptom Management Tools

Management tools	Examples and comments
Skeletal muscle relaxation	Series of muscle group relaxation techniques: The process: Muscle groups are tensed, then relaxed in sequence as shown in Table 7.
Abdominal breathing	Instructions: Lay, supine, and calm, right hand on abdomen and left hand on chest. Both hands raise and fall with each breath. Diverts focus from PTSD trigger to abdominal breathing. Can be used during ventilator weaning (see text).
Guided imagery	Helps patient create a “safe place” (for mental refuge from the PTSD trigger). Use of a guided script helps change mental focus to a calming, relaxing one.
Systematic desensitization	A process of gradually exposing patients to stressful images and thoughts while they utilize a relaxing skill. Potentially dangerous (professional oversight recommended).
Thought stopping	A distraction technique used to overcome distressing thoughts by inwardly or outwardly shouting, “stop” as these thoughts are called to mind.
Cognitive reframing	A process of restructuring cognitions or conclusions, which have been drawn as a result of the trauma. Reframing assists the patient to develop a different, reality based cognition of the event.
Sleep hygiene	This refers to the optimal conditions in which to sleep and induce good (i.e., restful) sleep without nightmares.

*Abbreviation:* PTSD, post-traumatic stress disorder.

taught in two forms, skeletal muscle relaxation and breathing techniques.

Skeletal muscle relaxation is a process that involves intentional skeletal muscle tensing, followed by relaxation in a sequential and repetitive fashion. The skill can be quickly taught and begins helping immediately. The entire process is described in Table 7, can be completed within several minutes. Muscle relaxation training must take into account the patient’s physical condition and associated fractures or dislocations, etc.

Considerable stress, tension, and anxiety can be maintained in the muscles of respiration and in the abdominal muscles. Abdominal breathing instructions are provided in Table 6. The abdominal breathing relaxation exercise can even be practiced by most mechanical ventilation dependent SICU patients when they have improved to the weaning phase guided imagery, systematic desensitization, thought stopping, cognitive reframing, and sleep hygiene are additional Criterion B and D management tools (Table 6).

Sleep hygiene is particularly important and relevant to the SICU, and refers to attempts at ensuring post-trauma

**Table 7** The Short Muscle Group Relaxation Process

Tense the muscles as listed below. Hold the tension for 5 sec then relax for 15 sec, before proceeding to the next set of muscles. Do them in the order listed here.

Tighten both fists. Flex your arms all the way in, tightly.

With head back, scrunch up the muscles of your face. With neck muscles tightened, roll your head clockwise then counterclockwise.

Shoulders up, jaw clenched.

Arch your back gently, tense your back muscles and breath in deeply and hold.

Toes up with tight shin and calf muscles.

Toes down with tight calf, thigh and buttock muscles.

*Note:* Muscle tensing relaxation training must take into account the patient’s physical condition and the other effects the muscle tension may have on body systems.

patients have normal restful sleep. Sedatives/hypnotics should be considered when the patient experiences difficulty in falling or remaining asleep.

**Post-traumatic Stress Disorder Criterion C (Avoidant Symptom) Management**

For the Criterion C (Avoidant) symptoms, treatment can be very complex. Because the manifestation of avoidant symptoms often involves major volitional components (i.e., deciding to stay home), avoidant symptoms are some of the most difficult PTSD symptoms to treat, and some of the worst in terms of long-term prognosis. Many of these symptoms may not emerge until the patient has left the SICU. Avoidant symptoms cause people to shun treatment, withdraw, and become unemotional. Trauma systems should have outreach programs to follow-up on those patients that fail to return to clinic (these may be the patients in greatest need). Selected tools for managing Avoidant (Criterion C) symptoms are provided in Table 8; many of these patients will also require antidepressant medications.

**Acute Stress Disorder Criterion B (Dissociation) Interventions**

Grounding techniques (Table 9) help to keep patients “in the present” when they are experiencing dissociative symptoms. The dissociation can take the form of flashbacks or alteration of one’s sense of self, but distortions of awareness of space, time, and location are particularly in acute need of grounding. Grounding tools used in the acute trauma setting help to return the patients’ awareness to the present from a dissociated state. These techniques can be performed by the bedside nurse and include sensory and cognitive grounding skills, which are described in Table 9.

**Psychotherapy**

Psychotherapy for PTSD can take many forms, including typical insight oriented therapy, CBT, and desensitization therapies (Table 10). Meta-analysis of studies from 1980–2003 of psychotherapy for PTSD showed that, as a whole, most patients treated with psychotherapy either recover or improve with treatment; however, a majority of patients continue to have substantial residual symptoms (133).

**Table 8** Post-traumatic Stress Disorder (PTSD) Criterion C (Avoidant) Symptom Management Tools

Management tools	Examples and comments
Positive memory anchoring	Allows the patient to focus on a positive memory in their life that they can recall at any time. Helps switch out of an intrusive traumatic memory. Facilitates reconnection to positive events.
Resuming past positive activity	Helps overcome the psychobiological pressure to avoid all emotions. Involves engaging in previously pleasurable activities (chosen by the patient) without any association with the trauma.
Reconnecting with important relationships	Helps the patient heal the disruption in social interaction that develops with PTSD. Reconnection should occur in a safe setting. The safe setting (not associated with the trauma) helps avoid creating associations between significant relationships and the trauma.
Emotional literacy	Helping the patient to experience emotions not related to the event helps them acknowledge the existence of emotions outside the trauma. This skill encourages patients to recognize and identify sad and happy events in their life prior to the trauma. Eventually the patient should acknowledge these emotions in their current experience.

**Cognitive Behavioral Therapy**

CBT is a common and effective technique utilized in PTSD patients, and is probably the most researched intervention for treating post-traumatic symptoms. In one example study, MVC survivors were evaluated in a controlled trial of CBT versus supportive therapy. At one year follow-up, the CBT group met diagnostic criteria for PTSD significantly less than the control group (134). Another study of nearly 100 MVC survivors with PTSD found that 11% of those treated with CBT remained positive for PTSD at nine months, whereas 61% of those given a self-help booklet covering the same CBT information remained diagnostic for PTSD, demonstrating the importance of ongoing psychiatric intervention in this population (135).

Exposure based CBT techniques include: (i) gradual exposure, (ii) flooding, and (iii) systematic desensitization, which are used to help the patient confront the avoided fears directly. By exposing a person to traumatic memories in the safe setting of therapy, and usually combined with stress reduction techniques, the overwhelming fear is reduced or eliminated. Compared to other psychotherapies for PTSD, patients tend to follow-up with exposure-based CBT to about the same degree as with others (136).

**Eye Movement Desensitization and Reprocessing**

Eye movement desensitization and reprocessing (EMDR) is an evolving therapy for PTSD (Table 10). EMDR are thought (by

**Table 9** Acute Stress Disorder Criterion B (Dissociative Symptoms) Interventions: Sensory and Cognitive Grounding Skills

Type of intervention	Examples and comments
Sensory grounding skills	Provides physical sensations, which will help the patient return their awareness to the present. These tools are facilitated by the bedside nurse <i>Examples</i> Open eyes, look at something; identify details of object Hold something; concentrate on physical sensation of touch Place a cool cloth on face; be aware of the cold sensation Listen to music that maintains awareness Place feet firmly on the ground; become aware of the sensation in feet and legs Focus on someone else’s voice or concentrate on details in conversation
Cognitive grounding skills	The SICU nurse asks the patient a series of orientation questions. Later the patient is encouraged to ask themselves Where am I? What is today? What is the date? How old am I? What was the most recent holiday?

*Abbreviation:* SICU, surgical intensive care unit.

some) to be analogous to rapid eye movement (REM), sleep related eye movements, and thereby could serve as a stress reducing function similar to sleep. Elements of exposure therapy are combined with physical actions (e.g., saccadic eye movements) in EMDR. Review of the randomized clinical trials of EMDR indicates symptom improvement duration of between three and nine months, but comparison study findings are equivocal with numerous methodological variations and small sample sizes (137,138).

**Group Therapy and Brief Psychodynamic Psychotherapy**

Survivors without major avoidant symptoms may feel more comfortable sharing their experiences and feelings with others who have been through similar events. Group therapy can help resolve issues of trust and improve interpersonal relations.

Brief psychodynamic psychotherapy focuses on the emotional aspects of the trauma, including their relation to early life experiences. Telling “one’s story” and exploring the trauma in an empathic, nonjudgmental setting has been shown to have psychologic benefit in the aftermath of trauma.

**Drug Therapy**

Medication usage (Table 11) is best implemented when PTSD has been evaluated and a formal diagnosis has been made. Symptom severity should be initially assessed and serial measurements made to help to monitor the treatment process. The PCL-C is included in this chapter (Table 3), and allows for initial and repeated evaluation of PTSD severity from both a specific and global perspective by

**Table 10** Post-traumatic Stress Disorder Psychotherapy Methodology

Type of therapy	Examples and comments
CBT	<p>The cognitive part of CBT addresses cognitions (mental conclusions drawn about the self, the world, and other people). With PTSD some cognitions become distorted.</p> <p>CBT works when the therapist helps reorder cognitions for the patient.</p> <p>The behavioral parts of CBT consist of skills training to cope with anxiety, anger, stress reactions, and to relate effectively with others.</p>
EMDR	<p>Elements of exposure therapy are combined with physical actions (e.g., eye movements).</p>
Group therapy	<p>Some survivors may feel more comfortable sharing their experiences and feelings with others who have been through similar events.</p> <p>Can help heal issues of trust and interpersonal relations.</p> <p>Focuses on how members are successfully coping, which helps bring positive attention to the here and now.</p>
Brief psychodynamic psychotherapy	<p>Explores the trauma in an empathetic, nonjudgmental setting.</p> <p>Focuses on the emotional aspects of the trauma, including their relation to early life experiences.</p>

*Abbreviations:* CBT, cognitive behavioral therapy; EMDR, eye movement desensitization and reprocessing; PTSD, post-traumatic stress disorder.

interrogating 17 areas, which address the triad of avoidant, arousal, and re-experiencing symptoms.

### Initial Pharmacotherapy (First Month)

Medication is typically used within the first month for patients who have already had some other kind of intervention such as psychological first aid, CBT, or other individual or group therapy following trauma. No medications have yet been Food and Drug Administration (FDA) approved for ASD treatment, and treatment guidance is mainly extrapolated from PTSD studies.

Prior to receiving medication for ASD/PTSD the patient should receive thorough psychiatric and medical evaluations. In the critical care settings, collaborative assessment is required to determine which symptoms and findings are due to current medications, delirium, brain injury, or other nonpsychiatric etiology, and which are likely attributable to the ASD/PTSD spectrum of symptoms.

In general, two populations of acutely traumatized patients should receive medication: (i) those who have received a therapy oriented intervention but remain symptomatic; and (ii) those who have symptoms that in themselves warrant immediate pharmacological intervention, such as patients who are dangerous (suicidal or homicidal), extremely agitated, or exhibiting psychotic symptoms.

Symptoms of extreme arousal, including severe anxiety, panic, hyper-vigilance, and insomnia, typically require acute

medication. In the past, high potency neuroleptics such as haloperidol were used for early symptom reduction. In current practice some of the atypical antipsychotics (i.e., olanzapine, risperidone, and quetiapine) are legitimate considerations since they have shown robust effects on PTSD symptoms, and are highly effective in reducing agitative symptoms.

Benzodiazepines, which decrease acute anxiety, have been shown to decrease anxiety in ASD/PTSD (139). Benzodiazepines are frequently and effectively used for initial symptom management in the acute trauma/critical care setting. Benzodiazepines, however, are of limited value in treating core symptoms, and with prolonged use, have actually been associated with an increase in the rate of PTSD development (140). Benzodiazepines must be used cautiously, due to their abuse potential and withdrawal symptoms with discontinuation.

Alpha-2 agonists (e.g., clonidine), and both alpha-1 and beta-adrenergic blocking agents (e.g., prazosin and propranolol respectively) have been used successfully to decrease symptoms of hyperarousal in ASD/PTSD. One trial has shown a secondary PTSD prevention effect in patients who received a 10-day course of propranolol beginning within six hours of the event (141,142). Each of these agents must be used with caution in the critical care patient due to effects on cardiovascular functioning. Clonidine, and the newer  $\alpha_2$  agonist, dexmedetomidine may be particularly useful (research pending).

Selective Serotonin reuptake inhibitors (SSRIs) are the pharmacologic agents of choice in treating PTSD. SSRI antidepressants have shown efficacy in reducing symptoms in all three-symptom clusters, (Criteria B, C, and D) in multiple double-blind and open-label studies. ⚡ **Although no medications are approved for ASD, sertraline, and paroxetine do have FDA indication for PTSD.** ⚡ These agents are usually well tolerated with a low incidence of side effects. SSRIs are a first line treatment for PTSD after acute crisis management, and in conjunction with continued psychological therapy. Dosage of these medications should start low and be increased slowly with close monitoring of symptom response. Similar to their effect in anxiety disorders, SSRIs can cause CNS activation and anxiety in PTSD when first started or when doses are increased. Full effect of SSRI treatment takes from weeks to a few months and the magnitude of improvement may be insufficient to achieve full PTSD symptom resolution.

### Maintenance Pharmacotherapy (After First Month)

After the first month, if PTSD symptoms either remain or develop, full psychiatric assessment is warranted. If PTSD or significant subsyndromal PTSD is present, a comprehensive treatment plan must be implemented. Acute trial literature indicates that either psychotherapy or psychopharmacology alone may leave significant residual symptoms even when effective (143). The most powerful combination is probably medication and psychotherapy, in conjunction with education and family support.

Only two medications (sertraline and paroxetine) have FDA approval for treatment of PTSD, but studies with other SSRIs and serotonin norepinephrine reuptake inhibitors (SNRIs) have also shown improvement. In addition to being first line pharmacotherapy for PTSD (144,145), the SSRIs are also useful in treating conditions, which frequently arise or coexist with PTSD (e.g., depression and panic disorder), and are effective in decreasing aggression and impulsivity. Beyond these medications, there is no definitive

**Table 11** Drug Therapy for Post-traumatic Stress Disorder Symptomatology

Type	Drug	Examples and comments
Initial (first month)	Benzodiazepines	Used to decrease anxiety in ASD/PTSD. Should only be used briefly, if at all; other drugs may have a lower incidence of subsequent PTSD development.
	Antiadrenergics	Have been used successfully to decrease symptoms of hyperarousal in chronic PTSD.
	Clonidine	
	Propranolol	Must be used with caution in the critical care patient due to effects on cardiovascular functioning.
	Prazosin	
Maintenance (after first month)	SSRIs	Have shown effectiveness in improving PTSD symptoms in all three-symptom clusters, (Criteria B, C, and D). Full effect from SSRI treatment takes from weeks to a few months.
	Setraline (Zoloft <sup>®</sup> )	
	Paroxetine (Paxil <sup>®</sup> )	
	SSRIs	First line pharmacotherapy in PTSD.
	Setraline (Zoloft)	U.S. FDA approved—effective in all three clusters of PTSD symptoms, in civilian and combat populations, in men and women, and in short-term and long-term studies.
Chronic	Paroxetine (Paxil)	
	Tricyclic antidepressants	Second line treatment after SSRI failure.
	Benzodiazepines	Do not specifically treat PTSD symptoms, but assists in anxiety and sleep improvement in the short-term.
	Antiadrenergic agents	Decrease hyperarousal symptoms.
	Prazosin	Prazosin showed beneficial effect on nightmares in combat related PTSD.
	Clonidine	
	Anticonvulsants/mood stabilizers	Useful in patients who are labile, impulsive, or aggressive.
	Atypical antipsychotics	Effective in acute psychiatric crisis. Atypical antipsychotics may be appropriate for patients with significant fear, hyper vigilant, paranoid, or psychotic PTSD symptoms.
	Risperidone	
	Olanzapine	
Quetiapine		
Chronic	SSRIs	Success shown using SSRIs for more than one year for the treatment of PTSD and prevention of relapse. Patients with a quick and robust response to treatment may need a shorter duration of therapy.
	Setraline (Zoloft)	
	Paroxetine (Paxil)	

*Abbreviations:* ASD, acute stress disorder; PTSD, post-traumatic stress disorder; SSRIs, selective serotonin reuptake inhibitors; U.S. FDA, United States Food and Drug Administration.

empirical evidence to guide second-line choices. Suggestions in the literature are made based on data available (146).

Twelve-week sertraline studies have shown 23% to 26% PTSD remission rates (147). Evaluating nearly 400 patients in sertraline trials, the average dose for response in PTSD was 125 mg and in PTSD with comorbid depression 147 mg daily. Average time to response was 4.5 weeks in PTSD and 5.5 in PTSD with comorbid depression (148). In depression, sertraline can be started as high as 100 mg daily. In PTSD, a starting dose of 50 mg is prudent; this may be decreased to 25 mg if necessary in order to reduce adverse effects, which are typically dose related.

Paroxetine has been well studied and shown to be effective in all three clusters of PTSD symptoms, in civilian and combat populations, in men and women, and in short- and long-term studies (149). In a landmark study, PTSD patients treated for one year with the SSRI paroxetine were shown to have an increase in hippocampal volume of 5% and an associated 35% increase in verbal declarative memory functioning (150). Effective doses of paroxetine are usually between 20 to 60 mg daily, often with a 10 mg starting dose.

Tricyclic antidepressants (TCAs) were used extensively prior to the introduction of SSRIs. They are still used in PTSD with SSRI failure, but remain second line due to their negative side effect profile, and their significantly increased lethality in overdose (151). There is also renewed

interest in reversible monoamine oxidase inhibitors (MAOIs) with several studies showing promise in reducing PTSD symptomatology.

Benzodiazepines do not specifically treat PTSD symptoms, but may assist in anxiety and sleep improvement in the short-term (2–4 days). With prolonged use (greater than one week), there is a possibility of increasing the rate of PTSD development, possibly through blurring of reality with sedation-related dreams. Buspirone, has been studied (open label) as an alternative to benzodiazepines, and holds promise as an effective antianxiety agent in PTSD.

Antiadrenergic agents have shown to benefit treating hyperarousal symptoms and may be appropriate for patients with significant arousal or dissociation. Prazosin has been studied in combat PTSD, showing a beneficial effect on PTSD nightmares (152,153). Propranolol has shown some potential for use in the emergency department with acutely traumatized patients to reduce the acute stress response. Early administration may decrease future physiological reactivity to trauma stimuli and PTSD development.

Anticonvulsant/mood stabilizer medications have been used for some time in PTSD. These agents may be particularly useful in patients who are significantly labile, impulsive, or aggressive (154). Open label studies have shown positive results with carbamazepine, (155) valproic acid, (156,157) topiramate, (158) phenytoin, (159) and

gabapentin (160,161). A small double-blind placebo-controlled study also supported the efficacy of lamotrigine (162). Valproic acid has been widely used in Veterans Administration (VA) treatment of combat-related PTSD. Dosing typically targets serum levels similar to those used for seizure control.

Atypical antipsychotics are effective for treating patients in acute psychiatric crisis. Atypical antipsychotics may be also be appropriate for patients with significant fear, hypervigilant, paranoid, or psychotic PTSD symptoms. Olanzapine has been studied in oral (PO) and intra-muscular (IM) formulations for stabilizing severely agitated patients (163–165). Olanzapine has shown efficacy in all three symptom clusters (166), and in treatment-resistant, combat-related PTSD (167,168). Doses up to 20 mg daily were studied in these chronic populations, while short-term use of doses as low as 2.5 mg daily were found effective in torture victims with acute PTSD (169). Risperidone has been studied in doses from 0.5 to 8 mg daily as monotherapy or more typically as an augmentation to an already stable regimen (170). The most typical dosing is between 2 and 6 mg daily in divided doses (171,172). Quetiapine has also shown symptom improvement in doses ranging from 75 to 300 mg (173,174). Psychotic symptoms in PTSD are not rare, and are particularly debilitating, given the overall symptom burden. Often, these symptoms go undetected due to the patient's reluctance to admit psychotic experiences (175).

### Postsymptom Medication Continuation

☞ **Medication continuation beyond the symptom period may be prudent in PTSD, in order to reduce or prevent relapse.** ☞ Recent SSRI studies suggest that longer continuation therapy (at least one year) should be considered in treating PTSD. In a study of patients stabilized on sertraline within 36 weeks, those who continued on medication for an additional 28 weeks showed a 5% relapse rate compared to a 26% rate for patients who had been switched to placebo (176,177). Other studies have also supported the extended use of SSRIs for improved response rates and PTSD relapse prevention. Patients who have a very quick and robust response to treatment may need a shorter duration of therapy. As with other SSRI use, gradually tapering is suggested.

### Multimodal Treatment

Multimodal treatment therapies may prevent or lessen PTSD symptoms. Combined therapeutic modalities may include, among others: CBT, pharmacotherapy, and collaborative care. In one study that compared patients who received standard therapy to those who received collaborative care, the latter showed decreased PTSD symptoms after one year as well as a 24% decrease in alcohol abuse. Usual care patients showed an increase in PTSD symptoms and a 13% increase in alcohol abuse (178).

### Non-traditional Therapies

Based on research conducted in trauma survivors, several nontraditional therapies have shown promise (Table 12). Writing about one's emotional aspects of trauma has been shown to produce measurable changes in physical and mental health (179). Prospective diaries have resulted in greater understanding of events and responses in the SICU, and have helped patients and families set more realistic goals for recovery (180).

**Table 12** Novel and Emerging Therapies

Type of therapy	Examples and comments
Writing exercises	Writing about the emotional aspects of trauma organizes thoughts, forces analysis. As little as 15–20 min/day for 3–4 days has produced measurable improvements in physical and mental health.
Meditation	Can help develop an accepting attitude of thoughts or emotions that arise during treatment. Effective in reducing chronic pain, stress, and anxiety in patients undergoing medical treatment.
VRET	VRET helps recreate trauma conditions such as combat and offers new potential in re-exposure therapy. VRET has been shown in small trials to decrease symptoms in all three clusters.
Hypno-therapy	Used in patients trying to access memories they cannot consciously recall or are too emotional to recall. No formal RCTs have shown hypnotherapy to be a beneficial treatment.
Peritrauma cortisol dosing	Recently, supplemental cortisol administration has been known to be protective of PTSD in certain populations. In a study of 91 patients undergoing cardiac surgery, half received a stress dose of hydrocortisone during the perioperative period and showed significant reduction of chronic stress and PTSD symptoms at 6 mo postsurgery.

*Abbreviations:* PTSD, post-traumatic stress disorder; RCTs, randomized clinical trials; VRET, virtual reality exposure therapy.

Meditation has been studied in numerous medical populations. Meditation has been shown to be effective in reducing chronic pain, stress, and anxiety in patients undergoing medical treatment (181). In postsurgical breast and prostate cancer patients, meditation-based stress reduction increased QoL, decreased stress, and had a potentially beneficial impact on the HPA axis functioning (182).

Virtual reality exposure therapy (VRET) helps recreate trauma conditions (e.g., combat) and offers new potential in re-exposure therapy. VRET has been shown in small trials to decrease PTSD symptoms in all three clusters (183,184). It has been used to treat survivors of the September 11 World Trade Center attack (183) and Vietnam veterans (184). The U.S. Navy is currently funding further research on VRET in veterans. VRET has not been tested in the SICU.

Hypnosis has been used for over a century in the attempt to treat post-traumatic symptoms. To date, no formal, randomized clinical trials have been completed to support its use as a definitive treatment in PTSD (185).

Another recent form of treatment is "Acceptance and Commitment Therapy." This is a therapeutic method designed to reduce experiential avoidance. It has been validated in randomized clinical trials to decrease self-harm among women with Borderline Personality Disorder (186), and in treating polysubstance abuse (187). It may be well suited for the use in PTSD populations (188).

Recently, supplemental cortisol administration has been shown to be protective of PTSD in certain populations of patients. In a study of 91 patients undergoing cardiac

surgery, half received a stress dose of hydrocortisone during the perioperative period and showed significant reduction of chronic stress and PTSD symptoms at six months postsurgery (189). The same researchers completed similar studies on long-term survivors of ICU treatment, again showing a protective effect from a stress dose of cortisol (57,190). Another study of septic shock treatment showed promising results for hydrocortisone in reducing PTSD symptoms in these patients (191). Currently however, there is insufficient evidence to support the use of cortisol in PTSD prophylaxis.

**LONG-TERM FOLLOW-UP**

**Observation and Reassessment During the First Month Following Trauma**

Formal diagnostic assessment typically requires a week to have passed since the trauma. The suitability of the patient for psychiatric evaluation depends on many factors, including the level of critical care being received, the potential for further traumatic interventions, prognosis for recovery, psychological state, and willingness to participate in therapy. Serial formal assessments in high-risk patients provide data for longitudinal evaluation of the patient’s condition and effectiveness of treatment. Collaborative efforts between in hospital and outpatient providers are essential to reduce the number of patients who drop out of treatment or are lost to follow-up.

**Formal Post-traumatic Stress Disorder Screening and Diagnosis After the First Month**

Screening for PTSD requires at least a month to have passed since the initial trauma. The setting a patient is in at the time of screening will have a significant impact on how formal screening is implemented. The National Center for PTSD promotes the Primary Care Screen (PC-PTSD) (192). The screening is designed for maximal sensitivity and is easily administered by appropriately trained healthcare providers at all levels. The screen consists of four questions (Table 13) that address the symptoms of hyperarousal, avoidance, and intrusive recollections. This screening is considered positive when the response to question three or any other two answers are positive.

**Table 13** Post-traumatic Stress Disorder: Primary Care Screen

In your life, have you ever had any experience that was so frightening, horrible, or upsetting that in the past month, you:	Yes	No
1. Have had nightmares about it or thought about it when you did not want to?		
2. Tried hard not to think about it or went out of your way to avoid situations that remind you of it?		
3. Were constantly on guard, watchful, or easily startled?		
4. Felt numb or detached from others, activities, or your surroundings?		

*Note:* This screening is considered positive in two cases. First, if any two or more questions are answered yes, it is considered positive. Second, if question three is positive, even by itself, the screening is considered positive.

*Source:* From Ref. 1.

**Prolonged Critical Illness and Post-traumatic Stress Disorder**

✎ Factors associated with prolonged critical illness may play a causative role in PTSD, and critical illness may, of itself, be considered a traumatic event. ✎ The severity and number of traumas experienced in the hospital setting can be the nidus for PTSD or increase the likelihood of its development. For example, compared to all patients who experience myocardial infarction, those who suffer cardiac arrest are almost three times as likely to develop PTSD (193).

Critical care interventions need to be implemented with the utmost consideration for the psychobiological impact. This is especially important in situations, which may be perceived as a threat to life (e.g., invasive procedures). Clinician interventions, such as calming presence, simple and clear explanations, and remaining with the patient following treatment may help to mitigate anxiety and reduce the perceived level of threat. Pharmacotherapy with sedatives and antianxiety agents should be used as appropriate.

**Permanent Disability and Post-traumatic Stress Disorder**

Permanent disability adds another significant level of impact to the patient. In the case of someone who recovers from a severe MVC, the person can feel as though they are disabled and permanently broken. This can be due to the severity of the PTSD symptoms, which causes disability in itself, or it can be a cognitive distortion. Those who experience both a life threat and a traumatic loss are at highest risk for PTSD and for symptom severity (194,195).

Perceived threat to life has been noted in many traumatized populations to be strongly associated with PTSD development (92). Some large studies of war survivors have shown that PTSD rates of disabled trauma survivors are similar to nondisabled survivors (196). A study of disabled foreign war veterans who were treated in substandard rehabilitation facilities found that the PTSD rate more than doubled in five years and was related to inadequate social support at home and deficient psychological care (197).

Even though depression is common with PTSD, the depression rate for disabled patients with PTSD is even higher, and the associated suicide risk is increased as well (198). In physically disabled patients, there will be a significant period of grieving the loss of functionality during which recovery from ASD/PTSD symptoms may not be possible.

In studies of SCI patients PTSD symptoms can impact methods of adaptation to disability e.g., shock, anxiety, denial, depression, internalized anger, externalized hostility, acknowledgment, or adjustment (199). In this population, death anxiety is highly correlated with total post-traumatic stress levels experienced (199).

**Importance of Long-Term Follow-Up Care**

Long-term follow-up is essential to identify patients who are initially asymptomatic, or with latent PTSD onset (200). A study of 231 men who required trauma services due to interpersonal violence found that while the need for mental health services to treat their PTSD was high, the use of these services outside the acute care setting was low (200). Psychoeducation is required to increase the number of people who take advantage of the services they need. Critical care providers are in a unique position to provide brief, but powerful screenings, education, and referrals for specialized

care and follow-up. Web-based education programs can help facilitate education and outreach for patients and families (201).

In relation to physical symptoms, trauma survivors with PTSD have significantly higher than normal rates of somatization, including conversion symptoms and chronic pain, even when compared to traumatized patients without PTSD (202–204). They are also at higher risk for developing physiological illnesses. Combat veterans with PTSD were found in a large study to have biological markers associated with cardiovascular and autoimmune inflammatory disorders (205).

Follow-up care providers must keep this in mind as they reassess for both physical and psychological effects of the trauma. Somatic complaints can lead to a seemingly endless series of medical evaluations and procedures. If the potential for a post-traumatic somatization etiology is not considered among the differential, the true cause of the symptoms may never be identified.

## EYE TO THE FUTURE

Although many risk factors for ASD and PTSD have been identified, much still needs to be learned. Very little is currently known about the interaction of specific injury event-related phenomena and treatment in the prehospital, resuscitation, SICU, and rehabilitation phases of trauma care. For example, although PTSD onset is common after MVCs that result in serious injury, it is not yet known what specific collision or prehospital conditions, such as crash severity or extrication time, are significant risk factors. Also unknown is whether the contribution of resuscitation and trauma treatment, such as the role of specific drug treatments and environmental conditions during the treatment and institution of invasive procedures, are harmful or beneficial to the early development of ASD and subsequent PTSD. In conjunction with the elucidation of risk factors for ASD and PTSD, further research efforts must also be directed toward evaluating the efficacy of treatment protocols in trauma patients. Hypocortisolemia may become one of the diagnostic markers for PTSD (206). Furthermore, cortisol or hydrocortisone therapy may be used in patients with high risk for PTSD. Indeed, the use of stress doses of hydrocortisone in high-risk cardiac surgical patients reduces perioperative stress exposure, decreases chronic stress symptoms, and improves health-related QoL at six months after cardiac surgery (190, 207).

In the resuscitation and critical care settings, relatively little is known about the efficacy of combined pharmacological and psychological therapeutic approaches to treatment. The elucidation of effective early intervention therapies to control early ASD symptoms during hospitalization will be a crucial focus of future research in order to decrease or eliminate ASD and PTSD onset.

The strong association of PTSD with significant long-term deficits in QoL and functional status after serious injury further underscores the importance of early secondary prevention and effective treatment addressing the physical, psychological, and emotional responses to traumatic injury. Patients treated in the advanced trauma care setting may receive optimal clinical care, but may not be able to return to preinjury QoL without advances in awareness of psychiatric pathology, long-range trauma care, and rehabilitation and support services.

## SUMMARY

Recent research has begun to elucidate the pathophysiology of ASD/PTSD and has increased our understanding of trauma on the brain's emotional and memory centers. An evolving understanding of the neurobiology of PTSD recognizes that structural changes in limbic system structures (chiefly hippocampus and the amygdala) along with neuro-hormonal changes in the HPA system are involved in the pathophysiology. The complex psychological and emotional factors that contribute to an individual's resiliency and adjustment following trauma are just now becoming elucidated. When making the formal diagnosis of ASD, PTSD is important for formulating proper treatment decisions, educating patients, and for research purposes. However, subdiagnostic acute stress symptoms constitute another important area of concern due to the physical and emotional distress to the patient, and the increased likelihood of progression to ASD or PTSD, if unchecked.

✎ **Although patient wishes regarding mental health intervention should be honored, formal diagnostic evaluation is indicated whenever ASD or PTSD symptoms are present and causing significant distress.** ✎ Practitioners caring for these patients should inform the patient and family about the common nature of the symptomatology in highly traumatized individuals. The symptoms and diagnoses should be destigmatized, given the high frequency with which these symptoms arise in trauma survivors who have experienced or perceived a major threat to their life or that of a loved one.

When patients are experiencing symptoms that are distressing, or causing functional impairment, specific treatment is warranted. ✎ **Optimum interventions for ASD and PTSD are symptom-targeted and should be individualized to the patient's phase of illness and overall clinical condition.** ✎

From the trauma survivor's perspective, PTSD symptomatology is often viewed as being far more significant than the nonpsychiatric medical and physical conditions resulting from injury. Accordingly, trauma care systems must adopt a more comprehensive conceptualization of trauma that extends beyond their fundamental *raison d'être* (saving lives), and addresses the associated life-altering consequences of traumatic injury. Comprehensive trauma systems must be responsive, not only to the immediate physical outcomes, but also to the long-term emotional, psychological, and social outcomes of severely injured individuals.

## KEY POINTS

- ✎ PTSD is a psychiatric ailment resulting from an individual experiencing or witnessing of an actual or potential life-threatening event.
- ✎ Research on trauma survivors cared for in U.S. Trauma Centers reveals that 10% to 40% develop symptoms of ASD and PTSD (1–8).
- ✎ Structural changes occur in the brains of patients whose PTSD symptoms have been allowed to persist untreated for too long.
- ✎ Four integral components of the limbic system are specifically involved in the pathophysiology of ASD/PTSD.

- ♀ Individuals with PTSD have dysregulation of the HPA axis (resulting in lower than normal cortisol levels), as well as an elevated basal adrenergic tone.
- ♀ The initial resuscitation, anesthesia, and critical care experiences may contribute (negatively or positively) to the development of ASD/PTSD.
- ♀ In one large study of critically ill patients the risk of PTSD was directly correlated with the duration of mechanical ventilation and inversely related to patient age (67).
- ♀ Trauma outcomes researchers have consistently identified PTSD as a significant factor in functional limitations and diminished QoL above and beyond the medical comorbidities associated with their physical wounds (7,62–67,69,70).
- ♀ The diagnosis of ASD symptoms helps to identify patients at risk for PTSD, in quantifying the severity of distress suffered by the trauma survivor during the first month following the event.
- ♀ Dissociative symptoms contribute to discontinuities in memory, identity, and perception; these are required for the diagnosis of ASD but not PTSD. Re-experiencing, avoidant, and hyperarousal symptoms are characteristic of both entities.
- ♀ Intrusive recollections are unwanted and unintentional memories of the trauma event that force themselves into awareness and, in so doing, evoke panic, terror, dread, or grief.
- ♀ Triggers (e.g., experiences, sounds, smells) can generalize to such an extent that what is initiating a flashback years after the event may not appear on the surface to be connected in any way to the original trauma.
- ♀ When previous trauma includes interpersonal violence, either as a child or adult, the risk of developing PTSD is particularly high following exposure to subsequent trauma.
- ♀ Peritrauma factors increasing the risk of PTSD development fall into three categories: characteristics of the trauma, survivor reactions, and psychosocial support.
- ♀ Perceived threat to life (92) and injury due to penetrating trauma (93) are consistently identified as major predictors for the development of PTSD.
- ♀ Trauma surgeons and intensivists should develop a level of expertise in counseling patients with these disorders, in addition to requesting early psychiatric consultation when appropriate.
- ♀ Treatment goals in PTSD are aimed at: reducing core symptoms, improving stress resilience, improving QoL, and reducing disability and comorbidity.
- ♀ The patient and family (when appropriate) should be made aware that there is a normal biological basis for their symptoms, and be reassured that treatment options are available to help them.
- ♀ Although no medications are approved for ASD, sertraline and paroxetine do have FDA indication for PTSD.
- ♀ Medication continuation beyond the symptom period may be prudent in PTSD, in order to reduce or prevent relapse.
- ♀ Factors associated with prolonged critical illness may play a causative role in PTSD, and critical illness may, of itself, be considered a traumatic event.
- ♀ Although patient wishes regarding mental health intervention should be honored, formal diagnostic evaluation is indicated whenever ASD or PTSD symptoms are present and causing significant distress.

- ♀ Optimum interventions for ASD and PTSD are symptom targeted and should be individualized to the patient's phase of illness and overall clinical condition.

### INTRODUCTION

Patients who survive massive trauma and critical illness must not only overcome the initial injury but also the profound debilitation of many other organ systems during their recovery. For example, orthopedic spine injuries may cause paralysis (with its multiple ramifications); pulmonary contusions may lead to severe acute respiratory distress syndrome and prolonged ventilatory dependence; and hemorrhagic pancreatitis will often cause anemia, as well as metabolic and nutritional complications. Organ systems not directly injured by the trauma may also become impaired following critical illness. For example, renal failure may develop from radio-contrast dye, hypotension, aminoglycosides, or immunosuppressant therapy. ICU psychosis may result from sleep deprivation and drug withdrawal, or the administration of multiple psychoactive compounds. Even in excellent specialized trauma units, critically ill patients may develop derangements in the hematological, endocrine, metabolic, and immunological systems. Furthermore, all patients confined to bedrest for prolonged periods of time will suffer deconditioning of cardiovascular and musculoskeletal systems and become susceptible to decubitus ulcers, deep venous thrombosis (DVT), muscle weakness, and joint contractures. All of these systems must be rehabilitated for optimum outcomes to occur.

☞ **The overall goal of rehabilitation is to achieve maximum restoration of the patient's physical, psychological, social, vocational, recreational, and economic functions within the limits imposed by the trauma, critical illness, or any other pre-morbid deconditioning that may have occurred.** ☞ Successful rehabilitation requires a dedicated multidisciplinary team working together toward the above stated goal. This multidisciplinary team includes the physicians, nurses, physical therapists (PTs), occupational therapists (OTs), speech and language pathologists, respiratory therapists, social workers, psychiatrists, vocational counselors, and the patient and family.

This chapter focuses upon the key role played by PT and OT teams during rehabilitation from trauma and critical illness. The review begins by defining the scope of practice for both PTs and OTs. Next, the consequences of prolonged bedrest and deconditioning are discussed. The methodology utilized to complete a formal PT and OT needs assessment, as well as the criteria for monitoring and discharge planning are then discussed. Specific rehabilitation for various organ system injuries are also provided, as

are important age-specific guidelines. The psychological hurdles that must be overcome for successful rehabilitation in the intensive care unit (ICU) are thoroughly presented, and factors affecting overall patient outcomes are summarized thereafter. Recently developed and emerging ideas for rehabilitation are presented in "Eye to the Future" section. The benefits of early rehabilitation following trauma and critical care are emphasized throughout this text.

### PHYSICAL AND OCCUPATIONAL THERAPIES DEFINED

#### Physical Therapy

☞ **PT involves the identification, prevention, correction, and rehabilitation of acute or prolonged movement dysfunction of any etiology.** ☞ The musculoskeletal, neuromuscular, and cardiopulmonary systems are most often impacted by trauma and/or critical illness (1). PTs assess the physiological factors that may contribute to any movement dysfunction, as well as the previous and current levels of gross motor function. The involvement of the various impairments is considered, while formulating goals and treatment plans that are instituted by the primary PT and the PT assistant. Just as in other specialties, the realm of rehabilitation medicine is replete with specific jargon and a large list of commonly employed abbreviations (Table 1). The ultimate PT goal is to maximize patients' gross motor function and achieve independent functional mobility. As integral members of the ICU team, PTs provide input to the primary service and critical care physicians through direct communication, during rehabilitation rounds, and through documentation, thus ensuring maximum progress for the patient.

Initiation of the PT process in the ICU is analogous to "jump-starting a car's battery," in order to prepare the patient for more aggressive PT in the future. Patients who are unable to actively participate in PT cannot be treated as aggressively as interactive patients. However, treatment goals will be established to prevent the secondary complications of prolonged bedrest. After ensuring maximum range of motion (ROM), contracture prevention, and caregiver education, the PT's next goal is rehabilitation of the patient's gross motor skills. In the ICU setting, these skills relate to functional mobility, including rolling, moving to and from supine and sitting, and transfers from bed to chair and back. In many instances, the initiation of gait training coincides with recommendations for the use of support devices such as an ankle foot orthotic. Assistive devices may be issued for out of bed activities.

**Table 1** Common Physical Therapy and Occupational Therapy Abbreviations

Abbreviation	Definition
Weight-bearing status:	
NWB	Non-weight bearing
TDWB	Touch-down weight bearing (<10%, unless otherwise stated)
PWB	Partial weight bearing (25 or 50%, unless otherwise stated)
WBAT	Weight bearing as tolerated
FWB	Full weight bearing
Adaptive equipment:	
w/c	Wheelchair
FWW	Front wheeled walker
PUW	Pick-up walker
PFW	Platform walker
HW	Hemi-walker
AC or CR	Axial crutches
QC	Quad cane
SPC	Single-point cane
BSC or 3:1	Bedside commode/"three-in-one" commode
Miscellaneous:	
A&Ox4	Alert and oriented to person, place, time, and situation
ADL	Activity of daily living
OOB	Out of bed
WFL	Within functional limits
HEP	Home exercise program
CI	Contraindicated

### Occupational Therapy

OT primarily focuses upon improving patients' abilities to perform activities of daily living (ADLs) and functional mobility. "Occupation" is defined as "specific 'chunks' of activity within the ongoing stream of human behavior, which are named in the lexicon of the culture (2)." In the context of a hospital, the patients' occupations are often limited to basic ADLs such as dressing, bathing, grooming, and self-feeding. Occupational therapists (OTs) use such occupations as therapeutic modalities to allow their patients to regain function, strength, and independence. Important functional mobility addressed by OTs in this setting include: transferring to and from a toilet, moving into and out of a bathtub or shower, as well as sitting and standing while performing ADLs. Other functional activities commonly addressed by OTs include: household management, driving safety, recreation, and work tasks, in addition to addressing various cognitive and psychosocial deficits. Adaptive equipment can be issued to expedite patients' progress toward regaining functional independence. Two commonly employed adaptive equipment devices (the reacher and the sock aide) assist patients with lower body dressing (Fig. 1). Because trauma and critical illness often lead to functional decline in numerous areas, OTs help foster maximal progress toward independence by employing these and other adaptive devices.

Patients in the ICU benefit from early OT intervention by promoting patient participation in ADLs, functional mobility, and cognitive or perceptual activities. OTs can help patients with tasks as simple as face washing or feeding, or with transferring to and from a bedside

**Figure 1** Reacher and sock aide: Both devices are commonly used by patients who are unable or instructed not to bend down during lower body dressing. The reacher can also be used to grab items that are low, high, or outside of the patient's base of support to prevent the need for reaching.

commode. These seemingly trivial activities provide major benefits to critically ill patients by helping them feel more independent. Additionally, the light exercise helps prevent further decline caused by inactivity. The OTs also address fine motor and eye-hand coordination, cognitive impairments, and visual/perceptual deficits, as they are all important components contributing to patients' functional decline. OT assistants also work closely with patients, expanding the range of patient care and providing key information in collaboration with the therapist for setting treatment priorities or revising goals.

Splinting is another important focus of OT. Splints maintain the body in a functional position and prevent the development of contractures. This is especially important for minimally-conscious or sedated patients who are immobile, as they present a higher risk for developing contractures and skin breakdown. Splints can be pre-fabricated or custom-made from thermoplastic or other materials. Splints are most commonly used to protect or support the hands, wrists, and ankles. However, splints can be fabricated for almost any joint, including the neck, knees, elbows, and shoulders. Note that there is some crossover between the interventions performed by OTs and PTs, however the final balance of roles and responsibilities is often institution-dependent.

### CONSEQUENCES OF PROLONGED BED REST AND INACTIVITY

For over sixty years, research has shown that prolonged bedrest is detrimental to a satisfactory post-surgical recovery. Indeed, as early as 1944, a study published in the *Journal of the American Medical Association* stated that physicians should "always consider complete bedrest as a highly unphysiologic and definitely hazardous form of therapy, to be ordered only for specific indications and discontinued as early as possible (3)." The sooner bedrest is discontinued and rehabilitation ordered, the better the patient's prognosis unless the patient has an unstable spine or other injuries requiring temporary immobility.

**Table 2** Preventative Measures to Combat Sequelae of Prolonged Bedrest

Organ system	Potential results of prolonged bedrest and inactivity	PT and OT preventative measures
Cognitive	Decreased cognitive function, confusion, hallucinations	Exercise, activity, daytime orientation
Psychiatric	Depression, anxiety, apathy, decreased pain tolerance	Exercise, activity, sitting, social interaction
Respiratory	Decreased oxygen saturation, pneumonia	Sitting, standing, activity, deep breathing
Cardiovascular	Increased heart rate, decreased aerobic capacity, orthostatic hypotension, DVT, PE	Exercise, AROM, standing, activity, compression devices
Muscular	Weakness, decreased muscle mass, muscle atrophy	AROM, exercise, stretching, activity
Skeletal	Decreased bone density, osteoporosis/osteopenia, fractures	Standing, exercise, weight-bearing, activity
Joints	Contractures, osteoarthritis	AROM, PROM, stretching, splinting
Skin	Pressure ulcers, tissue ischemia	Frequent turning, positioning, splinting

*Abbreviations:* PT, physical therapy; OT, occupational therapy; DVT, deep venous thrombosis; PE, pulmonary embolism; AROM, active range of motion; PROM, passive range of motion.

🦋 **Patients relegated to extended bedrest suffer more secondary disabilities and require longer recovery periods than patients who are mobilized out of bed early.** 🦋

Table 2 provides a summary of conditions resulting from prolonged bedrest and inactivity, along with preventive measures that can be employed by PT and OT. Common morbidities of chronic confinement to bed include musculoskeletal and cardiovascular deconditioning. Other common problems include contractures, decubitus ulcers, and DVTs. Accordingly, it is important to order rehabilitation for patients early in their hospital stay.

### Musculoskeletal Weakness

The wasting and other ramifications of muscle disuse are dramatic and may be long lasting. Within just four hours of strict bedrest, muscles begin to atrophy, exhibiting decreased mass, cell diameter, and number of cell fibers (4). Several studies regarding the effects of bedrest have confirmed that decreased activity in the ICU negatively affects a patient's functional status. In fact, muscle strength declines 1% to 1.5% per day following strict bedrest, and up to 40% after only one week (5–9).

Antigravity muscles, involved in activities such as standing and ambulation, face the highest rate of atrophy for patients on bedrest and without appropriate rehabilitation, these muscles may never return to their original strength (4). Patients subjected to prolonged bedrest are also at increased risk for pathological musculoskeletal damage from falls, especially if standing or ambulating before muscles and bones have sufficiently recovered (4). Osteoporosis is also exacerbated with prolonged bedrest, due to a lack of weight-bearing exercise. This further subjects patients to an increased risk of fractures upon resuming activity (10). Finally, ICU patients may develop new onset neuromuscular disorders, secondary to their critical illness (11). These myopathies, neuropathies, and neuromuscular junction disorders further contribute to the general wasting that occurs with bedrest. These lesions are reviewed in depth in Volume 2, Chapter 6.

### Cardiovascular Deconditioning

Cardiovascular deconditioning is another common accompaniment of prolonged inactivity, reflected by an increase in both the resting heart rate and the heart rate associated with activity. An increase of one half beat to several beats per minute at rest and more than 30–40 beats per minute

during activity can be expected after just a few weeks of inactivity (12,13). Although less dramatic than skeletal muscle atrophy, the cardiac muscle is also subject to atrophy from inactivity. Decreased ventilatory capacity as a result of bedrest and pulmonary pathology further impairs aerobic capacity (10).

However, it is the vascular and orthostatic control systems which are most affected by bedrest. Within only a few days of bedrest, the cardiovascular system adjusts to the decreased work required to pump blood throughout the body due to elimination of gravity's effects. Lying in a horizontal position allows the blood volume to diminish, and the vasculature and responsiveness to decrease. This tends to cause orthostatic hypotension when the patient eventually sits up or stands. Although this is reversed with activity over time, recovery often takes twice as long as it took to develop (14). Symptoms of hypotension are disconcerting and makes the debilitated patient feel lightheaded, and they naturally seek to return to a supine position, which will only lengthen the recovery process further. Encouraging patients to perform simple ADLs themselves can help begin to reverse the inevitable cardiovascular deconditioning and orthostatic hypotension which occur with prolonged critical illness.

### Contractures and Pressure Ulcers

Prolonged bedrest is also a leading factor in the development of joint contractures and skin breakdown (especially in neurologically impaired patients). Contractures limit recovery and contribute to further morbidity. However, they can be prevented if aggressive ROM and splinting programs are initiated early (15). The most common sites for decubitus ulcers are the coccyx, greater trochanters, and heels (10).

Joints should be fully ranged at least twice a day to prevent contracture development. Active range of motion (AROM) is preferred, as this also serves to maintain strength and motor control; however, passive range of motion (PROM) is still effective for patients who are unable or for whom active movement is contraindicated (15). Passive stretching minimizes muscle atrophy and stimulates growth by stabilizing muscles in lengthened positions (16). As part of their treatment plans, PTs and OTs educate patients, nurses, families, and other caregivers about proper PROM and AROM techniques. When patients are taught to perform PROM by themselves, this is referred to as self ROM (SROM). After performing the ROM exercises,

the therapist places the patient in an optimal static position to reinforce the positive aspects of treatment. For example, after cervical stretching of a patient with neck contractures, towel rolls are placed to maintain the neck in an optimal neutral alignment.

Ranging joints and extremities and frequently changing the patients' positioning play important roles in the prevention of decubitus ulcers by stimulating circulation (4). Frequent turning for bed-confined patients and those who are unable to move themselves helps minimize the constant pressure on bony prominences. At a minimum, patients should be turned from side to back to opposite side every two hours, using foam wedges and pillows to maintain appropriate positions; special mattresses are also beneficial for optimizing pressure-relief. Splinting also helps maintain a functional position and optimal tendon stretch, and also helps protect skin from breaking down.

**Deep Venous Thrombosis and Pulmonary Embolism**

Pulmonary embolism is a leading cause of death in trauma patients directly related to inactivity and consequent DVT formation (17). In fact, one study revealed that 13% of bedridden patients developed DVTs (18). For this reason, DVT prevention is critical, with a combined prophylactic approach of anticoagulation, lower extremity compression (through the use of support hose and/or sequential compression devices), and mobilization. Studies have shown that early ambulation for the majority of patients with DVTs is safe (19). Furthermore, ambulation also serves to reduce pain, swelling, and venous stasis associated with DVTs by increasing blood circulation, provided that patients are anticoagulated, and have compression bandages (20,21). Properly elevating a patient's heels—either on pillows or through the use of pressure-relieving orthotics—is another important maneuver, as it returns blood to the central circulation and may aid in decreasing DVTs. Encouraging mobility through early ambulation, therapeutic exercises, and out-of-bed activities help to prevent the development of DVTs by increasing circulation. Refer to Volume 2, Chapter 56 for additional discussions on the ramifications of DVT.

**Other Complications**

Development of aspiration pneumonia and urinary tract infections are additional complications that are commonly associated with complete bedrest in debilitated patients (3,10,22). Additionally, depression and other mood disorders may result from lengthy hospital stays. Learned helplessness is a common condition seen in long-term ICU patients, in which patients become accustomed to others doing even simple tasks for them, such as rolling, feeding, or hygiene (10). Another important complication is the development of an "ICU psychosis" which is characterized as decreased orientation and increased confusion, anxiety, and agitation. When severe, these patients may require antipsychotic medications. The elderly, those who have been sleep deprived, and those withdrawing from alcohol and other drugs are most frequently affected.

All of the above conditions can significantly lengthen a patient's stay in the hospital and prolong overall recovery. By eliminating or reducing the duration of bedrest, patients experience a more rapid recovery with fewer complications. Commencing rehabilitation services while in the ICU improves the outcome and better prepares patients for transferring to a general surgical floor and continuing therapy as they progress, thus resulting in shorter duration

of hospitalization. ⚡ **Ordering PT and OT early in patients' hospitalization will likely decrease medical and functional complications because patients will be stronger, more active, and mentally more interactive, leading to better outcomes.** ⚡

**REHABILITATION NEEDS ASSESSMENT AND MONITORING**

**Initial Evaluation**

Beginning with the initial evaluation, therapists review the patient's needs and rehabilitation expectations from a holistic perspective. The patient's current injuries and illnesses are assessed, noting neurological function, stability of the musculoskeletal system, and cognitive abilities. The patient's prior level of function (PLOF), including any previously needed supportive equipment (e.g., a walker or cane), is considered in order to set realistic goals. The patient's living situation is also evaluated to determine what assistance will be available after discharge and if caregiver or family training will be necessary.

Assessments are made for ROM, strength, sensation, endurance, tone, coordination, and pain. Balance is measured statically and dynamically for both sitting and standing. Mobility tasks are broken down into the basic elements of rolling, transitioning to and from supine, sitting, and standing, as well as transferring to a chair and toilet, gait, and wheelchair mobility. Patients also perform several ADLs, including grooming and hygiene tasks, upper and lower body dressing and bathing, toileting, and self-feeding. To assess cognition, therapists grade patients' orientation, safety and body awareness, judgment, and attention to detail. Refer to Tables 3–6 for examples of objective PT/OT assessment scales used at the UCSD Medical Center.

Once objective data are gathered, goals are set with patient and family input to establish treatment priorities. Appropriate treatment plans are then established to reach

**Table 3** UCSD Grading Scale for Motor Strength

Numeric grade	Letter grade	Abilities of patient
5	N	Full available ROM against gravity and max resistance
4	G	Full ROM against gravity and mod resistance
3+	F+	Full ROM against gravity and min resistance
3	F	Full ROM against gravity; no added resistance
3-	F-	Greater than 50% ROM against gravity; no resistance
2+	P+	50% or less ROM against gravity; no resistance
2	P	Full ROM with gravity eliminated; no resistance
2-	P-	Only a portion of ROM; gravity eliminated
1	T	Contraction can be palpated; no observable movement
0	0	Contraction cannot be palpated; no observable movement

*Abbreviations:* N, normal; G, good; F, fair; P, poor; T, trace; ROM, range of motion; max, maximal; mod, moderate; min, minimal.

**Table 4** UCSD Grading Scale for Sensation

Numeric grade	Definition	Abilities of patient
N	Normal	Able to correctly respond 100% of the time
I	Impaired	Able to correctly respond with inconsistency or incorrect responses
0	Absent	Unable to feel, respond, or patient appears to be guessing

these goals. Goals and treatment plans are modified as needed throughout the treatment sessions. Patient and family education begins during the initial evaluation and continues throughout all treatment sessions. Common goals for patients in an ICU setting include: sitting at the edge of the bed unsupported for 15 minutes, transferring to a chair with moderate assistance and sitting up for two hours, performing grooming tasks independently while seated, and performing simple exercise programs with assistance of the nurse or family.

**Treatment Frequency and Monitoring**

Treatment frequency is determined primarily by the patient’s need for and ability to participate in therapy. At UCSD, both PT and OT typically treat patients once a day, five days a week. Patients with neurological or orthopedic conditions often require more intensive rehabilitation, and

**Table 5** UCSD Grading Scale for Balance

Grade	Static abilities of patient	Dynamic abilities of patient
G+	Takes max challenges, maintains through max excursions of active trunk motion	Maintains through max excursions of active trunk motion
G	Takes mod challenges in all directions	Maintains through mod excursions of active trunk motion (i.e., weight-shifting)
G–	Maintains position with min challenges	Maintains through min excursions of active trunk motion
F+	Maintains position without supervision or cuing	Maintains within base of support
F	Maintains without assistance but unable to take challenges; requires supervision or cuing	N/A—cannot move within base of support without losing balance
P+	Needs min assist to maintain	N/A
P	Needs mod assist to maintain	N/A
P–	Needs max assist to maintain	N/A
U	Needs total assist to maintain sitting without back support	N/A

*Abbreviations:* TG, good; F, fair; P, poor; U, unable; max, maximal; mod, moderate; min, minimal; N/A, not applicable.

**Table 6** UCSD Grading Scale for Independence Levels

Grade	Assistance required
I	Independent
Mod I	Modified independent
S	Supervision
SBA	Stand-by assist
CGA	Contact-guard assist
Min A	Minimum assist (<25% needed)
Mod A	Moderate assist (25–50% needed)
Max A	Maximum assist (50–75% needed)
Dep	Dependent (needs >75% assist)

are therefore seen twice a day and/or on weekends. Patients who are unable to fully participate in daily rehab program, such as those who cannot follow commands or are on strict bedrest, may only be seen by a PT and/or OT professional two to three times a week. However, a plan of care for ROM and positioning is developed with nurses and family members so that these patients can receive daily therapy from the start. Before decreasing treatment frequencies for patients, therapists train family or staff until they can independently perform the exercise programs. Non-responsive patients who are unable to actively participate and need only occasional monitoring until becoming more alert and medically stable are typically followed once a week by PT and/or OT while ICU nurses continue established ROM and splinting programs to prevent secondary complications from developing. Table 7 lists the types of ROM programs.

During treatments, therapists and assistants monitor the patient’s abilities and future rehab needs. Pain and vital signs are assessed before, during, and after treatments, with activities and exercise programs graded accordingly. When pain is a limiting factor for progressing in therapy, patients should be offered pre-therapy analgesia (in coordination with the medical staff). Whenever possible, treatments are spread throughout the day, such as having OT in the mornings to address self-care and PT in the afternoons for gait training. This allows patients to rest between treatment sessions so that they can benefit most from the therapy.

Therapists caring for ICU patients must possess an understanding of various monitors and lines. Frequently used monitors include pulse oximetry, arterial lines,

**Table 7** Range of Motion

Type	Definition	How produced
Passive range of motion (PROM)	When no voluntary movement by the muscle is involved	External force (i.e., mechanical device, third party, or one of patient’s functioning body parts)
Active-assistive range of motion (AAROM)	When a primary contractile muscle uses an external force	Primary contractile muscle and external force
Active range of motion (AROM)	Active contraction of the muscle without an external force	Primary contractile muscle

electrocardiography, intracranial pressure (ICP) measurement devices, intravenous lines, catheters, drains, chest tubes, and naso-gastric or gastric feeding tubes. Caution must also be taken when a patient has a tracheostomy or is orally intubated and on a ventilator, especially during upper body activity. Care is exercised so that tubes and lines are not pulled during activity or by an agitated or confused patient. Information obtained from the monitors can be used to assess cardiopulmonary status and levels of pain, which is especially useful for the minimally-conscious patient who is unable to communicate. For example, an increase in heart rate, blood pressure, or ICP can indicate pain, fear, or anxiety. Similarly, a decrease in oxygen saturation can indicate excessive stress of the activity. Therapists use this information in the clinical decision-making process to determine when and how to progress the patient's plan of care.

### Therapeutic Progression

Therapists try to create a "just right challenge" for their patients (23). Grading treatment activity throughout the session assures that the patients' abilities are challenged but not overly exceeded. This concept refers to balancing the challenge of the task with the person's ability to perform that task. Finding the "just right challenge" ensures that patients do not become either frustrated by failure or bored by not being challenged at all.

With practice, performing activities should become easier as patients' skills improve, allowing the tasks to become more demanding. For example, a common goal in the ICU is for patients to be able to transfer from supine to sitting with only supervision and without using the bed rails. With patients' first attempts at this task, therapists will allow them to pull on the bed rail for rolling to the side and for pushing up when coming to a sitting position. Once this is mastered, patients are encouraged not to use the rail. The ultimate goal is to increase patients' independence without relying on an assistive device, such as the bed rail. Requesting patients to sit up without using the rail during the initial treatment is often too challenging, causing great frustration, a high level of anxiety, and an increased fear of falling out of bed without the protection of the rail. The use of the rail allows patients to learn proper bed mobility techniques (e.g., log-rolling), while having more assistance and security. This is an example of how therapists use graded challenges and assistive devices in the therapeutic progression.

### Rehabilitation and Discharge Planning

✎ **Discharge planning considerations are deliberated during the initial rehab evaluation, even for ICU patients. The more time the patient, family, and medical team have to prepare, the more successful the discharge plan.** ✎ Therapists help to determine whether a patient will likely be safe to return home after being discharged from the hospital. If not, the patient may require continued therapy at an acute rehabilitation facility, a skilled nursing facility, or may need placement at an assisted living or board and care facility. If the patient is being discharged home, therapists help to determine appropriate equipment needs (refer to Figs. 2 and 3 for examples of commonly-issued durable medical equipment). Table 8 lists common discharge destinations from the acute hospital and their rehabilitation criteria.

**Figure 2** Reclining wheelchair.

**Figure 3** Bedside commode, also known as a 3:1 (three-in-one) commode—named for its multiple uses as a portable commode, raised toilet seat, and shower seat.

**Table 8** Common Discharge Destinations and Rehabilitation Criteria

Destination	Rehabilitation criteria
Acute rehabilitation facility	Patient must be able to tolerate 3+ hours/day of aggressive therapies
Skilled nursing facility (SNF)	Therapy often averages 1–2 hours/day
Transitional care unit (TCU)	Intermediate level between acute rehab and SNF
Board and care or assisted living facilities	May or may not offer skilled PT/OT services
Home with home health PT/OT	Patient must be home-bound; therapies often 2–3 visits/week for short period
Home with outpatient PT/OT	Able to go into the community; therapy frequency and duration vary
Home with no needs	Patient is usually independent or at PLOF

*Abbreviations:* PT, physical therapy; OT, occupational therapy; PLOF, prior level of function.

## INJURY-SPECIFIC REHABILITATION CONSIDERATIONS

### Brain Injury

Once the brain-injured patient is medically stable and a physician's order is received, therapists perform their evaluations. The Glasgow Coma Scale is useful for assessing coma following head injuries. However, once patients are awake, a higher level of cognitive function needs to be determined. ⚡ **The Rancho Los Amigos Cognitive Scale provides the most useful and reproducible categorization of cognitive and behavioral status for patients who are awake and interacting with their environment (24).** ⚡ The Rancho Los Amigos Cognitive Scale (Table 9) is composed of 10 levels (24). Each level describes a patient's behavior as the patient progresses from a coma state through and beyond a confused state.

The initial goal of rehab following brain injury is the prevention of secondary complications of inactivity while the patient is recovering. As patients progress into less confused states, therapists provide a daily routine and structured environment while addressing the cognitive and behavioral dysfunctions as they relate to sensorimotor function. Treatments are influenced by cognitive and behavioral status and are focused on improving behavioral management, motor learning, motivation, attention, memory, and motor control.

Consistency in PT/OT training helps improve progress made in rehabilitation from cognitive and behavioral dysfunction. If possible, the same therapist should treat the patient throughout the hospitalization. Therapists must set limits and provide the patient with clear feedback, as well as redirect the patient's attention from sources of anxiety and frustration. Whenever appropriate, therapists include

the patient's interests and/or hobbies in the treatment to promote self-motivation.

The quality of therapy sessions can be improved by reducing outside noise, clutter, light, and the number of persons in the room. At UCSD, a "quiet room" has been designated for patients with brain injuries to facilitate rehabilitation therapy. Soothing music can also quell agitation, and help to focus (the use of music for relaxation is discussed in more detail later in this chapter). Familiar objects and photographs of family members provide a sense of security and assist in facilitating earlier thoughts and memories and should be liberally used in the patient's room.

Conversely, sensory-deprived patients who are categorized with low response levels on the Rancho scale, often benefit from intensive stimulation. One way to facilitate this is by optimizing the patient's environment. For example, altering the position of the bed so activity and patient's interests (e.g., watching television and talking to family and medical staff) take place on the affected, injured, and/or hemiplegic side of the body. Encourage head turning and looking toward the affected side. By using this approach, the affected side is forced to react, thereby increasing sensory stimulation to that side.

Properly positioning patients in bed plays an important role in their functional outcome. In patients with hemiplegia, lying on the affected side may reduce spasticity by elongating the structures of that side, providing added sensory input, and increasing body awareness. ADL performance is also improved because the more skillful hand is free to move and perform activities, (e.g., adjusting the sheets for comfort). Figure 4 illustrates proper bed

**Table 9** Rancho Los Amigos Levels of Cognitive Functioning

No.	Response level	Behavior	Dependency
I	None	Total absence of response to visual, auditory, tactile, or painful stimuli	Total dependence
II	Generalized	Response to repeated auditory or painful stimuli with associated physiological changes, gross body movement, or vocalization	Total dependence
III	Localized	Recognition of auditory or visual stimuli demonstrated by turning of the head or movement of the eyes; inconsistently responds to simple commands	Total dependence
IV	Confused/agitated	Alert, heightened state of activity; performance of motor activities without purpose; aggressive or exaggerated behavior; poor short-term memory	Maximal assistance
V	Confused, inappropriate, nonagitated	Lack of orientation to person, place, or time; ability to consistently respond to simple commands	Maximal assistance
VI	Confused, appropriate	Inconsistently oriented to person, time, or place; ability to attend to familiar task in non-distracting environment for 30 min with moderate redirection	Moderate assistance
VII	Automatic, appropriate	Consistently oriented to person, place; moderate assist to orientation to time; minimal supervision for new learning; unable to think about consequences of an action	Minimal assistance
VIII	Purposeful, appropriate	Consistently oriented to person, place, and time; independently attends to and completes familiar tasks for 1 hour in distracting environment; requires no assistance with newly-learned tasks; self-centered	Stand-by assistance
IX	Purposeful, appropriate	Use of memory devices to recall daily schedules; ability to think about consequences of decisions with assistance when requested	Stand-by assistance on request
X	Purposeful, appropriate	Ability to handle multiple tasks simultaneously in all environments and to recognize consequences of actions; social interaction behavior is consistently appropriate	Modified independence

**Figure 4** Proper bed positioning for patients with hemiplegia. The right side is the hemiplegia-involved (stippled) side. Source: From the International Clinical Educators, Inc.

positioning for hemiplegic patients. The supine position should be avoided as much as possible because it enhances abnormal reflex activity due to tonic neck and labyrinthine reflexes (22).

**Spinal Cord Injury Assessment**

Therapists should perform a standardized American Spinal Injury Association (ASIA) evaluation within the first 72 hours of admission following spinal cord injury (SCI). The ASIA evaluation quantifies both sensory and motor abilities of the patient (Fig. 5) (25). Sensation is assessed through light touch and pin prick, and motor function is assessed through manual muscle testing. This standardized assessment is used to objectively determine the level of SCI. It also predicts the patient’s functional expectations based on that particular level of injury. Refer to

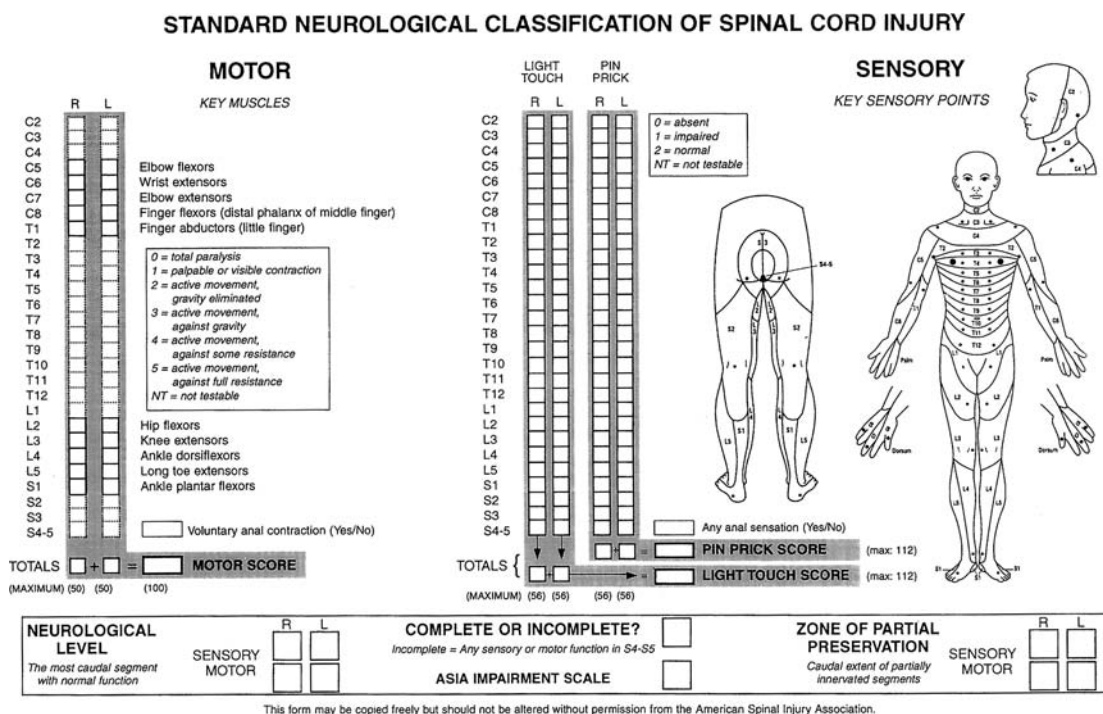

Table 10 for a summary of UCSD’s critical path for the treatment of patients with acute spinal cord injury (SCI).

**Pre-stabilization Phase**

Patients with an unstable spine who are awaiting surgical stabilization or receipt of an orthotic device are referred to as “pre-stabilization.” An activity level of strict bedrest is appropriate during this phase. Treatment in the pre-stabilization phase involves patient and family education in the areas of therapeutic exercise, positioning, and splinting (if needed). One common spine stabilizing brace is the thoracic-lumbar-sacral orthotic (TLSO). The patient is taught AROM exercises and to be the “director” of his/her own care, informing family and staff when and how to perform PROM and positioning. At UCSD, patients are initially placed on a rotating bed, which provides positional changes mechanically while maintaining spinal alignment. Resting hand splints or hand rolls are issued as needed for patients with a high level of SCI. Short opponant splints may be used to facilitate grasp for patients with at least a fair-plus grade in the manual muscle testing in the wrist extensors. Ankle splints are issued to maintain ankle alignment as well as prevent pressure sores from developing at the heels.

**Post-stabilization Phase**

Once the spine is stable, the patient can begin functional mobility and self-care training. The activity level should be definitively declared by physician’s orders as “spine cleared/OK for out of bed.” The patient is often transferred from the rotating bed and issued a bed with a mattress with pressure-relief mechanisms. The initial functional mobility goals are rolling and tolerating an upright/vertical posture. Rolling improves bed mobility and prepares the patient for self-pressure relief and lower body dressing in bed. A gradual progression into the vertical position is

**Figure 5** American Spinal Injury Association scale for assessing level of sensory and motor spinal cord injury.

**Table 10** Critical Path for Rehabilitation Following Acute Spinal Cord Injury

Area	Pre-stabilization	Post-stabilization days 1–3	Post-stabilization days 4–7
Evaluation	Complete ASIA evaluation	Clarify orders and complete second ASIA evaluation	Reassess as needed
Equipment required	Foot-drop and wrist splints and communication devices as needed	Issue an abdominal binder and ace wraps for BLE; adapt call light as needed; cardiac chair and reclining wheelchair with removal armrests and elevating leg-rests	Continue with necessary equipment
Caregiver and patient education	Education in skin integrity/breakdown; rehab expectations; issue and educate on PROM booklet	Education on pressure relief techniques (1 min every hour or 30 sec every 30 min)	Continue as tolerated
Treatment	Initiate PROM	Initiate dependent transfers to cardiac and/or wheelchair; begin BUE and BLE exercises including ROM and hamstring stretches	For C1-C3 SCI levels, continue exercise program and initiate mouth/neck therapeutic exercise. For C4-T3 SCI levels, same as above and progress to mat activities. For T4-L5 SCI levels, same as above and progress to ambulation

*Abbreviations:* ASIA, American Spinal Injury Association; BLE, bilateral lower extremities; PROM, passive range of motion; min, minutes; sec, seconds; BUE, bilateral upper extremities; ROM, range of motion; SCI, spinal cord injury.

most effective. This progression begins by just elevating the head of bed to 30 degrees, and then to 60 degrees. Once a patient can tolerate this position for approximately two hours, then the next step is sitting at the edge of bed followed by transferring into a reclining wheelchair.

When a patient begins the functional activity of sitting, lower extremity ace wraps and an abdominal binder are issued to the patient. Ace wraps are bandaged around the legs to increase venous return and decrease the possibility of postural hypotension. The abdominal binder improves the resting position of the diaphragm (making it more domed), thus increasing the excursion of the diaphragm during ventilation and increasing both vital capacity (VC) and maximum inspiratory force (MIF). The abdominal binder will typically increase these weaning parameters (VC and MIF) by 15% in patients with C5-6 SCI (26). The abdominal binder may also help maintain blood pressure in some patients. If a patient is having difficulty with this progression of upright/vertical sitting, the use of a tilt table is recommended (26).

Most patients with SCIs are discharged to acute rehabilitation facilities. There, they continue to receive

intensive therapies to achieve their maximum functional outcome. Table 11 lists functional outcomes for spinal cord injuries that patients should achieve when medical issues are stable and they have received optimal rehab.

**Mechanical Principles**

In the SCI population, some joints require increased flexibility while others benefit from increased tightness. Within the shoulder joint, PT and OT aim to increase extension and external rotation to ease transfers and seated self-care activities. Full elbow extension and triceps strength are necessary in order to use the locking technique to achieve the goal of independent sitting. Intact wrist extensors and normal range is crucial for the locking technique and tenodesis. To promote tenodesis, the long finger flexors must be of mild to moderate tightness. Lumbar tightness is encouraged, as this helps with transfers, lower extremity dressing, and balance activities. The primary ROM goal for the hips is full extension for a greater and more normalized gait pattern. Hamstring flexibility to 110–120 degrees is recommended for long-sitting activities such as lower body dressing and floor transfers. Full dorsiflexion of the ankles

**Table 11** Functional Outcomes for Spinal Cord Injuries

Level of SCI	Transfers	Activities of daily living	Wheelchair
C1-3	Dependent	Dependent	Electric with head controls
C4	Dependent	Limited independence using mobile arm supports and environmental control units	Electric with head or breathing controls
C5	Dependent	Independent with set-up	Electric with joystick
C6	Independent with slide board	Independent with universal cuff	Manual
C7-T3	Independent without slide board	Independent	Manual
T4-L5	Independent; may progress to ambulation with orthotics and/or assistive device	Independent	Manual

will allow for a normalized placement of patients' feet on footplates of the wheelchair.

Mechanical principles are used to increase functional mobility in the SCI patient. Agonist muscles are used to compensate for weakened deinvolved muscles. For example, the tightness of the long finger flexors allows for tenodesis grasp. Momentum is the "throwing" of a particular body part to complete a functional activity when it cannot be completed by going against gravity to place it in a particular area (27). Unweighing is a mechanical principle by which a body part is used to advance another body part. For example, the patient bears weight on the right hip while the therapist unweighs the left hip in order to scoot in sitting. Head-hip relationship is implemented when the therapist repositions the hips by actively moving the head and shoulders in opposite directions; this eases dependent transfers of a patient into and out of a wheelchair (27,28). All of these learned techniques take time and dedicated training by the PT and OT.

### Orthopedic Trauma

✎ Although a period of immobilization via traction or casting is necessary for the recovery of certain injuries and surgical repairs, therapy should be initiated as soon as medically appropriate. ✎ Early ranging will maximize joint ROM, ensure smooth tendon gliding, prevent or minimize adhesions from developing, provide sensory re-education and desensitization, and improve overall motor function. Exercises, with or without resistance, will strengthen both affected and unaffected muscles. Educating the patient, family, and staff in the proper techniques is critical for the success of home exercise programs, as they should be performed several times each day for an optimal outcome. To prevent secondary injuries from developing, therapy should be consulted to range and/or strengthen noninvolved joints while others are immobilized.

Edema management is important to a successful rehab program. The most effective method for preventing and/or minimizing edema is through extremity elevation. Positioning the arm or leg on pillows, wedges, or other elevation devices above the level of the heart while in bed not only helps with reducing or minimizing edema, but also provides support to minimize strain placed on the proximal joint. The use of a sling can help avoid keeping one's hand in a dependent position while out of bed; this can also increase the patient's comfort during ambulation. Patients are encouraged to perform frequent AROM, and this is taught early in most therapy programs and practiced several times a day to decrease edema. Other methods used for effective edema reduction include PROM, retrograde massage, and the use of compression devices.

### Axial Spine Considerations

Within the trauma setting, many patients are diagnosed with axial spine injuries. Treatment for this population is similar to that of spinal cord-injured patients with respect to protecting the fracture site(s). Often, orthotic devices such as a TLSO are prescribed for stabilization. For these patients, an additional goal for donning and doffing the brace is created. Patients are educated about the necessary precautions to protect their spine, which may include but are not limited to avoidance of bending, lifting, or twisting. To maintain these spine precautions, an assistive device called a reacher may be needed for lower body dressing and for picking objects off the floor, as well as for reaching items overhead (Fig. 1). Patients are also taught to limit sitting to

**Figure 6** Log-rolling technique: this is often the most effective method for a patient to safely get into and out of bed in order to protect the spine and/or minimize abdominal pain or trauma. The patient will roll to his side and push himself up with his arms while lowering his legs simultaneously. This procedure is reversed for moving from sitting to supine.

15–30 minutes at a time (this may vary with different procedures or surgeons). Therapists also instruct the patient in specific techniques to protect the spine while getting into and out of bed, referred to as log-rolling. Refer to Figure 6 for an illustration and description of this technique.

### Lower Extremity Considerations

Ambulation goals are initiated as soon as possible. Many studies have shown that early ambulation is critical to a good recovery. Conversely, prolonged bed rest is detrimental to recovery following hip fractures, particularly in the frail. A recent study of elderly patients following hip fracture demonstrated that early ambulation and progressive weight bearing after surgery was associated with less morbidity and improved ambulatory status (29). Another study suggested that twice-daily treatments during the first post-operative week following hip fractures increases the odds of regaining independent bed mobility and ambulation with a walker, as well as the likelihood of being discharged directly to home (30).

Weight-bearing status is an important consideration that varies depending upon the surgical procedure and type of injury. For example, nonweight-bearing is common for non-surgical calcaneal fractures, whereas weight bearing as tolerated is common for minor pelvic fractures. The use of assistive devices is necessary to maintain lower extremity weight-bearing restrictions during out of bed activity and ambulation. Refer to Figure 7 for examples of commonly used assistive devices for ambulation. The use

**Figure 7** Example of various ambulation devices: left to right—quad cane, hemi-walker, front-wheeled walker, and front-wheeled walker with platform attachment.

of a platform walker for ambulation allows the patient to maintain weight-bearing precautions on the distal upper extremities.

### Upper Extremity Considerations

Patients with upper extremity injuries will most likely need OT for proper ROM, strengthening, and positioning techniques, as well as fine-motor coordination and ADLs. Splinting is an effective method for providing proper hand position. Splints can be used to support joints, tissues, and bones as they heal or facilitate and maintain increased ROM. Collaboration between the OT and the surgeon is essential for the use of proper postoperative splints.

The most commonly issued splint for the ICU patient is the resting hand splint (Fig. 8). This splint allows for wrist extension and metacarpophalangeal (MP) joint flexion, thus placing ligaments and tendons in the wrist, hand, and fingers in maximal stretch and reducing the likelihood of contractures. Additionally, slight interphalangeal (IP) joint flexion of the fingers and carpometacarpal and

**Figure 8** Resting hand splint. This device places the hand in the so-called “position of function” with the wrist in moderate extension, the metacarpophalangeal (MP) joint in flexion, and the fingers in only mild flexion to maintain stretch on aggregate flexor and extensor tendons and limit contractures of prolonged disuse.

MP opposition of the thumb maintain the hand in the most functional position. Soft, off-the-shelf wrist cock-up splints are another frequently used option for providing wrist extension in patients who do not require finger or thumb support. This is a more economical approach and preferred by some patients because of their smaller size and padding for comfort. However, custom-made splints provide added support and comfort if properly fit. A large variety of splints are commercially available and even more splinting options are possible for the experienced splinter.

Once splints are issued, OTs then educate patients, staff, and families regarding correct protocols for donning and doffing the splints. Most often, splints are to be worn for two hours and removed for two hours throughout the daytime, and worn at night. Immobilization splints are usually worn at all times and removed only for hygiene and/or wound inspection, if cleared by the physician. Skin is inspected each time the splints are removed to assess for redness or pressure spots to ensure proper fit of the splint and to prevent skin breakdown. To combat stiffness, joints should be fully ranged upon splint removal when indicated.

Hand injuries are often associated with profound psychological effects on patients. Because most injuries to the hand are quite traumatic, patients can develop a post-traumatic stress disorder (PTSD) regarding the event that led to their injury (31). The hand is one of the most important body parts for performing daily activities and, therefore, the loss of hand function can significantly affect the patient’s personal, professional, and social life. Therapists endeavor to reassure and educate patients and caregivers that these conditions can improve or be coped with when the therapy program is properly applied.

### Amputations

♣ Patients admitted for elective amputations should be introduced to therapy pre-operatively. ♣ Table 12 shows a summary of the critical path for acute lower extremity amputations used at UCSD (because upper extremity amputations are more rarely performed, the focus of this section is on the lower extremity). During the pre-surgical phase, the PT prescribes an individualized exercise program in order to prepare the patient for the post-operative phase. The exercise program consists of strengthening both the upper and lower extremities, as well as continued functional mobility, which increases endurance and allows for bilateral lower extremity weight-bearing. These important considerations are not often practical or available for traumatic amputations.

Post-operatively, PT is resumed and OT is initiated to address ADL needs such as modified dressing techniques. Patient education and positioning of the residual limb is a key component in the postoperative PT program. Positioning assists in the prevention of joint contractures and the shortening of soft tissues. Prone lying is highly encouraged in order to prevent hip flexion contractures; however, special consideration should be taken with geriatric patients and patients with multiple injuries. A patient unable to lie prone should lie supine with his hip in extension against a supporting surface. In side-lying, the PTs can also perform stretches in order to increase hip extension. A pillow should not be placed under the knee for prolonged durations due to the increase in flexion moment, which leads to knee or hip flexion contractures. The patient who remains in a seated position, may use another supporting surface, such as a chair, to maintain knee extension. A patient seated with the knee flexed for a prolonged period of time may develop a

**Table 12** Critical Path for Rehabilitation Following Acute Lower Extremity Amputation

Area	Day 1	Days 2–4	Days 4–6
Evaluation	Complete evaluation	Re-evaluate patient	Re-evaluate patient
Equipment needs	Establish need for assistive devices and adaptive equipment	Re-evaluate need for assistive devices and adaptive equipment	Re-evaluate need for assistive devices and adaptive equipment
Caregiver/patient education	Initiate home exercise program and family training	Continue with home exercise program and family training	Continue with home exercise program and family training
Treatment	Begin functional mobility and edge of bed self care skills training	Progress functional mobility and advance self care skills to sitting at sink	Progress functional mobility and advance self care skills to standing at sink

flexion contracture and increased edema in the residual limb due to its dependent position. These complications delay the patient's fitting for a prosthesis.

Skin care is another important factor in the education of the amputee, especially if the patient suffers from diminished lower extremity sensation. Proper hygiene should be exercised to prevent skin breakdown in the uninvolved leg. This involves daily foot inspections, thorough washing of the foot, and careful selection of footwear. The skin should be kept clean and dry at all times. It is imperative that the patient also conducts daily inspections of the residual limb with a mirror, looking for signs of infection or drainage at the incision site. Friction massage therapy should be utilized daily to mobilize adherent scar tissue and to desensitize to touch and pressure.

It is recommended that the amputee keep the residual limb elevated to prevent increased swelling. Patients not fitted with a rigid cast can also use an elastic wrap called a "stump shrinker" to reduce the size and control edema. It should be worn at all times, except when bathing. An alternative technique to reduce edema is to use an ace wrap, which can begin to shape and shrink the tissue and control swelling in order to prepare the residual limb for a prosthetic fitting. The residual limb should be re-wrapped every 3–4 hours, or more frequently if the wrap becomes loose. When wrapping, always use diagonal turns, providing greater distal than proximal pressure to facilitate fluid return back into the body circulation, and ensure there are no wrinkles or bulges, which can cause tissue ischemia (32).

The main goal of pre- and post-operative amputation therapy in an acute care setting is to allow the patient to be functionally independent prior to the possible use of a prosthetic device. It is recommended that patients attend a support group whenever possible to address the emotional impact associated with losing a limb. With proper psychological support and routine follow-up PT, a patient with an amputation can return to an active lifestyle with or without a prosthetic device.

## Burns

More than 50,000 patients are admitted to burn units each year in the United States (33). Burn victims face a variety of complications related to their injury. These complications include, but are not limited to: decreased strength, ROM, endurance, mobility, and independence with ADLs.

The initial role of the therapists is to establish a functional baseline within the first 24–48 hours (or after resuscitation is finished) to compare with the patient's status as complications or limitations in the functional abilities arise. The initial evaluation and follow-up treatments

can be performed in coordination with the burn technicians during dressing changes to allow therapists to better observe the skin's mobility. Although the patient may be unresponsive, sedated, and/or on paralytics, therapy is vital to prevent complications of immobility. In this stage of rehab in the ICU, OTs fabricate splints for both upper and lower extremities to assist graft stabilization and/or wound closure, and to prevent contractures or damage to anatomical structures.

Also in this stage, therapists educate caregivers and the burn team members on proper positioning, splinting, ROM, and scar management to the involved and uninvolved joints (see Table 13 for rehabilitation guidelines following grafting). **☞ The success of the burn patient's recovery relies greatly on their positioning in and out of bed. It is important to note that a position of comfort is, unfortunately, one that will facilitate contractures.**☞ For example, allowing a burn patient's extremities to remain flexed can lead to contractures of flexor tendons.

Edema control is another crucial focus of therapy for burn patients because edema directly affects function, especially for the hand. If edema persists, it may lead to such problems as adaptive shortening, adhesions, and eventually to a loss of function (34–36). Coban self-adhesive wrap is frequently used to control edema, as well as to conform and compress the scarring (37). The use of Coban does not impede grip strength, hand mobility, or the patient's ability to perform self-care tasks (38).

As the patient weans off paralytics and increased active participation in the exercise program is evident, therapists should reassess the treatment plan. They perform a functional mobility and ADL assessment, as well as reassess the previous splinting, scar management, and therapeutic exercise programs. Prior to beginning weight-bearing activities, such as tilt table and/or gait training, the lower extremities may be wrapped with circumferential graded passive supports such as ace wraps. The ace-wrapping supports the new grafts, promotes venous return, and assists in the reduction of pain. If the patient cannot tolerate the upright position required to begin gait training due to orthostatic hypotension or increased pain in the lower extremities, a tilt table treatment can assist in preparing the patient for walking.

Burn patients are at risk for hypertrophic scarring. This abnormal tissue produces excessive amounts of collagen, minimal elastin, and may form thick rope-like bands. The scars may contract over joints, greatly limiting ROM and functional use. Scar management is critical to minimize the effects of hypertrophic scars. Modalities may include aggressive stretching, splinting, Compression garments (e.g., Jobst® compression stockings and gloves). Close attention should be paid to scarred areas for up

**Table 13** Critical Path for Rehabilitation Following Acute Burn Injury

Area	Admission	Pre-treatment	Post-treatment
Assessment	Complete a burn evaluation	Re-evaluate patient's progress and needs	Re-evaluate patient's progress and needs
Positioning and splinting	Issue splints and wearing schedule	Monitor effects of splints and make adjustments as needed	Monitor effects of splints and make adjustments as needed
ADLs	Determine deficits and establish treatment plan	Initiate activities designed to maximize self-care	Encourage active movement and ADLs with grafted extremity in accordance with post-op orders
Mobility	Determine ROM and mobility deficits; establish and implement treatment plan	Continue therapeutic exercise program and training for bed mobility, transfers, and gait	Advance treatment program to maximize mobility and ambulation in accordance with post-op orders
Strength	Instruct patient in exercise program	Monitor exercise program	Progress to independent exercise program
Scar management	Determine need for and initiate pressure management and proper skin care	Monitor changing needs for pressure management and instruct in proper skin care	Progress to independent pressure management and skin care

*Abbreviations:* ADLs, activities of daily living; ROM, range of motion.

to four years post-burn to minimize contractures and deformity. Surgical contracture release may be needed for more severe cases. Every patient who is hospitalized for the treatment of a burn should be referred for follow-up rehab upon discharge in order to achieve and maintain the ultimate goal of independence.

### Transplants

Most patients who have received organ transplants are quite deconditioned before their transplants as a result of organ failure, and therefore have lengthy recoveries. Pre-transplant therapies should be ordered when patients are admitted to the hospital so that they may be as strong as possible before undergoing surgery and become introduced to the therapy process. After the transplant, therapists continue working with the patient to return to his/her PLOF.

Mobilizing transplant patients as early as possible is important for their overall recovery. Sternal precautions are followed for patients who have received heart and lung transplants, avoiding strenuous movements to stretch the chest wall before the sternum has healed. All transplant patients must avoid resistive exercises and heavy lifting for several weeks or months following surgery. Patients are taught log-rolling techniques for bed mobility to minimize abdominal strain or pain at the incision sites (refer back to Fig. 6). Abdominal binders are frequently used for additional support and comfort.

At UCSD, the standard discharge goal for patients following liver transplants is to be able to walk at least 50 feet, climb one flight of stairs, and perform simple ADLs with no more than minimal assistance (39). Following discharge, most patients go to an acute rehab facility if needed and then home with their families.

### Minimally Conscious Patients

#### **Range of Motion, Positioning, and Caregiver Training**

For minimally-conscious patients, ROM should be performed to each joint at least twice a day to prevent the development of contractures. Most family members are eager to learn how they can help their loved one, and therapists can teach them appropriate ranging and positioning techniques. In the

absence of family or visitors, nurses need to be more proactive with rehab. Family involvement in therapy sessions has many benefits. They feel they are contributing to the patient's well being (which they are). Moreover, knowledge of proper techniques may also prevent potential injury from accidentally moving a limb in a contraindicated method or an unnatural position. The importance of passive stretching at end range when the patient is at risk for or has a contracture is also stressed to family members who may otherwise not perform the stretches properly. Families and caregivers are also trained in safe transfer techniques (utilizing mechanical lifts if necessary) and proper body mechanics while ranging and transferring the patient.

#### **OT Assessment for Splinting**

Some patients may require splints if they are unable to move a limb. Often, a patient's hands are closed at rest, which may result in shortening of flexor tendons, thereby preventing full finger or wrist extension. OTs can issue splints to ensure proper positioning and prevent contractures. Ankle splints are also commonly needed to prevent or combat foot drop contractures. Patients on chronic bedrest commonly develop a shortening of the heel cords due to a lack of stretching through standing. This is further exacerbated by sheets and blankets pressing down on their toes causing further plantar flexion at the ankles. **Consulting OT for splinting will ensure that minimally-conscious patients are properly positioned and do not develop contractures.**

### AGE-SPECIFIC CONSIDERATIONS

#### **Pediatric Patients**

Pediatric patients are more likely to present with a higher anxiety level than adults, as they are too young to fully understand what is happening around them. The ICU is a scary place for most patients, and especially so for a child with multiple IVs, monitors, and many physicians, nurses, and other medical professionals entering the patient's room at all hours (Table 14).

Bringing in stuffed animals or other toys from home can provide a sense of familiarity and comfort. Working with and training parents and family members are critical for pediatric therapists. This helps the patient feel more

**Table 14** Pediatric Considerations for Physical and Occupational Therapy

Age	Focus	Perceptions	Approaches	Possible adverse effects of hospitalization
Infants (newborn to 1 yr)	Bonding, trust formation, sensorimotor integration	Entire body feels and responds to pain, perceives world as uncaring if cries not attended, reacts with appetite and play	Consistent caregiver, eye-contact, smiles, maintain parent contact, stroking, holding, singing	Separation from parents may cause anxiety, inactivity may delay gross and fine motor skills
Toddlers (1–3 yrs)	Autonomy, gross and fine motor, exploration	Punishment, separation anxiety, regression with stress	Explain who you are and what you are doing, focus on what toddler can do to help, give choices when appropriate, establish routines	Increased dependence on parents, separation anxiety, delayed toilet-training, regressive behavior (may want a bottle)
Preschoolers (3–6 yrs)	Fantasy, motor skills, social skills, very independent	Punishment, fear of bodily harm or intrusive procedures	Same as toddler, use play as outlet for fear and anger, praise accomplishments	Parents become overprotective, regressive in behavior, lack of exposure to new experiences, bed wetting, eating and sleeping problems
School-age adolescents (6–13 yrs)	Separation from mother as individual, social/peer development,	Fear of mutilation, loss of control, or uncontrolled pain	Allow decisions when appropriate, explain what is affected, encourage peer support, offer coping methods and activities that promote mastery	Loss of body control
Adolescents (13–19 yrs)	Independence, role exploration, acquiring values	Views treatment as intimidation, loss of independence, body image is critical, idealistic	Give clear and detailed explanations, allow decisions, elicit input into treatment plans	Fears about ability to function in school, sense of isolation, fewer peer opportunities, resents loss of control

comfortable with the PT/OT process, partly because the therapy is provided by familiar individuals rather than by strangers. Finally, the developmental level of the child must also be considered when constructing treatment plans and goals.

### Geriatric Patients

As with children, special considerations must be made when working with geriatric patients, especially in the ICU. Therapy treatments are often less aggressive than for younger, typically healthy patients, as they often have secondary diagnoses that must be accounted for during therapy (Table 15). Older patients have significantly more comorbidities than younger or middle-aged patients (Volume 1, Chapter 37). Incidence of comorbid diseases rises from 9% for patients under age 45 to 65% for patients over 75 years (40). The most common comorbidities include diabetes, coronary artery disease, cirrhosis, chronic renal failure, and chronic obstructive pulmonary disease (15). Therapists also consider the presence of dementia when working with older patients. Presence of comorbidities likely extends the length of stay in the ICU and the patient's overall hospitalization.

Geriatric patients rarely function at a fully independent level even prior to hospitalization. It would therefore not be appropriate for therapists to set goals of complete independence for these patients. Caregiver/family training is an important component of PT/OT treatment sessions, as they must show that they are able to care for the patient appropriately and safely at home.

### PSYCHOLOGICAL REHABILITATION

☞ The psychological component of rehabilitation is just as important as the physical component. ☞ One must need a "drive" or motivation to recover to achieve and improve one's overall functional mobility and self-care. This is especially true for trauma patients because they need to overcome several psychological ramifications from being a victim of a traumatic event. A large number of trauma patients suffer from psychological problems that may have lead to the event. For example, alcohol abuse may contribute to the mechanism of injury such as a fall that causes a subdural hematoma, a motor vehicle accident that results in multiple orthopedic injuries, or chronic conditions such as liver disease, which may require a transplant.

Common psychological reactions of an ICU patient resulting from traumatic events and/or loss of functional independence include confusion, frustration, apathy, depression, worthlessness, denial, anger, and PTSD. Indeed, many hospitalized trauma survivors develop acute stress disorder or PTSD (refer to Volume 2, Chapter 65). In addition, over 30% of patients in the ICU suffer significant anxiety (41). These reactions must be taken into account when the PT and OT create individualized plans of care for the ICU patient.

### OUTCOME PREDICTION

☞ Continuity of care for rehabilitation begins in the ICU and is continued until after the patient is discharged. ☞ The goal

**Table 15** Adult Considerations for Physical and Occupational Therapy

Age	Cognitive changes	Approaches	Possible adverse effects of hospitalization
Young adults (19–45 yrs)	Mental abilities peak during twenties, reasoning, and information recall	Watch body language as a cue for feelings, allow for as much decision-making as possible, explore impact of hospitalization to work/job	Actual or perceived anticipation of harm, anxiety of the unknown, threats to physical self-image, change in role as a provider, loss of control
Middle adults (46–60 yrs)	Mood swings, decreased short-term memory and synthesis of new information	Allow choices and decision-making in plan-of-care, explore relationship of illness to body image, encourage as much self care as possible	Anxiety for an unidentified threat, threats to physical image and change in functional ability, fear of death, perception of aging, losing independence
Older adults (>60 yrs)	Decreased ability to respond to internal and external environment, decreased short-term memory	Teach stress reduction strategies, encourage social interactions	Aggressive or hostile behavior, withdrawal, non-compliance, apathy, dependency, shock, denial, information-seeking

of overall independence is not always met prior to discharge from the hospital, partly due to third-party payer restrictions. Patients often require continued rehabilitation after discharge to continue progressing toward independence (Table 8).

## EYE TO THE FUTURE

### Kinesio Taping

Kinesio Taping, developed by Dr Kenzo Kase, was first introduced to the United States in 1995 as a modality treatment for PT and OT. This treatment approach is based on providing a supportive exoskeleton during rehab while healing occurs and the muscles regain strength (42). The tape affects the skin, muscles, lymphatics, and joints (Fig. 9). In the skin, the tape relates sensory stimuli to mechanical receptors, decreases inflammation, and decreases pressure chemical receptors. The tape improves contraction of weak muscles and reduces muscle fatigue and over-contraction, in addition to relieving pain. In the lymphatic system, blood and lymphatic circulation improve. The tape promotes

**Figure 9** Kinesio taping graphical representation of blood, lymphatic, and interstitial fluid mobilization. Taped areas form convolutions, which intermittently increase, then decrease the space between skin and muscles, serving as a pump, which promotes the flow of lymphatic and interstitial tissue into capillaries, and back to the blood stream. *Source:* Adapted from Ref. 42.

lymphatic drainage from the extremity and reduces excess inflammatory chemical substances in the tissue. The tape is also believed to adjust joint misalignments caused by spasm/shortened muscle, thus improving AROM. Kinesio Taping is used in conjunction with therapeutic exercise programs and manual therapeutic techniques in order to assist the patient in achieving his/her goals to maximize functional independence with minimal pain.

### Body Weight Support Treadmill Training

Body weight support treadmill training (BWSTT) is a treatment intervention used to assist patients in more quickly achieving ambulation goals. The BWSTT is composed of the following parts: harness, groin piece, overhead straps, unweighting scale, adjusting handles, and a height adjuster. The idea to use this intervention with diagnoses of stroke and SCI was first introduced by Finch et al. and Barbeau and Blunt (43,44). Researchers have found that the spinal locomotor pools are highly responsive to phasic segmental sensory inputs as well as demonstrated motor learning during step training (45).

In patients post-stroke, BWSTT is shown to be more effective than treadmill training without any weight support, and treadmill training is more effective than conventional over ground gait training (46,47). A three-month study demonstrated that the BWSTT group continued to have increased motor recovery and ambulation speeds than the non-BWSTT group (47). Step training with BWSTT is most effective when stroke patients ambulate at speeds close to normal over ground walking velocities (48). For example, a speed of 2.0 mph on the treadmill is more effective than training at speeds less than 2 mph (48). It also recommended 40% body weight support, as this was found to be the most effective amount of support (47). In studying EMG recordings of the paretic limbs of patients post-stroke, Hesse et al. found that they were more phasic and had more symmetrical patterns following BWSTT, than over ground training (49). In patients with incomplete SCI, Wernig et al. found that BWSTT was most effective in progressing patient's ambulation (50). Prior to this study, 38 of 44 patients used a wheel chair. After BWSTT, 38 patients were able to ambulate with either a cane or a walker (50). In patients with Parkinson's disease, BWSTT

assists in the improvement of short step length (51). Further studies are required to determine the effectiveness of BWSTT for other neurological diagnoses.

### Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) is used as a therapeutic modality to increase muscle size and strength. This is especially useful during spinal cord injury rehabilitation, but it can also be used for post-surgical recovery (52,53). NMES can be utilized for maintaining and/or improving muscular contractions for patients restricted to bedrest (54). Other uses for NMES include maintenance or increase of ROM and substitution for various orthoses (52).

NMES uses pulses of current to activate the larger, fast-twitch muscle fibers, causing them to contract. These muscles can significantly atrophy during prolonged periods of immobilization or bedrest and are difficult to strengthen through exercise alone. Studies have shown that muscle atrophy can be prevented through the use of NMES (52). When nerves are impaired and active motion is limited, NMES can help to increase the movements. Some common indications for applying NMES are weakened wrist and finger extensors, in order to improve fine-motor coordination; and shoulder subluxation, to correct and maintain proper joint alignment (54,55). This modality is more commonly used in out-patient programs; however, it can also be a useful tool for therapists in the acute setting to address problems before they worsen or become chronic, thus complicating recovery.

### Complementary and Alternative Therapies

Various complementary and alternative therapeutic techniques can be implemented to promote relaxation for hospitalized patients. This is especially important for patients in the ICU, because of the "white noise," and frequent sleep-disturbing intrusions that are more common in the ICU than on general medical floors. The use of multiple monitors, IV machines, and ventilators, coupled with less privacy and numerous professionals entering the room around the clock can heighten anxiety and diminish rest. Patients with acute neurological injuries are also easily over-stimulated and cope better when relaxation techniques are utilized.

One calming technique utilized at UCSD involves dedicating programming on television sets located in patients' rooms. Each television set has one station that plays relaxing music and displays calming scenery 24 hours a day. This allows patients, families, or staff to "drown out" noxious noises so the patient can relax, sleep, or otherwise focus on something other than pain and the hospital environment. Focusing on music has been shown to reduce the effects of unwanted stimuli while stimulating endorphins, which produce pleasurable feelings (56). This noninvasive intervention is an excellent adjunct to therapy treatments, especially while performing ROM.

Relaxed patients typically have reduced perceptions of pain, thus facilitating better stretching by reducing resistance to passive movements. Easily distracted patients can also focus better on cognitive activities and require fewer cues for redirection when listening to relaxing background music. Music can also be a useful relaxation and distraction tool to offset painful or stressful activities such as dressing changes or wound care as an alternative to increasing pharmacologic dosages for improved pain control (57). The Joint Commission on Accreditation of Health Care Organizations (JCAHO) has recommended that facilities implement

non-pharmacological treatments such as music therapy to complement traditional methods of post-surgical pain control (58).

Animal-assisted therapy is another novel intervention known to help patients cope with painful and unpleasant conditions. Pet therapy involves visits from specially trained animals (typically dogs) that serve to improve patients' cooperation in cognitive or physical training. These animals also serve to combat the stresses and anxieties of hospitalization, improving patients' mood, and decreasing loneliness (59–61).

Pets can be used during PT and OT treatments to motivate patients to participate in therapeutic activities. For example, patients may be encouraged to sit up or use their injured arm to pet the animal. In addition to pet therapy visits, similar benefits can be gained from visitations by the patients' own pets (however, personal pets must be certified free of disease and vaccinated). At UCSD, volunteers take Polaroid photos of the pet therapy visits, providing mementoes of pleasurable events during their hospitalization. Pet visits can be permitted for ICU patients typically with a physicians' order, as long as they meet the medical criteria (not immuno-suppressed, allergic to animals, or have a communicable disease or unexplained fever). Having pets visiting the units can be a positive experience for patients, families, and staff members, which is important in such a highly stressful environment.

### SUMMARY

Early rehabilitation is essential for optimal treatment of trauma and critical care patients. The sooner therapy is initiated, the less likely patients will decline in the ICU and will therefore have better outcomes. Important points to consider when ordering therapy include a clear summary of all injuries and medical conditions, and the expected goals of rehabilitation. Additionally, the orthopedic surgeons and/or neurosurgeons should clearly declare the stability of the spine, pelvis, and extremities to both the trauma team and the PT/OT consultant. A daily review of weight bearing restrictions and/or other precautions regarding physical movement of the spine or extremities is useful and should be reflected in the patient's activity orders.

Activity orders must further indicate whether patients are cleared for edge of bed, out of bed to chair, out of bed with assistance, or out of bed as tolerated. Out of bed orders should be written as soon as the patient is medically appropriate. Spine precautions must be cleared prior to therapy or out of bed orders to ensure that the patient is safe to participate in therapy programs. Orders for weight-bearing (for each involved extremity), type and wearing schedule for orthotic devices (e.g., if a specific back brace is required when out of bed), other specific precautions or contraindications (e.g., following anterior or posterior hip replacement surgeries), any ROM limitations, and any other critical information necessary for therapists to treat the patient appropriately and effectively must be included with the therapy orders. If in doubt, consult PT and/or OT for a patient evaluation.

*An individualized plan of progressive exercise initiated as soon as possible in the recovery process is the best way to ensure the total recovery of the patient in the least amount of time and with fewest complications (4).*

## KEY POINTS

- ✎ The overall goal of rehabilitation is to achieve maximum restoration of the patient's physical, psychological, social, vocational, recreational, and economic functions within the limits imposed by the trauma, critical illness, or any other pre-morbid deconditioning that may have occurred.
- ✎ Physical therapy (PT) involves the identification, prevention, correction, and rehabilitation of acute or prolonged movement dysfunction of any etiology.
- ✎ Occupational therapy (OT) primarily focuses upon improving patients' abilities to perform activities of daily living (ADLs) and functional mobility.
- ✎ Patients relegated to extended bedrest suffer more secondary disabilities and require longer recovery periods than patients who are mobilized out of bed early.
- ✎ Ordering PT and OT early in a patients' hospitalization will likely decrease medical and functional complications because patients will be stronger, more active, and mentally more interactive, leading to better outcomes.
- ✎ Discharge planning considerations are deliberated during the initial rehab evaluation, even for ICU patients. The more time the patient, family, and medical team have to prepare, the more successful the discharge plan.
- ✎ The Rancho Los Amigos Cognitive Scale provides the most useful and reproducible categorization of cognitive and behavioral status for patients who are awake and interacting with their environment (24).
- ✎ Therapists should perform a standardized American Spinal Injury Association (ASIA) evaluation within the first 72 hours of admission following spinal cord injury (SCI).
- ✎ Although a period of immobilization via traction or casting is necessary for the recovery of certain injuries and surgical repairs, therapy should be initiated as soon as medically appropriate.
- ✎ Patients admitted for elective amputations should be introduced to therapy preoperatively.
- ✎ The success of the burn patient's recovery relies greatly on their positioning in and out of bed. It is important to note that a position of comfort is, unfortunately, one that will facilitate contractures.
- ✎ Consulting OT for splinting will ensure minimally-conscious patients are properly positioned and do not develop contractures.
- ✎ The psychological component of rehabilitation is just as important as the physical component.
- ✎ Continuity of care for rehabilitation begins in the ICU and is continued until after the patient is discharged.

## Ethical and Legal Issues in Trauma and Critical Care

John M. Luce

Department of Medicine and Anesthesia, UC San Francisco School of Medicine, San Francisco General Hospital,  
San Francisco, California, U.S.A.

### INTRODUCTION

Patients with trauma and critical illness present physicians and other health professionals with a host of ethical considerations. Ethical behavior is aspired to by the vast majority of physicians and health care workers around the world. Although there is broad agreement on fundamental principles, complex ethical dilemmas can arise in clinical practice that challenge even the most erudite and ethically sophisticated of clinicians.

The fields of ethics and law have occasionally been outpaced by the rapid technological changes in health care. Consequently, disagreement and uncertainty can occur when formulating clinical decisions, which uphold legal and ethical precepts. The situation is complicated further by the global mobility of patients and family members—some countries, the interpretation of ethical issues have been enshrined in local and national law. As might be expected, the legal interpretation of ethical issues tends to reflect the values of individuals and the society to whom these laws apply.

✎ **Important ethical issues in trauma and critical care include medical decision-making, informed consent, resuscitation, brain death, organ transplantation, the withholding and withdrawal of life support, and the allocation of medical resources.** ✎ These issues are addressed in this chapter after providing a background to the field of biomedical ethics. The relationships between ethical and legal considerations are discussed with specific reference to the American and British case law. In the “Eye to the Future” section, suggestions are provided regarding how this field may evolve in coming years.

### BACKGROUND TO BIOMEDICAL ETHICS

#### Ethical Principles

Beauchamp and Childress (1) have described four ethical principles that govern the attitudes and behaviors of physicians and other health professionals. In addition to influencing professional standards, these four principles (based on Western philosophical thought) inform most health care law. The oldest ethical principle is *beneficence*: acting to benefit patients by sustaining life, treating illness, and relieving pain. A correlative principle is *nonmaleficence*: refraining from causing harm as per the dictum of “*primum non nocere*” (“first, cause no harm”). A third principle, which has increasingly gained importance in the United States and some other countries, is that of *autonomy*: respecting the patient’s right to self-determination. A fourth ethical principle, enumerated by Beauchamp and Childress, is *distributive justice*: the fair, equitable, and appropriate

allocation of medical services in society. Underlying these ethical principles are the covenantal virtues of *trust* (or *fidelity*), as articulated in the Hippocratic Oath (Fig. 1) (2), and *honesty*, the obligation to tell the truth (not explicitly referred to in the Hippocratic Oath). Patients have the right to expect that all physicians and health care workers will be honest and trustworthy at all times.

An additional ethical principle increasingly emphasized over the last decade is that of *confidentiality*: the respect of privileged patient information (this concept is explicitly mentioned in the Hippocratic oath). The four ethical principles of Beauchamp and those additional precepts addressed in the Hippocratic oath (trust and confidentiality) are summarized in Table 1.

#### The Fiduciary Relationship

The first three ethical principles outlined above also constitute the foundation of the fiduciary relationship through which physicians hold a special relationship of trust, confidence, and responsibility and, as such, are expected to serve the best interests of their patients. Such a relationship is expected by society, because patients are assumed to be vulnerable and medically naïve compared to physicians (and other health professionals) who possess superior medical knowledge. In keeping with the principles of beneficence and nonmaleficence, physicians and other knowledgeable health practitioners may feel compelled to decide what is best for their patients. The principle of autonomy, which respects the individual’s right to self-determination, is viewed ethically and legally as having priority, even if the patient’s choice is contrary to that of the practitioner (3).

✎ **In keeping with the principle of autonomy when capable of rational informed decision-making, patients should always be allowed to define their own interests.** ✎

#### Increased Legal Emphasis upon Confidentiality

Confidentiality in health care involves the respect of privileged patient information. Respect for confidentiality is firmly established in codes of ethics and in law. As an element of the principles of fidelity (promise keeping), confidentiality is an essential component of trust as part of the fiduciary relationship. The Hippocratic Oath explicitly demands that physicians respect their patient’s confidences.

Confidentiality is linked with rights to privacy and is prescribed in law, including the 1996 Health Insurance Portability and Accountability Act (HIPAA), which was passed as Public Law 104–191 by the 104th congress. The HIPAA regulations call for series of privacy standards to be met in all patients, including trauma and critically ill (4).

I swear by Apollo the physician and by Asclepius and by health [the God Hygieia] and Panacea and by all the Gods as well as Goddesses, making them judges [witnesses], to bring the following oath and written covenant to fulfillment, in accordance with my power and my judgment:

To regard him who has taught me this techné [art and science] as equal to my parents, and to share, in partnership, my livelihood with him and to give him a share when he is in need of necessities, and to judge the offspring [coming] from him equal to [my] male siblings, and to teach them this techné, should they desire to learn [it], without fee and written covenant, and to give a share both of rules and of lectures, and of all the rest of learning, to my sons and to the [sons] of him who has taught me and to the pupils who have both made a written contract and sworn by a medical convention but by no other.

And I will use regimens for the benefit of the ill in accordance with my ability and my judgment, but from [what is] to their harm or injustice I will keep [them].

And I will not give a drug that is deadly to anyone if asked [for it], nor will I suggest the way to such a counsel. And likewise, I will not give a woman a destructive pessary. And in a pure and holy way I will guard my life and my techné. I will not cut, and certainly not those suffering from stone, but I will cede [this] to men [who are] practitioners of this activity.

Into as many houses as I may enter, I will go for the benefit for the ill, while being far from all voluntary and destructive injustice, especially from sexual acts both upon women's bodies and upon men's, both of the free and of the slaves. And about whatever I may see or hear in treatment, or even without treatment, in the life of human beings—things that should not ever be blurted outside—I will remain silent. Holding such things to be unutterable [sacred, not to be divulged]. If I render this oath fulfilled. And if I do not blur and confound it [making it to no effect] may it be [granted] to me to enjoy the benefits both of life and of techné, being held in good repute among all human beings for time eternal. If, however, I transgress and perjure myself, the opposite of these.

**Figure 1** Classical version of Hippocratic Oath—as translated and relayed by Miles SH: *The Hippocratic Oath and the Ethics of Medicine*. Oxford University Press, 2004.

### Special Circumstances of Trauma and Critical Illness

The fiduciary relationship is relatively easy to maintain when patients have minor or chronic illnesses and are seen in primary physicians' offices or in hospital rooms. Disagreements about what is best for patients can be discussed unhurriedly in such settings, and both parties have ample opportunity to engage in deliberate conversation regarding the plan of care and treatment goals. Such relationships are more difficult to establish in the emergency department (ED), the Trauma Resuscitation Suite (TRS), the operating room (OR), and the Surgical Intensive Care Unit (SICU). One reason that the fiduciary relationship may be compromised during critical illness is that primary physicians usually have to share responsibility for their patients with specialists or, in many cases, transfer it entirely. In this process, physicians who have no prior familiarity with the patients must develop new fiduciary relationships of their own.

At the same time, the ethical principles outlined earlier can be more complex and difficult to apply in the ED, the

OR, or the SICU than in other settings. Beneficence and non-maleficence often collide when critical care technologies that support life also cause pain or loss of dignity. Autonomy is more difficult to preserve when patients are unresponsive, because their prior wishes are unknown and the pace of medical intervention is accelerated. Finally, the interests of patients and society may clash over issues such as the triage of multiple trauma victims and the continuation of life support in the face of a poor prognosis or limited space in the SICU.

### MEDICAL DECISION MAKING

#### Competent Patients

In the United States and some other countries, most medical decisions are made jointly by patients and their physicians. Some patients may make unilateral decisions; others may prefer to let physicians decide for them in some, if not all circumstances. Nevertheless, most mentally competent

**Table 1** Principles of Biomedical Ethics

Principle	Explanation
Honesty	Perhaps the paramount ethical principle. In past eras (of paternalism), honesty with patient regarding his or her condition may have been a secondary concern; whereas, beneficence and nonmaleficence were held as more important.
Beneficence	Acting to benefit patients and promote good”cure sometimes, relieve often, “comfort always.”
Nonmaleficence	Avoiding injury or harm <i>primum non nocere</i> “first do no harm.”
Autonomy	<i>Auto</i> = self, <i>nomy</i> = govern: Respecting a patients’ right to self-determination.
Distributive justice	Allocating resources fairly, and allowing equal access to health care.
Confidentiality	Information gained as part of the doctor/patient relationship is privileged and not to be shared with a third party without the consent of the patient.

patients seek physicians’ opinions, weigh the medical options available to them, and either accept or reject their physicians’ recommendations.

The propriety of competent patients to make medical decisions is supported by the ethical principle of autonomy and by the legal rights of consent and refusal, which have been contained for centuries within British and American common law. In keeping with this legal tradition, court decisions, such as that in *Bartling v. Superior Court* (5) and *Bouvia v. Superior Court* (6) in California, have established that competent patients have the right to accept or refuse any and all medical treatments, including those that are potentially life saving. Similarly, in its *Cruzan* (7) decision, the U.S. Supreme Court confirmed that competent patients have such a right under the 14th Amendment to the Constitution.

### Use of Surrogates for Incompetent Patients

Some previously competent patients remain so following trauma and/or throughout a critical illness and, therefore, can participate in medical decisions. However, many critically ill patients are decisionally incapacitated due to illness-related factors. When patients are incompetent to begin with, or are unable to communicate because they are comatose or sedated, their surrogates may become involved in the decision-making process. The proper role for the surrogates is to represent patients’ interests and previously expressed wishes. Surrogates are less helpful when they represent their own interests or speak only from their own points of view. Failure of surrogates to fully comprehend the patient’s clinical condition can also impair their ability to fully convey the patient’s true beliefs about decision-making.

The legal authority to use surrogates in making medical decisions for incompetent patients was established in the United States with the case of *in re Quinlan* (8), in which the New Jersey Supreme Court allowed a parent to exercise the incompetent daughter’s right of refusal through the mechanism of substituted judgment. The U.S. Supreme Court, in its *Cruzan* (7) decision, allowed the states to require “clear and convincing evidence” of patients’

wishes before allowing surrogates to refuse life-sustaining interventions for them. Nevertheless, the U.S. Supreme Court did not mandate that other states adopt this strict standard, and states other than New York (9) and Missouri (10) generally do not inhibit surrogates from exercising the rights of consent and refusal on behalf of the incompetent.

☞ **The most ideal surrogates are those who have been designated by patients before or during their critical illness to make medical decisions in the event of incapacity.** ☞ In California and many other states, such surrogates may be granted a durable power of attorney for health care (DPAHC) (11). Proxy directives of this sort are legally binding so long as patient’s interests are being protected. Properly executed DPAHCs are more helpful than living wills and other instructional directives, most of which are either too broadly or too narrowly drawn (12).

Proxy and instructional directives are prepared for the most part by patients with chronic illness who anticipate further decomposition. Yet, only a minority (<20%) of such patients draw up directives despite passage of the Federal Patient Self-Determination Act of 1990, which requires that healthcare institutions inquire whether patients have advance directives, and help them to obtain such directives if they have not already done so (13). Living wills and DPAHCs are even more rarely thought of by healthy persons, even though they may become trauma victims. As a result, unofficially designated surrogates, usually spouses, parents, children, or siblings must make decisions for patients, usually in a shared decision-making model with physicians.

States vary in their processes and rules for medical surrogacy. In general, these variations fall into two categories: rules for determining the surrogate decision-makers and rules stipulating what surrogates can decide. Rules involving the first category are addressed by family consent laws. Thus, many states, including Illinois, Ohio, Virginia, and Washington, have enacted statutes that allow close family members to act on behalf of incompetent patients when the patients have not delegated this responsibility before losing competence. All of the statutes prescribe a hierarchy of family members and require agreement among members at the highest available class in the hierarchy (14). With respect to what surrogates are allowed to decide, differences also exist between various states.

In the *Wendland Case* (15), the California Supreme Court unanimously decided to restrict sharply the authority of a patient’s wife, who was also her husband’s conservator, to limit life-sustaining interventions in the face of opposition from the patient’s mother. In this case, the patient was conscious, and expected to survive for many years if the interventions were continued.

In contrast, Terri Schiavo was a woman who remained in a persistent vegetative state after suffering cardiac arrest. Mrs. Schiavo had been sustained by artificial hydration and nutrition through a feeding tube for 15 years. In the *Schiavo case* (16), the husband served as her surrogate and expressed her wishes that life-supporting therapy (in this case, food and water) be withheld, despite vehement disagreement from Terri’s parents. The parents were waged in a legal battle to continue the tube feedings and obtained surrogacy rights for over a decade.

The Pinellas County Circuit Court initially ruled in favor of the husband citing a previous decision by the Florida Supreme Court in *Re: Guardianship of Estelle M. Browning* (17). Judge Greer and the Circuit Court held that Michael Schiavo (Terri’s husband) was the proper

surrogate, that prior to developing anoxic encephalopathy (and while mentally competent) Terri Schiavo had made credible and reliable statements regarding her wishes that she not be kept alive by tubes if she entered a chronic vegetative state. The court was also satisfied that Mrs. Schiavo was in such an irreversible and chronic vegetative state (18).

Subsequently, the case was appealed numerous times; eventually going to the Florida District Court, which also held in favor of the spouse's right to serve as the proper surrogate, conveying Terri Schiavo's wishes not to remain in a persistent vegetative state. This ruling was further upheld by the district court of appeals and ultimately the U.S. Supreme Court.

Unlike most incompetent patients for whom decisions must be made about life-sustaining interventions, in the Wendland Case (15), the patient was conscious and was expected to survive for many years as long as the interventions were continued. If the Wendland ruling were extended to others like the Schiavo case, where the patient was in a chronic vegetative state, patients could be subjected to burdensome interventions that offer little clinical benefit, which they might not have ever wanted. In the Schiavo case (16), the court ruled differently and held that the husband was the proper surrogate to convey her wishes that she not remain in a persistent vegetative state.

In English law, the surrogate situation is different. No one may give consent on behalf of an incompetent adult. If the patient, when competent, made his wishes known and the circumstances are unchanged, those wishes must be respected. The only exception to this rule is when patients are detained under the Mental Health Act of 1983 (19). If the patient is incompetent and has not made his or her wishes known, it is generally accepted that life-saving treatment may be given if physicians and surrogates agree that such treatment is essential and in the patient's best interest. If there is time and the decision is difficult, guidance may be sought from the High Court. Examples of High Court involvement include separation of conjoined twins when one is almost certain to die and withdrawal of feeding for patients with severe brain damage.

### When Surrogates Are Lacking

Legal guidelines are less clear for cases in which incompetent patients lack surrogates. Two states—Connecticut (20) and Hawaii (21)—allow physicians to make decisions for incompetent patients based on wishes expressed by the patients to the physicians when the patients were competent. However, no state explicitly authorizes unilateral decision-making by physicians based on any other standard, including the patients' best interests. As such, where patients have not stated otherwise, physicians can make decisions they consider in the patients' best interests under the principle of beneficence, especially when urgent decisions must be made.

An alternative approach is for physicians to ask the court to appoint conservators or other advocates to help preserve the autonomy of their patients. This approach is cumbersome and time-consuming, and conservators often rely upon the physicians to make medical decisions because the conservators are seldom experts in health care. In certain situations, and time permitting, this approach may be justified. Otherwise, rather than make unilateral decisions, physicians are best advised to review these decisions with their colleagues or consult with members of the institutional ethics committee. Such review is in keeping with good medical practice, even though it has no legal standing.

☞ Physicians may make decisions they consider in a patient's best interests in an emergency, unless the patient has stipulated otherwise. ☞

## INFORMED CONSENT

### Forms of Consent

The ethical principle of autonomy is contained in the concept of informed consent, which Beauchamp and Childress (1) define as "... an autonomous authorization by individuals of a medical intervention or of involvement in research." According to these authors, consent can only be informed if patients or their surrogates are competent insofar as they can understand what they are being asked to do. In addition, information that is material to them and their situations must be disclosed to them. They must also be able to deliberate about this information. Finally, they must be free of undue influence or coercion in giving consent. In health care decision-making, a fully informed, capable, and freely consenting patient (or surrogate) has the right to make an autonomous decision (Table 2). In certain situations, the state has the right to override the principle of autonomy as discussed later in this chapter.

Beauchamp and Childress (1) note that informed consent differs from other forms of consent, including implicit consent. Implicit consent exists when approval of one medical procedure is implicit in approval of another; for example, consent to anesthesia may be implicit in consent to surgery. Another form of consent is implied consent. Consent may be implied in emergency situations, wherein physicians feel obligated to provide medically necessary treatment when patients or surrogates have not expressed their wishes. The rationale for treatment in such situations is that patients or surrogates would consent if they could be informed and that harm would result if care were delayed (3).

The practice of trauma and critical care medicine frequently involves the institution of emergency life saving treatment, and physicians frequently use implied consent to justify invasive treatments, including immediate surgery. Although this may be appropriate in true emergencies, informed consent should be sought prior to procedures whenever possible, even if it requires an extensive family search or the appointment of a conservator or other advocate to protect patient interests. ☞ If a true emergency exists, then consent may be considered to be implied. ☞

### Evolution in the Concepts and Standards of Informed Consent

The concept of informed consent is supported by the rights of consent and refusal that are inimical to British and

**Table 2** Required Elements of Informed Consent

Requirement	Explanation and examples
Competence	Patients or surrogates can understand what is asked of them (legal status).
Full disclosure	Information that is material to patients and their situation is disclosed to them.
Specificity	Consent for each component of healthcare and each procedure (no blanket consent).
Freedom of coercion	Patients or surrogates are free of coercion. Patients or surrogates can deliberate.

American common law, as discussed earlier. Common and constitutional law also have held that physicians have a number of professional duties to patients, including the duty to do good (i.e., beneficence) and avoid harm (i.e., nonmaleficence). Failure to fulfill these duties is a tort, which may result in punishment under the criminal law or in an obligation to compensate patients monetarily under civil law (22).

Modern considerations for informed consent emanate from the ethical principle of autonomy. However, until the 20th century medical paternalism prevailed. Indeed, the concept of consent was not even mentioned in the first medical ethics code of the American Medical Association (AMA) in 1847 (Table 3). The ethical paradigms of consent evolved as society changed, but also changed in response to legal decisions.

The legal obligation of clinicians to obtain consent before treating patients was established by several landmark rulings in the United States in the early 20th century. In the first case, *Schloendorff v. Society of New York Hospitals* (23), which occurred in 1914, the Court of Appeal of New York determined that “Every being of adult years and sound mind has the right to determine what should be done with his own body; and a surgeon who performs an operation without his patient’s consent commits an assault, for which he is liable in damages, except in cases of emergency when the patient is unconscious, and when it is necessary to operate before consent can be obtained.”

Only assent (the agreement to proceed) was required for an operation at that time; no true consent was needed until the late 1950s. In 1957, the case of *Salgo v. Trustees of Leland Stanford Hospital* (24) involved a patient, Mr. Salgo, who underwent transabdominal aortography that resulted in paralysis, a known risk of the procedure of which he was not informed. Mr. Salgo contended that he would not have consented to the procedure had he known about the

risk. The judge ruled in favor of Mr. Salgo, and clarified difference between assent and consent (which is legally required), when he stated: “A physician violates his duty to his patient and subjects himself to liability if he withholds any facts which are necessary to form the basis of an intelligent consent by a patient to a proposed treatment.”

The next step in the progression of consent rulings occurred in 1960 with the case of *Natanson v. Kline* (25), in which a patient, (Ms. Natanson) sustained radiation burns while undergoing radiation treatment for a tumor, a known complication for which she was not informed. This decision established the “Professional Practice Standard” later known as the “Reasonable Doctor Standard.” The Judge asserted that disclosure to a patient should be to the extent “a reasonable practitioner would make under the same or similar circumstances.”

The “reasonable doctor standard” prevailed until the case of *Canterbury v. Spence* (26) in 1972, which involved a patient (Mr. Canterbury) who sustained quadriplegia during a cervical laminectomy, a known but uncommon complication. In this case, Mr. Canterbury was not informed of the possibility of this complication because it was not customary local practice to do so. Mr. Canterbury sued, and the court agreed that the “reasonable doctor” threshold was too low. The Court held that disclosure to a patient should include all material that a “reasonable person” would consider important for decision making. So was born the “reasonable patient standard” which is used today.

In another case, *Cobbs v. Grant* (27), the Supreme Court of California clarified in 1972 that the battery theory of *Schloendorff* (23) “should be reserved for these circumstances where a doctor performs an operation to which the patient has not consented.” Other actions may constitute negligence, especially if a patient is harmed and a physician did not uphold his/her duty, for example, if physicians applied an intervention that caused harm without “reasonable disclosure of the available choices with respect to the

**Table 3** Historical Standards and Landmark Legal Cases that Impacted or Altered the Ethical Paradigms Underpinning Informed Consent

Era	Prevailing ethical principles of era	Examples of societal focus or legal cases prompting ethical paradigm shift
Antiquity	Paternalism	“Conceal most things from the patient while you are attending to him . . . revealing nothing of the patient’s future or present condition,” Hippocrates.
Late 19th century	Paternalism	“Consent” not even mentioned in first American medical ethics code, American Medical Association, 1847.
Early 20th century	Assent = consent	“Surgery without consent = assault” (23).
Mid 20th century	Autonomy but, only assent (agreement to have a procedure) was required.	Increased emphasis on civil and consumer rights in the United States and western countries led to increased emphasis on autonomy.
Mid 20th century	Full disclosure (not defined)	Must provide all facts required to form an intelligent decision (24).
Mid 20th century	Full disclosure (Reasonable Dr Std)	Disclosure should be to the same extent “a reasonable practitioner would make under the same or similar circumstances” (25).
Mid-late 20th century	Full disclosure (Reasonable Pt Std)	Disclosure should include all material a “reasonable person” would consider important (26).
Mid-late 20th century	Full disclosure (Reasonable Pt Std) Ruling clarified breach of duty.	Clarifies difference between battery (operation without consent) versus negligence (improper treatment) versus dereliction of duty (failure to provide indicated treatment or information) (27).
Late 20th century to current	Full disclosure (Clarifies fiduciary duty of M.D. during medical research)	Physician must disclose conflicts of interest that can affect patient care (31).

proposed therapy and the dangers inherently and potentially involved in each."

With the continuing escalation in medical technology, physicians have the duty to be knowledgeable of the latest treatment options, and the most potentially beneficial treatments should be made known to the patient, even if the physician disclosing the information cannot personally provide them (due to training or resource availability).

### Consent for Clinical Research

In recent years, the same legal principles and precedents that deal with informed consent for treatment have been applied to clinical research. Research conducted by institutions that receive federal funding is governed by the Code of Federal Regulations (CFR) for the protection of human subjects. According to the 1991 version of the CFR (28), "... no investigation may involve a human being as a subject in research unless the investigator has obtained the legally effective informed consent of the subject or the subject's legally authorized representative."

Most states have not clarified which surrogates are legally authorized to represent subjects in issues regarding research. However, the California Health and Safety Code recently was amended to allow agents pursuant to an advanced directive, conservators or guardians, and family members to provide consent for subjects who are incompetent and cannot consent for themselves. If a subject is in a nonemergency room environment, consent may be sought from available surrogate decision-makers in descending order of legal priority. In an emergency room environment, any available surrogate may give consent. In both environments, when two or more proxies are present and at least one disagrees with the participation of the subject in the medical experiment, surrogate consent is not valid (29).

Recognizing that surrogates are not always available, the 1991 CFR also permits that consent be waived if "(i) the research involves no more than minimum risk to the subjects, (ii) the waiver... will not adversely affect the right and welfare of the subjects, (iii) the research could not practically be carried out without the waiver..., and (iv) whenever appropriate, the subjects will be provided with additional pertinent information after participation." The definition of "minimum risk" here is that "... the probability and magnitude of harm or discomfort anticipated in the research are not greater in and of themselves... than those encountered in daily life or during the performance of routine physical or psychological examinations or tests."

Although the 1991 CFR provides some latitude in enrolling incompetent subjects without available surrogates, its definition of minimal risk was interpreted by some to preclude investigations of emergency interventions such as cardiopulmonary resuscitation. This situation led trauma and critical care investigators to enroll patients under a "deferred consent mechanism" which the government declared inappropriate. They then argued that the minimal risk standard should be changed to allow incompetent patients access to potentially beneficial treatment in clinical trials.

In response to these arguments, the 1991 CFR was revised in 1996 to allow research to be conducted in emergency situations without patient or surrogate consent if the following provisions are met: (i) the human subjects are in a life-threatening situation, (ii) obtaining consent is not feasible, (iii) participation in the research holds the prospect of direct benefit to the subject, (iv) the clinical investigation could not practically be carried out without the waiver,

(v) the proposed investigation plan defines the length of the potential therapeutic window (during which the surrogate will be contacted for consent), (vi) the Institutional Review Board (IRB) has revised and approved informal consent procedures, and (vii) consultation (will occur) with representatives of the communities in which the clinical investigation will be conducted and from which the subjects will be drawn (30).

The 1996 CFR revisions were rapidly implemented by most IRBs. However, there has been variability on how the IRBs ensure that investigators consult "with representations of the communities in which the clinical investigations will be conducted and from which the subjects will be drawn..." The 1996 CFR did broaden patient access to clinical research in areas restricted by the 1991 CFR to include trauma and cardiopulmonary arrest while also protecting patient autonomy.

Many critical care interventions have yet to be subjected to prospective randomized, controlled trials. This is partly due to the reluctance of physicians to participate in trials that involve current practices that they believe are beneficial. However, new and unproven treatments, such as the use of hypothermia for head injury, and the introduction of new drugs, such as activated Protein C, have and should continue to be subject to rigorous scientific testing before their generalized introduction. It may not be possible to reduce current costs without depriving some patients of beneficial treatment, but critical care physicians can fulfill their obligation to individual patients and society by only offering interventions that are of proven or likely benefit.

Another important ethical conflict that can arise during the consent of subjects for clinical studies is that of financial or intellectual rights conflict. For example, a physician scientist investigating the clinical efficacy of a device or drug that is produced by a company in which he or she holds stock, or receives research funds from, should be fully disclosed to the potential study subject (31). This information should also be disclosed on any publications that result from the research.

### Patients with Unusual Beliefs: The Example of Jehovah's Witnesses

Physicians and other health professionals occasionally seek consent from patients whose personal beliefs appear unusual or unreasonable. Some of these patients clearly are incompetent to make medical decisions due to drug use, delirium, and chronic neurologic or psychiatric conditions such as schizophrenia. Other patients, however, are capable of making decision but refuse medical interventions because of beliefs to which adherence is not ipso facto a sign of incompetence. Among these patients are herbalists, advocates of faith healing, followers of homeopathy rather than allopathic medicine, Christian Scientists who prefer care from practitioners within their faith, and Jehovah's Witnesses who refuse blood and blood products. Because obtaining consent for transfusions is common during the management of trauma and critical illness, and because Jehovah's Witnesses are representative of patients with unusual beliefs, they will be discussed here.

In general, Jehovah's Witnesses believe that blood contains the essence of life and that the mingling of one's blood with that of another is prohibited by the Bible (32). Whereas the biblical passage on which this belief is based refers to the art of drinking blood, its interpretation by Jehovah's Witnesses precludes the receipt of whole blood, red blood

cells, platelets, and plasma, though not necessarily of clotting factors or plasma proteins such as albumin. Jehovah's Witnesses also have accepted preblood loss hemodilution with a continuously flowing circuit, but not an extracorporeal circuit with a heart-lung or dialysis machine that may be "tainted" by blood from another. Their beliefs hold that exposure to another's blood risks eternal damnation and ostracism from one's family and other members of the faith, instead of eternal life after death and resurrection. As a result, saving the life of a Jehovah's Witness may condemn that person not only to a life not worth living but also salvation unrealized.

As an affirmation of their faith, Jehovah's Witnesses may be asked on an annual basis to sign a wallet-sized advance directive called a "blood card" to document their informed refusal of blood and blood products in emergency situations (33). When seen in an ED or in other areas of the hospital, they may be surrounded by family and other members of the faith who try to reinforce their resolve to forgo transfusions. Although such reinforcement may be effective, not all Jehovah's Witnesses ultimately refuse blood and blood products. A recent study (34) of 58 trauma victims who were Jehovah's Witnesses revealed that four patients were given blood and three were given autotransfusions that were potentially "tainted." Documented consent to receive blood was found in the charts of two of these patients. This situation and others has reinforced the need to question Jehovah's Witness patients individually (apart from family and friends) to ensure autonomous, uncoerced decision-making.

Court decisions such as that in *re Estate of Brooks* (35) have stated "... even though we may consider (an individual's) beliefs unwise, foolish, or ridiculous, in the absence of an overriding danger to society we may not permit interference therewith ... for the sole purpose of compelling (an individual) to accept medical treatment forbidden by (his or her) religious principles, and previously refused by (him or her) with full knowledge of the probable consequences." Such decisions and the ethical principles of autonomy they reflect mandate that Jehovah's Witnesses, who are competent and can articulate their wishes, may refuse blood and blood products in both emergency and elective circumstances.

The law is less clear regarding emergencies in which wishes cannot be articulated by patients, and the exhortations of family and members of the faith or a "blood card" must be relied on. Some physicians would prefer not to treat patients without a court order in such situations, even though a delay might mean death. Most would rely on legal precedents such as in *Re The Estate of Varrell Dorne* (36), in which the Pennsylvania Supreme Court said that "... when there is an emergency calling for an immediate decision, nothing less than a fully conscious contemporaneous decision by the patient will be sufficient to override evidence of medical necessity."

Neither in emergencies nor elective circumstances do Jehovah's Witnesses have an ethical or legal right to prohibit the administration of blood or blood products to their children if these treatments are needed to sustain life. This principle was established in the 1944 case of *Prince v. Commonwealth of Massachusetts* (37) which did not involve transfusions. The court held that "Patients may be free to be martyrs themselves. But it does not follow that they are free in identical circumstances to make martyrs of their children." In all cases since *Prince*, the courts have agreed that children should receive transfusions if they are

medically indicated. Indeed, many physicians will give blood and blood products to the critically ill children of Jehovah's Witnesses before the court order is granted. According to Jonsen (38), the courts likely would judge in the same way if the life of a viable fetus were in question.

Above and beyond the ethical issues, management of Jehovah's Witnesses may not require transfusions at all. It is our duty as health-care providers to keep abreast of medical developments that allow us to treat Jehovah's Witnesses in a manner that not only saves life but also respects their religious beliefs. Experience with these patients, among others, has demonstrated that patients with trauma and other conditions may tolerate hemoglobin levels in the range of 5 gm/DL (39). Such tolerance may be enhanced by decreasing the patients' metabolic rate with hypothermia, sedatives, and neuromuscular blocking agents; and by increasing oxygen delivery to the tissues with volume expansion and by dissolving more oxygen in blood by providing a higher inspired oxygen fraction. Red blood cell production can be maximized in Jehovah's Witnesses and other patients with erythropoietin. Red blood cell loss may be minimized by discouraging unnecessary phlebotomies, using hemodilution and hypotensive anesthesia, administering DDAVP, and employing blood salvage devices in surgery. Finally, patients may benefit by the development of practical blood substitutes some day (40,41).

✎ **Consent is required from Jehovah's Witnesses for transfusion in elective situations but may not be needed in emergencies, unless the patients refuse this therapy.** ✎

## RESUSCITATION

### Evolution of Hospital Resuscitation Policies

Cardiopulmonary resuscitation (CPR) is a potentially life-saving medical intervention. It must be applied rapidly to be effective, so physicians and other health professionals who perform CPR have little time to consider the consequences of their actions. In addition, patients who require CPR often have not thought out their preferences for or against their therapy. For these and other reasons, CPR was applied universally after its introduction in the 1960s. Subsequently most hospitals adopted policies that advocated CPR in all circumstances, and most practitioners felt obligated to administer CPR to everyone.

Eventually, however, physicians appreciated that not all patients, especially those with terminal illness, want to be resuscitated. Cardiopulmonary resuscitation also was shown to be ineffective in many critically ill inpatients (42). As a result, hospital CPR policies became discretionary rather than universal. Physicians today are advised to ensure the ethical principle of autonomy by obtaining informed consent from patients or surrogates regarding CPR. ✎ **In situations where patients (or surrogates acting on the patient's wishes) do not want CPR performed, valid Do Not Attempt Resuscitation (DNAR) orders should be written in the medical record.** ✎

Although obtaining consent is appropriate, it may be difficult to do after trauma and during critical illness. Some patients are hospitalized in these circumstances because they already have been resuscitated, with or without their permission, and their caregivers are hesitant not to use CPR again. Physicians also may be reluctant to raise the issue of resuscitation because of concern that patients might feel abandoned if the possibility of not being resuscitated is brought up. In fact, because they associate the ED, the OR, and the

SICU with maximum support, many physicians consider it illogical, if not unethical, to ever follow or write DNAR orders in these settings.

### **Do-Not-Attempt-Resuscitation Orders in the Emergency Department, the Operating Room, and the Surgical Intensive Care Unit**

Despite these sentiments, and despite the fact that DNAR orders frequently are overruled in other areas of the hospital (43), they generally should be respected and may even be initiated in the ED, the OR, and the SICU. Regarding the first location, increasing numbers of patients in community facilities such as nursing homes now have DNAR orders, and emergency medical services in many states have developed policies enabling their personnel to accept DNAR orders for patients transported by ambulance (44). Most EDs have similar policies that limit resuscitation if patients or surrogates so request. At the same time, although the ED is not an ideal place to discuss DNAR orders with patients and families, DNAR orders are written in some EDs when the patient's condition warrants withholding of CPR to honor their wishes (45).

The OR is a difficult environment for implementation of DNAR orders, in part because of the intimate relationship between the practice of anesthesia and resuscitation itself. Because of this relationship, some (46) have argued that when a patient's DNAR order does not preclude surgery and there is a reasonable chance of achieving the patient's treatment objectives, a preexisting DNAR order should be suspended perioperatively. Others (47) have stated that the patient's right to refuse treatment outweighs physicians' concern about the possibility of perioperative mortality. Procedure-specific DNAR order forms that allow for surgery but not for prolonged intubation thereafter have been developed. These forms have facilitated the institution of certain beneficial procedures within limits they find acceptable. Such forms avoid an all-or-none approach and allow individualization of patients' values and goals (48).

Procedure-specific DNAR orders also are appropriate in the SICU, where they are used with increased frequency (49). Patients who require the SICU for monitoring or therapeutic purposes but are unlikely to benefit from CPR are potential candidates for such DNAR orders. An example here might be a person who needs intensive nursing care but who should not be resuscitated in the event of a cardiopulmonary arrest because they have an underlying irrecoverable malignancy. Another situation in which DNAR orders are called for in the SICU involves patients, including those with multiple organ system failure, in whom further care is considered non-beneficial. In such patients, DNAR orders frequently represent a philosophic turning point in attitude on the parts of physicians and families from restorative to palliative care (50). ✎ **Procedure-specific DNAR orders are useful in many hospital environments, including the ED, the OR, and the SICU.** ✎

### **Must Resuscitation Always Be Attempted?**

Even if DNAR orders are appropriate in the ED, the OR, and the SICU, it is not clear whether or at what point patients and their surrogates should be offered CPR. Some physicians believe that CPR always should be offered and would do so at the earliest opportunity if the issue has not been raised outside the hospital. Others (51) have argued that CPR, like renal dialysis and other technologies, may be potentially more burdensome than beneficial and is not a

required option if a patient's condition becomes so grave that CPR would be futile. "Slow codes," during which physicians pretend to perform CPR but do not attempt aggressively to bring patients back to life have been pursued as a means of limiting resuscitation without actually obtaining DNAR orders (52). Most hospital policies do not allow this; rather, efforts must be made to identify the patient's wishes (or surrogate's decision) beforehand to avoid CPR in futile or unwanted circumstances.

Unilateral DNAR orders written by physicians represent another way of withholding treatment they consider futile in some circumstances. Although physicians are not obligated to provide treatment they believe to be futile, unilateral orders, in conflict with the patient's wishes (or those of the surrogate) violate the principle of autonomy. Physicians should transfer care of the patient to another doctor, rather than unilaterally make decisions in conflict with the patient or their surrogate. Actions may be called futile when they are incapable of achieving a desired goal.

If CPR cannot possibly restore life in a given patient, the procedure may be considered physiologically futile and may be foregone unilaterally by physicians (53). However, if CPR may succeed in restoring the patient's life but physicians consider the patient's life not worth living, the procedure itself is not physiologically futile and, therefore, should not be foregone without the patient's or surrogate's consent. The concept of futility invoked in the latter case is vague and value-ridden, and it fails to provide an ethically coherent rationale for limiting life-sustaining treatment (49). Like the "slow code" approach, DNAR orders written unilaterally by physicians violate the principle of autonomy. They also preclude important discussions between practitioners, patients, and surrogates, undermining the practice of informed consent that is essential to the fiduciary relationship.

## **WITHHOLDING AND WITHDRAWAL OF LIFE SUPPORT**

### **History and Present Practice**

The DNAR order is a specific example of withholding treatment. The withholding and withdrawal (WH/WD) of life support are processes by which various medical interventions either are not given to or are removed from patients with the expectation that they probably will die from their underlying disease, or from an acute intercurrent process, thus avoiding an anticipated slow, painful, and sometimes undignified death.

These processes were uncommon in American hospitals until approximately 20 years ago, largely because physicians and health-care institutions felt obligated to preserve life whenever possible, regardless of the human and economic costs. In recent years, however, this obligation has been challenged, just as hospital expenses have been scrutinized. Clinical research (54,55) has revealed that many patients do not survive critical illness or do so only after prolonged pain and suffering. Patients and providers alike have questioned the advisability of supporting life in all circumstances. Legal cases have promoted patient and surrogate autonomy in decision-making, and the advent of medical cost-consciousness has restrained the application of therapies that merely prolong death with little hope of long-term cure or recovery (56). As a result of these and other factors, physicians (especially intensivists), with the implicit or explicit support of the hospitals in which they

practice, have become increasingly involved in managing death in the ICU (57).

The first major observational study (58) of how critically ill patients die was conducted in 1987–1988 in two medical SICUs at hospital affiliated with the University of California, San Francisco. During this one-year period, 13% of the patients admitted to the ICUs died. Of the patients who died, 51% did so after a decision had been made to limit treatment, and DNAR orders were written for almost all of them. A study (59) performed five years later in the same two ICUs revealed that, of the 13% of patients who died over a one-year period, a decision was made to WH/WD of life support from 90%, compared with 51% in the first study. Again, DNAR orders were written for almost all of the patients.

Following these studies, a national survey (60) of end-of-life care was conducted in 131 ICUs from 110 institutions in 38 states. Of all the patients admitted to these ICUs over a six-month period, 9% died. Of the patients who died, only 20% did so despite full support including attempted CPR. On the other hand, 24% did so after receiving full support but not CPR; 14% had life support withheld; 36% had life support withdrawn; and 6% were declared brain-dead. Thus, of the patients who died in the ICU and were not brain-dead, 74% received less than full support. Their percentage probably would have been higher if the study included patients who died shortly after being transferred out of the ICU with no provision for readmission.

One striking finding of the national survey was the wide variation in end-of-life care practices: the range of proportions of death preceded by failed CPR was 4% to 79%; for DNAR status the range was 0% to 83%; and for WH/WD of life support the range was 0% to 67% and 0% to 79%, respectively. This considerable variation could not be explained by the types of ICUs, the kinds of hospitals, or their geographic regions. However, a pattern was observed in the two states with strict legal standards for care limitation by surrogates: ICUs in New York and Missouri had lower proportions of deaths preceded by withdrawal of support than did the mid-Atlantic and Midwest regions, in which these states are located.

Although the national survey did not demonstrate changes in ICU deaths over time, as the studies from the University of California, San Francisco did, it suggested that limits to life support have become so commonplace in the United States as to represent a de facto standard of end-of-life care for critically ill patients. Nevertheless, the extreme variation in the categories of ICU death underscores the absence of a true consensual approach to end-of-life care attitudes and practices. Hopefully, consensus can be reached by the development of guidelines on limiting treatment when appropriate. Such guidelines are contained within recent position papers by professional societies (61,62) which have emphasized the need for improving the quality of end-of-life care in the ICU (see Volume 2, Chapter 69).

♣ **Most patients who die in ICUs in the United States do so during the WH/WD of life support.** ♣

### **Justification of the Withholding and Withdrawal of Life Support and the Administration of Palliative Care**

In the United States, the WH/WD of life support is legally justified by the theories of informed consent and refusal discussed earlier. To reiterate, a series of court cases, including *Bartling* (5) and *Bowvia* (6) in California, have

established that competent patients may refuse life-sustaining treatment, a position upheld by the U.S. Supreme Court in *Cruzan* (10). The use of surrogates to exercise the right of refusal for incompetent patients was facilitated in New Jersey under *Quinlan* (8) and has been adopted by most state. Exceptions are Missouri and New York, which require clear and convincing evidence of patients' wishes before they become incompetent.

Although state courts generally have allowed surrogates to request that life-sustaining treatment be foregone on behalf of incompetent patients, the patients themselves usually have been severely compromised in that they are both critically and terminally ill. The recent case of *Wendland v. Wendland* (15) suggests that surrogates may not be allowed to forego treatment for patients who are less severely compromised. In this case, the California Supreme Court reasoned that a conservator could not discontinue tube feeding from a patient who, although unable to feed himself, control his bowels or bladder, or communicate consistently, nevertheless was conscious and able to follow commands. Furthermore, although the patient had expressed some sentiments before he became incapacitated that he would not want to be supported indefinitely, the court felt that those statements were not clear and convincing, and because the comments did not address his current condition they were not necessarily intended to direct his medical care.

The ruling in *Wendland* need suggest no more than that American courts are willing to apply a clear and convincing evidence standard in cases involving patients who are not terminally ill. Nevertheless, some physicians may fear that the same standard will be more broadly applied to critically ill patients and consider it legally prudent to continue life-sustaining interventions regardless of the patients' circumstances. Continuing interventions violates the fiduciary relationship, however, if the burdens imposed by these interventions outweigh their benefits (63). In this regard, *Wendland* is best interpreted as a reminder that, in considering WH/WD of life support, the courts are most interested in what patients or their surrogates desire.

Underscoring this idea is the fact that courts have almost uniformly ordered treatment when asked to resolve disputes between families who favor treatment and physicians who oppose it on the grounds of futility. Judges seem unwilling to cause the death of a patient, as was seen in the case of *Baby K* (64), where the court refused to approve an advance physician decision to withhold life support over an anencephalic child's mother's negation. However, judges and juries seem equally reluctant to punish physicians who act carefully and within professional standards in refusing to provide treatment that they consider inappropriate. In this regard, the only clear legal rule on medically futile treatment is the traditional malpractice test, which measures a physician's treatment decisions against the relevant standard of medical care and then requires that any substandard care causes the patient injury.

The issue of malpractice was raised in *Gilgunn v. Massachusetts General Hospital* (65), in which a Massachusetts jury imposed no liability on a hospital or the physicians who issued a DNAR order and removed the ventilator from a critically ill patient over the objections of her daughter. *Gilgunn* conforms to a trend in futility cases in which physicians are likely to get better results when they refuse to provide nonbeneficial treatment and then defend their actions in court as being consistent with professional

standards rather than seeking advance permission from a court to withhold care.

Despite the outcome of *Gilgunn* and studies showing that physicians frequently limit treatment they consider futile, unilateral actions based on futility generally are undesirable. Such actions certainly may be ethical in that they are supported by the principles of beneficence and nonmaleficence. Nevertheless, autonomy remains the first ethical principle for removing life-sustaining treatment, even though most critically ill patients must exercise their autonomy through surrogates. Ethics here reflect law, because informed consent and refusal are the primary legal theories that underlie this practice. Unilateral action also can be risky: disagreements between families and physicians can increase the potential for lawsuits.

In addition to ruling on the issue of surrogate refusal in *Cruzan*, the U.S. Supreme Court recently provided guidelines for administering palliative care. This provision comes for the *Glucksberg* (66) and *Vacco* (67) cases, in which the Court drew distinctions between physician-assisted suicide and WH/WD of life support. In *Vacco*, the court wrote "Everyone, regardless of physical condition, is entitled, if competent, to refuse life-saving medical treatment; no one is permitted to assist a suicide." "When a patient refuses life-sustaining medical treatment, he dies from an underlying disease or pathology; but if a patient ingests lethal medication prescribed by a physician, he is killed by that medication."

### Administering Sedatives and Analgesics for Palliative Care

Although the Supreme Court condemned the administration of sedatives and analgesic to achieve physician-assisted suicide in *Glucksberg* and *Vacco*, it sanctioned palliative care for critically ill patients, even to the point of terminal sedation, if informed consent is obtained and the care does not contradict the rule of double effect. This rule, which derives from medieval Catholic theology, distinguishes between intended and foreseen consequences. Under it, acts such as giving drugs that lead to morally good effects, such as the relief of pain, are permissible even if they produce morally bad effects, such as the hastening of death, provided that only the good effect is intended. The bad effect may also not be a means to the good effect, and the good effect must outweigh the bad one.

The rule of double effect is limited in that it comes from a single religious tradition. More important, the rule overlooks the complexity of human intention and does not recognize that the patient's consent to an action that causes death may be more important than a physician's intent (68). The complexity of human intent was demonstrated in a study by Wilson et al. (69) from the University of California, San Francisco in which some physicians ordered and nurses administered benzodiazepines and opioids primarily to prevent pain and dyspnea (but occasionally to also treat family members anxiety or even to hasten death) during the WH/WD of life support from SICU patients. A subsequent survey by Asch (70) revealed that 16% of a sample of critical care nurses felt they had engaged in assisted suicide or euthanasia when trying to relieve suffering, often without physicians' knowledge.

Just as some physicians and nurses have mixed motives in caring for dying patients, so do some family members want to ease pain and hasten death simultaneously when their loved ones are suffering. That such motivation is widespread presumably accounts for the fact that few

healthcare professionals who are suspected of participating in assisted suicide or euthanasia have been punished through the criminal justice system (71).

Although the Supreme Court found no constitutional right to physician-assisted suicide in *Glucksberg* and *Vacco*, it nevertheless allowed states to authorize this practice. Experience in the state of Oregon, which permits physicians to prescribe lethal doses of controlled substances to terminally ill patients, suggests that physician-assisted suicide is not widespread and this practice rarely occurs in SICUs. In Oregon, most patients who request prescriptions for potentially lethal medications do so, because of concern about loss of autonomy and not because of uncontrollable pain (72). **☞ The WH/WD of life support and the provision of palliative care have both been sanctioned by the U.S. Supreme Court. ☞**

### Satisfying Ethical and Legal Requirements

The foregoing of life-sustaining therapy is only legally justified if such therapy is unwanted by the patient or surrogate, or deemed futile by the treating physicians. Accordingly, therapy should only be withheld or withdrawn with the consent of patients or their surrogates. When futility is the reason for withholding or withdrawal of treatment, this should not occur without patients' or surrogates' knowledge, or over their objections. Indeed, even if they practice in hospitals that have developed futility policies, physicians should recognize that such policies serve primarily as vehicles for reinforcing joint decision-making between health professionals and patients and their surrogates, not as devices for enforcing decisions made by physicians unilaterally (73). Where surrogates are lacking, or patients cannot make decisions, physician practice should be guided by their best understanding of what the patients would have wanted, or in the absence of such understanding, on what they believe to be in the patient's best interest.

Because the goal of palliative care is to provide comfort, measures that do not relieve suffering but merely hasten death should be avoided. Although most patients die within 24 hours after life support is withheld or withdrawn, the dying process may last for several days. Whatever time is required for death to occur, the palliative measures undertaken and their tempo should be dictated by objective manifestations of patient distress whenever possible. For example, physicians should order sedatives and analgesics for patients who can benefit from these agents, and initial doses should be substantial (as many of these patients may be tolerant of these drugs). However, dosages should not so large as to suggest they are given primarily to cause death (when dose is reviewed in the context of the patient's history and current clinical condition). Instead, the drug dosages should be titrated upward or downward in response to physiological manifestations of pain and discomfort, such as grimacing or hypertension, and ideally according to written protocols (see Volume 2, Chapter 69).

**☞ Neuromuscular blocking (NMB) drugs that could prevent spontaneous breathing should never be administered during the withholding or withdrawal of ventilatory support. ☞** Otherwise, the caring physician and nurses will not be able to ensure that the patient died peacefully with a minimum of pain or anxiety. In patients already receiving these agents, restoration of neuromuscular function should be documented in all situations prior to withdrawing mechanical ventilation. Some have advocated allowing NMB drugs during withdrawal of ventilatory support, claiming that waiting for the drugs to wear off

would unduly burden the patient (74). However, examples of why this would be burdensome were not provided by authors, and most clinicians do not adhere to this practice. Increasingly, processed electroencephalograph monitoring devices such as bispectral index monitors are being employed to supplement clinical assessment for maximizing the likelihood that the patient does not suffer during the withdrawal of futile life support (75). Injections of potassium chloride have no place during the WH/WD of life support, because they do not contribute to patient comfort and suggest a primary intention of hastening death.

Because mechanical ventilation is one of the therapies most frequently withdrawn from patients, and because its withdrawal may cause discomfort, physicians should pay particular attention to how the ventilator is withdrawn. Some practitioners prefer rapid extubation, whereas others use “terminal weaning” in which supplemental oxygen and positive end expiratory pressure are discontinued before the ventilator is withdrawn, and the patient usually remains intubated throughout the procedure. Either approach is ethically or legally justified even if death is unintentionally hastened, provided that informed consent has been obtained, and the patient receives sedation and/or analgesia titrated to minimize suffering.

Finally, because intent can be conveyed in words as well as through actions, the goal of palliative care and the means of achieving that goal should be spelled out in the medical record. In their notes, physicians should document how decisions were made to forego life-sustaining treatment, how consent was obtained from the patient or surrogate, and how the process of achieving patient comfort was conducted. In their notes, nurses should describe what steps they took to achieve the goals of palliative care, including an indication for all sedatives and analgesics they have administered. The ethical and legal requirements for the withholding or withdrawal of therapy are summarized in Table 4.

✎ **When life support is withheld or withdrawn, palliative care should be provided so that patient suffering is avoided and ethical and legal requirements are satisfied.** ✎

## BRAIN DEATH AND ORGAN TRANSPLANTATION

### Definition of Death

Death once was defined as the cessation of cardiopulmonary functions, in keeping with the concept that life is made poss-

**Table 4** Satisfying Ethical and Legal Requirements During the Withholding and Withdrawal of Life Support

Withhold or withdraw life support only with the consent of patients or surrogates
Involve patients or surrogates in decisions regarding how life support is withheld or withdrawn
Administer sedatives and analgesics to relieve suffering, not to hasten death, in whatever dosages are necessary
Do not use neuromuscular blocking drugs when the ventilator is withdrawn
Do not give potassium chloride or other agents that do not contribute to patient comfort
Document decisions and actions in the medical record
Eliminate unnecessary treatments which increase suffering or burden

ible by the flow of vital fluids (also see Volume 2, Chapters 16 and 68). However, the advent of CPR and postresuscitation life support in survivors of “sudden death” rendered this traditional definition obsolete, and brought about the realization that the brain is the only organ whose function cannot be replaced by medical intervention. At the same time, the development of organ transplantation required that death be legally redefined, so that physicians who remove organs from patients whose cardiopulmonary function is being supported following irreversible brain damage are not accused of murder. Here again, as in other areas of critical care medicine, technological advances outpaced existing philosophical paradigms and prompted ethical and legal change (3).

At present, in the United States, death is defined as the total and irreversible loss either of cardiopulmonary function or the function of the entire brain and brain stem (76). Death by neurologic criteria, which also is known as brain death, must be distinguished from other conditions in which patients merely appear to be dead. These conditions include transient coma, in which cerebral hemispheric function may be lost only temporarily; the persistent vegetative state, in which cerebral hemispheric function is lost for at least a month but brainstem function remains intact; and the locked-in state, in which cerebral hemispheric function is preserved but patients cannot move (77). Other conditions such as the Guillain Barre syndrome and encephalitis may also mimic brain death, but the loss of brain stem reflexes and the ability to breathe do not result from irreversible structural brain damage and are recoverable.

### Determination of Whole Brain Death

The determination of death by whole-brain and brainstem criteria is thoroughly reviewed in Volume 2, Chapter 16. The following summary briefly highlights the key principles. The initial requirements for the determination of brain and brainstem death includes the demonstration of coma, which is characterized by lack of alertness and awareness and signifies the loss of cerebral hemispheric function; and the documentation of absent corneal, oculo-vestibular, oropharyngeal, and ventilatory reflexes, indicating loss of function of the brain stem (Table 5).

The patient must be in an unresponsive coma and apneic on a ventilator. A diagnosis compatible with irreversible structural brain damage leading specifically to death of the brain stem must have been made. All drugs that can cause reduced consciousness including alcohol, analgesics, and sedatives must have been excluded as a potential cause of coma. In addition, electrolyte abnormalities, metabolic derangements, and hypothermia must have been excluded as a cause of coma. Furthermore, drugs that compromise the ability to breathe such as muscle relaxants must have been reversed or allowed to wear off.

The final step in the determination of brain death frequently is apnea testing (fully described in Volume 2, Chapter 16). In brief, such testing involves giving intubated

**Table 5** Determination of Brain Death

Lack of potential reversible causes of coma, for example, hypothermia, drugs, metabolic derangements, etc.
Lack of alertness and awareness
Lack of corneal, oculo-vestibular, oropharyngeal, and ventilatory reflexes
Lack of ventilatory efforts during apnea testing

patients insufflated oxygen through the endotracheal tube and observing them for respiratory efforts while they are not mechanically ventilated and while allowing the arterial carbon dioxide tension to rise from a normal level to at least 60 mmHg. Brain death is confirmed if patients do not make ventilatory efforts during apnea testing.

If the patient's surrogates have been prepared for this confirmation, accept the fact that the patient is dead, and agree with discontinuation of support, mechanical ventilation need not be reinstated unless organ transplantation is planned. In this case, cardiopulmonary function will be maintained temporarily, prior to organ procurement. Although it is useful in certain circumstances, laboratory confirmation of brain death by cerebral blood flow studies in adults is not generally required (78).

Surrogate approval is not required before brain death is determined in either group because such determination is a medical issue. Nevertheless, approval should be sought before such determinations, because apnea testing is not riskfree and subsequent decision-making regarding organ procurement also should be known. Furthermore, although there are good reasons to honor patients' previously expressed desires to donate organs despite surrogates' wishes to the contrary, most physicians find it difficult to do so and guidelines from Regional Organ Procurement Agencies require surrogate consent.

Finally, it is important to note that brain death need not be determined before the withholding or withdrawal of life support, which represents the forgoing of unwanted treatment in living patients. Indeed, most patients from whom life support is withheld or withdrawn are not brain-dead.

### **Brain Stem Death: The British Alternative to Brain Death**

Some countries accept the determination of irreversible loss of brain stem function only as an alternative cause of death rather than requiring death of the entire brain and brain-stem. England is an example and has a strict Code of Practice that describes how and when the diagnosis can be made. The diagnosis is made in two stages by two senior doctors. First, the same set of preconditions must be met, as required in the United States. Brain death should not be declared in patients whose central nervous systems are depressed by hypothermia, metabolic abnormalities, or drugs. Only if these preconditions are fully met may the doctors proceed to the second stage and perform the tests. The tests are designed to demonstrate the absence of cranial nerve (II–X) reflexes bilaterally and to confirm apnea in the presence of a PaCO<sub>2</sub> of 50 mmHg (or an increase of 20 mmHg). If after meeting the preconditions and performing the tests, the diagnosis of brain stem death is made, the entire process is repeated. Although the second set of tests is required to confirm the diagnosis, legally death is deemed to have occurred at the time the first set of tests was completed.

The British Code of Practice is based on the belief that the brain stem is the part of the brain that is vital for integrated functioning. Not only is the brain stem essential for the transmission of afferent information and the responses to this information but also it contains nuclei that control cardiovascular, respiratory, and thermoregulatory functions.

### **Promoting Organ Transplantation**

The major limitation to more widespread transplantation in most countries is physician reluctance to discuss this issue with the surrogates of patients such as trauma victims

who, by virtue of their young age and lack of chronic disease, are ideal organ donors (see Volume 2, Chapter 16). Although this reluctance is understandable with families whose religious or cultural values prohibit organ donation (e.g., gypsies and some Asians) (see Volume 2, Chapter 68), many people are consoled by the knowledge that their loved ones are helping to keep others alive through the gift of their organs. With this in mind, many states have adopted legislation that requires discussion of transplantation with the surrogates of patients who are likely to be brain-dead. Physicians, who hold such discussions are not subject to legal liability in the United States (79).

## **ALLOCATING MEDICAL RESOURCES**

### **Physicians as Patient Advocates**

A historical view, which can be traced to Hippocrates, holds that physicians own a duty only to their patients (80). This concept of duty is supported by the ethical principles of beneficence, nonmaleficence, and autonomy. It also is reflected in the fiduciary relationship through which physicians are expected to maintain their patients' medical interests in trust. According to one author (81), "... physicians are required to do everything that they believe may benefit each patient without regard to costs or other social considerations. In caring for an individual patient, the doctor must act surely as that patient's advocate, against the apparent interests of society as a whole, if necessary."

A corollary to this concept of duty is the idea that physicians cannot be providers and rationers of healthcare service simultaneously. Although they may advise society about certain issues, including the allocation of scarce or costly medical resources, physicians must not bring such issues to the bedside. In one author's (81) words, "... it may be difficult for doctors to separate their roles as citizens and expert advisors from their role in the practice of medicine as unyielding advocates for the health needs of individual patients." When practicing medicine, doctors cannot serve two masters. It is to the advantage both of society and of the individuals it comprises that physicians retain their historic single-mindedness. However, physicians can and should help save money and resources by knowing the approximate costs of various therapies and diagnostic tests, and choosing the ones which are the most cost-effective.

The single master view of medicine has prevailed over time for several reasons. One is that the fiduciary relationship traditionally has allowed physicians' broad discretion in determining what their patients' interests are. At the same time, while operating under the principles of beneficence, nonmaleficence, and autonomy, physicians have encouraged patients to expect, if not demand, that everything possible be done on their behalf. Of course, under fee-for-service reimbursement, physicians have benefited financially from the tests they have ordered for patients and the procedures they have performed on them. As a result, physicians who have advocated for the health needs of individual patients have also acted, whether they know it or not, as advocates for themselves.

Another reason for the prevalence of the single master view of medicine is that it and the ethical principles supporting it have not conflicted until recently with the principle of distributive justice, under which medical resources are to be allocated fairly, according to need, and to patients most likely to benefit from them. Until the last half of the 20th

century, physicians had relatively few diagnostic and therapeutic services to offer patients, and hospitals were viewed primarily as places to die. However, healthcare has become more promising with new developments, such as trauma services, new operative techniques, and critical care facilities. It also has become more expensive and, arguably, less available to the uninsured.

That over 40 million Americans lack health insurance makes the single master view of medicine seem somewhat incomplete. Indeed, the principle of distributive justice demands that physicians not only serve individual patients but also strive to improve access for all. It also requires that the interests and needs of all patients be balanced. To meet this requirement, physicians cannot hoard critical care resources solely for their own patients. They also cannot waste resources that are of limited benefit or benefit only a few patients. The responsibility for conserving medical resources is shared both by ICU directors and by the physicians who care for patients in the ICU.

### Rationing Resources and Managed Care

Ideally, the judicious allocation of critical care resources will prevent their rationing either at the bedside or as a result of social policies. The United States has no acknowledged policy on rationing medical services; instead, the government and private insurance companies simply refuse to pay for them. One current manifestation of this “policy” is managed care, which is widely identified as a tool for increasing corporate profits by denying medical services. Managed care organizations commonly pay physicians through capitation rather than fee-for-service, and they have induced them to do less for patients through the use of incentive plans that reward physicians for using fewer and less costly services. In the process, managed care has made patients suspicious of the physicians and the healthcare institutions they once relied on (82).

Fortunately, the interference of managed care organizations into the physician–patient relationship has lessened in recent years, largely in response to protests from both physicians and patients. Physicians also have learned how to act as fiduciaries under capitation, just as they have learned how to provide cost-conscious care without overt rationing. Whether such rationing ever becomes commonplace remains to be determined. One reason it might become commonplace is the perception that healthcare costs can be reduced by limiting intensive care at the end of life.

### Can Health Care Costs Be Reduced by Limiting Intensive Care at the End of Life?

Because the terminally ill are often hospitalized and may be candidates for intensive care and because the ICU is particularly resource-intensive, reducing the use of the ICU among such patients appears to present unique opportunities for cost reduction. The quality of these patients’ end-of-life care also may be improved if those who would benefit more from palliation than from heroic restorative efforts were identified early, and the patients received this treatment in places other than the ICU.

The major reason that cost reduction might be possible in the ICU is that critical care is so expensive (see Volume 2, Chapter 68). Of the \$989 billion spent on health care in the United States in 1995, hospitals costs were around \$350 billion. Assuming that ICU costs were 20% of hospital costs, they amounted to \$70 billion or 1% of the Gross

Domestic Product. The costs of ICU care are higher today not only because total hospital costs are higher but also because ICU costs represent a larger fraction of hospital costs, inasmuch as a greater percentage of hospitalized patients are cared for in the ICU (83).

In addition to its high cost, sufficient geographic variation exists in the use of intensive care to suggest that this treatment is overutilized in some institutions. On average, patients who die in the ICU are more expensive (unless they die quickly, e.g., head injury) than those who live, and sustaining their lives may not be cost-effective. Furthermore, cost-reduction strategies are possible in the ICU. In support of this idea, investigators (84) retrospectively identified ICU patients who either died during admission or within three months of discharge and were in the upper 25% of all critically ill patients in terms of resource use. Were such recipients of “potentially ineffective care” identified and their ICU stays restricted to five days, the investigators estimated, charges at the study hospital could have been decreased by \$1.8 to \$5 million a year.

Although limiting potentially ineffective care is appealing, shortening stays in the ICU may not reduce costs unless beds are taken out of circulation, personnel are relocated, and other fixed costs are decreased. Although patients who die in the ICU generally are more expensive than those who survive on an individual basis, the most expensive patients are those with indeterminate outcomes, who defy prognostication. The most cost-ineffective care actually is provided to a small number of patients; whereas the majority of patients benefit from ICU care. Furthermore, although the study of potentially ineffective care suggested that considerable savings could be realized if such patients were identified and their ICU stays reduced, a follow-up study (85) suggested that efforts to decrease access to the ICU might actually increase overall mortality. Finally, even if terminal care were provided in hospice rather than the ICU, the savings would be minimal over the patients’ last year of life (86).

Clearly, ICU costs can be saved by not opening beds in the first place, as is the approach taken in countries with limited healthcare resources (87). Yet the price of such rationing would be to dash the expectations of patients and surrogates and sacrifice lives that could be saved or at least prolonged through ICU admission. This idea of not providing critical care services has proven to be politically untenable in the United States, and has led to growing dissatisfaction in other countries (88).

In the final analysis, healthcare costs cannot be reduced appreciably by limiting intensive care at the end of life. That said, providing timely and intensive palliative care is desirable in its own right, independent of economic implications. In countries with adequate medical resources such as the United States, all critically ill patients should receive a trial of intensive care unless they or their surrogates specify otherwise, or if, in the absence of available information in the patients’ wishes, such care can be deemed to not to be in their best interests. When restorative efforts fail, they should give away to a palliative approach if patients or surrogates agree, not because the approach will save money, but because palliation will be of the greatest benefit to the patient in achieving the goal of a comfortable and dignified death, regardless of its impact on healthcare costs. **Improving care, rather than reducing costs, is the most appropriate reason to provide palliative treatment.**

## EYE TO THE FUTURE

The basic principles of biomedical ethics presumably will remain the same in the foreseeable future, but they will be increasingly adopted throughout the world in developing nations. For example, the principle of autonomy is becoming more and more accepted outside the United States and Canada. For example, in Western Europe, where physicians traditionally (paternalistically) made most decisions regarding the WH/WD of life support, patients and families increasingly are involved in decision-making (89). In other countries predominated by religious or tribal traditions, paternalism will likely persist in the near future.

The principle of distributive justice is receiving more attention in the United States and elsewhere, and it will receive even more as biomedical ethics continue to evolve. A growing burden of acute traumatic illnesses and of chronic conditions, such as obesity and diabetes, in developed countries, coupled with the advancing age of the populations of these nations, should increase the demand for medical services within them. At the same time, poor economic conditions should create difficulties in meeting the demand, especially as technological innovations occur. The problem of equitable distribution of limited resources is common in underdeveloped nations, where morbidity and mortality from infectious diseases and illness caused by poverty is all but overwhelming. Increasingly, distribution schemes—in a word, rationing—may need to be followed in more affluent countries if distributive justice is to be realized.

Clarification of patient outcomes and what constitutes futility are important considerations that impact ethical decision-making in the SICU (90). Increasing emphasis on outcomes research should continue to clarify disease processes that are treatable versus those that are irrecoverable (with current technology) for which further therapy is futile.

## SUMMARY

Traumatized and critically ill patients present many ethical issues to physicians and other health professionals. These patients should be encouraged to define their own interests whenever possible. Unfortunately, many patients cannot make decisions about clinical care or research participation for themselves, so surrogates must do so for them. Patient autonomy is contained in the concept of informed consent, and may be considered to be implied for clinical purposes in situations where a true emergency exists. Consent cannot necessarily be considered to be implied in patients with known (but unusual) beliefs, such as Jehovah's Witnesses, unless the patients have clearly stipulated beforehand. Procedure-specific DNAR orders are useful in the ED, the OR, and the SICU. Brain death demonstrated by the absence of cerebral and brainstem function or, in some countries (i.e., U.K.), brain stem death, are vital diagnoses made in critical care areas because they (i) are essential to the concept of a dignified death and (ii) contribute to the salvage of life brought about by organ transplantation.

Most patients who die in ICUs do so during the WH/WD of life support. 🐍 **The WH/WD of life support and the provision of palliative care have both been sanctioned by the U.S. Supreme Court.** 🐍 While the administration of sedatives at the time of WH/WD of life support is ethically

quite different than prescribing lethal drugs for the sole goal of assisting suicide, a recent (Jan 17, 2006) six to three decision by the U.S. Supreme court to uphold the 1997 Oregon Death With Dignity Act has an effect on the former (91). The significance of this ruling in terms of the WH/WD of life support is (i) the courts affirmed the patients right to self determination, (ii) physicians are empowered to prescribe drugs at the end of life according to their judgment as regulated by states (rather than federal) oversight, and (iii) had the decision not been upheld, it would have likely had a chilling effect on the compassionate administration of sedatives and analgesics to dying patients during the WH/WD of therapy. In the words of Quill and Meier (92), who raised concerns if the Court ruled the other way: "physicians may become hesitant to prescribe the best available medications to manage the pain, agitation, and shortness of breath that sometimes accompany the end stages of illness. As a result, they may, in essence, abandon patients and their families in their moment of greatest need."

Life support should be WH/WD and palliative care should be provided at the request of patients or their responsible surrogates when treatment is physiologically futile. The ethical and legal requirements are summarized Table 4. Improving care, rather than reducing costs, is the most appropriate reason to provide palliative care.

## KEY POINTS

- 🐍 Important ethical issues in trauma and critical care include medical decision-making, informed consent, resuscitation, brain death, organ transplantation, the withholding and withdrawal of life support, and the allocation of medical resources.
- 🐍 In keeping with the principle of autonomy when capable of rational informed decision-making patients should always be allowed to define their own interests.
- 🐍 The most ideal surrogates are those who have been designated by patients before or during their critical illness to make medical decisions in the event of incapacity.
- 🐍 Physicians may make decisions they consider in a patient's best interests in an emergency, unless the patient has stipulated otherwise.
- 🐍 If a true emergency exists, then consent may be considered to be implied.
- 🐍 Consent is required from Jehovah's Witnesses for transfusion in elective situations but may not be needed in emergencies, unless the patients refuse this therapy.
- 🐍 In situations where patients (or surrogates acting on the patient's wishes) do not want CPR performed, valid Do Not Attempt Resuscitation (DNAR) orders should be written in the medical record.
- 🐍 Procedure-specific DNAR orders are useful in many hospital environments, including the ED, the OR, and the SICU.
- 🐍 Most patients who die in intensive care units in the United States do so during the WH/WD of life support.
- 🐍 The WH/WD of life support and the provision of palliative care have both been sanctioned by the U.S. Supreme Court.
- 🐍 Neuromuscular blocking (NMB) drugs that could prevent spontaneous breathing should never be administered during the withholding or withdrawal of ventilatory support.
- 🐍 When life support is withheld or withdrawn, palliative care should be provided so that patient suffering is

avoided and ethical and legal requirements are satisfied.

- ✎ Improving care, rather than reducing costs, is the most appropriate reason to provide palliative treatment.

### INTRODUCTION

Before mass emigration and global travel were the norm, it was common for members of the caring professions to share the same background and belief systems as their patients. Today, however, most countries contain populations from numerous ethnicities, cultures, and religions, with varying legal experiences and degrees of trust of the medical professions (Table 1).

Religious and cultural influences permeate all segments of society, including medical decision-making. Physicians, whether consciously or unconsciously, conform to values and behaviors reflecting family and society, as well as professional standards. Personal influences often affect one's interactions with patients and general approach to practice, yet these tendencies are not necessarily apparent to the practitioner.

Most clinicians are cognizant that patients possess their own belief systems; however, the need to respect these differences and incorporate them into patient decision-making still requires emphasis from time to time. Religious and cultural backgrounds tend to be the most significant influences underlying patient and family belief systems in terms of life, death, brain death, medical futility, organ donation, and trust in doctors. Accordingly, understanding these considerations can aid the traumatologist/intensivist in avoiding or rectifying ethical dilemmas due to these factors that complicate end of life decision-making and care.

This chapter addresses these considerations and provides cultural and religious guideposts for readers who may, or may not, be familiar with the general principles and ethical beliefs underlying most of the world's organized religions. In addition, other cultural influences that relate to specific geographic regions or are unique to certain ethnic groups are reviewed. **Medical goals in end of life care must be responsive to the needs and preferences of individuals within their socio-cultural, religious, and family contexts.**

### FACTORS INFLUENCING END OF LIFE DECISION MAKING

#### Culture and Custom

Culture can be defined as the ideas, customs, and art of a society. The term is also used to describe a particular society at a particular point in time. Customs tend to be

activities that are long established. Although cultures change over time, current thinking within a given culture is often influenced by customs established in an earlier era and passed down over generations. **Cultures tend to embrace specific beliefs, perceptions, and values. These cultural norms and values strongly influence how individuals and groups think about death, dying, and end of life issues.**

Cultural development has historically been slow to evolve, and was deeply enmeshed in the context of community, family, and religious values. However, with the global society, cultural transformations occur far more quickly and are more readily influenced by changing societal, legal, and ethical norms. For example, in the Western world, medical behavior has been altered by pressure from patient advocates and bioethicists. These forces have altered Western culture from a custom of medical paternalism to an ethic of patient autonomy (the principle that underlies the ethical concepts of informed consent, and use of advanced directives). **The ethnicity, culture, and religion of patients and families strongly influence bioethical differences regarding end of life issues. Likewise, the ethical and legal climate within countries influences physician practices and medical decision-making surrounding end of life care.**

Decision-making by individuals is not a feature of all cultures even in the Western world. For example, in Italy, paternalism is still an accepted method of practice in some provinces. Hispanic cultures also place important emphasis on patriarchal decision-making within the family. In some North American native populations such as the Inuit, Cree, Navajo, and Dene, decision-making is often situational, and always dependent on the values of the individual within the context of family and community (1).

In Eastern cultures, including members of the Hindu, Muslim, and Sikh religions, decision-making involves not only the individual but also the family. In Japan, the culture of medical paternalism existed until very recently and is only just beginning to change (2). Japanese attitudes regarding disclosure, decision-making roles, and end of life choices reflect a shifting emphasis toward autonomy, much as has occurred in the United States in recent generations.

**Table 1** Factors Influencing Decision Making Related to Death, Dying, End of Life Care, and Organ Donation

Factor	Description
Culture	Values, beliefs, ideas, customs, and art of a society
Religion	Worship or belief in a supernatural power(s) or divine transcendent being(s)
Law	Rules regulating members of a society or community typically within political borders of authority
Trust in the medical profession	Varies according to cultural and religious customs and among groups within society, depending on their personal or aggregate recent experience

## Religion

Religion can be described as a specific part of culture and custom. Religion is the worship of or belief in a supernatural power or powers. "Life" after death is a key feature of most organized religions. This often involves beliefs about the soul or spirit of a person that survives even though the biological body has died. Interestingly, the soul/spirit is often thought to embody the individual's personality, intellect, will, and emotions, features that scientists attribute to the brain (see philosophical discussion in Volume 2, Chapter 16). Some theologians view spirituality as a global concept which encompasses the transcendent values that promote human fulfillment and connectedness with others as well as with a transcendent being or higher power.

The relationship between the soul and the body of the deceased varies across different religions and cultures (Table 2). For Christians, Jews, and Muslims, the soul is thought to leave the body to be reunited with their God in the afterlife. For Hindus, Sikhs, and Buddhists, the soul is

**Table 2** Religious Views on Organ Donation

Religion	Donation allowed (yes/no)	Explanations and comments (regarding the official position of the religion)
AME Zion	Yes	Supported as an act of love and charity.
Amish	Yes	Supported when organs are likely to benefit recipient. Reluctant if outcome is questionable.
Assembly of God	Yes	No official position—decision up to the individual.
Baptist	Yes	Individual decision, but considered charitable.
Brethren	Yes	Considered a charitable act as long as donor death is not hastened, and tissue not from an unborn child.
Buddhist	Yes	Individual decision, but considered honorable.
Roman Catholic	Yes	Support and encourage donations as an act of charity.
Christian Church <sup>a</sup>	Yes	Support and encourage organ donation.
Church of Christ	Yes	No prohibitions—decision up to the individual.
Christian Science	Yes	No official position—decision up to the individual.
Episcopal	Yes	Supported and viewed as part of their ministry.
Greek Orthodox	Yes	Not opposed as long as organs used to better human life (i.e., for transplantation or research).
Gypsies	No	Not a formal religion, rather a grouping of ethnicities, with common folk beliefs against organ donation.
Hindu	Yes	No prohibitions—decision up to the individual.
IC Evangelical	Yes	No official position—decision up to the individual.
Islam	Yes	Most Islamic scholars believe transplantation is noble.
Jehovah's Witness	Yes	Individual decision—all blood must be removed from organs and tissues before transplantation.
Judaism	Yes	All four branches (orthodox, conservative, reform, and reconstructionist) support donation.
Lutheran	Yes	Support and encourage organ donation.
Mennonite	Yes	No official position—decision up to the individual.
Mormon	Yes	No opposition—decision up to the individual.
Pentecostal	Yes	No official position—decision up to the individual.
Presbyterian	Yes	Supports and encourages organ donation.
Shinto	No	Injuring a corpse is a serious crime in Shinto folk beliefs. Thus, families may be reluctant to donate.
Quakers	Yes	No official position—decision up to the individual.
Unitarian	Yes	Supported and viewed as an act of love.
United Church of Christ	Yes	Support and encourage organ donation.
United Methodist	Yes	Encourages members to become card carrying organ and tissue donors.

<sup>a</sup>Disciples of Christ.

seen as reincarnated as a new life in another body. Gypsies believe that the spirit of the person remains on earth for a year after biological death, and requires its earthly body to wander freely. Many Japanese believe that the dead body must be in perfect condition or the soul will be unhappy in the next world. They also believe, as do others, that the dead person's spirit can communicate with the living and that the sadness of the dead person's soul can affect family members. ✎ **Historically, members of those religions and cultures that believe that the body is needed even after death have been less likely to accept organ donation than those who believe the soul leaves the physical body following death and no longer needs it.** ✎

### Law

Laws are rules regulating what may or may not be done by members of a society or community. Usually, laws reflect the cultural and religious beliefs of the majority of individuals in the community to which they apply. As such, laws tend to change over time in line with changing societal beliefs and moral values. Consequently, a law that is right for one generation or century may not be right for the next. Similarly, various countries, or locales within countries, change their beliefs at differing paces, so laws that work well in a cosmopolitan European capital, may not function well in Saudi Arabia, or in a small village in the Amazon rain forest.

### Trust in the Medical Profession

Trust implies confidence in the truthfulness, honesty, and reliability of a person. Specifically, the relationship between physicians and their patients is based on trust. The patient's trust in his or her doctor places an obligation on the physician to care for the patient based on the highest medical and ethical standards. ✎ **Death is the final diagnosis. Patients, their relatives, and their religious and societal mentors honor doctors by trusting them to accurately declare when biological life has ended.** ✎ Trust is expected as a moral imperative, despite the fact that physicians, scientists, clergy, and bioethicists continue to struggle with the precise definition of death in the context of medical advances (as discussed subsequently).

### DIAGNOSIS OF DEATH

The diagnosis of biological death is made when clinical examination and appropriate tests have been performed

(see Volume 2, Chapter 16 for specific clinical determinants and confirmatory studies). These may include tests to identify irreversible cessation of heart beat, irreversible cessation of breathing, or irreversible cessation of brain (and/or brain stem) function. The tests are chosen to demonstrate that certain criteria have been fulfilled. It is argued, however, that criteria for death cannot be definitively determined until death is better defined, the definition which itself relies on resolving philosophical and biological concepts of death (3).

### Concept of Human Death

Biologically, death marks the transition of the human body from the living to the nonliving state. An alternative concept of human death is loss of personhood. Inevitably, personhood means different things to different people, but usually loss of consciousness is a key element. Philosophers have stipulated that sentient death occurs when self-awareness is permanently lost, that social death occurs when a person has lost his or her role in society and lastly, sociological death where a person is cut off from his community (4). Examples include people exiled because they have betrayed their country, or people who are legally declared dead in the absence of a body because they have been missing for many years. ✎ **Ultimately, medical goals in end of life care must be responsive to the needs and preferences of individuals within their sociocultural, religious, and family contexts.** ✎

### Definition of Death

Defining death is both complex and controversial. This is because a single definition cannot include all the concepts of death described earlier. From a religious or cultural perspective, the definition of death as the end of a particular biological life is acceptable but incomplete, because it ignores other important events that occur when a person dies (Table 3).

The nascent idea of brain death emerged as physicians and families grappled with the reality that medical technology had advanced beyond the philosophical constructs available. In particular, a definition of brain death was needed to account for the fact that brain necrosis could occur despite continued tissue perfusion, due to artificial support of heart and lungs. From a medical perspective, defining death of an individual as the biological event that marks the transition from being alive to being dead is hard to argue against, but is incomplete because it does not provide any actual criteria for being dead.

**Table 3** Religious and Cultural Events After Biological Death

Event	Religion or culture	Comments
The soul is reunited with a deity	Christians, Jews, and Muslims	Body no longer relevant.
Soul is reincarnated in a new body	Hindus, Sikhs, and Buddhists	Body is no longer relevant. The soul lives on in numerous bodies until nirvana is achieved. Quality of the soul's next biological life is influenced by deeds in the previous life.
Soul exists on earth after biological death	Gypsies and Japanese	A whole body is needed if the soul is to wander freely and be happy.
Spirit exists on earth after biological death	Aboriginal groups	Spirit beings need a whole body. They often play a role in the decision-making of the living.
Immortality	Various	As illustrated by beliefs about the soul but also biological/conceptual for example, living on in our children.

Thus, some suggest that death be defined as “permanent cessation of the critical functions of the organism as whole” (3). In this definition, critical functions are divided into three groups. These groups are the vital functions of spontaneous breathing, autonomic cardiovascular control, and integrative functions such as neuroendocrine feedback loops and consciousness that allow the organism to respond to essential needs such as hydration and nutrition. Inevitably this definition, and others similar to it, facilitate acceptance of the brain death concept.

### Criteria for Pronouncing a Patient Dead

When a definition of death is agreed upon, criteria can be listed to show that the definition has been fulfilled. In the medical context, criteria have been described for cardiorespiratory death, brain death, brain stem death, and neocortical death (5). **Currently, cardiorespiratory and brain death are diagnosed widely and brain (and brain stem) death are accepted in most modern societies.**

In ancient times the criteria for death, such as lack of breathing associated with a cold body, were common to all cultures and religions. More recently, cessation of heartbeat has been an additional criterion. Acceptance of cardiac arrest as a new criterion was facilitated because irreversible cardiac and respiratory arrest are normally so closely linked that in both practical and philosophical terms, the moment of death is unchanged. Consequently, religious teaching and traditional beliefs remained valid, according to the accepted criteria.

### Tests Confirming the Criteria for Death

In past times, it was relatively easy to sense breathing and skin temperature. Nevertheless, there is evidence that the ancient Greeks and Romans delayed burial for several days, perhaps because they needed to be certain that death had occurred. The advent of cardiac arrest as a criterion began the process whereby the recognition of death was removed from the population as a whole, and became the province of doctors and nurses. However, advances in resuscitation and the advent of the diagnosis of brain death have meant that physicians are now the only ones formally able to diagnose death. Furthermore, the brain dead person no longer “looks dead” according to traditional criteria. Consequently, although all religious and cultural groups still discuss the concept and definition of death, they rely on physicians—not only to decide what exams and tests are necessary to diagnose biological death, but also to perform those tests. It is freely acknowledged that events such as the soul leaving or entering a new relationship with the body is not amenable to naturalistic tests.

**Tests currently used to establish that death has occurred do not pinpoint the actual moment of death. Only when irreversible cardiac or respiratory arrest is witnessed is the time of death known.** Even then, a period of delay can occur, all owing for resuscitation attempts before death is diagnosed formally. Current criteria and tests diagnose the state of being dead, not the moment of death. In critically ill and patients, death may proceed more as a process than an event (6). Death of the person often proceeds as a process is in accordance with current definitions, which describe the sequential loss of several vital organ systems.

In the United Kingdom death is defined as death of the brain stem (see Volume 2, Chapter 16). The U.S. definition is based on “whole brain” death. The diagnosis of brain death has clinical criteria (sufficient in the majority of

cases) and confirmatory tests (occasionally required to expedite diagnoses), both of which are completely reviewed in Volume 2, Chapter 16. However, both the brain stem and the cortex undergo a dying process. After the function of certain critical cells is lost, breathing and cardiovascular control becomes erratic, brain stem reflexes are lost one by one, and, finally, control of body temperature is lost. The dying process is even more complex for the whole brain, as additional cells and pathways are involved.

Until scientists and doctors define more precisely which critical functions determine death, death will always be a process and not an event. This is one reason why it has been so difficult for religious leaders to incorporate concepts of brain death into their teachings. Perhaps more precision in the use of words is needed and acknowledgment that diagnosis in its current form specifies the condition of being dead, not the actual moment of death itself.

## RELIGIOUS CONTROVERSIES

### Written and Oral Tradition

Most religions rely on texts that record the thoughts of prophets who lived in an era when absence of breathing was the main criterion for death. **Modern medicine has developed to the point where it has become very difficult for religious leaders to interpret ancient religious texts in a manner meaningful to contemporary society.** A review of the extensive literature illustrates that how difficult it is for religious groups to reach a consensus view on the definition of death, and explains why although most major religious groups support organ transplantation programs and tacitly accept the diagnosis of brain death there is still debate about the meaning and definition of death. Written texts provide a common basis for discussion but are open to a variety of interpretations. Furthermore, societal changes and attitudes toward death continue to evolve, along with changes in the practice of medicine.

Aboriginal tribes throughout the world rely on oral tradition. Oral history changes as it passes down the generations, and ethics are best understood as a process rather than correct interpretation or a unified code (1). Spirit Beings participate in decision-making. We can only speculate about whether this very different ethical approach makes the task of decision-making, in relation to brain death and organ donation, easier or more difficult. Given the intense and intricate discussions still ongoing in many religious and cultural groups, the following sections are an interim but honest attempt to summarize the issues they face. For a greater understanding of the ethical views held by the major organized religions, the reader is referred to a recent series on end of life issues for various religions published in *Lancet* (7–13).

### Life as a Valuable Gift

**Although all religions celebrate life, attitudes regarding both life and death and how it occurs vary.** Most religions teach that life is sacred and that killing is wrong. Most also believe that life is a gift which must be valued. Suicide and euthanasia are therefore, generally forbidden. Buddhist belief is complex. Experience is divided into five skandhas. In Buddhism, the teaching of nonself (anatman) asserts that in the five skandhas, no independent self or soul can be found. Thus, Buddhists are encouraged to be compassionate, to meet death mindfully, to look beyond their own needs, and to serve the needs of everyone in society. Thus,

although a dignified death is an acceptable personal goal, suicide in the interests of others is not only accepted but also considered laudable, if the person's motives are pure and in accordance with Buddhist teaching (14). Judaism also forbids killing. Some Jewish leaders argue that accepting donated organs would make the recipient an accessory to murder of the donor. Others, however, teach that the organ would have been removed anyway, and so as long as there is more than one potential recipient, a Jew may accept an organ if it is offered (15). Most Jewish scholars now believe that organ donation is acceptable, providing the donation does not hasten the death of the donor, or in any other way cause pain or suffering. Other groups, such as the Jehovah's Witnesses (JWs), forbid the transfusion of blood products. They believe that death from profound anemia or lack of clotting factors is Jehovah's will. Clinicians from other cultural or religious traditions find this attitude hard to accept and some might interpret this particular religious teaching as tantamount to suicide (see Volume 2, Chapter 67 for ethical issues involved in the care of JW patients).

Within the medical community, there are those who believe that brain death is not death (16). Others argue that the diagnosis of brain death is a strategy that is used solely to facilitate transplantation programs (17). They suggest that the diagnosis should be abandoned, and those patients with devastating brain damage, or who are nearing death for other reasons, should be allowed to donate organs before they die from irreversible cardiorespiratory arrest. This is likely to be interpreted as killing or suicide by some religious groups and would be unacceptable to them.

### Religion and Organ Donation

☞ **Almost all religious groups have leaders who encourage the altruistic donation of organs for the benefit of others and tacitly accept the diagnosis of brain death.** ☞ These recommendations have not been achieved easily. It is clear that within many religious groups, guidance has been provided in an inconsistent and piecemeal way. For example, Muslims follow the teachings of Islam but are divided into Shi'a and Sunni branches. Jurists from the Shi'a branch have ruled that organ donation by brain dead patients is acceptable, but their rulings were made at different times in Iran, Egypt, Saudi Arabia, Singapore, and the United Kingdom. The Sunni branch has made similar rulings but generally later than the Shi'a branch (18). For Hindus, conscious death at home is the ideal. An unknown Hindu author has written "under no circumstances should organs be removed for use by others" (19). In contrast, a leading Hindu neurosurgeon has advocated acceptance of brain death and organ donation (20). The Sikh religion teaches that a person's soul is their real essence, and encourages followers to serve god by helping others. Because the body is of minor importance compared to the soul, organ donation is encouraged (21). Senior Rabbis from the Jewish community disagree about the definition of death according to religious texts. There is debate about whether breathing alone or heartbeat and breathing must have stopped. Another requirement is that the person must be "comparable to a dead man who does not move his limbs." Spastic movement, which is not normal, is acceptable to some. Yet others argue that even if the limbs do not move, a beating heart's movements are not spastic and therefore death can only be declared when there is no rhythmic heart beat (15). Consequently, the majority of Rabbis support organ donation, though a few do not.

In all these religious groups, acceptance of brain death and organ donation appears to have been achieved more quickly in some countries than others. This suggests that cultural and religious factors have a significant influence. In Japan, for example, the diagnosis of brain death and organ donation are very recent developments. Cultural rather than religious beliefs seem to have been the major barrier to acceptance (2). In particular, medical paternalism has led to mistrust of doctors by patients.

### IMPLICATIONS OF RELIGIOUS AND CULTURAL DIVERSITY

Bioethical attitudes are influenced by religion and culture. ☞ **Ethical behavior accepted as the norm in Western countries may not be appropriate for minority groups within these countries or in Eastern countries where the majority religion and culture is fundamentally different.** ☞ Reference to attitudes among the Japanese and North American native populations have already been made and are good examples. Whatever their ethnic origin, most individuals conceptualize death in a complex manner that is both personal and within cultural and spiritual contexts. In addition to biological and religious concepts of death, other ill-defined concepts exist. An illustration is the fear of elderly Westerners that their body will not be found for several days after death that suggests that life in their abstract thought somehow extends beyond biological life (4). Another example is the pressures on Western women to bear children, which may be linked to the concept of "living on in our children." Although biological transfer of genes is real, whether this really represents continuation of our personhood in our dependants is debatable.

All cultures and religions have rules, customs, and beliefs that require individuals to lead a "good" life. Most also describe a "good" death and require that the dead and dying are treated with dignity and respect for their values and beliefs. ☞ **As medical practitioners, we can facilitate a "good" death by recognizing that our patients' beliefs may differ from our own, and by attempting to elucidate what patients (or their families) believe is right for them, without imposing our own ethical values.** ☞ Recent correspondence in the British Medical Journal serves as a timely reminder that even within the medical profession, the definition of a "good" death varies enormously (22). Discussions with families about death and organ donation should occur in the context of their beliefs rather than ours. ☞ **Many intensive care units have access to support from a variety of religious communities, as well as social and spiritual care services and ethics committees whose assistance can be extremely helpful in facilitating appropriate end of life discussions (see Volume 2, Chapter 69).** ☞

In regard to organ donation, all the major religions allow, and most support, organ donation after death (Table 2). Often, however, these teachings do not filter down to the church membership (18). Educational material provided by transplant organizations (which includes religion-based recommendations) needs to be specifically targeted to relevant groups to enhance understanding.

The media can also have a profound effect on societal attitudes. Some years ago in Britain, a sensational television program purporting to show patients living normal lives after brain stem death had been mistakenly diagnosed led to an almost total cessation of the U.K. kidney transplantation program. Although the claims were later retracted, the accompanying publicity was minimal and it took many

months for public confidence to return. Conversely, publicity about individual children nearing death because a suitable donor cannot be found usually leads to a flood of offers of organs.

Varying interpretations of a “good” death have already been described. Many religions encourage believers to aspire to a dignified death and teach respect for the body after death. To most, a dignified death implies that futile medical intervention should not proceed for long periods, and that patients should not suffer, justifying the use of sedation and analgesia at the time of withholding or withdrawing of nonbeneficial medical therapy. Additionally, it is incumbent on the medical profession therefore to ensure that suffering is not prolonged and the diagnosis of death is made promptly.

Not all brain dead patients become organ donors. However, ventilation and other life support should be discontinued as soon as brain death is declared if the patient is not an organ donor. The exception to this rule occurs when a patient dies so quickly that family has not had the opportunity to pay last respects. In this setting, a modest prolongation of mechanical ventilation of the deceased is acceptable. When patients have irrecoverable injuries or medical conditions, but are not brain dead, critical care practitioners may withhold or withdraw treatment reflecting ethical principles of autonomy (patient, family, or surrogate), beneficence, and nonmaleficence, as well as legal directives. Because the decision to withhold or withdraw treatment is based on medical opinion, some families may not agree, may believe it is unacceptable, or may cling to the hope that the patient will recover. Discontinuing ventilation in the presence of brain death is different than withdrawing ventilation, because the decision to discontinue is based on a diagnosis made by applying strict criteria rather than on the physicians’ opinion of futility. However, families may still challenge the diagnosis and request that the diagnosis be confirmed by an independent physician.

In the truly brain dead patient, the heart usually stops after a couple days. In some patients, however, the heartbeat may continue for more than a few days, albeit at a slow rate, as other organs begin to fail and die cell by cell. Doctors who practiced in the era when discontinuation of futile treatment was not ethically or legally acceptable still remember the smell of putrefaction that surrounded these patients (due to generalized tissue necrosis and liquefaction). Such deaths were neither dignified nor “good.” If brain death is abandoned as a definition of death, it is probable that some patients will be denied a dignified death. Thus, it is imperative that the apparently incontrovertible link between the diagnosis of brain death and organ transplantation is severed. This suggestion has been made before (23) (see Volume 2, Chapter 16).

## EYE TO THE FUTURE

Advances in trauma care have already reduced the pool of potential organ donors and have triggered the development of alternative donation techniques. There is increasing interest in obtaining organs for transplantation from living relatives or nonheart beating donors. As techniques develop, the need for brain dead donors may diminish. Gene therapy will revolutionize many aspects of treatment for an enormous variety of diseases. This too may reduce the need for organ donors. Gene therapy and cell transplants may also alter outcomes from brain injury and irreversible brain injury may eventually become reversible.

☞ **As medicine advances, and more and more parts of the biological organism (including the brain) become treatable or replaceable, the need for a precise definition of biological death becomes increasingly important.** ☞ Although this is the remit of scientists and doctors, we should learn the lessons of the past. The adoption of brain death as a medical diagnosis and its effects on cultural and religious communities serve as a good example. As we strive to define biological death more precisely, we must facilitate a concurrent dialogue with philosophers, theologians, and cultural leaders so that society as a whole participates in the debate. Although the diagnosis of biological death is a task allocated to physicians, we must recognize that the diagnosis has implications that extend far outside of our realm of expertise (24).

It is clear from the available literature that the knowledge and wisdom of numerous senior individuals throughout the world have contributed to the debate about brain death and organ donation. Consensus opinion has evolved within various groups, but international consensus has not yet been achieved. It is equally clear that within the medical profession, the procedures for diagnosing brain (and brainstem) death have been agreed by committee. A relatively limited number of individuals have contributed in the literature to the discussion about the definition of death. For such an important subject, perhaps we are right to rely on experts. However, physicians are called on to diagnose death, and for our patients, this is the final and most significant involvement we will ever have in their care. More individuals from diverse backgrounds will need to contribute to the debate to achieve a broader consensus on the biological definition of death.

## SUMMARY

Culture creates unique patterns of beliefs and perceptions, and cultural norms and values profoundly influence how individuals and groups think about death, dying, and issues surrounding the end of life. Religious traditions, as well as one’s individual spirituality, also significantly influence attitudes and beliefs about death and the existence of an afterlife. Furthermore, societal changes and attitudes toward death continue to evolve, along with changes in the practice of medicine.

These ideas are inextricably linked to the meaning of death and what defines a “good death.” Although definitions vary among philosophers, theologians, and some clinicians, it is clear that a dignified death is a goal sought by all. Physicians, by virtue of their role, are entrusted to make what is a final diagnosis—the diagnosis of a patient’s death, based on clinical and legal standards, in accordance with moral/ethical principles. ☞ **Currently, cardiorespiratory and brain death are diagnosed widely, and brain (and brain stem) death are accepted in most modern societies.** ☞ The diagnosis of brain- and brain-stem death is vital diagnoses made in critical care areas, which are essential to the concept of a dignified death, and contribute to the salvage of life brought about by altruistic organ donation for the benefit of others in society.

As medical practitioners, the most important contribution we can make in facilitating a “good” death is by recognizing that the values and beliefs of our patients may differ from our own, and by attempting to elucidate what patients (or their families) believe is right for them, without imposing our own biases and belief systems. Ultimately, medical goals

in end of life care must be responsive to the needs and preferences of individuals within their sociocultural, religious, and family contexts.

## KEY POINTS

- ✦ Medical goals in end of life care must be responsive to the needs and preferences of individuals within their sociocultural, religious, and family contexts.
- ✦ Cultures tend to embrace specific beliefs, perceptions, and values. These cultural norms and values strongly influence how individuals and groups think about death, dying, and end of life issues.
- ✦ The ethnicity, culture, and religion of patients and families strongly influence bioethical differences regarding end of life issues. Likewise, the ethical and legal climate within countries influences physician practices and medical decision-making surrounding end of life care.
- ✦ Historically, members of those religions and cultures that believe that the body is needed even after death have been less likely to accept organ donation than those who believe the soul leaves the physical body following death and no longer needs it.
- ✦ Death is the final diagnosis. Patients, their relatives, and their religious and societal mentors honor doctors by trusting them to accurately declare when biological life has ended.
- ✦ Ultimately, medical goals in end of life care must be responsive to the needs and preferences of individuals within their sociocultural, religious, and family contexts.
- ✦ Currently, cardiorespiratory and brain death are diagnosed widely and brain (and brainstem) death are accepted in most modern societies.
- ✦ Tests currently used to establish that death has occurred, do not pinpoint the actual moment of death. Only when irreversible cardiac or respiratory arrest is witnessed is the time of death known.
- ✦ Modern medicine has developed to the point where it has become very difficult for religious leaders to interpret ancient religious texts in a manner meaningful to contemporary society.
- ✦ Although all religions celebrate life, attitudes regarding both life and death and how it occurs vary.
- ✦ Almost all religious groups have leaders who encourage the altruistic donation of organs for the benefit of others and tacitly accept the diagnosis of brain death.
- ✦ Ethical behavior accepted as the norm in Western countries may not be appropriate for minority groups within in these countries or in Eastern countries where the majority religion and culture is fundamentally different.
- ✦ As medical practitioners, we can facilitate a “good” death by recognizing that our patients’ beliefs may differ from our own, and by attempting to elucidate what patients (or their families) believe is right for them, without imposing our own ethical values.
- ✦ Many ICUs have access to support from a variety of religious communities, as well as social and spiritual care services and ethics committees whose assistance

can be extremely helpful in facilitating appropriate end of life discussions (see Volume 2, Chapter 69).

- ✦ As medicine advances, and more and more parts of the biological organism (including the brain) become treatable or replaceable, the need for a precise definition of biological death becomes increasingly important.

### INTRODUCTION

The withholding (WH) and withdrawal (WD) of life support (LS) are processes by which various medical interventions either are not given to patients or are removed from them with the expectation that the patients will die from their underlying disease, or from an acute intercurrent process. Life-sustaining treatment includes, among other therapies, mechanical ventilation, vasoactive drugs, chemotherapy, antibiotics, renal dialysis, artificial nutrition, and hydration. **Consistent with the principle of autonomy, it is medically ethical to WH/WD-LS whenever it is unwanted, or no longer desired, by the patient or his/her surrogate.**

The WH/WD-LS is also appropriate when further treatment is deemed futile (1). A therapy is defined as futile when it has no realistic chance of providing benefits that the patient has the capacity to appreciate. This definition encompasses treatment that merely preserves permanent unconsciousness, or cannot end permanent dependence on medical care only available in an intensive care unit (ICU) (2). It is important to recognize that treatments which are futile in terms of overall outcome can, and often do, produce measurable improvements in individual physiological parameters. The key aspect of these improvements is that when they are futile, their sole function is that of delaying the dying process. Futile treatments do not contribute to cure or palliation of the underlying disease processes.

The concept of futile treatment is not new (1,2). However, significant controversy surrounds this topic when one tries to quantify futility (3–7). One recent study retrospectively evaluated Acute Physiologic and Chronic Health Evaluation (APACHE) scores and found a good correlation with outcomes; however, no specific futility threshold was identified (8). **Recent thinking emphasizes the notion that futility occurs when the burden of treatment far exceeds any anticipated benefit to the patient.** The concept of futility is important when balancing the ethical principles of beneficence (the obligation of physicians and nurses to endeavor to benefit the patient) and nonmaleficence (the obligation of caregivers to “not cause harm”). Medical futility occurs when a medical treatment has an inordinately greater burden (harm) than good.

Palliative care has been defined by the World Health Organization (WHO) in 1990 as “the active total care of

patients whose disease is not responsive to curative treatment” (9). In the critical care unit, the administration of sedatives and analgesics represent one of the pillars of palliative care, aimed at mitigating unnecessary pain and suffering. In addition, meticulously maintaining the patient’s cleanliness and appearance, among other aspects of comfort care, are essential to respecting the patient. Providing this level of attention to the patient also fulfills the need of the family to see that their loved one is cared for at the highest level, even at the time of death. Palliative care is multidisciplinary and is provided from the moment WH/WD-LS has been decided until the end of life (EOL), and is also extended to families in bereavement.

The WH/WD-LS and the implementation of palliative care in critical care settings have evolved over the past several decades. When initial recommendations for discontinuing ventilator support were made in the early 1980s, the provision of sedatives, analgesics, and other elements of palliative care were variable and not well studied.

Currently, one in five Americans (>500,000 people) die in an ICU every year, and of this group the majority die following decisions to limit or forego life-sustaining therapy (10–12). Initiatives addressing palliative care in the critical care setting have expanded recently in the wake of numerous studies and several major consensus publications focused on efforts to improve EOL care in the ICU (12–16).

Although many ICU clinicians deal with EOL considerations in an optimal fashion, the landmark SUPPORT study, among others, demonstrated that many critically ill patients at the EOL receive care that is incongruent with their wishes, and that some still die suffering needlessly prolonged and painful deaths (17–19). To address these issues, the Society of Critical Care Medicine (SCCM), published “Recommendations for End-of Life Care in the Intensive Care Unit” in 2001. This report identified the humanistic competencies, technical knowledge, and clinical skills required to ensure patient comfort during the WH/WD-LS (15). Recently, the Robert Wood Johnson Foundation (RWJF) “ICU Peer Workgroup Promoting Excellence in End of Life Care Project” proposed a set of essential EOL care domains as a national agenda for practice, education, and research to improve care of patients dying in ICUs (Table 1) (16). Additional information can be found regarding the “Promoting Excellence”

**Table 1** Quality Indicators for Palliative Care in the Intensive Care Unit

Quality indicator	Examples/comments
Patient and family centered decision-making	Decision-making should be in accordance with the patient's wishes. Surrogates must not interject their own philosophical beliefs, may need guidance in reaching decisions, and should not be made to feel responsible for the patient's death, if/when they decide to WH/WD-LS. It is appropriate for physicians to recommend WH/WD-LS when further treatment is considered futile. <sup>a</sup> Methods of WH/WD-LS vary according to patient's condition and family wishes, but usually involves removal of mechanical ventilation (i.e., terminal weaning vs. extubation). Physicians should address conflict issues early, directly, and compassionately.
Communication with patients, family, and multidisciplinary team members	Goals of care should be clear, and the WH/WD-LS plan coordinated with the multidisciplinary team. The medical record should explicitly document the rationale and plan for WH/WD-LS. The family should be prepared for what to expect.
Continuity of care across clinicians and settings	Consider nontransfer status of patient to maintain continuity of care in ICU. Maintain plan of care with new clinicians if transfer required or requested by family. Request palliative care, ethics consultations, and support service referrals (e.g., social services, pastoral care) as indicated.
Symptom management during WH/WD-LS	Analgesia and sedation should be provided to maximize comfort, and avoid distress (e.g., pain, dyspnea, anxiety, agitation) during preparation for and during the process of WH/WD-LS. Opioids and benzodiazepenes (or propofol) provide analgesia and sedation. NMBAs should be strictly avoided in order best avoid masking patient discomfort. Clear guidelines must be stipulated for PRN indications and dosage titration of opioids and sedatives for nursing staff. Interventions that cause patient discomfort should be discontinued/avoided.
Emotional and practical support for families	Comfort care and patient dignity should be maintained during WH/WD-LS. Privacy and unrestricted family visitation are important aspects. Environmental stressors of ICU should be reduced: avoid unnecessary monitoring, alarms, and imposing equipment. Ensure practical support needs for the family are met. Meticulously attend to patient's physical comfort, hygiene, and appearance. Facilitate cultural and spiritual EOL rituals.
Institutional support systems	Consider use of standardized order sets for WH/WD-LS and "comfort care" orders. Develop ICU policies/protocols for WH/WD-LS and interdisciplinary accountability according to best practices. Establish mechanisms for ongoing support and education of novice and seasoned clinicians regarding palliative ICU care.

<sup>a</sup>Futility is defined within the chapter.

*Abbreviations:* EOL, end-of-life; ICU, intensive care unit; NMBAs, neuromuscular blockade agents; PRN, pro re nata as needed; WH/WD-LS, withholding or withdrawal of life support.

*Source:* From Ref. 16.

project at the following web address: [www.promotingexcellence.org](http://www.promotingexcellence.org).

This chapter reviews the legal and ethical justification for the provision of sedatives and analgesics during WH/WD-LS, as well as the indications and decision-making process. The techniques utilized are variable, and are ethically acceptable only if the primary goals of maximizing patient comfort, avoiding suffering, and promoting patient dignity and respect are observed. Some guidelines in this regard are offered. In addition, various techniques for optimizing the management of symptoms, as well as for promoting a caring environment are emphasized.

## LEGAL AND ETHICAL JUSTIFICATION

### Legal Principles of Informed Consent and Right to Refuse Medical Treatment

In health care decision-making, a fully informed, capable, and freely consenting adult has the legal right to decide whether to

accept (consent to) or refuse any and all medical treatments, including those where death is a consequence. The legal and ethical justifications for the WH/WD-LS rest on the principles of informed consent and autonomy. In terms of consent to treatment, or the WH/WD-LS, patients must be fully informed of the expected benefits and burdens of treatment. Accordingly, when further provision of life-sustaining therapy is unlikely to benefit the patient, physicians are ethically required to inform the family or surrogate(s) of the patient's prognosis and initiate palliative care discussions (when appropriate). The legal foundations of informed consent are further discussed in Volume 2, Chapter 67.

## Ethics

### Autonomy (Right to Self-Determination)

The principle of autonomy from the Greek, *auto* = self and *nomos* = govern, respects the freedom and right of self-determination in decisions affecting the individual. Regard for autonomy honors the patient's right to choose to limit

or forgo life-sustaining therapy. The majority of patients dying in ICUs must exercise their autonomy through surrogate decision makers (20,21), since less than 5% have adequate decision-making capacity and an estimated 10%–15% (even less in trauma patients) have existing advanced directives (see Volume 2, Chapter 67)

### ***In the Case of Futility: Balancing Beneficence with Nonmaleficence***

☞ **When futile conditions are recognized by the care team, physicians are obligated to convey this information to the family to ensure full disclosure of medical information, a necessary prerequisite to shared decision-making.** ☞

When there is little hope of meaningful recovery the WH/WD-LS is consistent with the ethical principles of beneficence and nonmaleficence. The principle of beneficence requires physicians to “do good” and take actions that benefit or contribute to the welfare of the patient. The principle of nonmaleficence is based on the dictum *primum non-nocere* “above all do no harm.” This principle obliges physicians to inform patients/families and act with diligence in avoiding therapy known to cause suffering or harm in cases where treatment has no realistic chance of providing benefit that the patient has the capacity to appreciate, that is, futile therapy. Under these circumstances, physicians should also suggest that the emphasis of treatment be shifted from an intent to cure to a focus of comfort.

Although no consensus has been achieved on the definition of what constitutes medical futility, futile conditions do occur regularly in critically ill-trauma and postsurgical patients, and most intensivists incorporate some form of this concept into their decision-making regarding the aggressiveness of therapy and during deliberations regarding the WH/WD-LS. Accurate prognostication of individual patient outcomes is both difficult and controversial, and the probability of survival is only one of several factors (i.e., clinical judgment and experience) used in determining the appropriateness of treatment (22–24).

### ***Use of Sedatives and Analgesics: Ethical Principle of Double Effect***

☞ **The ethical principle of “double effect” when used to justify comfort care conveys that analgesics and sedatives can have the dual effect of relieving suffering as well as hastening death, and that the administration of these drugs is ethically appropriate if the primary goal is to provide symptom control (e.g., relief of pain and suffering), even if death, a secondary, unintended effect is hastened in the process (25–27).** ☞ The fundamental difference between symptom management during the WH/WD-LS and euthanasia is based on what is intended (palliation) versus what is foreseen, but not the primary intent (death).

### ***Ethical Equivalence of Withholding and Withdrawal***

Distinctions between the WH and the WD of treatment have been made by some physicians who have felt justified in not initiating treatment, but not comfortable with the discontinuation of life-sustaining therapy. ☞ **From an ethical perspective there is no difference between the WH and the WD of treatment that only prolongs life without a realistic chance of cure, and such distinctions are morally irrelevant.** ☞ Accordingly, when treatment is not wanted by the patients (or surrogates), is contrary to the patient’s

values, and/or is unwarranted due to medical futility, it is ethically and legally permissible to WH or WD treatment. The moral equivalence of WH and WD also permits the initiation of life saving interventions and time-limited trials of therapy, with subsequent discontinuation of treatment, if later determined to be futile.

☞ **It is important to recognize that it is never an emergency to WH/WD-LS.** ☞ Although discussions may be urgent and intense, particularly when families and/or the care team are in disagreement, it is nearly always best to continue supportive care until consensus can be reached. An additional reason to briefly continue supportive care arises when families are en route to the hospital from out of town and wish to be with the patient as he/she expires. In this instance, it is best to maintain life support for the patient until the family is present and prepared to discontinue LS.

## **SHARED DECISION MAKING BETWEEN PHYSICIANS AND SURROGATES**

Most clinicians and family members advocate a shared decision-making model of mutual negotiation between the physician(s), patient, surrogates, and the medical team caring for the patient as the best approach for deciding when to limit or forgo life-sustaining therapy. When the patient’s previous wishes are unknown, the goal is to act in accordance with the best-known evidence.

Family members acting as surrogates should not make decisions according to their own values, but rather acting as the patient’s advocate, in accordance with the wishes of the patient they represent.

As families look to physicians for guidance, it is entirely appropriate to make recommendations to surrogates, and it should be considered a disservice to the patient and family not to do so. This advice is first focused on the best judgment in terms of likely outcomes with continued treatment in terms of meaningful recovery and final rehabilitation potential.

With regard to the order of events during the WH/WD-LS, limiting options to the most relevant approaches is most appropriate during initial discussions. Confusing families with a diffuse array of unguided options is often more likely to overwhelm them during the stressful deliberations. However, when families express preferences of how the WH/WD-LS should proceed, these wishes should be incorporated into the plan of care whenever possible.

In addition, it is critical for physicians to impart to family members that making the decision to WH/WD-LS when indicated is not analogous to active euthanasia or causing death, but rather that the decision allows the patient to die naturally without further prolonging unnecessary, and potentially painful, treatment through the institution or continuation of life support.

Finally, once the decision has been made to pursue palliative care goals, discussions regarding the WH/WD-LS should conclude with affirmation of the active interventions that will be provided to ensure the patient’s comfort and meet the family’s needs. Before leaving from these discussions, family members should be invited to ask any final questions and/or to make any other requests known.

### Preparing Family and Loved Ones

The emotional burdens and uncertainty family members experience over decisions to withdraw life-sustaining treatment are well known. Research exploring the process has shown that as families come to terms with the patient's prognosis, consideration is given to what the patient would have wanted, and eventually hopes are redirected from cure to a comfortable and dignified death for their loved one. Family preparation needs to center on support and guidance, affirmation of the appropriateness of their decisions, and reassurance that the patient's suffering will be minimized (28–33).

✎ **Family members should not be left to feel alone with the burden or guilt that their decisions are responsible for ending a loved one's life. Clinicians can effectively guide families through the process of reorienting goals from therapeutic to comfort care through honest, timely, and compassionate communication (28).** ✎

To diffuse the burden of guilt, as much as possible, it is important for loved ones to feel that the patient is making the decision. Accordingly, it is important to emphasize that the WH/WD-LS never means the withdrawal of care. Assurance that quality care will continue to be provided, focusing on the patient's comfort and dignity is imperative. ✎ **Families also need to be assured that WH/WD-LS is legally permissible and ethically humane, and that the administration of sedatives and analgesics is not analogous to euthanasia.** ✎ When the decision-making process is handled sensitively by clinicians, the family is usually able to develop a sense of satisfaction from doing what they perceive as right and noble (e.g., carrying out the patient's wishes and limiting unnecessary suffering) (31,34–36).

### Developing Consensus and Conflict Resolution

Emphasizing that it is the patient's preferences which are paramount is often helpful in gaining consensus from all those involved in decisions to forgo further treatment. This requires explicit discussion and effective communication, often over the course of several days. Multidisciplinary family conferences, led by the attending physician, are extremely valuable to consensual decision-making and the prevention of conflict between clinicians and surrogates. When the decision to pursue comfort care is made, a consensus regarding the plan for how life support will be withdrawn is essential.

When conflicts arise, specific issues of misunderstanding (e.g., values conflicts, inadequate knowledge) should be elicited and dealt with accordingly to reduce discordant expectations. Skillful negotiation resolves most conflicts including futility disputes. In situations where conflict with families is ongoing or anticipated, early ethics consultation is often helpful. When there is dissent within the family, which is often due to prior unresolved issues, emotional support from the social worker or spiritual care services, if appropriate, can be invaluable. When conflicts exist among interdisciplinary team members, it is important to clarify goals of care before the family becomes involved in the discussions so that efforts are coordinated, and family members are not burdened by divergent medical views. One member of the medical team should serve as the main spokesperson with the family; this is traditionally the attending physician or his/her designate, and should not be left to house staff or junior clinicians.

### PROCESS OF WITHHOLDING OR WITHDRAWAL

#### Transition from Life-Sustaining Care to Comfort Care

Management goals in the transition from life-sustaining treatment to comfort care should focus on ensuring that the patient and family are prepared, patient suffering is avoided, and that death occurs in the best manner possible within the ICU, thus preserving the patient's dignity, respect, and comfort. As such, only interventions aimed at achieving the goals of comfort care should be pursued; all previous therapies or procedures that do not specifically contribute to the patient's comfort should be avoided or discontinued.

#### Documentation of DNaR and Withdrawal of Life Support Orders

Do not attempt resuscitation (DNaR) orders are one form of withholding life support intervention. Often in the critical care setting, the determination of DNaR precedes the decision to withdraw other life support measures (e.g., mechanical ventilation, vasopressors, etc.). As such, DNaR orders alone carry no implications regarding other EOL treatment plans, and therefore must be specified separately. DNaR order protocols require the stipulation of whether all resuscitative efforts are to be withheld, or attempted with limitations (e.g., medication or defibrillation only).

✎ **With the decision to WH/WD-LS, all orders should be rewritten to reflect that the intent of treatment has shifted to providing comfort care to the patient, without regard to physiologic stability.** ✎ Documentation should be explicit regarding the patient's condition, the agreed on goals of care, and the procedure for WH/WD-LS, including the plan for the assessment and management of symptoms. ICU nurses should be given latitude in pharmacologic dosing with clear guidelines for PRN indications and dosage adjustment (e.g., pain, dyspnea, anxiety, and agitation). Several authors have recommended the use of standardized order sets (37), though this practice is not currently in widespread use. If needed, palliative care or pain management consultation can be sought. This is done proactively in some institutions. Appropriate multidisciplinary consultation for support services for example, social work and pastoral care should also coincide with orders for WH/WD-LS.

#### Confirming Patient Preparation

✎ **Before any active WH/WD-LS, the patient needs to be started on sedatives and analgesics and made comfortable as assessed by the bedside nurse and/or attending physician.** ✎ If neuromuscular blockade agents (NMBAs) were used to this point, they must be stopped. Suggestions for sedatives and analgesics to achieve this goal are detailed subsequently.

Although the vast majority of patients have already lost consciousness, by the time WH/WD-LS is considered, any conscious patient should be prepared for what they will experience.

#### Ensuring Family Preparation

The patient's family and loved ones require particular preparation and ongoing support during the transition process. Anticipatory guidance in relation to the dying process, for example, how the patient will look, and in general terms, the patient's expected length of survival (though rarely predictable), can help prepare family members for what to expect. Specific needs and wishes regarding the moment of death should be clarified; though most family members

wish to be present, this is neither universal nor always possible. Postponing withdrawal to await the arrival of geographically distant loved ones when requested is another important consideration since WH/WD-LS is never an emergency. Adherence to the planned time of WD is essential, as families should not be burdened with the emotional upheaval of waiting due to competing clinician time demands.

Cultural and religious traditions have a significant influence on the experience of death. **Traditional rituals or practices should be respected and allowed to occur whenever possible, as their observance in preparation for death is frequently a source of comfort for the patient/family.** Cultural and spiritual values and beliefs may differ markedly from those of clinicians, emphasizing the importance of elucidating patient/family goals and preferences before the process of WH/WD-LS (see Volume 2, Chapter 68).

Clinician presence and time spent with the family to learn about the patient as an individual is invaluable. **Encouraging reminiscence of positive life experiences and important relationships in the patient's life often helps to facilitate the family's grieving process at the EOL.**

Before withdrawal of therapy it is also important to discuss with families what will happen after the patient's death. Consideration should be given to issues such as death notification procedures, autopsies, handling of the body, and resources for funeral arrangements.

### Technical Details of Withdrawing Therapy

The withdrawal of life support is a clinical procedure and deserves the same level of physician preparation and involvement as any other medical intervention. Physicians need to decide which life support measures will be WH/WD, in what sequence, and by whom. This decision-making should be in accordance with family preference. However, since families are seldom experienced in this regard, clinicians should facilitate the process by supplying options that are most suitable to a peaceful death.

**Discussions with families regarding the WH/WDSL should not be left to novice clinicians.** This is the time when experienced senior clinicians are required. However, most families are agreeable for novice clinicians to sit in on discussions for the purposes of training, especially if the novice is known to them or has already participated in the patient's care. **The family should be reassured that clinicians will remain available and that their loved one will be kept comfortable and free of pain, suffering, or any distress throughout the entire process.**

### Considerations for Therapy Withdrawal

When determining which therapies to withdraw, physicians should be guided by the goals of care, that is, mitigation of patient suffering and needs of the family, rather than a prescribed pattern. In general, once the decision to WH/WD-LS has been made, all focus should be on maintaining the patient's comfort. Owing to their lack of impact on the dying process, it generally is best to WH/WD all drugs and therapy except for the administration of sedatives and analgesics, unless other agents are needed for symptom palliation (e.g., antiemetics, seizure prophylaxis).

Occasionally, the family will ask that certain therapies, for example, enteral nutrition and hydration, continue to be administered, and that treatments be WH/WD in a stepwise fashion. When this approach is used, the ordering sequence should be prioritized such that any treatment that is

potentially uncomfortable be WH/WD first. The only therapy that should be considered for a staged WH/WD is ventilator support, because absence of nearly any other therapy is not associated with pain or discomfort (38). Indeed, the gradual WH/WD of other therapies risks exposure of the patient to additional suffering, and is not legally necessary or ethically appropriate. There is no ethical reason for gradual withdrawal, and a valid ethical case against gradual withdrawal can be made on the grounds that partial treatment strategies or stepwise withdrawal when death is inevitable may expose the patient to further suffering, and prolong the family's grief as well (38).

### Abrupt Ventilator Withdrawal vs. Terminal Weaning

Several methods of withdrawal from mechanical ventilation can be used depending on the patient's clinical condition and physician experience. In terminal weaning, the endotracheal tube is left in place following stepwise reductions in ventilatory support, which can take place gradually or rapidly. In some cases, extubation follows the wean. Terminal extubation entails a rapid cessation of mechanical ventilation and artificial airway removal. Arguments in favor of extubation following rapid weaning focus on the removal of unnecessary equipment, maximization of comfort, and reducing the prolongation of dying as well as the family's anguish. Those who favor of terminal weaning reason that it minimizes dyspnea, and prevents airway obstruction (19,39). Limited data are available to justify one method over the other for any particular set of clinical circumstances. Accordingly, practice patterns vary widely in terms of approach at WH/WD-LS, with most studies demonstrating that terminal weaning is currently more common, although this is changing. However, terminal weaning lasting for many hours should be avoided as it only prolongs the dying process. Regardless of the method employed, patient comfort and support of the attendant family are the primary concerns. Dyspnea and anxiety should always be anticipated, and patients should be appropriately medicated with sedatives or analgesics before the initiation of WH/WD-LS (14,15,40).

### Recommended Approaches

The optimal approach to WH/WDSL will vary between institutions, physicians, patients, and clinical circumstances. However, several key principles (Table 2) should be observed regardless of the specific details. These considerations have been articulated in other sections of this chapter. Above all else, providing a humane environment for the patient and family and ensuring that the patient is allowed to die with respect, dignity, and with the least discomfort possible represents the optimal approach.

The optimal approach also requires that the family is involved in the decision-making process to WH/WD-LS. Once the plan has been decided, it should be clearly articulated to the nursing staff, documented in the patient record, and corresponding orders should be written. Patients on NMBAs should have these discontinued, and those not receiving sedatives or analgesics should have these started, with orders to select and titrate dosing as required to prevent symptoms of dyspnea, pain, or anxiety.

The environment should be made conducive to the WH/WD-LS, with particular attention to comfort and esthetic elements. A private room, soft lighting, and reduced noise are often comforting, as are presence of photographs and other meaningful mementos of the patient's life.

**Table 2** Key Considerations During the Withholding or Withdrawal of Life Support in the Intensive Care Unit

Key consideration	Examples/comments
Ensure family agreement and preparation	Ascertain consensus and acceptance of transition to palliative care goals. Explicitly address and attempt to resolve any conflicts before WH/WD-LS. Once the decision has been made to WH/WD-LS, family preparation centers on support and guidance during the process. Reassurance that the patient's comfort and dignity will be maintained is critical to the family's well-being. Specific needs and preferences regarding the time of death (e.g., wish to be present) should be elicited and accommodated whenever possible.
Document orders are written for WH/WD-LS	Distinguish DNaR orders from WH/WD-LS orders; DNaR orders alone carry no implications regarding other EOL treatment plans, and must be specified distinctly. Documentation should be explicit regarding the patient's condition, the agreed on goals of care, and the procedure for WH/WD-LS.
Confirm patient preparation (including adequate analgesia/sedation)	Initial IV bolus dosing and continuous IV infusion of analgesics and sedatives should be started before the active WH/WD-LS, and PRN bolusing to treat any symptoms of distress is optimal. Provision of adequate dosages of opioids and benzodiazepenes will provide effective analgesia and sedation in virtually all patients.
Physical care and comfort of the patient	Remove invasive lines and discontinue interventions that may cause discomfort to the patient. Disable audible monitors and alarms (except at central station). Disable pacemakers and automatic internal (or external) cardiac defibrillators. Allow family to participate in care of patient as desired; encourage physical touch/contact. Respond to family member's concerns regarding patient comfort as often they are able to accurately interpret patient behaviors indicative of distress.
Appropriate setting, quality, and continuity of care	Transfers out of the ICU should be the exception, rather than the norm; ICU care ensures lower nurse: patient ratios, close surveillance, and availability of multiple resources for aggressive symptom management. If transfer is required or requested, assure family members that continuity in the plan of care will be maintained. New clinicians should be introduced to the family, and transfer protocols clearly specified.
Privacy and environmental modifications	Ensure privacy of family for personal expressions of words, emotions and cultural/spiritual rituals. Modify environment to reduce noise, soften lighting, and make as comfortable as possible. Remove unnecessary machines/technology.
Multidisciplinary support	Maintain clinician access and close presence to inform and support family members during the dying process. Offer support services (pastoral care, ethics consultation, bereavement specialists) as appropriate.

*Abbreviations:* DNaR, do not attempt resuscitation; EOL, end-of-life; ICU, intensive care unit; IV, intravenous; PRN, pro re nata as needed; WH/WD-LS, withholding or withdrawal of life support.

For some patients and families, playing calming music can also help transform the environment and keep the emphasis on pleasant, loving memories. Visitation policies should be liberalized, allowing loved ones who wish to be present to remain with the patient during the WH/WD-LS.

✎ **Throughout the entire WH/WD-LS the patient should be as clean and meticulously cared for as possible.** ✎ This helps the family and loved ones remember the dying patient in a more positive way and to ensure that the patient's dignity at the time of WH/WD-LS. Moreover, this also communicates to the family that the medical and nursing staff care for, respect, and share their concerns for the patient.

Once all the arrangements previously described are complete, the patient should optimally have all tubes removed, except for the infusion line for sedatives or analgesics, and drainage tubes that may result in obstructive symptoms and pain without their presence. Alarms on all ventilator devices, infusion pumps, and monitors should be disabled. The monitor screen at the bedside should also be turned off, although an ECG or pulse oximetry signal transmitted to the central nursing station can give helpful

clues about the speed of the patient's decline. In addition, pacemakers and automatic internal cardiac defibrillators should be deactivated.

It is important for the bedside nurse to keep a watchful eye over the patient to check for signs of inadequate sedation and analgesia as well as monitoring for the cessation of ventilatory efforts, and cardiac function. The nurse's presence at the bedside during this time can be an invaluable source of information and emotional support for family and loved ones.

Last, the ventilation should be discontinued and, when sedation and analgesics are optimally titrated, the ETT should also be removed providing that removal is not expected to lead to stridor or immediate partial/complete airway obstruction. Often, careful positioning of the patient in the "recovery position" can reduce symptoms of airway obstruction. The benefit of removal of the ETT is that the patient will appear more natural and like themselves. In the case of patients with expected stridor or obstruction following extubation despite adequate positioning, the ETT should remain in place, with the patient removed from the ventilator circuit and placed on humidified room air.

## SYMPTOM MANAGEMENT

### Administration of Sedatives and Analgesics

There is no sound rationale for withholding analgesia or sedation when the goal is comfort and symptom relief. During the WH/WD-LS, conventional administration rules do not apply and optimal dosing is determined by the control of symptoms (e.g., pain, agitation, and dyspnea), without concern for cardiopulmonary side effects of the drugs, regardless of the dosage required. ⚡ **When administered in adequate dosages, opioids and benzodiazepines (or propofol) provide adequate analgesia and sedation in virtually all patients during the WH/WD-LS.** ⚡ Anticipatory dosing should also occur whenever the patient has any presumptive reason for distress. Medical orders should clearly specify the intended use for analgesia and sedation, guided by the principle of double effect.

Opioids provide the foundation of pharmacologic management during the WH/WD-LS by providing analgesia, some sedation, and blunting of respiratory and cough responses. In most cases morphine is the ideal opioid because it is easily titratable with rapid onset of action and few adverse effects; fentanyl and hydromorphone are equally effective. Fentanyl is less likely to cause histamine-related effects and is useful in patients allergic to morphine, although it produces less sedation. Meperidine should be avoided because its active metabolite normeperidine can theoretically produce seizures. Age, organ system function, and prior use of opioids (opioid naive vs. tolerant) also necessitate dose adjustment. Occasionally nonopioids are used adjvantly to manage concomitant inflammatory or neuropathic pain.

Benzodiazepenes are indicated for sedation and anxiety, are synergistic with opioids, and have useful anterograde amnesic effects and anticonvulsant properties. Benzodiazepines are generally preferable to antipsychotics (e.g., haloperidol). However, propofol can be used as well. As with opioids, benzodiazepenes or propofol are optimally administered by continuous IV infusion with bolus dosing as needed for symptom control and drug level maintenance. Haloperidol is generally not required at this juncture in patient care.

Neuromuscular blockade agents should be avoided or discontinued before the WH/WD-LS as there is no therapeutic purpose for paralytic use during ventilator withdrawal. NMBAs mask assessment of patient distress, making it impossible to determine the efficacy of analgesics and sedatives in achieving comfort, and may cause suffering without adequate analgesia (12,14,15,38,41).

Physiologic assessment tools, sedation scales, and so on are useful (though not always reliable in unconscious patients) to quantify evaluation of pain or other distress (see Volume 2, Chapter 5). In addition, family members are often able to accurately interpret patient behaviors associated with pain or anxiety and should be encouraged to share opinions and concerns regarding symptom management with the nursing staff.

### Nonpharmacologic Management of Pain and Suffering

Palliative care in the ICU involves more than analgesia and sedation. ⚡ **Nonpharmacologic management of suffering involves discontinuation of “routine” interventions in the ICU that cause unnecessary discomfort to the patient.** ⚡ Any treatment that is not essential to achieving comfort should be stopped; this includes blood draws, diagnostic exams, painful wound care, and repeated vital sign monitoring.

Aggressive pulmonary hygiene including endotracheal suctioning should be avoided unless it aids in comfort, although this is rare. In contrast, gentle suction of secretions from the mouth of a recently extubated patient can reduce the noise of breathing. Noisy breathing is distressing for families and loved ones who often refer to it as “the death rattle” which is historically associated with a prolonged and painful death.

Invasive lines, for example, Swan Ganz catheters, arterial lines, ICP monitoring devices, and so on, can be removed and monitor alarms disabled. Environmental stressors such as excessive noise, light, and activity should be minimized. Removal of restraints, equipment, and lowering of bedrails allows loved ones more intimate contact with the patient (12,15,35,41).

Even though family members may be fully cognizant of the withdrawal process, they are often reluctant to touch the patient. This is probably a consequence of their previous experience when active care was still in progress and they may have been fearful of dislodging vital monitoring devices or equipment. ⚡ **During the WH/WD-LS process, family members should be explicitly informed that it is entirely permissible, and usually beneficial, to touch and hug the patient, if this is their wish.** ⚡

### Physical Care and Comfort of the Patient

Attentiveness to the physical care of the patient is important from a patient comfort perspective, as well to assure family and loved ones that the patient is receiving excellent care from clinicians. Meticulous attention to the patient’s physical comfort, hygiene, and appearance conveys caregiver respect and protects dignity. To meet both, patient and family needs, ICU staffing patterns should reflect requirements for higher, not lower, intensity and acuity in the nursing care needs of dying patients.

## PROVIDING A CARING ENVIRONMENT

### Appropriate Settings, Quality, and Continuity of Care

When death is imminent in critically ill-ventilator dependent patients, it is recommended that the patient remain in the ICU for comfort care; transfers should be the exception, rather than the norm. This ensures continuity of caregivers, higher nurse: patient ratios, and availability of multiple resources needed when aggressive symptom management or close surveillance is required (e.g., ventilator or vasopressor withdrawal). Efforts should be made to adapt the ICU environment to provide a comfortable, private, and less technology dominant setting.

If the family requests transfer, or when needs may be more effectively met in another setting, the patient can be transferred out of the ICU, especially if not ventilator dependent. When the patient is transferred to a new location, it is imperative that the transition to floor care (or although rare for critically ill patients, to a hospice environment), be as seamless as possible. In circumstances where a new set of clinicians must be involved, introductions should be made to family members, and transfer protocols should include a detailed report of the patient’s status to ensure the plan of care will not be disrupted. The receiving clinicians must be made specifically aware of the rationale for WH/WD-LS as well as the agreed on plans for implementation so that continuity of care is maintained.

### Ensuring Patient and Family Preferences for Privacy

Family members should be allowed to spend as much as they wish with the dying patient with unrestricted visiting hours. Although preferences for the level of involvement in care vary, family members can be allowed to participate in care at a level which they feel most comfortable. Private time spent together as a loved one is dying is, for many families, a time of reflection and reconciliation.

### Providing Emotional and Physical Comfort to Family and Loved Ones

The support and presence of clinicians, especially the ICU nurse, is vital to the family's emotional well-being during this vulnerable time. Distress is reduced when the family is kept informed of the withdrawal process, and expressed concerns are assiduously addressed (28,42,43). Private space for families away from the general visitors waiting room to eat, rest, make phone calls, and so on, is important to provide respite and accommodate practical support needs (see Volume 2, Chapter 64).

### Multidisciplinary Support

✎ The combined efforts of a multidisciplinary team including nurses, physicians, social workers, and spiritual care providers are essential to providing comprehensive palliative care in the SICU. ✎ No one discipline can address the multidimensional needs of patients and families, and each offers expertise in achieving the goals of care. Ideally, clinicians involved in the patient's care should be available at the time of death to support bereaved family and loved ones.

### Emotional Support for the Clinical Staff

The death of any patient is often difficult for medical staff to reconcile, particularly if that patient has already been subject to intensive efforts directed at saving life. Other factors that tend to make it more difficult than usual for caregivers is when the dying patient is young, was talking or active for some portions of the critical care management, and when the patient has an unforeseen sudden catastrophic event, such as a massive pulmonary embolus.

Although one's professional responsibility is concerned primarily with the care of the patient and family, the emotional needs of colleagues, particularly those who are inexperienced, should also be considered. Senior clinicians should ensure that there is a mechanism for dealing with the impact of the death of a patient on those staff members who have been involved in the patient's care.

### EYE TO THE FUTURE

Although WH/WD-LS is common practice for general intensive care patients, its application and benefits are less well studied in trauma populations (44). The unexpected, often tragic nature of life-threatening injury and the fact that trauma patients tend to be young and previously healthy complicate the traditional notions of palliative care and create enormous levels of stress and uncertainty in both family members and clinicians. Although increasing attention is being given to palliative care, current models do not always fit the clinical realities of a trauma/surgical ICU. At present there is a dearth of studies specifically addressing EOL issues in trauma populations, and hopefully more will come in the future.

Much remains to be learned regarding best methods of WH/WD-LS and optimizing comfort of the dying patient, as well as the most effective intervention strategies to support grief-stricken family members through the process of decision-making and the transition to EOL care following trauma. Because death is inevitable the culture of the trauma service necessitates an expansion of the mission and focus from one solely aimed at saving lives to one which also addresses the physical and emotional EOL issues for those patients who will not survive their injuries.

Palliative care must not be considered as a sequel to "failed" intensive care but rather an integrative component of caring for critically ill and injured patients (45). Further research is needed to explore trauma-specific intervention strategies regarding WH/WD-LS, and to identify the most effective quality measures for improving palliative care in trauma populations.

Although this is changing, trauma care providers have had little formal education in the principles and skills of palliative care. Numerous efforts are underway such as those by the SCCM, RWJF, and the AMA Education for Physicians on End-of-Life Care (EPEC) Project. California has led the way by enacting law AB487, which requires all MDs to take 12 hours of continuing medical education in pain management and palliative care by Dec 31, 2006.

Furthermore, in the clinical setting, experienced critical care practitioners have many opportunities which enable them to serve as role models and mentors to junior clinicians, in teaching and demonstrating the knowledge and skill sets required to provide excellent palliative care in the ICU.

### SUMMARY

As most patients who die in an ICU do so following WH/WD-LS, compassionate clinical management of death is an important goal. As providers of EOL care, trauma surgeons and critical care clinicians must be knowledgeable and skilled in both the humanistic competencies of shared decision-making surrounding EOL issues and the technical competencies required to provide quality palliative care to patients and their families during this stressful time.

Legal and ethical justification for WH/WD-LS rests on the principles of informed consent and patient autonomy. In ICU patients, this right is most often exercised through surrogates (usually a family member or other loved one) acting on behalf of and in accordance with the patient's values and beliefs.

When medical futility is evident, it is incumbent on physicians to inform and advise surrogates of the limitations of medical treatment and technology. In preparing families for EOL decision-making, clinicians must recognize the emotional toll involved and be prepared to guide them through the difficult process, avoiding undue guilt or burden. A shared model of decision-making is the optimal approach.

When hope for recovery is ended, and the decision to WH/WD-LS has been made by families and the medical staff, the focus of patient care changes from curative interventions to comfort care, where the primary goal is the provision of nonpainful supportive measures and the elimination of needless suffering and distress. Adequate analgesia and sedation is achievable in virtually all patients during the WH/WD-LS, and based on the principle of

double effect, no maximum dose of analgesics or sedatives exists when the intent is to relieve pain or suffering.

Families and loved ones of dying patients require the utmost support and compassionate care from clinicians. Care provided to the patient which emphasizes comfort, dignity, and respect is vital to achieving this end. Individual preferences and spiritual and cultural values and traditions should be honored. All families should also be offered supportive services from multidisciplinary experts in pastoral care, ethics, and social services during this vulnerable time, as well as being provided with information on referral sources for bereavement support (see Volume 2, Chapter 64).

## KEY POINTS

- ✦ Consistent with the principle of autonomy, it is medically ethical to WH/WD-LS treatment whenever it is unwanted, or no longer desired by the patient or his/her surrogate.
- ✦ Recent thinking emphasizes the notion that futility occurs when the burden of treatment far exceeds any anticipated benefit to the patient.
- ✦ When futile conditions are recognized by the care team, physicians are obligated to convey this information to the family to ensure full disclosure of medical information, a necessary prerequisite to shared decision-making.
- ✦ The ethical principle of “double effect” when used to justify comfort care conveys that analgesics and sedatives can have the dual effect of relieving suffering as well as hastening death, and that the administration of these drugs is appropriate if the primary goal is to provide symptom control (e.g., relief of pain, and suffering), even if death is hastened in the process (25–27).
- ✦ From an ethical perspective there is no difference between the WH and the WD of treatment which only prolongs life without a realistic chance of cure, and such distinctions are morally irrelevant.
- ✦ It is important to recognize that it is never an emergency to WH/WD-LS.
- ✦ Family members should not be left to feel alone with the burden or guilt that their decisions are responsible for ending a loved one’s life. Clinicians can effectively guide families through the process of reorienting goals from therapeutic to comfort care through honest, timely, and compassionate communication (28).
- ✦ Families also need to be assured that withdrawal is legally permissible and ethically humane, and that the administration of sedatives and analgesics is not analogous to euthanasia.
- ✦ With the decision to WH/WD-LS, all orders should be re-written to reflect that the intent of treatment has shifted to providing comfort care to the patient, without regard to physiologic stability.
- ✦ Before any active WH/WD-LS, the patient needs to be started on sedatives and analgesics and made comfortable as assessed by the bedside nurse and/or attending physician.
- ✦ Traditional rituals or practices should be respected and allowed whenever possible, as their observance in preparation for death is frequently a source of comfort for the patient/family.
- ✦ Encouraging reminiscence of positive life experiences and important relationships in the patient’s life often

helps to facilitate the family’s grieving process at the EOL.

- ✦ Before withdrawal of therapy it is also important to discuss with families, what will happen after the patient’s death.
- ✦ Discussions with families regarding the WH/WDLS should not be left to novice clinicians.
- ✦ The family should be reassured that clinicians will remain available and that their loved one will be kept comfortable and free of pain, suffering, or any distress throughout the entire process.
- ✦ Throughout the entire WH/WD-LS the patient should be as clean and meticulously cared for as possible.
- ✦ When administered in adequate dosages, opioids and benzodiazepines (or propofol) provide adequate analgesia and sedation in virtually all patients during the WH/WD-LS.
- ✦ Nonpharmacologic management of suffering involves discontinuation of “routine” interventions in the ICU that cause unnecessary discomfort to the patient.
- ✦ During the WH/WD-LS process, family members should be explicitly informed that it is entirely permissible, and usually beneficial, to touch and hug the patient, if this is their wish.
- ✦ The combined efforts of a multidisciplinary team including nurses, physicians, social workers, and spiritual care providers is essential in providing comprehensive palliative care in the SICU.

### INTRODUCTION

The training of medical students, interns, and residents in busy trauma and critical care services are generally focused on the basic science principles and clinical treatment guidelines required to manage severely injured patients. Often missing in the curriculum is expert guidance regarding the most efficient methods of data collection, patient presentation on rounds, and clear note writing. This chapter provides guidance in these areas, and also suggests techniques for obtaining appropriate assistance and input from consultant specialists.

### PREROUNDING

Some of the most tedious and at times stressful portions of a young physician's life on a trauma and critical care service are spent chasing down information and evaluating patient conditions in preparation for the subsequent presentation of this data on attending rounds. Some of this stress is natural and unavoidable due to the numerous tasks that need to be accomplished during the typically short time window. However, the guidance summarized in this chapter provides some structure to these activities and, if followed, should help to facilitate the process. ✎ **In general, the resident should collect and organize the information in the same way that he/she plans to present the data on rounds.** ✎

Much of the information can be collected (and arranged) prior to the morning "preround scramble." For example, the night before, the resident can compile lists of information to be presented (listed subsequently) on a card or piece of paper, organized in the same order as it will be used for presentation in the morning. All the information that is known to have occurred since the last attending rounds and not expected to change can be included in these lists, leaving blank spots for the new data (which can be obtained in the morning).

Data that can often be chronicled in the evening prior to rounds include: (i) radiographic and other imaging results, including computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (U/S); (ii) laboratory

studies ordered and completed that day, such as gram stain and culture data; (iii) progress made during spontaneous breathing trials of weaning patients, along with weaning parameters; (iv) tolerance of enteral nutrition, and so on. These precollected data points only need brief verification in the morning. Items that are expected to change and need to be evaluated in the morning include: (i) the physical examination, with particular focus on the neurological, and cardiopulmonary status; (ii) fluid balance; (iii) laboratory results from the morning blood draws; (iv) morning radiographs, and so on. Asking the bedside nurse about the important events that transpired through the evening and speaking directly to the various consulting teams will also help fill in the blanks.

✎ **New computerized patient information systems allow automatic incorporation of vital signs, laboratory, and even radiographic reports into templates that can be used for prerounding.** ✎ Often rounds can be expedited by printing these templates first thing in the morning, and transcribing (or appending) the precollected data from the prior day to the prerounding template. In order to make these written notes useful for rounds and subsequent note writing, they must be organized according to a logical scheme, generally in the same order as it will be used for the presentation itself.

### PRESENTATION ON ROUNDS

Because of the limited time available for rounds, typically one and half hours to review up to 20 critically ill patients, no longer than five minutes should be routinely spent presenting the data and summarizing your assessment and plans for any one particular patient. Accomplishment of this goal requires that data be transmitted to the team in an accurate, timely, and concise yet comprehensive manner. This requires a high level of sophistication of the resident, as well as hard work. More extensive discussion on specific patients can occur at case conferences, during patient management tasks. On any given day expect that some percentage of patients will require more in-depth discussion, further evaluation, and management discussion time during attending rounds.

**Table 1** Elements for Presentations in the SICU

Topic	Relevant data	Details required
Identification	Identify patient Reason for admission Days in the SICU	Detailed
Past medical problems	Conditions medications	Detailed first day and then abbreviated
Specificity of presentation (trauma patient)	Mechanism of injury Full admission trauma evaluation listing the GCS and VS in TRS, as well as ABG, Hct Full list of imaging studies involving head, C-spine, chest, abdomen, pelvis, and extremities	Detailed first day—only refer to pertinent studies as appropriate subsequently (note this is the tertiary survey of the trauma patient)
Specificity of presentation (other surgical Hx)	Chief complaint History of present illness Work up	Detailed first day only abbreviated subsequently
Past medical problems	Conditions Medications	Detailed first day and then abbreviated
Systematic review	Significant events since last rounds System by system review to include physical exam and relevant medications	Detailed
Current medications and prophylaxis	Discussion of medications not discussed in systems review Discussion of need for deep venous thrombosis and gastrointestinal bleeding	Detailed
Assessment	Identification of problems	Detailed
Plans	Recommendations of management of problems	Detailed

*Abbreviations:* ABG, arterial blood gas; C-spine, cervical spine; GCS, Glasgow Coma Scale; Hct, hematocrit; SICU, surgical intensive care unit; TRS, trauma resuscitation suite; VS, vital signs.

Many different models are available for presentation of critically ill patients, which can vary in sequence but are similar in content (1,2). The six elements that should be present in surgical intensive care unit (SICU) patient presentation, corresponding with the six steps of the presentation, are summarized in Table 1.

### Step 1—Identification of the Patient

All presentations in the SICU should begin with identification of the patient. The most up-to-date diagnoses and problems should be presented up front, just as if one is reading the headline of a newspaper. **Identification of the patient should explain to all the team members exactly what is wrong with the patient (i.e., why the patient is here) and where the team is in the work up of, or therapy for, the patient's pathological conditions.**

An example of a good identification (for a new trauma admission) is as follows: Mr. "X" is a 70-year-old man with steroid dependent chronic obstructive pulmonary disease (COPD) who was a restrained passenger in a motor vehicle collision yesterday. He is now postoperative day #1, status post exploratory laparotomy and splenectomy.

### Step 2—History of Present Illness (Includes the Trauma Workup)

Following the identification for a new patient, a focused but complete history of present illness (HPI) is provided that includes only the pertinent data (positive and negative studies). In the case of a trauma patient, pertinent prehospital details as well as the radiographic and laboratory results of the primary (see Volume 1, Chapter 8) and secondary (see Volume 1, Chapter 14) surveys of the trauma evaluation are

presented on the first day. In addition, operative and nonoperative interventions are described and any pertinent changes in neurological or cardio-pulmonary stability that occurred during the procedures are noted; the operative estimated blood loss (EBL) and resuscitation fluids are also presented when significant.

Pertinent trauma evaluation data includes mental status in the trauma bay (head CT if altered), results of chest X-ray (CXR), pelvic, and cervical spine (C-spine) radiographs or CT results and the methods used to objectively evaluate the abdomen [focused abdominal sonography for trauma (FAST) versus diagnostic peritoneal lavage (DPL)] (Table 1). Trauma patients will require a detailed and accurate list of all injuries enumerated at this time. An abbreviated version is presented on subsequent days. This subsequent day list should be a short summary of all known injuries presented either with the most significant injuries first, or a listing of injuries in a head to toe fashion.

### Step 3—Past Medical—Surgical History

Often large portions of data from the past Medical—Surgical history (PMHx) are missing in the obtunded trauma patient upon initial presentation. Young healthy patients usually have an insignificant PMHx and in this population the missing information is often of little consequence. However, with the increasing number of elderly patients presenting with trauma, the PMHx can be particularly pertinent. Accordingly, efforts should be made to call family or primary physicians to obtain such data in these individuals.

In one or two sentences, the presenter should list the known medical problems as well as prior surgeries,

trauma, and often pre-existing conditions (e.g., missing kidney, prior stroke, etc.). An abbreviated version of this step (including a list of all significant ongoing medical or surgical problems) should be presented daily. This practice, in concert with listing all known injuries as mentioned in step 2, serves to remind members of the team of: (i) the original injuries or pathology; (ii) the current status of treatment; along with (iii) the possible confounding issues that help put the patient's response to therapy into proper context. Any new information obtained about the patients PMHx should also be presented at this time, and on subsequent days.

#### Step 4—Current Review of Systems

The next phase in the critical care presentation of trauma patients involves a stepwise update of the patient's current physiological status in terms of each major organ system. The presenter should provide a clear picture of the current condition, along with any important perturbations that have occurred since the last rounds. 🐉 The systematic review of the patient's various organ systems should

proceed methodically, but with only the detail required to provide the listeners with a clear understanding of the patient's status. 🐉

The systems review is usually best accomplished using a format that covers each organ beginning with the most important, the brain (Table 2). The review then proceeds with the other systems: cardiovascular, pulmonary, and so on, providing a head to toe review.

Medications relevant to each organ system are typically listed during that portion of the presentation. For example, during the neurological presentation, sedative, analgesics, neuromuscular blockade, seizure prophylaxis, mannitol, and so on, are mentioned; during the cardiovascular report, inotropes, vasodilators, and pressors are discussed; during the hematological discussion anticoagulation drugs employed therapeutically [or for deep venous thrombosis (DVT) prophylaxis] are usually mentioned. Any new findings on the physical exam, as well as laboratory or imaging data, is also reported when the relevant organ system is discussed.

**Table 2** Systems Review of Patients in the Surgical Intensive Care Unit

System	Physical examinations	Monitoring/lab values	Medications/therapy
Neurologic	GCS Ox3 Pupils RASS Motor and sensory CN I–XII	ICP measuring devices Pain and anxiety level	Analgesic Anxiolysis Paralytics Osmotic agents Antiseizure
Cardiovascular	Auscultation Murmurs Skin perfusion Pulse character	Mean arterial pressure ECG Pulmonary pressure monitoring Troponin	Pressors Inotropes Vasodilators
Pulmonary	Breath sounds Secretions Ventilatory pattern	Level of support (ventilation mask, FIO <sub>2</sub> , V <sub>T</sub> , PEEP) PIP, ABG results	
GI	Inspection (distension) Auscultation Palpation	Nasogastric tube output Bowel movements (constipation or diarrhea) Laboratory (amylase, lipase, LFT's, etc.)	Motility agent Nutrition (enteral or parenteral laxatives) Antidiarrheals
GU	Is & Os	Electrolytes to include BUN and creatinine	Diuretics IV fluids
ID	T <sub>MAX</sub> Line (peripheral and central)	WBC Culture results Sputum Lines Blood CSF Urine Wounds	Antibiotics GM + coverage GM – coverage Anerobe coverage Antifungal/antiviral Total days therapy
Hematology	Blood Hematomas Telangiectasias	Hematocrit Coagulation profile	Heparin, FFP SCDs
Endocrine	Goiter, etc.	Glucose, TFTs	Insulin, synthroid

**Abbreviations:** ABG, arterial blood gas; BUN, blood urea nitrogen; CN, cranial nerves; CSF, cerebral spinal fluid; ECG, electrocardiogram; FFP, fresh frozen plasma; FIO<sub>2</sub>, forced inspiratory oxygen; GCS, Glasgow Coma Scale; GM–, gram-negative; GM+, gram-positive; GU, genitourinary; ICP, intracranial pressure; ID, infectious diseases; LFT, liver function tests; Is & Os, Inputs and Outputs; Ox3, oriented x person, place, time; PEEP, positive end expiratory pressure; PIP, peak inspiratory pressures; RASS, Richmond agitation sedation scale; SCDs, sequential compression devices; TFTs, thyroid function tests; T<sub>MAX</sub>, maximum temperature; V<sub>T</sub>, tidal volume; WBC, white blood cell count.

### Neurological

In terms of neurological examination, the highest level of functioning is reported, along with any alteration or new deficits discovered since admission or the last rounds. Patients who are awake are described in terms of alertness and orientation. Those who are comatose are assigned a Glasgow Coma Score (GCS). Those with intracranial pressure (ICP) monitoring devices, and/or ventriculostomy outputs should have those values reported at this time, along with the cerebral perfusion pressure (CPP) when relevant. A pupillary exam is also reported along with the infusion doses of sedatives, analgesics, and neuromuscular blockade drugs (if used), as these will affect both the neurological exam and CPP indices.

Patients who are sedated but not comatose are reported in terms of their pain score and a sedation agitation score such as the Richmond Agitation Sedation Scale (RASS) further described in Volume 2, Chapter 5. Patients with subarachnoid hemorrhage may require nimodapine and triple H (hypervolemia, hemodilution, and hypertensive) therapy. Those patients receiving seizure prophylaxis medication should have dosing and blood levels reported, along with mention of any recognized seizure-like activity since admission, or the last rounds. Patients with spinal cord injury are described in terms of motor and sensory level per the American Spinal Injury Association (ASIA) guidelines (also see Volume 1, Chapters 16 and 26, and Volume 2, Chapter 13).

### Cardiovascular

The presenter should declare the type of electrocardiogram rhythm (sinus or otherwise) manifested by the patient's heart. This along with the heart rate (HR) and blood pressure (BP) constitutes the minimal cardiovascular (C/V) data that must be presented for each patient. Those with peripheral vascular disease or limb injuries should have mention of the pulse presence and character, capillary refill, and color/warmth of the skin on the extremities. Patients who are hemodynamically unstable and/or with invasive monitoring of filling pressures and hemodynamics should have that data reported in a logical and coherent fashion.

In the case of invasive monitoring, it is often useful to report pressures in sequence from the right side to the left side of the heart, followed by the cardiac output ( $\dot{Q}$ ) and derived variables [e.g., central venous pressure (CVP), pulmonary artery (PA) pressure, wedge,  $\dot{Q}$ , systemic vascular resistance (SVR), pulmonary vascular resistance (PVR), etc.]. The type and quantities of vasopressors and inotropes, should also be provided during the cardiovascular report so that the hemodynamic data can be interpreted within the proper context. Patients who have had U/S evaluations, troponin values, or other C/V data performed should have those results reported at this time. For patients who are hemodynamically stable and off inotropes, the preceding statement alone can in many times suffice, allowing the presenter to proceed to the next system which may be more relevant for that patient.

### Pulmonary

If the patient is oxygenating and ventilating adequately on room air (RA), little more needs to be said, other than the RR and pulse oximetry saturation level on RA. Patients receiving mechanical ventilatory support but still oxygenating adequately should have a brief mention of the mode of ventilation, forced inspiratory oxygen (FIO<sub>2</sub>), RR, tidal volume (V<sub>T</sub>), level of positive end expiratory pressure

(PEEP), as well as a report of the pH, PaO<sub>2</sub>, and PaCO<sub>2</sub> achieved on those settings, for evaluation of the ventilation settings. Whenever patients are oxygenating and ventilating without significant support, (i.e., PaO<sub>2</sub> > 60 mmHg, on FIO<sub>2</sub> < 40 and PEEP ≤ 5) then progress in weaning status should be reported. Minimal data regarding suitability for weaning involves the RR/V<sub>T</sub> achieved during any spontaneous breathing trials that were tolerated (Volume 2, Chapter 28).

In contrast, the patient with severe acute respiratory distress syndrome (ARDS) will require a detailed review of ventilatory settings beyond the FIO<sub>2</sub>, RR, V<sub>T</sub>, and PEEP, including peak inspiratory pressures (PIP), lung compliance, I:E ratio, V<sub>E</sub>, and so on. The associated arterial blood gas (ABG) is more carefully scrutinized in this condition, as is the CXR, and discussions of confounding oxygenation issues are appropriate at this time. Any relevant bronchoscopy, pulmonary secretion or chest tube data should also be offered at this time.

### Gastrointestinal/Splanchnic

The gastrointestinal (GI) system is typically reviewed here (Table 2). Pertinent positives include tolerance of enteral nutrition and naso-gastric tube (NG) outputs (if NPO and/or receiving parenteral nutrition). Prealbumin values should be reported every couple days until in the normal range is achieved, then evaluated and reported weekly thereafter (also see Volume 2, Chapter 31). Other considerations regarding the patient's nutritional status can be mentioned as well [e.g., results of metabolic cart, respiratory quotient (RQ), etc.].

GI stress ulcer prophylaxis can be mentioned here or later (when institutional protocols are reviewed). Liver function tests—amylase and lipase when pertinent—are mentioned in the GI presentation only when pertinent [e.g., following liver transplant (LFTs), pancreatitis (amylase)]. Patients with hepatic encephalopathy may have their dosing of lactulose and neomycin (or rifaxamine) mentioned in the neuro section, or here in the GI review. Plans for paracentesis are usually mentioned here or below with the fluid management presentation.

### Genitourinary-Fluid Status, Electrolytes, Blood Urea Nitrogen/Cr

The fluid, electrolytes, and genito-urinary data is generally presented next. Most important of which includes the 24° inputs and outputs (Is and Os) from various sites, of which the amounts and type of fluids infused are important, and the outputs from urinary catheters, naso-gastric (N-G) or oro-gastric (O-G) tubes, chest tubes, and other drains as well as stool are all important.

The daily assessment of blood urea nitrogen (BUN), creatinine, electrolytes, and glucose are monitored closely in critically ill patients. Abnormalities should be reported and corrective measures suggested. Some individuals may prefer to discuss glucose levels and insulin administration later in the review of endocrine considerations. Patients with oliguria (see Volume 2, Chapter 40) may have fractional excretion of sodium (FeNa) reported, and dialytic therapies are mentioned at this juncture.

### Infectious Disease

The infectious disease (ID) considerations are reviewed daily in all patients following trauma, surgery, or critical illness. The presenter should start by reporting the maximum temperature (T<sub>MAX</sub>) and the white blood cell (WBC) count along

with a differential (if known). This is followed by a report of gram stain and culture data from likely or known sources of infection including sputum, blood, invasive lines, and wounds. Urine is also reported and although commonly colonized, the urinary tract is an infrequent source of infection and fever in SICU patients, whereas the most common sources of infection in trauma and critical care followed by wound infections are lungs and invasive lines.

After presenting the culture data, the current antibiotics should be reported. A useful organization for presentation of antibiotics is to discuss them in terms of gram positive, gram negative, and anaerobic coverage. Patients receiving antifungal therapy will have this discussed after the bacterial considerations are dealt with. Rarely atypical organisms, viral, and/or parasite coverage is pertinent in trauma or postsurgical patients, but if so, these values are also mentioned. Each antibiotic being used should be reported in terms of the organism(s) it is covering and the number of days it has been used thus far, as well as the total number of days of therapy planned.

### Hematological

The hematological data presentation begins with a report of the current hematocrit (Hct), platelet counts, and coagulation values—for example, protime (PT), partial thromboplastin time (PTT), and the international normalization ratio (INR). The number of transfusions of blood, platelets, fresh frozen plasma (FFP), or other components that were infused since the last rounds is also summarized. Any ongoing sources of blood loss is also mentioned (e.g., Jackson-Pratt drains, wound vac outputs, concerns about nonoperative spleen or liver injury, GI bleed, etc.). Because all trauma and critically ill patients are at risk for thromboembolic complications, the current method of DVT and/or pulmonary embolism (PE) prophylaxis is often mentioned here or later in a catch-all category.

### Endocrinological

The need for insulin therapy should be addressed in patients with elevated serum glucose levels. Most SICUs are now following aggressive insulin infusion protocols with targeted glucose levels between 80 and 120 mg/dL (see Volume 2,

Chapter 60). A review of other pertinent endocrinological issues is also provided at this time, if not already mentioned. For example, patients with steroid requirements, thyroid, or other endocrine issues may have those discussed here.

The suggested data in Table 2 does not fully represent the minimal data on a simple patient, or the maximal data on a complicated patient, but rather the commonly evaluated parameters that must be known to the presenter on a daily basis. The amount of data that should be provided on rounds depends upon myriad pertinent factors for that patient. The residents will need to learn what is relevant, and the considerations will vary over time.

### Step 5—Review of Missed Drug or Therapeutic Measures

A review of all medications and therapies not previously discussed should be quickly carried out next. Drug discussions should include the name of the medication, route of administration, dose, indication, and therapeutic endpoint. The participation of a pharmacist during this phase of the patient presentation can greatly enhance the management of SICU patients (3).

☞ **Most attending will take some time to review and ensure that various institution-specific protocols of care are being adhered to.** ☞ Others will prefer that each protocol based treatment is mentioned during the review of systems. In either case a discussion of DVT prophylaxis should determine whether or not it is indicated and possible therapies such as heparin, coumadin, sequential compression devices (SCDs), and inferior vena caval (IVC) filters.

In those patients receiving stress ulcer prophylaxis, the route of the medication and dose should be reviewed. All patients in the ICU should have the head of the bed elevated, unless clinically contraindicated, in an attempt to decrease aspiration pneumonia (4). A recently proposed mnemonic to cover these areas utilizes the acronym FAST HUGS (Feeding, Analgesia, Sedation, Thromboembolic prophylaxis, Head-of-bed elevation, stress Ulcer prevention, and Glucose control—Table 3) to review the commonly accepted beneficial therapies used in the SICU (Fig. 1) (4).

Other considerations such as extremity management of casts, traction, or fitting for orthotics or braces should be discussed. The results of occupational therapy, physical

**Table 3** The Seven Components of the Fast Hug Approach

Component <sup>a</sup>	Consideration for SICU/trauma team
Feeding	Can the patient be fed orally? If not, begin enteral nutrition. If not tolerated or contraindicated, consider starting parenteral nutrition, and (unless contraindicated) trophic tube feeds.
Analgesia	All trauma and critically ill patients should receive adequate analgesia.
Sedation	Patients who require sedation should receive it, but excessive sedation should be avoided; “calm, comfortable, collaborative” is typically the best level.
Thromboembolic prevention	All should receive SCDs and LMWH unless unable (e.g., 4 extremity casts) or contraindicated (e.g., DVT), those at high risk contraindications should also receive LMWH. Those with contraindications and prolonged high risk should be considered for IVC filter placement.
Head of the bed elevated	Optimally, 30° to 45°, unless contraindications (e.g., threatened cerebral perfusion pressure) untreated spine injury.
Stress Ulcer prophylaxis	H <sub>2</sub> RA, PPIs, gastric feedings, control of anxiety
Glucose control	Within limits defined in each ICU

<sup>a</sup>Other components to consider include surveillance for causes of fever, mechanical ventilation in patients with ARDS using lung protective strategies (V<sub>T</sub> 6–7 cc/kg, PEEP as required to keep lungs open), review of decubitus ulcers, aggressive PT/OT, use of splints and orthotics in patients with chronic neurologic ailments to prevent tendon contractures. Daily spontaneous breathing trials for patients on mechanical ventilation, and so on.

*Abbreviations:* DVT, deep venous thrombosis; H<sub>2</sub>RAs, histamine 2 receptor antagonists; ICU, intensive care unit; IVC, inferior vena cava; LMWH, low molecular weight heparins; PPIs, proton pump inhibitors; SCDs, sequential compression devices; SICU, surgical intensive care unit; V<sub>T</sub>, tidal volume.

*Source:* Adapted from Ref. 4.

**Figure 1** Attending rounds at UCSD Medical Center. Dr. W. C. Wilson (*top left*), and Dr. R. Coimbra (*top right*) demonstrate to residents and fellow that the Fast Hug concepts (Feeding, Analgesia, Sedation, Thromboembolic prophylaxis, Head-of-bed elevation, stress Ulcer prevention, and Glucose control), are being employed in a 38 year old male admitted to the intensive care unit three days prior following a traumatic brain injury, left pulmonary contusion, and splenectomy.

therapy, or the need to order these or other rehabilitation-related treatments or devices should be considered, along with plans for discharge and/or placement.

### Step 6—Assessment and Plans

At this point, an overall assessment of the patient (brief sentence) followed by a summary of each significant problem suffered by the patient should be enumerated, and recommendations should be made to address each significant problem. This provides for an organized systems approach to the presentation, yet a problem-oriented assessment and management review at the end.

The critical care resident should also be aware of the assessment and plans being made by the other consulting services (e.g., neurosurgery plans to remove a ventriculostomy, renal wants to stop continuous veno-veno hemodialysis (CVVHD), critical trauma team wants to wean to a trach collar, ID wants different antibiotics, etc.). However, it is the presenting resident's assessment and plans that are most important to the critical care attending. When these are contrary to the assessment and plans of another team, particular energy must be put forth to diplomatically arrive at a cooperative management plan that addresses all

concerns. The final plans should be clear, and the rationale should be provided.

Finally, the presenter should note that very few patients will require long descriptions of data for each organ system. **✎ The skillful presenter will separate the important/essential information from the mass of normal, or insignificant data generated daily.** **✎** Only the relevant information should be presented, and all of this should occur in less than five minutes, including the brief assessment and specific recommendations for each of the patient's active problems. The plans or recommendations for therapy are the most important aspect of the presentation and becomes easier if the preceding information is collected and presented in a logical and organized way. The time spent by the resident organizing and reprioritizing patient care issues as conditions change will improve presentation quality as well as patient care.

### CRITICAL CARE NOTES

Notes are required for the documentation of events (for later review), and are also important for communication between teams. **✎ If notes are too extensive they tend not to be read; if they are too short, they tend not to contain enough data to convince team members of the logic underlying the plans.** **✎** In the current era of computerized records, increasing amounts of redundant information is often included.

The authors believe that information which is already a part of the pertinent medical record (e.g., SICU flow charts of parameters) does not bear significant repetition. Rather, the notes should highlight pertinent positives, include all relevant data that would otherwise be missing from the automated record, and should also emphasize the assessment and plans for the patient. The notes should be placed in the record in a timely manner (immediately after important procedures, surgeries, or events), should always include the date, time, and signature, and also should be most clear as to both recommendations and rationale.

SICU notes should clearly identify the service and level of training (e.g., medical student, intern, resident, attending, etc.) of the individual writing the note, and include the following seven elements (as summarized in Table 4): (i) identification, (ii) title (e.g., Post op day #2, S/P exploratory laparotomy and splenectomy), (iii) mention of significant events, (iv) systems approach patient status (abbreviated from the amount delivered on rounds). In hospitals where only one team is caring for critically ill patient, and there is no automated information in the chart, then all

**Table 4** Critical Care Note Format

Element	Topic	Examples/comments
I	Identification	R-4 resident critical care note
II	Title	Post-op day #2 S/P exploratory laparotomy and splenectomy Post-op day #1 S/P take back for bleeding
III	Significant events	Patient has been hemodynamically unstable requiring large quantities of blood products due to mesenteric bleeding
IV	Systems review	Neuro, C/V, pulmonary, GI, GU, ID, heme, endo, extremity, and skin
V	Assessment	Initially unstable due to missed mesenteric bleeding vessel, now repaired and stable
VI	Plans	As appropriate for each system problem
VII	Documentation and authentication	Time, date, and signature

of the information provided in the above presentation sections will need to be included in the note. However, in situations where much data is automatically placed in the chart via computerized systems (including vital signs, trends, and laboratory information), this information should not be duplicated in the note. Instead, the usual SICU note should only chronicle the important data points along with the two following elements: (v) assessment; and (vi) plans. Finally, documentation with time, date, and authentication with signature are required components.

In some settings items 4, 5, and 6 may be coupled together for brevity and to minimize repetition of information already in the chart. Whenever significant events occur, the additional elaboration of items 4, 5, and 6 is required. Finally, all notes must be dated, timed, and signed by the author. The author should also provide a stamp or printing of their name and contact information (pager number), so that questions can subsequently be asked in case of confusion.

## ASSISTANCE FROM CONSULTANTS

☞ **When consultants are needed to assist the critically ill patients with the care of trauma, a clear focused question should be asked of them.** ☞ Rather than asking for a blanket cardiology evaluation, ask the cardiology consult team the specific question you need assistance with. For example, the best method to convert the atrial fibrillation, or does this patient require U/S evaluation of pump function, and so on. Whenever possible, direct communication between the SICU team member and the consultant should be carried out. Optimally, the SICU team member will be present during the consultant's exam and chart review as well, to both provide and receive information. This person-to-person conversation will help prevent miscommunication and lead to better patient care. Whenever, the SICU team member cannot be at the bedside during the consultant's evaluation, a clear note should be left in the chart citing the key questions for which the consultant's help is requested.

## CONFLICT RESOLUTION

Conflicts between the teams occur in all aspects of medicine from time to time. These disputes should not be played out in the medical chart or on teaching rounds, and especially not at the patient's bedside. When one team disagrees with another, a calm and civil discussion needs to occur regarding the interpretation of the patient status and goals of therapy envisioned by one team and compared to that of the other team. The critical care team is often charged with helping the other various consulting teams sort out their differences. In the case of the trauma patient, the trauma service will usually have the final say on the management of their patient, but they often need help from the others; thus, relations need to be unstrained and dialogue needs to be collegial and open.

## OPEN VS. CLOSED INTENSIVE CARE UNITS

Recent studies have reviewed the advantages and disadvantages of closed versus open ICUs (5–7). In closed units patients are managed by the critical care team who serve

as the patient's primary physicians. The data suggests that closed ICUs may improve patient outcome and decrease time spent on the ventilator. This type of approach is gaining popularity and tends to decrease the amount of consults obtained in the ICU. However, for trauma and the usual post surgical patient, important information and expertise belongs to the primary surgical team who admitted the patient. Hence, a comanagement model with the critical care team closely managing sedation, analgesia, fluids, acute hemodynamic, and ventilator considerations as well as other critical care-related support supervision such as enteral nutrition, and so on, is probably the best model. Thus open units will continue to be used in most trauma and SICUs in the near future.

## EYE TO THE FUTURE

The challenges for physicians taking care of critically ill patients have become increasingly complex. The accumulation of large volumes of data from each patient can, from time to time, overwhelm the practitioner. As we continue to learn about the pathophysiology of critical illness, computerized filtering systems will likely be used to help filter out noise, target early treatment goals, and help minimize complications.

Handheld computer technology that allows real time updating is now widely used (8). These systems can be connected by wireless network to the SICU patient data systems and, if properly formatted, to portable digital assistants (PDAs), which can decrease the amount of prerounds time spent acquiring data, and with the proper software, can also help to organize it. This computer technology may be able to prompt the practitioner when an opportunity arises to follow best practices clinical guidelines and also decrease the time of order entry (9).

The use of picture archiving communication system (PACS) is now widely available and this has decreased the time needed to look for hardcopy films (10). The next step will be to have this information available in a handheld format, using high resolution data compression files.

Physician extenders such as nurse practitioners and physician assistants will play a greater role in the management of patients in the ICU (11). The health care providers will help bridge the gap left behind in academic medical centers with the 80 hour work week for residents. This contribution to patient care will likely provide improved continuity of care, better dissemination of information to family members, and improved compliance with best practice guidelines.

## SUMMARY

The accurate distribution and presentation of information between the SICU team members is both an art and science. This is a skill that takes time to acquire. Although, the acceptable format can vary between attendings and institutions, the basic elements should remain. These include identification of the patient, a systematic review of the patient, assessment, and a plan for management.

Understanding the scientific foundations underlying the pathophysiology of various problems in trauma and critical care helps the presenter organize the data into a cogent format. Being cognizant of the needs to be complete while at the same time succinct helps motivate the presenter

to carefully organize the contents. Presenting with a spirit of enthusiasm and sincere interest in the patient also helps other team members to focus and pay attention.

Consultants should be asked to participate in a patient's care when appropriate and to answer specific management questions. The daily note should avoid redundancy but provide enough information to serve as a guide to other consultants and team members as to the patient's condition and management strategy.

## KEY POINTS

- ✍ In general, the resident should collect and organize the information in the same way that he/she plans to present the data on rounds.
- ✍ New computerized patient information systems allow automatic incorporation of vital signs, laboratory, and even radiographic reports into templates that can be used for prerounding.
- ✍ Identification of the patient should explain to all the team members exactly what is wrong with the patient (why the patient is here) and where the team is in the workup of, or therapy for, the patient's pathological conditions.
- ✍ The systematic review of the patient's various organ systems should proceed methodically, but with only the detail required to provide the listeners with a clear understanding of the patient's status.
- ✍ Most attending will take some time to review and ensure that various institution-specific protocols of care are being adhered to.
- ✍ The skillful presenter will separate the important/essential information from the mass of normal, or insignificant data generated daily.
- ✍ If notes are too extensive they tend not to be read; if they are too short, they tend not to contain enough data to convince team members of the logic underlying the plans.

- ✍ When consultants are needed to assist with the care of trauma and critically ill patients, a clear focused question should be asked of them.

## Economics of Trauma and Critical Care

Pedro Alejandro Mendez-Tellez and Todd Dorman

Departments of Anesthesiology, Adult Critical Care Medicine, and Surgery, School of Medicine,  
Johns Hopkins University, Baltimore, Maryland, U.S.A.

### INTRODUCTION

The United States operates a health care system that is unique among nations. It is the most expensive of systems, outstripping by over half the health care expenditures of any other country (1). U.S. Health care expenditures continue to rise. The growth in national health care spending is principally due to new technologies and medications, the aging of the population, and the increasing number of uninsured and under-insured. Globally, health care costs are also on the rise. However, most countries around the world are able to deliver health care to their citizens for a fraction of what is spent in the U.S. (2).

A large portion of U.S. health care funding pays for the care of critically ill and injured patients. **✎ Even though intensive care unit (ICU) beds account for about 10% of all inpatient hospital beds, critical care expenditures account for 15–20% of inpatient costs (3), and near 1% of the gross domestic product (GDP). ✎**

Trauma care is also extremely resource-intensive. Severely injured patients consume one-third of all hospital days utilized for trauma care, almost 70% of all days in the ICU, and they account for 45% of the total charges generated (4).

Health care financing impacts the delivery of critical and trauma care. As critical and trauma care consume increasing portions of the national health care resources, factors that maximize health and societal benefits, such as resource allocation, economic impact, and costs, have become more relevant (5).

This chapter provides the reader with an overview of health care economics and the costs and funding of trauma and critical care. It also introduces some of the economic tools used for assessing the value of medical practices, including cost-effectiveness analyses.

### HEALTH CARE ECONOMICS

**✎ The costs of health care in the U.S. have been rising sharply over the past four decades and currently consume approximately 15% of the GDP. ✎** In 1960, the national health care bill totaled a mere \$26.9 billion. Between 1966, (when the Medicare and Medicaid programs began), and 1993, health care expenditures increases averaged 11.7% annually, inflating the national health care bill to \$895.1 billion by 1993. Over the period of 1993–1997, the rate of growth in health-care spending was unusually slow, averaging only five percent per annum as a result of low general

and medical-specific inflation, the growth and impact of managed care, and the capacity of health care plans to negotiate “discounts” from provider systems (6). Despite the downward trend in the rate of growth of health care spending, U.S. health care costs surpassed \$1 trillion by 1996. It is estimated that the costs of health care will double to an astronomical \$2.2 trillion by 2008 (6,7).

The proportion of the GDP consumed by health care has been rising almost linearly since 1960, when the U.S. spent 5.1% of its GDP on health expenditures. By 1993, the percentage of the GDP spent had already exceeded 13% and by 2002, it was 14.9% (6). Projections indicate that the share of GDP spent on health care will rise to 16.2% by 2008 (7).

By comparison, in 1998, when the U.S. spent 14% of its GDP on health care, other industrialized countries such as Germany, France, the United Kingdom, Canada, and Japan spent a substantially less (i.e., 7–10%) of their GDP on health care (Fig. 1). In Taiwan, which has a national health-care system, individuals pay an average of \$20.00 per month for full coverage (including maternity care, dental, vision, and all medical visits) (2). This is approximately 1/20 of the cost to U.S. individuals for the same coverage (2). The \$400 to \$500 per month that is paid by the average U.S. citizens for their health care insurances is “out-of-pocket,” or, is paid by their employer. These huge healthcare expenditures paid by employers are the principle reason many U.S. jobs have moved overseas to countries like India, China, Russia, and Mexico (2).

Aging of the U.S. population, new technologies, a growing number of uninsured and “under-insured,” and the expectation (and perception) by the U.S. citizens and foreign nationals living in the U.S. that they receive the highest level of health care constitute the most important demographic, cultural or psychological factors that are continually driving up costs.

Ageing is important because of the comorbid disease “burden,” such that when these patients become ill, the severity of the illnesses increase, and resource consumption also increases (see Volume 1, Chapter 37). The introduction of new medical technologies (drugs, devices, procedures) always seem to come at a high price. Most experts attribute the continued rise in health care expenditures as a percent of GDP in the U.S. to the impact of technological changes. The uninsured and under-insured also contribute to rising health care costs because they seldom seek preventative care, and instead wait for interventions involving acute high resource-consuming care episodes (6).

**✎ For the past three decades, the U.S. government has attempted (ineffectively) to reduce the growth of**

**Figure 1** Health care expenditures. *Source:* From Ref. 51.

**health-care expenditures.** The extraordinary increases in health care costs that financially threaten the purchasers of health care services (individuals and businesses) led in the mid 1980s to the implementation of several measures aimed at restraining the rising health costs such as price control and the prospective payment system.

Since these initial measures failed to control the rising costs of health care, the federal government then chose to control health expenditures with a number of mechanisms loosely referred to as “managed care,” including a wide-range of government subsidies and programmes made available to assist the development of these entities. Managed care organizations (MCOs) were originally successful in controlling health care costs by reducing fees paid to providers, and by participating in the decision-making process of health care [i.e., denying services to enrollees that did not meet (arbitrary) benchmark criteria, and delaying services to those that did qualify, i.e., “queuing”]. More recently, premiums are increasing and MCOs no longer seem capable of controlling the rise in health care expenditures. This is partly due to the consumer revolt regarding denied and delayed services, as well as other factors such as realization of an increasing proportion of funds devoted to administrative overhead, salaries and bonuses paid to executives, and distribution of profits to publicly listed MCOs.

### The Role of Government

Health care expenditure funding is not distributed evenly. The government finances the Medicare and Medicaid programmes as well as the Veteran’s Administration Hospital system, the Department of Defense military care system, the Public Health Service, and the Indian Health Service (8). In 1997, public funding financed nearly 47% of the health care bill. Other funding sources include private health insurance and out-of-pocket consumers. In 1997, private health insurance and out-of-pocket consumers funded 32% and 17% of health care spending, respectively (9). Though the total funds spent have increased, these percentages have remained fairly stable over the last decade (Fig. 2).

### Medicare

**The Medicare program is by far the largest and most influential health insurance program.** The original congressional act provided health care insurance for the elderly who were eligible for social security. Before the establishment of Medicare, only about half of those who were 65 years of age or older had health insurance. By 1970, 97% of

**Figure 2** National health expenditures: *Source:* From Ref. 52.

older Americans were enrolled in the program. Today, the Medicare program covers nearly 40 million people, including persons over the age of 65 years, many disabled persons of all ages, and persons with chronic renal failure (CRF). Currently, Medicare insures one of every seven Americans. By 2030, the program is projected to cover 77 million people (i.e., more than one of every five Americans) and will consume 4.4% of the GDP (9,10).

Medicare consists of two related insurance programs. The Medicare Hospital Insurance Fund, also known as “Part A,” covers inpatient services, skilled nursing care, and home health care, and is funded by compulsory federal payroll taxes on employers and employees. Payroll taxes raised \$115 billion in 1997 (88% of the Trust Fund). Medicare “Part B,” the Supplemental Medical Insurance Program, covers physician fees, outpatient hospital services (emergency room visits, and ambulatory surgery, as well as laboratory and other diagnostic tests) and durable medical equipment. Medicare pays 80% of the approved amount of “Part B” services in excess of an annual deductible. Medicare “Part B” is funded by general federal tax revenues that are appropriated by Congress, and by premiums paid by the beneficiary.

Since the late 1970s, slowing the growth of Medicare spending has been a sustained priority for legislators. In the 1980s, Medicare shifted from a cost-based system to one in which payments were predetermined (9). These and other cost-containment efforts slowed the growth rate of expenditures for some time, yet costs have continued to rise.

In another cost-containment effort, Medicare beneficiaries have been allowed to enroll in private health maintenance organizations (HMOs) and private fee-for-service plans (e.g. “Medicare Plus,” or “Medi-Gap” Choice plans) instead of remaining exposed to traditional fee-for-service payments. In 1997, the program expanded the types of plans that could participate in Medicare and to further reform the payment system.

Medicare’s benefit package has been termed “inadequate” because it leaves beneficiaries liable for nearly half the cost of their acute care and also grossly underpays doctors for their care. Beneficiaries have to rely on supplemental policies, because Medicare is an inefficient method of care delivery. Currently, over 85% of the beneficiaries have supplemental insurance. Medicaid, (possessed by 15% of Medicare beneficiaries) and employer-sponsored retirement benefits (used by one-third of beneficiaries) fill in part of the “gap” in coverage. Private supplemental plans (e.g. Medi-Gap), which serve about one-fourth of beneficiaries, are increasingly perceived as unaffordable for those with an average income (9).

When the Medicare program became operational in 1966, its primary orientation was the treatment of acute, episodic illness. Medicare maintained this orientation for 40 years despite the trend of people living longer with chronic diseases. The Medicare Prescription Drug Improvement and Modernization Act of 2003 took the first step at re-orienting Medicare toward the care of chronic conditions (11). It provides seniors, and those with disabilities a prescription drug benefit, but has also added costs to the program (11). The initial three diseases to be covered (beyond CRF) are diabetes (DM), chronic obstructive pulmonary disease (COPD), and congestive heart failure (CHF).

The modernization program will be implemented in two phases. Phase one utilizes a pilot study (certain states and regions were selected on December 8, 2004) that will be responsible for providing services to all Medicare beneficiaries who have DM, CHF, or COPD in those locales. Payments in Phase 1 are dependent on improvements in "quality of care," "satisfaction" of beneficiaries and providers, and a success in lowering costs. Phase 2 (scheduled to begin in 2007), is expected to expand nationally, if Phase 1 is successful (11).

Although the Medicare Modernization Act is the first step toward reform and the cost-effective treatment of beneficiaries with multiple chronic conditions, additional changes in financing will be required. In 2001, out-of-pocket spending by Medicare beneficiaries increased by an average of nearly \$400 for each additional chronic condition (Fig. 3) (11). To cover these costs for the chronically ill, some have suggested restructuring the cost-sharing arrangements in fee-for-service Medicare by "shifting" costs to the less ill. Alternatively, lowering other fixed costs may be more palatable (and resource preserving), such as developing a national electronic medical record to the secure data repository that can be accessed when trauma patients or other emergency patients enter the hospital and are unable to provide their past medical history. These and other technology-driven strategies purported to be "cost-savers" constitute the only currently identified techniques that will both improve medical care and reduce costs in the near term.

**Medicaid**

Medicaid provides supplemental federal funding to states operating approved medical-assistance plans. Medicaid is a federal-state funded health insurance program for certain low income citizens, as well as other individuals in need. Unlike Medicare, eligibility for Medicaid is "means-tested"

**Figure 3** Annual out-of-pocket spending by Medicare Beneficiaries in 2001 according to number of chronic conditions. Source: From Ref. 53.

(i.e., there are financial criteria for enrollment); like Medicare, however, Medicaid is an individual legal entitlement. Medicaid is the single largest source of financial support for community health services to low income patients. It covers over 45% of inpatients in public hospitals, and more than one-third of patients who obtain care at federally-funded community health centers.

There are two basic criteria for eligibility: financial need and a federally recognized eligibility category. Both criteria should be met for enrollment. Each state independently establishes eligibility criteria within those general federal guidelines; sets the type, amount, and duration of services; sets the rate of reimbursement; and administers its program. Medicaid policies of eligibility, services and payments are complex and vary considerably among states.

In 1998, obstructive pulmonary covered over 40 million people, one of every 10 people under the age of 65 years, including nearly 30 million pregnant women, parents under the age of 65 years, and children, as well as more than 11 million persons with disabilities and elderly persons who had low incomes or who were impoverished because of medical expenses.

By 2004, Medicaid was helping to finance long-term health care for more than 55 million low-income children and parents, people with severe disabilities, and elderly at an annual cost of \$300 billion to the federal and state governments (12). The program now provides health coverage for one in four U.S. children, as well as coverage for illegal aliens. Although children and their parents account for the majority of enrollees, elderly and those with disabilities account for 70% of the expenditures (Fig. 4).

The program's impact on certain sectors of the health care system is enormous: in 1998, Medicaid paid the costs of one-third of all births in the United States, nearly half of all nursing home care, and health care for 25% of children under the age of five years. The Medicaid program actually pays for much of the care for elderly and disabled Medicare beneficiaries, who also qualify for Medicaid on the basis of poverty.

Federal financing of state Medicaid plans is open-ended. Each participating state is entitled to payments up to a federally-approved percentage of state expenditures, and there is no limit on total payments to any state.

**Figure 4** Medicaid enrollees and expenditures in 2004 according to enrollment group. The graph shows values estimated by the Kaiser Commission on Medicaid and the Uninsured on the basis of data from the Congressional Budget Office and the Centers for Medicare and Medicaid Services, 2005. Totals may not add to 100% because of rounding. Source: From Ref. 54.

Payments are calculated based on a federal formula linked to state revenue, and ranged from 50% to 80% of approved state medical expenditures. In 2000, Medicaid accounted for 50% of total state health care costs.

Between 2000 and 2005, individual states began to more aggressively restrain Medicaid spending by limiting prescription drug coverage, provider payments, and eligibility. Several states have restructured their programs. Utah created a new primary care benefit package that does not include hospital or specialty care. Tennessee and Missouri are contemplating plans that would drop 200,000 and 90,000 adults, respectively (12). Connecticut and Minnesota are petitioning the federal government for permission to extend the period of time that must elapse before Medicaid begins to cover nursing home fees. California, Georgia, Kentucky, and New Hampshire are all preparing to reduce spending on acute care by adding new premiums, raising cost-sharing premiums, and by limiting coverage for prescription drugs (12).

### **Centers for Medicare and Medicaid Services (CMS)**

In 1965, the Social Security Act established both Medicare and Medicaid. Medicare was a responsibility of the Social Security Administration (SSA) while federal assistance to the State Medicaid Programs was administered by the Social and Rehabilitation Service (SRS). SSA and SRS were agencies in the Department of Health, Education, and Welfare (HEW). In 1977, the Health Care Financing Administration (HCFA) was created under HEW to effectively coordinate Medicare and Medicaid. In 1980, HEW was divided into the Department of Education and the Department of Health and Human Resources (HHS). In 2001, the Health Care Financing Administration (HCFA) became known as the CMS (10,13).

☞ **CMS was established as a federal agency that administers several programs including Medicare, Medicaid, State Children's Health Insurance Program (SCHIP), Clinical Laboratory Improvement Amendments of 1988 (CLIA) and Health Insurance Portability and Accountability Act of 1996 (HIPAA).** ☞ CMS oversees the reimbursement of health care providers and hospitals under Medicare and Medicaid, including promulgating the regulation for physician documentation, and charging submission and payment. Most insurers adopt CMS/HCFA's standards and regulations for physician reimbursement. A thorough knowledge of these standards and regulations is therefore mandatory for successfully billing (and receiving payments from) Medicare, as well as most other insurers (10).

### **Employer-Sponsored Health Insurance Plans**

Collectively, private employers and employees are the most important purchasers of health care through the insurance premiums they pay together for coverage (1). The premiums that finance coverage are paid in "Part B" by the employee. Much of the private insurance bill (usually 80% or more), however, is paid for by employers through their employee benefits packages. Approximately 70% of the non-elderly U.S. population is covered by some form of private medical insurance.

As medical costs go up, health insurance costs also rise and businesses owners must either pass on higher premium and co-payment costs to their employees, raise their prices (potentially impairing their competitive position in the

marketplace), or reduce their profit margin (unpopular with stockholders). Like the government, businesses can also negotiate lower prices with health care providers and/or health insurance plans.

"Managed care" is a generic term that embraces a wide spectrum of health insurance systems that integrate the financing and delivering of health care. Managed care organizations contract with doctors and hospitals to provide comprehensive care to enrolled members for a fixed, prospectively set premium. These MCOs also shop their services to various employers. Employer-sponsored health insurance plans include traditional indemnity plans, health maintenance organizations (HMOs), preferred-provider organizations (PPOs), and point-of-service plans (14,15).

In the traditional indemnity plan, patients would choose their physicians from among all those in the community. After receiving treatment, a bill was then submitted to the insurer. Insurers would in turn pay "usual and customary" fees set by the local physicians in each community.

In the early 1980s, insurers were permitted to contract with selected providers. With this new option, insurers were able to exclude providers that did not accept their rules and fee schedules. Insurers began to build physician networks such as PPOs to care for their enrollees. As managed care and the demand for expanded services grew, insurers broadened the network of preferred providers to include some coverage from providers who were not part of the network, leading to the development of "point-of-service plans."

More recently, insurers have begun to offer "multi-tiered" plans which give patients three different options: full coverage in an HMO with a limited number of providers; access to a PPO, with slightly higher co-payments; and use of out-of-network providers, with the highest co-payments (i.e., traditional indemnity) (14).

### **The Uninsured and Underinsured**

As previously discussed, the U.S. health care system is a mixed system of public and private insurance. Most working-age persons receive insurance through their employers. Medicare provides health care to all persons over 65 years of age as well as to persons with disabilities or end-stage renal disease, and Medicaid covers low-income individuals

Apart from those covered by private or public plans lays a substantial population without any health insurance (16). Data from the U.S. Census Bureau indicate that 45 million people had no health insurance of any kind during a typical month in 2003, representing 15.6% of the U.S. population (17). The great majority of uninsured individuals either work for small employers who do not offer health insurance benefits or, more commonly, cannot afford the premiums of the plan(s) that are offered (18). About 80% of the underinsured are either workers or live in families with workers. They typically have low-wage jobs or work in small businesses in which the employer does not offer health insurance, or, if it is offered, they decide not to purchase it (often due to high cost, and competing needs for their wages) (16).

Underinsurance has a significant impact on the "working poor" by presenting them with the burden of paying out a substantial proportion of their family's income for health insurance premiums and out-of-pocket medical costs (deductibles, co-payments, and uninsured

care) (18). The underinsured are much more likely to delay or forgo needed treatment, have their conditions diagnosed at a later stage, and to be admitted to the hospital for avoidable conditions (16).

Some states have experimented with expanded coverage through their Medicaid programs to help the uninsured poor (such as the Oregon Medicaid program). For the foreseeable future, however, it does not appear that the federal government is inclined to comprehensively address this problem (18).

## THE ECONOMICS OF CRITICAL CARE

Over the past four decades, intensive care medical advances have markedly improved our ability to treat the critically ill and the injured (18). During this time, the demand for ICU services has grown dramatically. However, the care of critically ill patients has consumed a disproportionately large fraction of the health care resources (7). Even though ICUs contain only 5–10% of total hospital beds, they account for 15–20% of total hospital costs, which in turn comprise about 38–40% of all U.S. health care expenditures (19). Thus, in the U.S., critical care costs alone comprise over one percent of the GDP.

The resources used to care for ICU patients includes the physical plant, equipment, supplies, professional staff, and all of its support services and personnel. Modern ICUs provide three major types of services: (i) active treatment, which includes life-supporting therapies or techniques; (ii) ICU monitoring and nursing and technological services that are observational rather than therapeutic; and (iii) standard floor care services that are not unique or limited to ICUs (20).

☛ **Critical care costs are mainly generated by human resources, expensive drugs, and newer technologies, all promising to prolong the lives of critically ill and severely injured patients.** ☛ The largest fraction of ICU costs goes to personnel-related expenditures. Human resources account for approximately 64% of total ICU cost per stay. The largest personnel component in terms of number and costs is critical care nursing. There is an enormous salary expenditure due to the high nurse:patient ratio. Nursing salary expenditures approximate 65% of the typical critical care human resource budget (8). Accordingly, efforts to control ICU costs necessitate consideration of organizational costs, supplies, and most importantly, staffing.

Technologies such as mechanical ventilation, hemodynamic monitoring and hemodialysis require costly equipment in conjunction with specialized personnel. Other technology-intensive “capital resources” include diagnostic imaging and laboratory testing equipment (3). Similarly, critically ill patients receive a wide variety of medications, and an ever-increasing number of particularly costly innovative treatments. Pharmaceuticals comprise some 7.4% of ICU budgets (8). Today, critical care is caught between an increasing demand for services and constrained global resources. Until recently, much of ICU care was excluded from economic scrutiny. Times are changing. There is a strong perception that ICU care can become a financial burden to the institution. ICU costs are high and the majority of such health care resources are consumed by a remarkably small segment of the population. Furthermore, the true impact and efficiency of the delivery of such services has yet to be defined. Lastly, ICU care is perceived as a

way for “prolonging the inevitable” in many patients, and thus representing a “waste of resources” to some commentators (21).

## Budgeting and Revenues for the ICU

Financial resources directed to the ICU are usually allocated through the hospital or organizational budgetary process. The ICU budget may be entirely related to known, estimated, or pre-negotiated input costs (human and capital resources), and the ICU may operate as a budget or cost center. In other words, the budgeted revenue is the estimated amount required to pay for the services the hospital wishes to deliver. In other circumstances, the ICU budget may be allocated as a profit center, in which all corresponding revenues and expenditures are accounted for and the ICU is expected to achieve a designated financial performance (8).

The “DRG System” attempts to predict resource consumption in a defined patient population, using variables such as diagnoses, operative procedures, complications, comorbidities, and discharge status (8). Reimbursement for a patient’s hospital stay is fixed through diagnosis-related groups (DRGs). DRG weights (or relative values) do not directly include ICU utilization. One DRG using more ICU days than another is meant to be reflected in the relative values attributed to the entire stay; the ICU component is not separated out. However, substantial data support inequities in the DRG system for reimbursement of patient care in the ICU. For certain patient types (and corresponding DRGs), the ICU generates large losses, especially in elderly patients and those with prolonged ventilatory management (8).

## Economic Analysis Models Used for Critical Care

Traditionally, decision-making in critical care has focused on “patient outcomes” (such as treatment effectiveness, morbidity, and mortality). Because of increasing pressure to reduce the growth of health care expenditures, considering only “patient outcomes” as a decision-making tool is no longer acceptable to health care financing entities. To achieve the most effective care, physicians must now regard outcomes not only from a clinical perspective, but also with integrated consideration of resource allocation, length of stay, patient satisfaction, and economic impact and costs, among other factors (5).

Delivering “cost-effective care” is becoming a qualifier to compete. As critical care consumes an increasing proportion of health care resources, economic analyses must be incorporated into clinical decision-making to help make resource allocation decisions (22,23). Physicians now need to become educated on how to accurately analyze these situations.

The purpose of economic analysis is to demonstrate a more beneficial use of critical care resources (22,23). Traditional cost analysis (i.e., comparing which option is cheaper) did not take patient outcomes into account. More recently, methodologies measuring both outcomes and costs have been developed. These methodologies attempt to measure and compare different interventions by counting and combining costs with real data from patient outcomes (5).

Four different types of economic evaluations are quoted: cost-effectiveness, cost-utility, cost-benefit, and cost minimization analyses. Even though these analyses all

**Table 1** Comparison of Various Economic Evaluation Models

Economic analysis model	Numerator	Denominator (net benefits)	Example
Cost-effectiveness	Costs (dollars)	Specific measure of effectiveness (years of life saved)	Thrombolysis for acute myocardial infarction
Cost-utility	Costs (dollars)	A common utility metric (QALYs)	Prophylaxis against recurrence of PUD
Cost-benefit	Costs (dollars)	Costs (dollars)	Use of aminoglycoside dose-monitoring program for burn patients with gram-negative sepsis
Cost-minimization	Costs (dollars)	None	Antibiotic therapy for ICU patients with low risk of nosocomial pneumonia

*Abbreviations:* QALY, quality-adjusted life year; PUD, peptic ulcer disease; ICU, intensive care unit.

have costs in the numerator, the denominator is different (Table 1) (25).

### Cost-Effectiveness Analysis

In general, cost-effectiveness is defined as cost divided by net benefits. The numerator (cost) is expressed in a reference currency (such as dollars), and the denominator (net benefits) is expressed as beneficial outcomes minus adverse outcomes. Although the primary goal of cost-effectiveness is to maximize benefits in relation to available resources, cost-effectiveness is also a reflection of health care quality (24).

Cost-effectiveness analysis (CEA) is the most common type of economic assessment, probably because the outcome data (effectiveness) in such analyses are relatively simple to calculate, and often comprise clinical measures of health that are routinely collected in clinical trials (e.g., percentage deduction in blood pressure, reduced incidence of hip fracture). To improve comparability between studies, generic measures of outcome are sometimes used, such as life-years saved or disability-days avoided (21).

CEA attempts to link the economic consumption and clinical utility in one “summary” measure. In CEA, the added costs and health outcomes of multiple interventions are used to calculate a cost-effectiveness ratio (9). Essentially, CEA estimates the incremental cost required to improve the clinical outcome by 1 unit. Lower ratios imply improved cost effectiveness, as fewer resources are expended to procure the desired level of benefit (21).

### Cost-Utility Analysis

Cost-utility analysis (CUA) is identical to CEA, except that the outcomes are measures in terms of a single composite index that combines length of life with quality of life [quality-adjusted life-year (QALY)] and this measure is preference based (14). This is very useful, as many patients discharged from ICU may require extensive intervention and their quality of life may be very low (such as ongoing dialysis, home ventilation, or full nursing support in a specialist facility) (25).

### Cost-Benefit Analysis

CEA and CUA aid in decision-making and are generally used to compare treatment alternatives (25). Cost-benefit analysis (CBA) has a broader scope than both CEA and CUA, and differs mainly in that its outcome measures are defined in monetary terms (14). There are two ways to assign economic values to health consequences. “Willingness-to-pay” (WTP) is the most popular way of expressing

cost-benefit in a healthcare environment and can be inferred from decisions that people make about trade-offs between health and money. Alternatively, quantifying human capital attaches a value to health such as those people working in an economy versus those consuming health care resources through chronic disability.

The CBA determines the net social benefit of a program and then determines the overall costs of the program. The incremental effects of a program is calculated as the benefits minus the costs, with both expressed in monetary terms (5).

### Cost-Minimization Analysis

If there are equivalent outcomes for two different interventions, costs are compared in cost-minimization analysis (CMA), a type of CEA. The fundamental assumption of CMA is that outcomes as measured by clinical benefit or use are equivalent (5). CMA looks only at resources used and assumes that the clinical benefit is self-evident (21).

As hospital budgets tighten, economic analyses will help hospitals and ICU managers maximize health benefits while minimizing waste for any given resource (21). Implementation of cost-effective strategies will ensure the best outcomes by providing evidence-based care and by reducing costs through controlling variability and implementing cost-effective interventions (5).

### Cost-Containment in Critical Care

Critical care resources are finite, and therefore limited. A significant limiting factor in the availability of critical care services is related to their extraordinary costs. Much of the pressure for rationing is brought about because of the cost. Demonstration of effective containment of these costs would do much to allay the perceived needs for rationing of this form of care.

Cost containment can be defined as either (i) preventing further increases in cost, (ii) slowing the rate of rise, or (iii) actually decreasing the costs. Cost containment can be achieved by limiting the use of critical care, by improving the efficiency with which it is delivered (changes in process), or by limiting other inputs. Conceptually, there are four major ways to control medical spending: (i) control prices, (ii) control volume of care provided, (iii) control the total budget available to pay for care, and (iv) shift costs to another payer (18).

✎ **Two of the most important price control initiatives in medicine have been the Medicare Hospital Prospective Payment System and the Medicare Fee Schedule for**

**physicians.** In 1983, Medicare replaced its retrospective cost-based hospital reimbursement system with a prospective payment system noted above, the DRG system. The DRG system was designed to promote efficiency and cost-containment in hospital-based care. While it has helped to control Medicare costs, it has not reduced overall U.S. health care costs, possibly because of substantial cost-shifting by hospitals to the private insurance sector (18). Under DRGs, hospitals have been severely under-reimbursed for all types of patients requiring ICU care. Additionally, under DRGs, critically ill patients who are transported to tertiary care centers place the accepting institutions at financial risk because allotted reimbursements to the accepting institution are substantially below the costs that are generated (26).

Recognizing the importance that physicians play in health care expenditure (i.e., physicians have control over patient care—procedures, length of stay, hospital admission), a physician payment system based on the use of a “resource-based relative value scale” (RBRVS) was introduced in 1992. The Medicare Fee Schedule has three components: (i) a measure of the total work (incorporating both time and complexity) involved in each physician service, and standardized across all specialties, (ii) a practice expense to cover the cost of running an office, and (iii) an amount to cover malpractice insurance costs. The Medicare Fee Schedule classifies all physician services using the American Medical Association’s Current Procedural Terminology (CPT) codes. Each CPT code has an associated “relative value units” (RVUs) weight. The RVU weights are multiplied by a national conversion factor to generate the actual physician fee associated with a particular service. Even though efforts at price controls seem attractive for effective cost-containment because they are less expensive, they generally do not achieve control of costs because of compensatory responses by providers (e.g., cost-shifting to other sectors) (18).

Volume controls include programs to limit utilization rates, for example, the widespread use of expensive technologies or extra hospital beds. Limits can be operationalized using either a regulatory approach [such as certificate of need (CON) programs] or a budgetary approach. Utilization review protocols attempt to discern which expensive care items, and how many days of ICU care are medically necessary (18).

**Budgetary controls are simpler to employ than either price- or volume-control approaches.** In Canada, for example, hospitals have global annual budgets. How the money is spent is decided by each hospital. If the budget is exceeded, there are no guarantees that the shortfall will be covered (18); in many cases certain types of care are no longer delivered during the remainder of that fiscal period.

Finally, payers can control their costs by “cost-shifting” to other willing (or unwitting) payers. For example, as health insurance premiums rise, employers can choose to shift a greater proportion of these costs to employees. Hospitals and doctors who earn less money caring for Medicare patients can try to make up short falls in some instances by charging more to private insurance patients. Alternatively, insurance companies can choose to offer limited or no coverage for certain pharmaceuticals, shifting the full cost of expensive new medicines directly to patients (8).

## THE ECONOMICS OF TRAUMA CARE

Trauma care is resource-intensive. The 2001 National Trauma Data Bank (NTDB) Report found that severely injured patients consumed one-third of all hospital days

utilized for trauma care. They also consumed almost 70% of all days in the ICU, and accounted for 45% of the total charges generated. Even patients with less severe injuries, (although requiring only 21% of all ICU days), utilized more than half of all hospital days, and accumulated charges almost equal to those of the more severely injured (4). Hospital charges varied widely from stab wounds not requiring ICU care (average per case \$6373) to major burns requiring ICU care (average per case \$49,600). The total estimate hospital charges for the entire group of trauma patients was more than \$3 billion (4).

## Trauma Systems

Trauma systems are designed to provide an organized and coordinated response to injury (22). Their goal is to deliver prompt, high-quality, and cost-effective care for seriously injured patients. Fully operational trauma systems ensure a continuum of care involving public access to the system, out-of-hospital emergency medical services, and timely triage and transport to definitive acute care and rehabilitation (27). When a trauma care system is established, severely injured patients in the region are triaged and transported to the regional trauma center, a designated hospital offering the expertise of trauma care professionals available 24 hr per day. Trauma centers require other support elements including emergency operative capabilities, intensive care, and rehabilitation (28,29).

In 1976 the American College of Surgeons Committee on Trauma (ACS/COT) published criteria for categorizing hospitals according to the resources required to provide various levels of trauma care. Yet, uniform implementation of regional trauma systems in the U.S. has been somewhat limited because of financial considerations. A 1987 report found that less than 25% of the U.S. geographical area was served by a trauma system (19). Those areas not served were primarily in the Midwest, the Rocky Mountain region, and other rural areas (29).

A 2002 national inventory of hospital trauma centers found that the number of trauma centers has more than doubled since 1991. In 2002, there were 1154 trauma centers in the U.S., including 190 level I centres and 263 level II centres (27). The number of level I and II centers per million population ranged from 0.19 to 7.8 by state, and all but one state (Arkansas) have at least one level I or II trauma center (27).

The number of states that formally designate or certify trauma centers has also increased. In 2002, a total of 35 states and the District of Columbia had developed formal designations or certified trauma centers. Fifteen states were yet to establish their own trauma systems (27,30). Poor access to trauma systems is particularly pronounced in the more rural areas of the country (27). Despite the growth in trauma systems there is still a wide disparity in trauma center distribution and variation in both the availability and configuration of trauma resources (27,30).

Financial considerations have factored in on the slow development of trauma systems in some (especially the geographically isolated) regions. Increasing numbers of uninsured, declining reimbursement for both physicians and hospitals, soaring malpractice premiums, and new limits on resident-physician hours have contributed to a tenuous environment for trauma centers (27).

Unlike other medical centers, trauma centers care for a disproportionately high number of patients unable to pay for their care. Young adults and the poor make up a

high proportion of these critically ill, injured patients. These patients are less likely to have insurance coverage or be eligible for public assistance programs. Trauma centers care for the sickest and most expensive injured patients (28). However, said this, geographic location and demographics of the local trauma (i.e., MVC vs. “knife and gun” vs. “work-related” trauma) generally determines the profitability. In certain locations, trauma centers are the most profitable service within a given hospital system.

Regional variations in the implementation of trauma centers has also been due, in part, to the lack of strong evidence of trauma center effectiveness coupled with high costs associated with verification of trauma center capabilities. Hospitals have difficulty justifying the expense of maintaining trauma centers without strong evidence of their effectiveness. The National Study on the Costs and Outcomes of Trauma (NSCOT) was designed to address these limitations and determine differences in outcomes and costs associated with treatment at level I trauma centers and non-trauma center hospitals.

In their first report, MacKenzie et al. (50) examined the differences in mortality in 18 level I trauma centers and 51 non-trauma center hospitals located in 12 states. **The results of the NSCOT study showed that the overall risk of dying is significantly lower in trauma centers versus non-trauma centers and argues for continued efforts at regionalization.** The risk of dying within one year after injury was significantly lower in trauma centers (10.4%) versus non-trauma centers (13.8%) (relative risk = 0.75; 95% confidence interval: 0.60–0.95). The effects of trauma centers on mortality were seen primarily for patients with AIS scores of four or higher. The study has also highlighted the difficulty in improving mortality outcomes for elderly trauma patients. Trauma center effects were larger for younger patients, less than 55 compared to those 55 and older, although differences in relative risks by age were not statistically significant except for mortality at 365 days (50). An important limitation to the study was the smaller number of older patients with severe injuries.

### Financing Trauma Care

“Regionalization” is the economic foundation for trauma systems. Regional trauma systems control the number of trauma centers serving a geographic area. Regionalization is intended to limit the duplication of services while achieving both high quality and cost-effective care; major savings can be achieved if the number of hospitals providing trauma care is limited and coordinated. Furthermore, the expertise of trauma care professionals is concentrated in fewer hospitals (28,29), resulting in optimization of facilities, practitioners, and patients.

Trauma care is also frequently financed by “non-traditional” funds. These funds include publicly sponsored programs for the elderly, disabled, and underprivileged, as well as an extensive array of health insurers and managed care plans, workers compensation programs, automobile insurance systems, additional taxes, and cost-shifting measures, such as public lotteries, tobacco, or motor vehicle registration surcharges.

Public funds secure full and unimpeded access for the uninsured. Some states support trauma care for all indigent patients with special funding, such as Medicaid payments. Other states and counties provide specific funding to trauma centers to offset the burden posed by uninsured, underinsured, or indigent patients (28).

An intervention aimed to support regional trauma systems is the functional monopoly of the market granted by state governments. Trauma systems with an optimum number of designated trauma centers and with enforced triage systems are examples of a publicly granted monopoly (28).

Motor vehicle accidents account for a large proportion of the trauma population. Auto insurance plays an important role in financing trauma care. Each year, U.S. automobile insurance pays approximately \$14 billion for the care of trauma victims. The amount of these funds reaching trauma centers varies considerably depending on the given state’s automobile insurance system. Furthermore, since auto insurance has defined coverage limits, a “first-come, first-paid” system develops whereby transport services and the transferring hospital will be paid before the trauma center and physicians caring for such patients (28). To some extent this is also a function of effectiveness and timeliness of the business unit responsible for submitting the bills for payment—whoever submits their charges first will be more likely to be paid.

The NTDB (31) published an updated analysis of 430,557 records from 130 trauma centers in the United States for the period of 1994–2001. Self-pay was the largest source of payment for hospital charges (20.81%), followed by Medicare (17.43%), commercial insurance (14.52%), managed care (13.34%), and Medicaid (10.81%). Automobile insurance was the source of payment for less than 5% of cases (Fig. 5) (31).

### Cost-Containment and Managed Care

Cost-containment, through careful utilization monitoring and cost control, is an important goal for MCOs. Unlike other illnesses where the costs of health care fall within predictable limits, trauma has a wide spectrum of severity and associated costs. Trauma occurs suddenly and unpredictably, eliminating the planning review and approval process that are important components for cost containment (32).

**An element of cost containment is lost when MCO patients are injured and transported to non-participating institutions (33).** Trauma victims meeting specific injury criteria are triaged to regional trauma centers directly from the scene or are transferred from local hospitals after stabilization. Managed care organizations have no power in determining the patient’s destination, so treatment is often provided at out-of-network facilities. This out-of-network status for MCO injured patients enables trauma centers the possibility for extensive cost-shifting. Cost-shifting, or charging insured patients more for the uncompensated costs of treating uninsured and under-reimbursed patients, has become a fundamental trauma center financing mechanism (33,34). Trauma centers often increase charges to the out-of-network providers to push pricing and revenue well beyond the level required to meet costs. Cost shifting is particularly prevalent in regions where uncompensated care is high.

A measure to bring costs under better control is repatriation. Repatriation is the act of transferring an acute care patient from a non-participating institution to an institution with MCO contract to reduce the cost of out-of-system care (32). In most cases, the repatriation process results in transfer from a designated trauma center to a non-trauma center, potentially resulting in the delivery of substandard trauma care. The value of

**Figure 5** Source of payment for hospital charges. *Source:* From Ref. 55.

repatriation as a cost-effective measure has been questioned. Repatriation may actually increase costs, presumably because of unnecessary or repeated studies done by the receiving institution (32). Moreover, besides the possibility of delayed and/or substandard care, such practices place the medical professionals caring for these patients in an awkward position. This repatriation doctrine can also raise the specter of quasi-criminal activities by MCOs by unduly influencing emergency medical decisions, in effect “practicing medicine without a license.”

A major concern for MCOs is that the costs for trauma care cannot be controlled and are often excessive. Specific concerns range from patients with minor injuries being transported by air, over-triaging, excessive utilization of ancillary tests and ICUs, and high costs for treating patients with minor injuries. MCO responses include payment denial and reduction in payment schedules, immediate or early repatriation, and initiatives to limit triage of patients into trauma systems (28,32).

Although regionalized trauma care systems have been shown to improve outcome, such systems have been developed at high expense. The financial burden imposed to trauma centers not only originates from uncompensated care. Causes of underfunding include (i) more self-pay patients compared with other hospitalized patients (possibly as an inter-relationship to “trauma prone” behavior of such individuals), (ii) a reduced bill-collection ratio for patients covered by Medicare and Medicaid, (iii) the inability to shift cost to other payers, and (iv) inappropriate assignment and poor definition of DRGs for Medicare prospective payment (35,36).

### Costs and Cost-Effectiveness of Trauma Care

Trauma systems can reduce trauma deaths (37–41). Ten years following initial trauma system implementation, mortality due to traffic crashes began to decline; about 15 years following trauma system implementation, mortality was reduced by 8% (42). Similarly, preventable death rates declined significantly after implementation of a regional trauma system (37,43).

Although several studies have reported the costs of trauma (44–46), the cost-effectiveness of trauma systems has not been properly evaluated. In 1988, the costs for the care of 597 injured patients ranged from \$5446 to \$24,107

(44). Within each body region, both length of stay and hospital charges increased as a function of injury severity (44,47). The direct and indirect costs of trauma were estimated in \$11 billion per year (45). Similarly, a study of 12 trauma centers and 43,219 patients in the state of New York, where trauma patients were categorized according to DRGs for comorbidities and complications, it was reported that the trauma cases cost 27.5 million dollars more than non-trauma patients in the same DRG designations (46). The implication is that the care of the injured is inherently more costly.

However, these studies did not provide any measurement of the “value of health” that resulted from the economic expenditures. None of these studies conformed to standard economic models for the evaluation of medical technologies (47). The use of quality-adjusted life years (QALYs) is now considered an integral component of all economic models of health care evaluation (47). Consequently, any economic evaluation of trauma care that does not incorporate an estimate of QALYs is less useful (47).

Séguin et al. (47) demonstrated the potential benefits of using both costs and QALYs in performing economic evaluations of trauma care. Cost-effectiveness was determined by estimating the incremental cost/QALY attributable to treatment at a trauma center. Their results suggested that tertiary trauma care is cost-effective and less costly than treatment programs for other diseases when the QALY gained is included in the evaluation.

✎ **Future economic evaluations of trauma care must include both measurement of costs as well as estimates of QALYs gained to truly determine whether trauma care is cost-effective.** ✎ Only by capturing the “health state achieved” through estimation of QALYs gained from a given health-care technology, can a meaningful denominator be derived for the economic cost of trauma care (the numerator) (47).

### EYE TO THE FUTURE

Over the next decade, it is anticipated that the growth in health care spending will continue to increase. The government can not sustain these costs indefinitely. Indeed, between 1980 and 1998 national health expenditures in

**Figure 6** National Health Expenditures 1980–2002. *Abbreviation:* GDP, gross domestic product, the total value of final goods and services produced in the United States. *Source:* From Ref. 56.

the U.S. were skyrocketing both in terms of dollars spent and as a percentage of the GDP (Fig. 6). Since 1998, the expenditures have continued to increase, but at a less rapid rate. Immense pressures are now being exerted on all governmental agencies to limit these expenditures; similar forces are being felt by corporations, in the private sector, and by the consumers. Thus, there will be significant impetus placed upon providing care at lower costs.

Key developments in the health care sector that will likely affect the (rate of) growth in health spending include (i) the impact of managed care, (ii) the role of the private health insurance, (iii) the effect of a rising uninsured population, (iv) the impact of the Balanced Budget Act (BBA) of 1997 on Medicare and Medicaid spending, (v) the growth or contraction in real capita income, (vi) the economy-wide inflation, and (vii) demographics such as the aging and overall growth of the U.S. population (7).

Changes in the various health care financing systems must occur. A medical financing system that meets the basic needs of the entire U.S. population will require the efficient use of health care expenditures, while at the same time ameliorating medical care inflation and encouraging innovation, productive competition, and progress toward quality cost-effective health care (48). Neither the current market-driven system nor Medicare and Medicaid programs meet these requirements (48).

Cost-effective analyses will play an increasingly important role in the evaluation of medical care. A new cost-effective health care system is needed to balance quality, choice, and access to care. As with other health-care services, trauma and critical care will have to be measured by new standards of cost-effectiveness. Economic evaluations will be crucial when evaluating the efficacy of existing and future changes in trauma and critical care management, as well as to provide necessary information for policy decisions about ongoing resource allocation in these areas (47).

A specific focus on critical care medicine is crucial because of the disproportional spending in that arena (49). Similarly, mechanisms for accurate cost-allocation and cost-accounting will need to be implemented. These mechanisms will maximize health benefits and minimize waste for any

given resource. Finally, the health care industry will need to implement cost-effective strategies that ensure the best outcome by providing evidence-based care, while reducing costs and controlling variability (5).

## SUMMARY

The health care system in the U.S. remains a “paradox of excess and deprivation.” The U.S. spends more on medical services than any other nation in the world (24). A large percentage is spent on under-insured and uninsured patients, another large percentage is spent on research and development of new medical technologies.

Unlike other developed nations that rely on centralized planning for provision of health care, the U.S. depends on a mixed health care system of public and private insurance (26). Most working-age Americans effectively purchase health care through their employers (at group discount rates). Medicare provides health insurance to individuals over 65 years of age and to persons with disabilities or end-stage renal disease, whereas Medicaid covers low-income individuals (24). On the other hand, a growing number of individuals in the U.S. either lack health insurance or possess minimal, often substandard, coverage. It has been broadly reported that over 40 million persons in the U.S. are uninsured or underinsured (24).

U.S. health care is being reshaped. Over the last decade, U.S. health care has undergone major changes in modes of delivery and payment (7). In the private sector, managed care has been somewhat successful in containing costs, at least in the short term. On the other hand, public health spending growth has exceeded private health spending growth by a substantial margin (7).

Health care spending will continue to impact the delivery of critical and trauma care. As critical and trauma care consume increasing portions of the national health-care expenditures, practitioners, patients, and families must consider not only outcomes but resource allocation, economic impact, and costs. Appropriate use of evidence-based care and economic analyses will provide

high-quality care and will ensure the best outcomes by reducing costs and implementing cost-effective interventions (5).

Finally, little will likely change without an acceptance or realization by large segments of the U.S. population that certain patients (e.g. illegal aliens, the elderly, and the chronically ill) consume a grossly disproportionate share of the resources with respect to their contributions to the financing system.

## KEY POINTS

- ✂ Even though ICU beds account for about 10% of all in-patient hospital beds, critical care expenditures account for 15 to 20% of inpatient costs (3), and near 1% of the GDP.
- ✂ The costs of health care in the US have been rising sharply over the past four decades and currently consume approximately 15% of the GDP.
- ✂ For the past three decades, the U.S. government has attempted (ineffectively) to reduce the growth of health-care expenditures.
- ✂ The Medicare program is by far the largest and most influential health insurance program.
- ✂ Medicaid is the single largest source of financial support for community health services to low income patients.
- ✂ CMS was established as a federal agency that administers several programs including: Medicare, Medicaid, State Children's Health Insurance Program (SCHIP), Clinical Laboratory Improvement Amendments of 1988 (CLIA) and Health Insurance Portability and Accountability Act of 1996 (HIPAA).
- ✂ Critical care costs are mainly generated by human resources, expensive drugs, and newer technologies, all promising to prolong the lives of critically ill and severely injured patients.
- ✂ Two of the most important price control initiatives in medicine have been the Medicare Hospital Prospective Payment System and the Medicare Fee Schedule for physicians.
- ✂ Budgetary controls are simpler to employ than either price- or volume-control approaches.
- ✂ The results of the NSCOT study showed that the overall risk of dying is significantly lower in trauma centers versus non-trauma centers and argues for continued efforts at regionalization.
- ✂ An element of cost containment is lost when MCO patients are injured and transported to non-participating institutions (33).
- ✂ Future economic evaluations of trauma care must include both measurement of costs as well as estimates of QALYs gained to truly determine whether trauma care is cost-effective.

## Remote Management of Trauma and Critical Care

José Manuel Rodríguez-Paz and Todd Dorman

Departments of Anesthesiology, Adult Critical Care Medicine, and Surgery,  
School of Medicine, Johns Hopkins University, Baltimore, Maryland, U.S.A.

Joseph F. Rappold

Division of Trauma and Critical Care, Department of Surgery, Naval Medical Center San Diego, San Diego, California, U.S.A.

### INTRODUCTION

In 1966, a report was published by the National Research Council, entitled "Accidental Death and Disability—The Neglected Disease of Modern Society" (1). This publication led to the passage of the 1966 Highway Safety Act, and subsequently to the establishment of the Emergency Medical Services (EMS) program by the Department of Transportation. In 1976, the American College of Surgeons (ACS) Committee on Trauma (COT) recommended guidelines for designing and implementing trauma centers be adopted (2). Since then, trauma centers have been established in numerous communities. A recent meta-analysis of level I trauma centers have shown a 15% improvement in patient outcomes since the implementation of these facilities (3). Numerous reasons are responsible for the improved outcomes, including the requirement to have an attending trauma surgeon present within 15 min of a seriously injured patient's arrival to the Emergency Department (ED) (4,5). Similarly, a high-intensity model of critical care staffed by intensivists has been shown to decrease morbidity and mortality, and length of stay in both in the SICU and in the hospital overall (6–10).

✎ **The regionalization of trauma care has improved overall outcome, but not solved the significant problem of providing high-level trauma and critical care services to remote locations, where organized trauma systems do not exist.** ✎ To further complicate the problem, an estimated third of the U.S. population reside in rural areas (11). This population shares more than 50% of the deaths from motor vehicle collisions (MVCs), and a rural trauma patient is twice as likely to die as an urban victim wounded by a similar mechanism of injury (12). Delays in therapy have been proven to worsen outcomes in trauma patients (especially in cases of injuries to the spinal cord, brain, and internal organs).

The flow of injured patients is of even greater complexity in military trauma. Currently, approximately 77% of all deaths occur on the battlefield before an injured soldier reaches a medical treatment facility (MTF), while only 23% who expire die of wounds after reaching a MTF (13). These data demonstrate improvements in management and coordination of patient care in the current conflicts compared to past wars. However, more needs to be done, and telemedicine can play an increasing role in the future.

Even modern, adequately staffed triage systems can be inadequate in disaster situations where patient numbers can overload existing resources. Current established level I trauma centers can have as many as half of their admissions resulting from transfers from other institutions (14). In the case of critical care, as many as 90% of adults in intensive care units (ICUs) do not have a high-intensity physician staffing model with trained intensivists (15,16), and this is more of a problem, but not exclusive, to smaller communities.

✎ **A potential solution to delivering trauma and critical care to remote locations and to address shortages of subspecialty-trained physicians is the use of telemedicine.** ✎ Telemedicine holds the significant advantage of resolving the issue of delivering care to these distant locations, while at the same time maintaining the current structure and organizations of advanced trauma centers and ICUs. Telemedicine brings expert physicians (whether trauma surgeon or intensivists) to the site of the emergency via advanced telecommunication systems and can allow them to evaluate patient data and direct care more effectively than would occur with nontrained personnel that might respond to the trauma scene. The goal of any trauma and intensive care delivery system is not only a reduction in mortality and morbidity associated with the injury or critical illness, but also to prevent further injuries due to treatment errors. The use of telemedicine can accomplish these goals by permitting better triage and prioritization of care, avoiding delay of care in those patients in remote areas that need it the most, and optimizing the available resources.

In 1997, the telemedicine report to the U.S. Congress established that "Telemedicine can mean access to health care where little had been available before. In emergency cases, this access can mean the difference between life and death. In particular, in those cases where fast medical response time and specialty care are needed, telemedicine availability can be critical" (17).

The topics that will be examined in this chapter include the historical uses of telemedicine through 2006, the definition and technical aspects of telemedicine, as well as the current applications of telemedicine in trauma and critical care, with particular attention focused on telemedicine considerations for remote and austere locations. Financial and legal issues have slowed the forward progress of

telemedical advancements; accordingly, these considerations are also explored.

✎ **Military research has helped develop many aspects of telemedicine, and the direct applications to both military and civilian care are enormous.** ✎

This chapter discusses how advanced technology has been used in military planning and the execution of battle-field maneuvers. However, many currently available telemedical applications have yet to be fully deployed in trauma care in the combat zone, or at level II military treatment facilities (MTFs).

Historically, medical care improves after the initiation of each major military campaign, but further development tends to regress with contraction of responsibilities. Current U.S. and coalition military medical leaders are committed not only to revising this trend but also to expediting the application of currently available telemedicine technologies, increasing future development, and improving maintenance of institutional memory about the needs of the injured soldier during war. Indeed the application of telemedical technologies has improved significantly in both Afghanistan and Iraq over the last year. One of us (JRR) has been to Iraq twice in the last two years and witnessed significant improvements in the intelligent use of these technologies, as will be described herein.

## HISTORY

Since 1920, when S.G. Brown was able to demonstrate the first “electrical stethoscope and telephone relay” in London at a distance of over 50 miles (17), numerous examples of telemedicine techniques have been employed. In 1950, the first application capable of transferring radiograms across standard telephone lines was created. In 1959 the University of Nebraska College of Medicine was able to use, for the first time, video communications for a telemedical consultation (18). During the 1960s an escalation of telemedicine techniques occurred. One such example includes a project carried out by NASA and Lockheed Corporation, called STARPAHC (Space Technology Applied to Rural Papago Advanced Health Care), in which remote health care was provided to the Papago Indian reservation in Arizona by two Native American paramedics employing radiographic and electrocardiographic (ECG) peripherals transmitted via microwave system to a Public Health Service facility (19,20). This study was designated to pilot equipment planned for use to provide medical services to astronauts while on their missions. In 1968 medical data [such as ECGs, blood pressure (BP) readings, stethoscope sounds, and blood smear images] were transmitted between first-aid stations at Boston’s Logan Airport and physicians at the Massachusetts General Hospital (MGH) (21).

In the late 1970s, Canada was already testing a satellite transmission system for telemedical use in remote provinces. At the same time, in the U.S., several states began establishing large statewide networks to connect large centers of knowledge with government and rural communities, thus creating an information highway that serves multiple purposes and includes large medical centers.

In the late 1980s the Picture Archival and Communication Systems (PACS), a system that could transmit radiographic images over telephone lines, became very popular among radiology departments. Also by then, the U.S. Navy was testing a system for the support of personnel onboard ships and at remote locations. However, PACS was

first clinically available in the United States and United Kingdom in the early 1990s. It has taken until now for PACS technology to become widely available worldwide.

In 1982, Grundy et al. (22) reported a direct association between reduced mortality and a higher proportion of recommendations enacted by using a real-time, interactive video consultation between the University Hospital of Cleveland and the ICU at Forest City Hospital of Cleveland. Other examples of the use of telemedicine techniques for trauma care included the 1988 Spacebridge Project. Established by NASA, it provided real-time connectivity between physicians in the U.S. and Armenian surgeons after an earthquake that caused more than 150,000 casualties.

More recently, in 1998, a research project carried out by NASA and Yale University allowed monitoring the medical conditions and vital signs of climbers on Mount Everest using radio transmitters and audio and video data via a satellite link (23).

✎ **Computer-assisted surgical robotics is a technological area whose immense potential will likely facilitate telemedicine applications for trauma in the near future.** ✎

Computer-assisted surgical robotics began to be utilized clinically in 1999, the year the *da Vinci*<sup>®</sup> Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA) was introduced. The original, prototype for the *da Vinci* System was developed in the late 1980s at a former Stanford Research Institute under contract to the U.S. Army. Today, Intuitive Surgical is the global leader in the rapidly emerging field of robotic-assisted minimally invasive surgery (MIS) (clinical applications are discussed further below). As of April 2006, nearly 300 *da Vinci* Systems have been installed in hospitals worldwide.

## DEFINITIONS AND TECHNIQUES

The American Telemedicine Association defines telemedicine, telehealth or e-health as “the use of medical information exchanged from one site to another via electronic communication for health and education of the patient or health care provider and for the purpose of improving patient care.” ✎ **Telemedicine connects two physically separated locations (which can be positioned anywhere on the globe), and facilitates the sharing of clinical information between health care providers (or between patient and provider) for the diagnosis and/or management of medical and surgical conditions.** ✎

There are two major categories of telemedicine interactions: Pre-recorded (“store-and-forward”), also known as *asynchronous* telemedicine, and “real time” or *synchronous* telemedicine. In the asynchronous mode, static images or audio-video clips can be sent either physically or via electronic means to a remote storage device. Once at the storage site (file cabinet, or on-line server with remote download capabilities), the information can be subsequently sent over numerous modes of delivery or stored for analysis when convenient. The second form of telemedicine data transfer involves “real-time” interactions, also known as interactive or *synchronous*. Both types are utilized, and will be discussed below.

✎ **Telemedicine can be used in a variety of situations from consultative care, triage, and direct patient care, to image transfer and continuing medical education.** ✎ The routine use of telemedicine techniques has been around for quite some time. The everyday use of phone communication

and the use of facsimiles have been part of the routine way of communication between health providers for many years.

The high-speed development of personal computers and the increasing capabilities of mainframe supercomputers have fostered capabilities not previously available. The development of communication tools [e.g., e-mail, and internet protocols (IPs) that allow streaming voice and data] have permitted and improved the methodology for the transmission of both text and images in most medical environments (from small offices to state-of-the-art medical facilities). Also, real-time interactive, multi-point videoconferencing with application sharing has become commonplace and technically easier to use. Furthermore, the development of wireless technologies (from cellular phones to satellite-based technologies) have permitted the transmission of all this information from remote locations that would otherwise lack the standard hardware technology that would allow routine communication.

## TECHNICAL ASPECTS/PHYSICAL CHARACTERISTICS

### Central Consultation Unit (Command Module)

The central consultation station can be physically located anywhere on the globe. It should be ergonomically arranged with a user-friendly interface, which should include video and voice communication, as well as text messaging capabilities. Computer-based patient data evaluation tools should also be employed (e.g., assisted diagnosis, linkage to databases, etc.). Generally this receiver station consists of a dedicated workstation which can be used by the medical expert to handle and record all the data, and should be able to transmit back all of the information needed. Security and confidentiality are also critical issues in the design of these units, which require encryption coding.

✎ **The specific computer-based elements needed for each telemedicine application varies, but when dealing with trauma or critically ill patients, the system requires capability to handle real-time, synchronous interactive videoconferencing.** ✎ In contrast, routine care for less acute patient care situations may only need data sent to the clinician via a store-and-forward technology.

The software used in this workstation should be able to work in a stand-alone fashion, capture, display, and transmit data to multiple sites using asynchronous protocols (two-way communication in which a time delay between transmission and reception is allowed). These systems also need to support all required hardware devices and have a simple interface.

Ideally these software applications should be capable of real-time screening and interpretation of certain types of data that it handles. For example, ECG recordings or rhythm strips should yield an instantaneous diagnosis to both the remote site and at the command module. Discussion on management can then proceed while a simultaneous text message of ACLS<sup>®</sup> protocol recommendations are displayed on a running header display on the video monitor. In addition, the drug recommendations and the detection of any errors are important and necessary tools.

Another type of peripheral device that could be useful in this setting includes telemanipulators that enhance the ability of the physician to perform tissue manipulation on the patient (surgical procedures) from a distance, via

multisensory input that recreates remote tactile and visual environments. These devices are similar to some of the operating room robotic devices presently in use today (as will be discussed in greater detail below) (24).

### Data Transmission Media

✎ **The main characteristic that defines the quantity of data that can be transmitted over a line or other medium is bandwidth.** ✎ Bandwidth is defined as the information-carrying capacity of the information transport medium, and is normally expressed in bits per second (bps). The bandwidth requirements increases with the complexity of the task; a telephone/fax transmission takes only approximately 100 kbps or (0.1 Mb)/sec whereas virtual presence or telepresence (the highest end in telemedicine) takes 100,000 kbps or (100 Mb)/sec.

Two important basic concepts in telecommunications that limit bandwidth in various systems are that (i) the slowest part of the connection determines the real throughput rate, and (ii) once approximately 20% of the available bandwidth is consumed by usage, degradation in performance is observed. In addition, the link ideally should have a minimal delay factor or latency, which in some cases, such as satellite communications, could be as long as 1 to 2 seconds.

Transmission over conventional telephone lines and utilizing standard modems are the simplest way to send information. These systems are referred to as plain old telephone service (POTS). They provide data transmission at a maximum rate of 64 kbps. Although their major advantages include low cost, near ubiquitous availability, and high levels of international standardization, the major disadvantage is their low bandwidth. This becomes especially problematic when trying to transmit data-dense applications such as real-time data.

More modern telephone lines include digital networks and asymmetric digital submission lines. The digital networks include Integrated Services Digital Networks (ISDNs) which are protocols permitting the delivery of high bandwidth data to homes and offices by standardizing high-speed digital transmission, allowing integrated transmission of video, data, and voice. Normally it requires installation of special input and output devices. Digital subscriber lines (DSL) or T1 lines (24 channel, high-capacity circuit for data, voice, and video transmission) provide a rate of transmission of from 1.5 to 2.0 megabytes (Mb)/sec and offer some increase in bandwidth.

The highest end bandwidths occur through fiber optic networks (i.e., OC3 fiber optic cable connection, a 243-channel, high capacity circuit—up to 155 Mb/sec—for data, voice, and video transmission), and satellite [i.e., Low Earth Orbiting Satellites (LEOS), Advanced Communications Technology Satellite (ACTS)] that can deliver up to 1 billion bits/sec. The major disadvantage of these networks is their cost, limited range, and lack of international standardization. In addition, in the case of satellites, bandwidth may not always be immediately available. However, there is an increasing array of satellites in orbit, with increasing opportunities; these can be tracked by anyone with a computer by logging in to the NASA website (<http://science.nasa.gov/temp/StationLoc.html>).

A common solution to the use of large and expensive bandwidths is the compression of the data before transmission. Two basic algorithms are available: lossy and lossless (25). The difference between the two algorithms is

based in whether or not data are lost during transmission. The higher the quality of data (i.e., lossless), the more expensive is the compression technology.

New compression technologies and greater bandwidth opportunities are being made available; projects like Internet Two and Next Generation Internet (NGI) may fill holes left by the current technology. The National Library of Medicine has ongoing research projects in the specific applications and uses of NGI in medical applications, including trauma. Another alternative is the asynchronous transfer modes (ATM), one the newest high-speed ways of telecommunication. Its advantage is that offers high-quality and low-decay conditions ideal for high-speed communications.

### Remote Unit and Systems

The remote system consists principally of telemedicine peripheral devices. These devices are used to acquire patient data (e.g., vitals, image, video). They need to be portable, lightweight and easy to use with sufficient power autonomy. They also require a user-friendly interface. The system must allow bi-directional audio and visual communication (transmission of critical biosignals, images of the patient, and other vital data, including radiographs).

Typical examples of telemedicine peripherals are analog-based audio stethoscopes, digital BP meters, video otoscopes, etc. More advance technology includes devices like the FDA, approved remote "Life Support for Trauma and Transport<sup>®</sup>" (LSTAT<sup>®</sup>) (Fig. 1). This device is a self-contained stretcher platform designed for in the field stabilization and transport of severely injured patients. This LSTAT<sup>®</sup> incorporates a series of monitors which allows a remote team to follow respiratory and hemodynamic data, blood chemistry, mechanical ventilator settings, inhaled and exhaled O<sub>2</sub> and CO<sub>2</sub> values, infusion pumps for drugs and intravenous fluids, etc. The LSTAT<sup>®</sup> also incorporates an automated external defibrillator. The LSTAT<sup>®</sup> can be linked to a prepared medical facility while the patient is transported, allowing for both remote monitoring as well as remote manipulation of care (including all of the above mentioned support systems).

## TRAUMA APPLICATIONS

### Currently Employed Remote Trauma Applications

It is not unusual that most current emergency department Trauma Resuscitation Suites (TRSs) are connected via simple models of telemedicine with prehospital providers to assist in trauma care and to initiate triage long before the trauma or patient arrives to those facilities. Emergency telemedicine has been evolving during the past few years and has become a common interactive video application used in telemedicine.

In most rural or remote facilities teleradiology utilizing PACS technology is a common standard procedure. Also in this setting, teleconferencing both for consultation or education are common techniques used to take care of patients. For example, the St. Francis Hospital in Tulsa has, besides the teleradiology services, developed a system by which emergency medicine physicians are available for consultation with other practitioners located in small surrounding rural hospitals (26). This system has been shown to improve specific areas of patient care, especially the triage of critically ill patients, decreasing the transfer rate of patients who did not actually require a higher level of care

**Figure 1** Life Support for Trauma and Transport (LSTAT<sup>®</sup>). The patented LSTAT system is an individualized, portable, networked ICU and surgical table in a patient-care platform. Integrated within the LSTAT system are a state-of-the-art defibrillator, ventilator, suction, three-channel fluid and drug infusion pump, point-of-care blood chemistry analyzer, and patient monitoring subsystems. The platform, which is only 5 inches thick, also incorporates on-board power and oxygen subsystems. The medical subsystems are further integrated into an on-board computer that captures, stores, and transmits continuous, real-time, multi-device, multi-parameter, time-synchronized patient data. Patient data is also available at bedside on a handheld secondary display (with optional wireless capability) and over numerous patient data information systems, including over the Internet through secure web sites that protect patient privacy. Information about the platform itself (battery status, oxygen supply, device health, etc.) is also available to a distant monitoring center. *Source:* Photo courtesy of Integrated Medical Systems, Inc., Signal Hill, California, U.S.A.

and thus resulting in better utilization of the available emergency services.

This sort of model has also been used in the United Kingdom (27,28) where Armstrong and colleagues have reported a successful initial experience with a system that linked the emergency department of a large tertiary care hospital with a small rural facility in Scotland, via a land integrated digital network and also a satellite link, to diagnose and manage mild to moderately injured patients. In another study, low cost ISDN videoconferencing units were successfully installed in England, in what is called minor injuries units (MIUs). In that study, the researchers found no difference in diagnosis or management in over 45 patients seen during a period of six months (mostly with fractures, soft-tissue injury, and suspected fractures), but there was a significant reduction in patients transferred to higher level of care centers (29).

A preliminary follow up study of this experience performed by Tachakra et al. (30) showed that it is clinically safe and effective. This successful system of telemedicine applied to minor injuries prompted the opening of over 20 MIUs around the U.K. There are several case reports of describing the successful diagnosis of patients with severe undetected injuries admitted to remote/rural facilities that were properly diagnosed by an experienced specialist via telemedicine (i.e., spinal cord compression) (31).

Multiple evaluations have been done to validate the different telemedicine technologies when used in a trauma setting. The great majority of these studies showed that clinical data in trauma patients can be successfully obtained by standard video and audio telemedicine technologies (32–35).

The current concept of advance trauma care is based on a team approach, and the role of the team leader (an ATLS® trained physician) is considered crucial for the success of this model. Several studies have investigated the effect of physically removing the team leader from the TRS and evaluated whether this role could be assumed by a remote ATLS® trained physician via telemedicine (36). In London a resuscitation room in a community hospital was linked via a teleconferencing system using three ISDN lines linking three cameras working at 384 kbps to a trauma center (36). Fifteen scenarios from the ATLS Course Manual were analyzed. The researchers found no statistical differences when they compared primary survey, resuscitation, and secondary survey performed via telemedicine or standard care. **The role of trauma leader can be safely provided by a traumatologist not physically present in TRS settings where the trauma training of the other team members is insufficient but telecommunication understanding is adequate (36).**

Subsequently, the same group studied this model using real patients (37). In this study, two separate rooms were linked using a telemedicine videoconferencing system in a London ED. Two hundred patients with minor to moderate injuries admitted to the ED were evaluated by the remote attending physician. The study evaluated a series of physical parameters associated with the clinical exam and found that the quality of treatment offered compared well with face-to-face consultation. Similar results were found in a pilot study in Houston (Ben Taub General Hospital) where researchers found >90% accuracy between remote clinical data (using video technology) and that assessed via standard techniques in almost half of the ATLS® clinical variables evaluated; however, it was <70% accurate in another 15 variables in the assessment of acute trauma resuscitations (32). The ATLS® clinical variables included in this study were demographics, primary and secondary survey, initial and subsequent vital signs, physical exam (including advanced diagnostic tools like diagnostic peritoneal lavage), data (radiographs, MRI, CT, ECG), and diagnosis and disposition (32). Authors concluded that the remote supervision of trauma care by the trauma leader can provide accurate and safe evaluation and stabilization of injured patients.

Following these findings, the same team studied seventeen trauma victims who were randomly selected to have their assessment done via telemedicine (38), using a closed circuit analog television system linking several trauma rooms to a centralized trauma command center. The majority of victims had sustained blunt injuries (mostly MVCs). Immediately after arrival to the ED, an attending trauma surgeon located in the remote centralized trauma coordinator's office was called and was in direct communication with the third-year surgical resident via a wall-mounted video camera (which provided a full room view), microphone, and a hands-free telephone worn by the resident (via a dedicated telephone line).

The study evaluated 44 specific ATLS variables, with concurrent assessment by the attending surgeon as they occurred. Then, an independent party compared the assessment done remotely with that recorded in the clinical

chart, and discrepancies were noted. All patients survived their injury and were subsequently discharged alive. On two occasions, two simultaneous resuscitations were performed. On average, the remote evaluations included 28 of the 44 variables. The variables that showed the highest degree of concordance were demographics (92%), primary survey (76%), initial vital signs (70%), and secondary physical exam and diagnosis (76%). Technical difficulties with the communication link happened in only one instance. This study confirms the feasibility of remote evaluation of trauma patients under controlled circumstances.

Another example of the use of telemedicine for real-time video consultation for remote trauma care was reported by Rogers et al. (39). They described the use of a videoconferencing system via a dedicated ISDN line that linked four community hospitals in rural Vermont and New York with trauma surgeons located at their homes. Over a period of eight months, 26 telemedicine consults were completed. In general, the patients included in the telemedicine project were more severely injured and had higher mortality than the general trauma population. The types of trauma in this study included MVCs (50%), followed by all-terrain vehicle (ATV) accidents and pedestrians struck by vehicles. In two cases, the telemedicine intervention was considered lifesaving. In approximately 50% of the patients the recommendation made by the trauma surgeon was to transfer the patient to the trauma center (secondary to the lack of neurosurgeon or orthopedic surgeon in the referring facility) and in another 25% of the cases the recommendation was to keep the patient in the referring facility. Other interventions included recommending placement of chest tube, CT scan, diagnostic peritoneal lavage (DPL), and transfusion.

Telemedicine has also been studied for the provision of emergency orthopedic care. In a study done over two years in North Dakota (40), orthopedic surgeons performed over ninety teleconsultations, mostly evaluation and treatment of fractures, swollen joints and infections. In this study, a level II trauma center was connected to three rural facilities staffed with primary care providers via a network with a two-way videoconferencing system and computer software that enabled the physicians located at both locations to send and receive graphics, slides, radiographs, patient information, and other data. The orthopedic teleconsultations were done by board-certified orthopedic surgeons and divided into emergent (23%), urgent (39%), and scheduled consults.

No adverse outcomes were detected and there were no major discrepancies in diagnosis between radiographs read during teleconsultation and after the fact. Of all the consults, 68% of the patients remained in the rural facility and one procedure was performed via teleconsultation (removal of a pin by the primary care physician). The orthopedic surgeons rated the technology utilized as satisfactory or excellent. In another study by the same group (41), a series of 100 patients were included in consecutive teleconsults between a Level II Trauma Center and three rural sites staffed by primary care providers via a video teleconferencing system and a T1 communications network. The majority of patients included in this study (60%) were considered urgent. Half of the consults were done with orthopedists but emergency medicine physicians and neurosurgeons were also consulted.

The most common reason for trauma teleconsults in this study was diagnosis and treatment of extremity and pelvic trauma. Radiological images were sent (via PACS)

for interpretation and the hardcopies were reviewed *a posteriori* by a radiologist to confirm diagnosis. No significant discrepancies were found between the two modes of interpretation. Almost 70 patients in the study stayed in their local community for further care. Since these studies were published, the Dakota Telemedicine System (DTS) has extended specialty telecare to several rural hospitals, and performs on average 25 teleconsults every month (42).

A prospective controlled trial completed in New Jersey by Brennan et al. (43) studied management at two EDs [one defined as low volume (rural), and the other as high volume (suburban)] where the physicians and nurses were trained in telemedicine techniques. Fifteen patient scenarios were studied in 104 patients, who were randomized to either a control group ("high-volume"—suburban on site physician) or an experimental group ("low-volume"—rural with remote physician access via telemedicine system).

The experimental group consisted of patients who had arrived to the "high-volume" ED. Once the patient was managed via telemedicine, he or she was re-evaluated by the "in-situ" physician. The outcomes measured included diagnosis, treatment and return visits, need for additional care, as well as patient, physician, and nurse satisfaction. Although a range of medical and trauma conditions were evaluated, the most common diagnosis seen was extremity injuries (62% of patients). None of the variables studied showed any significant difference between the control or experimental groups and the level of patient and physician's satisfaction was rated as very satisfying.

More recently, the Southern Arizona Teletrauma and Telepresence (SATT) Program was launched by the Section of Trauma and Critical Care at the University of Arizona Medical Center (UAMC), the only Level 1 Trauma Center in Southern Arizona (44). The SATT program was developed to assist trauma patients in rural communities. Using advances in technology, SATT provides a live consultation link including videoconferencing, telemetry, digital radiographs, and ultrasound (via PACS) between the trauma team at UAMC and rural emergency departments in the southern section of the state. The SAAT program has been found to save both lives and resources, and is being expanded (44).

Burn assessment is an area of trauma management where frequent discrepancies can contribute to both delayed appropriate transport to a burn center as well as overuse of air transport resources (45). The ability to evaluate burn patients by telemedicine has the potential to assist decisions regarding transfer, avoid errors in initial care, and reduce costs. Saffle et al. are currently developing and testing such a system (45).

### **Evolving Applications in Trauma Care**

Another potential remote management application for trauma care involves expansion of the Telemedicine Emergency Neurosurgical Network (TENNS) project, which was created to facilitate decision-making by neurosurgeons before the patient was transported to tertiary facilities (46). The TENNS project could be expanded to facilitate the placement of burr holes in craniotomy patients whose outcomes would be improved by emergent decompression and stabilization prior to transfer to a level I facility. This system might save lives when transport times exceed some threshold time limit (e.g., 1–2 hours) as set by the supervising neurosurgical team.

A similar project that could have trauma applicability is the use of wireless technology in ambulances to see what impact telemedicine has on stroke mortality. The pilot project has been conducted with the intention of diminishing the time between onset of ischemic stroke and initiation of therapy. This project, funded by the National Library of Medicine and carried out by the University of Maryland Hospital and BDM Federal, Inc., enables video images, audio, vitals signs, and ECG rhythm to be transmitted from a moving ambulance through an off-the-shelf digital wireless telephone system using a commercial telephone service. The data is reviewed in real time by a tertiary care center (neurologists) via workstations. The intention of the research team is to conduct a pilot study to investigate whether early treatment via telemedicine significantly reduces morbidity and mortality of strokes. Results of this project are still pending.

The camera-phone has recently been studied as a tool for remote evaluation regarding the replantation potential of completely amputated fingers. The pilot study demonstrated that the camera-phone (Fig. 2) is both feasible and valuable for remote evaluation of replantation potential of completely amputated fingers and holds significant promise for future clinical application with the advent of further-evolving technology (47). The technology holds promise in avoiding both missed opportunities to replant digits, and unnecessary patient transfer by providing useful information.

**Figure 2** Camera phone image of severed fingertip. The camera-phone has been utilized as a tool for remote evaluation regarding injuries from remote locations. In this case, the replantation potential of amputated digits is evaluated. *Source:* From Hsieh C-H, Jeng S-F, Chen C-Y, et al.: Teleconsultation with Mobile Camera-Phone in Remote Evaluation of Replantation Potential. *J Trauma* 2005; 58(6):1208–1212.

Telepresence trauma surgery is the ultimate management modality tested to date in the field of telemedicine. Telepresence surgery has been used in the past and there are numerous instances (48–54) in which this technique has been successfully used since Dr. Mouret performed the first video-assisted laparoscopy in France in 1987, which has since revolutionized MIS.

✎ **The application of telepresence in trauma surgery has evolved to include use of the *Da Vinci*® computer-assisted robotics system.** ✎ This device utilizes a telemanipulator (Fig. 3A) permitting the remotely located trauma surgeon a stereoscopic (three dimensional) video display of the remote operative field (Fig. 3B) where the computer-assisted robotic device employs surgical instrumentation with far greater dexterity and degrees of freedom than standard MIS surgical techniques. The remote telemanipulator workstation site is typically linked to the robotic device by coaxial cable, though fiber optic cables or computer uplinks could also provide the needed bandwidth.

During initial experimentation using an early prototype of the *Da Vinci*® system, surgeons repaired vascular anastomoses and other procedures following multiple trauma in animals (55). Anesthetized swine were operated upon, and surgeons performed two-layer closure gastrotomies, cholecystectomies, and hemorrhage control from liver lacerations (55). Although the *Da Vinci*® system was used to perform all of these surgeries, it increased the time for completion of surgical maneuvers (like tying knots) and procedures by up to 3 times. This prototype

demonstrated that robotic manipulations of surgical instruments could be precisely carried out, and that complete surgical procedures could be accomplished without complications. Several subsequent studies demonstrated that general surgical procedures can be performed successfully using telemanipulators (56–58).

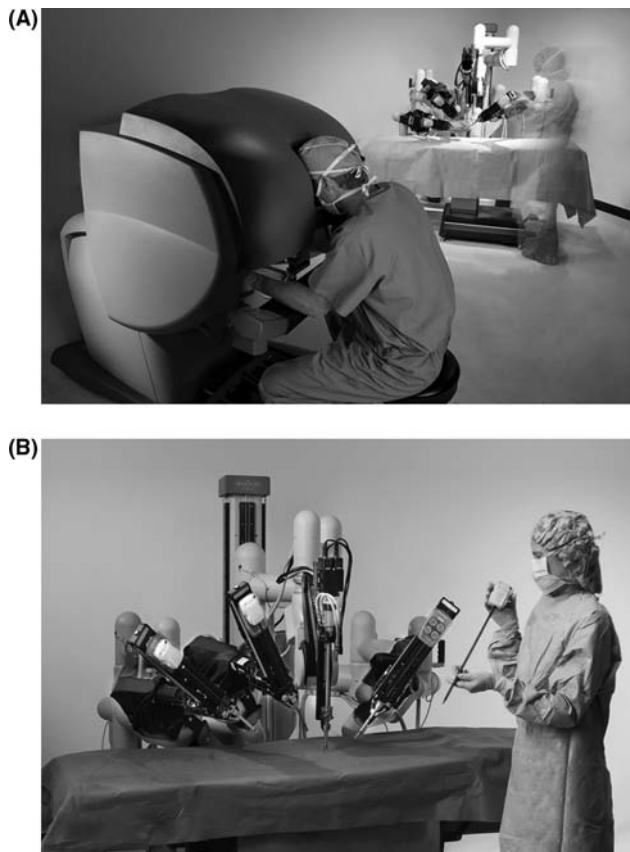

More recently the Academic Robotics Group prospectively studied 211 robotically assisted operations in patients to assess the safety and utility of the FDA-approved *da Vinci*® robotic system (59). A variety of procedures were undertaken, including 69 antireflux operations, 36 cholecystectomies, and 26 Heller myotomies (59). Of direct interest to trauma surgery (although these were performed electively) included a variety of relevant procedures: 17 bowel resections, 15 donor nephrectomies, 14 left internal mammary artery mobilizations, seven splenectomies, six adrenalectomies, and three exploratory laparoscopies. There were eight (4%) technical complications, none of which caused harm to the patient, and only two of which required conversion to standard laparoscopy (none required open laparotomy). The robotic-assisted surgery was demonstrated to be safe and effective with expectation that the technology will rapidly expand into other realms (including urgent and remote assistance in surgery) (59).

The current version of the *da Vinci*® system allows seven degrees of freedom, and has improved stereoscopic (three dimension) visualization of the operative field. Although there is an initial steep learning curve (60,61), the development of the *da Vinci*® device, along with tools for laparoscopic splenectomy that isolate and seal the large blood vessels surrounding the spleen, have reduced intraoperative bleeding and minimized conversions to open splenectomy (62). Improvements in optics and instrumentation, as well as robotic technology, will further facilitate the acceptance of laparoscopic splenectomy (62) and increase the likelihood that these devices will someday be utilized in remote locations, and ultimately even in austere battlefield situations.

✎ **The theoretical goal of minimally invasive computer-assisted robotic techniques in trauma is that they will be applied in resuscitative (including damage-control) surgery as a potential method to stabilizing selected patients.** ✎ The drawback at the present time is that this technology is too slow for acute hemorrhage, and massive bleeding will likely eliminate visualization. In addition, the current technology requires high bandwidth in order to provide instantaneous throughput and to display real-time operative field visualizations. More safety and efficacy studies need to be conducted before these procedures can be initially used in trauma patients.

Telemedicine was recently utilized during the care of victims in the Indian Ocean Tsunami (Dec. 26, 2004), and was reported in a case involving a young tsunami victim who subsequently developed a brain abscess (63). A clinical-response team at the MGH was formed to work with Project HOPE (Health Opportunities for People Everywhere) volunteers along with the U.S. Navy Ship (U.S.N.S.) *Mercy T-AH19* in Operation Unified Assistance, off the coast of Banda Aceh, Sumatra, Indonesia. The ability to transmit high-level digital images from the Navy ship to the conference of faculty in Boston, and for the clinicians in the Indian Ocean to engage in a real-time consultative conference with their Boston counterparts, helped make a diagnosis and formulate a plan of therapy (63).

Telemedicine can also be used for the follow-up of trauma patients. In a study done by Boulanger et al. in

**Figure 3** *Da Vinci*® surgical system. This device utilizes a telemanipulator workstation (A), and a remote computer assisted robotic device (B). *Source:* Photos courtesy of Intuitive Surgical, Inc., Sunnyvale, California, U.S.A.

Kentucky (64), 22 trauma patients (average ISS on admission of 18) were followed after discharge from a trauma center at a Teletrauma Clinic run by a registered nurse at a remote location via a T1 line and a videoconferencing system with multiple peripheral devices (cameras with macro lenses, electronic stethoscope, ENT scopes). Both surgeons and patients showed high degrees of satisfaction with this method of follow-up care, and there was a significant reduction of traveled miles by the patients for follow-up care.

## CRITICAL CARE APPLICATIONS

As mentioned previously, the first example of telemedicine applied to critical care was published in *Critical Care Medicine* in 1982 (22). In that article, Dr. Grundy at Case Western Reserve University published an article reporting provision of daily consultations between university-based intensivists and a smaller inner city hospital without intensivists on staff via telemedicine. Rounds started at the nurse's station where the nurse reported directly to the intensivist. After reviewing each case, and if possible after interacting with the patient, recommendations were made. The outcomes measured were mortality and estimated patient disability at discharge. Considering the technology used in 1982, the results were quite good, with the system being functional 85% of the time. The system allowed the intensivist at Case Western to gather enough information to provide consultation, including physical findings (such as ventilatory chest patterns and mental status). In approximately 78% of the cases recommendations were made, although recommendations were carried out in only 30% of the cases. The investigators were able to demonstrate a correlation between increased survival rate and fewer disabilities in those cases in which the recommendations were carried out.

Data regarding telemedical applications in the ICU that are used continuously and interactively have recently entered the literature (65–68). Real-time bi-directional data and video conferencing using personal computers and a telephone access system allowed a group of University-affiliated intensivists, located at home, to monitor and manage from a distance a community-based teaching hospital 10-bed Surgical Intensive Care Unit. At the remote location, a roll-about videoconferencing unit was available and allowed the follow-up and management of patients by using video conferencing and computer-based data transmission. The study compared a 16-week period of study with seasonally matched adult patients from the previous year. The primary outcome measured was ICU and hospital mortality, and the secondary outcome was length of stay and costs. Every day an intensivist was responsible for the management of the ICU patients. Each day after reviewing all the data available, the intensivist formulated a plan and discussed this with the surgical team. Approximately every two hours after the initial assessment and plan, the intensivist reviewed all the available data for each patient and, if needed, changes were made by discussing the data with the available team. The study showed a statistically significant 68% reduction in APACHE III-adjusted ICU mortality and in-hospital mortality (34%), with a reduced number of ICU complications (44%) and a decreased length of stay in the ICU (30%) in the experimental group. Additionally, this study showed a 33% reduction in total ICU costs. The most likely cause of reduced mortality is attributed to the decreased number of adverse effects associated to medical errors.

One of the earliest efforts to apply the concepts of telemedicine to critically ill patients was developed by Breslow and Rosenfeld in 1998 with the founding of a venture-backed company, VISICU, Inc. (Baltimore, MD). A recent study from Sentara Health System in Virginia utilizing a telemedicine system provided by VISICU provides insight into the future of critical care (67). The study included more than 600 patients discharged from 16 ICU beds during a six-month period. These units included a general ICU (10 beds) and a vascular ICU (six beds), which were wired into a remote VISICU monitoring site (eICU). This system permitted the remote intensivist not only to detect deviations from normal or early pathology at the beginning of a disease process, but also to make interventions that otherwise would have to wait for the physical presence of a physician in the ICU (i.e., weaning mechanical ventilation during the night or making adjustment in medications).

The study compared patients discharged from the same units before the implementation of this new system to the cohort cared for with the new system. The study showed a 30% reduction in the mortality rate in the ICU, which represents approximately 60 lives saved per year or one person per week. The study also showed a 17% average reduction in length of stay for both the ICU and subsequent recovery on a regular floor. The added benefit of the system implemented is that, despite the initial expense, it produced an annualized net financial benefit of approximately three million U.S. dollars. These savings included an increased patient turnover rate (20%) secondary to the reduction of ICU days and increased number of patients admitted to the ICU.

In a more recent study by Breslow et al. a total of 2140 patients receiving eICU care for 19 hr/day were evaluated with similar positive results (69). The remote care program used intensivists and physician extenders to provide supplemental monitoring and management of ICU patients for 19 hr/day (noon to 7 am) from a centralized, off-site facility (eICU). **✎ The addition of supplemental, telemedicine-based, remote intensivist programs has been associated with both improved clinical outcomes and hospital financial performance.** **✎** The magnitude of the improvements was similar to those reported in studies examining the impact of implementing on-site dedicated intensivist staffing models.

## FINANCIAL AND LEGAL CONSIDERATIONS Centers for Medicare and Medicaid Services (Previously HCFA) Requirements

As of 1999, the Health Care Financing Administration (HCFA and now CMS) started reimbursing physicians for telemedical care for Medicare patients, though the acceptable reimbursable conditions are restricted to only a few specific conditions. These include: that the patient must be located in a rural area, that the referring physician must be present, and that part of the reimbursement that the consultant physician receives needs to be remitted to the referring physician. The type of technology used is limited only to real-time interactions and excludes store-and-forward technology. However, effective as of October 2001, Medicare has expanded its coverage of telemedicine services to include broader geographical areas and physician services (70).

On the other hand, some health insurance providers have seen the benefits of the use of telemedicine and have started reimbursing for some telemedicine services, and in

some states laws have been passed that require reimbursement of telemedicine services. ✎ **Effective as of October 2001, Medicare has expanded its coverage of telemedicine services to include broader geographical areas and physician services (70).** ✎

### Medical Guidelines and Technical Standards

Guidelines help physicians by being tools that help in decision-making in improving patient's outcomes. The establishment of telemedicine guidelines has the additional benefit of being a framework that offers better quality and improves these systems during their early development (operational and technical guidelines), facilitates the establishment of clinical research, and reduces risk of litigation. At present, there are very few clinical telemedicine guidelines applicable to trauma care. These include limited guidelines for the handling of emergencies that the British Association for Accident and Emergency Medicine has established (71). These guidelines cover teleconsultation protocols, drugs use, radiographic evaluation, and management protocols, and applies to all minor injury units linked to their nearest Accident and Emergency facility.

Establishing technical standards has also become very important. The available standards for telemedicine techniques are based on the definition of the International Telecommunication Union (ITU) for videoconferencing, including the H.320 standard using ISDN and the more recent H.323 standard using IP networks (72). Another set of standards are included in the DICOM standard (Digital Imaging and Communications in Medicine) widely recognized for medical imaging communication (transmission of X-ray images and other medical image types). DICOM defines a standard network interface and data model allowing interoperability between equipment from different manufacturers. Interoperability using standards will facilitate telemedicine growth, whereas proprietary systems serve as short term solutions, but limit growth over the long term.

### Legal Aspects

Most of the legal aspects of telemedicine include licensure of physicians, hospital credentialing, clinical privileges, patient confidentiality, and liability. This is not different when applied to trauma and intensive care.

Universal clinical privileges do not exist in the U.S. In some cases, some state licensure statutes have provisions that allow a licensed physician to request consult from an out-of-state physician. Unfortunately most licensure boards do not allow practicing out-of-state physicians to provide telemedicine services unless they hold a valid license for that state. Moreover, this is not a problem exclusive to physicians but also to nurses, physician assistants, and nurse practitioners. There have been several attempts to address this problem but they have been unsuccessful to date. ✎ **The Joint Commission on Accreditation of Hospitals (JCAHO) has recently dictated a requirement of credentialing in hospitals, which are establishing telemedicine care.** ✎ The physician that practices in that institution, via telemedicine or not, needs to go through the process of credentialing approved for the institution.

Patient confidentiality must also be addressed and maintained. The regulation of transmission of information and establishing protocols that keep information safe and confidential, especially the information sent over e-mail and through internet access, is crucial to maintain the success of this technology.

Liability is also another issue that has affected the development of telemedicine technology in the areas of trauma and critical care. This is especially true in the area where more patient-physician interactions have been particularly significant, and for high risk conditions where prompt and accurate diagnoses are most critical. Interestingly, new technologies (e.g., real-time interactive videoconferencing) could conceivably decrease liability if full consensus is gathered from the group, even if it later turns out not be the best choice.

## MILITARY CONSIDERATIONS

### Initial Trauma Medevac and Resuscitation

The ongoing wars in both Afghanistan and Iraq have once again placed the U.S. military at the forefront of the telemedicine revolution. Ranging from the conveyance of patient information between far-forward positions and more sophisticated levels of medical care to the tactical decision making regarding site location for forward surgical teams, etc., the Department of Defense (DoD) has put into place a series of telemedicine systems.

✎ **Much more can and must be done to utilize current technological capabilities to improve medical communication between levels of care.** ✎ These capabilities can assist providers with both the transfer of information as well as assisting those providers with the expertise of medical experts in the initial management of complex wartime casualties.

Currently the bulk of initial care provided to U.S. and Coalition forces is done at Level I and II Medical Treatment Facilities (MTFs) which are often located in very isolated and austere environments (see Volume 1, Chapter 5). Rapid telecommunication systems are in place that allow providers at these locations to request and obtain the assistance of more experienced and seasoned personnel for the initial triage and treatment of these casualties. This is mostly in the form of secure satellite communication systems, but can also include technology as simple as cellular phones (when discussed information is not necessarily privileged). Although the technology now exists, the use of video conferencing between the level II [Army Forward Surgical Team (FST) or Marine Forward Resuscitative Surgery System (FRSS)] MTFs, and the higher level III Combat Support Hospital (CSH) is not yet available in most austere environments. Accordingly providers in these locations have had to adapt and change as the battle space evolved.

### Communications Between Levels of Care for Patient Transport

Logistics communications between MTFs at various levels of care is of the highest quality, thus casualty evacuation (casevac) and patient transport is highly coordinated. The reader can review current methodologies involving casevac to a FST or FRSS (level II MTF) or to a CSH (Level III MTF) and the use of U.S. Air Force Critical Care Air Transport Teams (CCATs) in Volume 1, Chapter 7. However, transmission of patient management information from the initial level II field surgery facility to the next level of care, often a level IV facility, can still improve, though improvements have occurred during the campaigns in Iraq and Afghanistan.

As recently as one to two years ago, the mechanism for sending injured soldier medical information between the

FST or FRSS and higher levels of care was provided by writing brief descriptions of operative findings on transfer papers, and by writing directly on the patient's skin or bandages (as shown in Volume 1, Chapter 7). Although this practice is helpful, and continues, the development of the Combat Trauma Record (a simple two page document) has significantly improved the transfer of information. In addition, several new-technology-based techniques have been employed by industrious military physicians and core men to obtain and package digital information to be transported with the patient. For example, digital photos of wounds and operative findings, are now routinely placed on transportable digital media and transferred with the wounded soldier to the next level of care.

Because the digital media can become lost or destroyed during transport, an additional improvement in care would occur if the digital data were transmitted digitally in real time to high capacity servers for storage, along with real-time relay of information to the expected destination. Dedicating portions of the satellite bandwidth for real-time video and voice conferencing and transmission of radiographs via PACS, etc. is another important idea that could improve care.

As patients are subsequently moved through the evacuation chain, more sophisticated means of telemedicine are now being utilized. Weekly patient care conferences as well as weekly morbidity and mortality conferences are held via real-time video teleconferencing between Iraq, Germany, and military medical facilities within the continental United States. These real-time, interactive events have greatly enhanced patient care and facilitated feedback to providers in the field who in the past never had feedback on the patients they initially helped stabilize, treat, and operate upon.

As discussed above, these sophisticated telemedicine devices come at a price, and that is the bandwidth required to achieve them. This is of particular concern in the military as medical providers are often at odds with the war-fighters over access to limited bandwidth. With improved technology and communication systems there will hopefully come a time where both the medical community and the operational forces will have unlimited access to real-time bandwidth which will allow the simultaneous care of patients as well as the ability to execute the military campaign.

## EYE TO THE FUTURE

The greatest technical problem inhibiting the growth of telemedicine today is the lack of cost-effective, dependable technology with enough bandwidth to transmit the amount of information needed for acute care in real-time. Wider availability of high-speed fiber optic lines and even satellite communications will facilitate not only the diffusion and use of existing technologies but the development and application of advanced technological telemedicine modalities, like the use of telepresence technology. The development of new networks systems like Second Generation Internet (SGI) may solve some of these problems. Current technologies such as global position satellites (GPS) can help locate EMS personnel and transport devices, facilitating more efficient deployment. The application of artificial intelligence to supplement technological advances will likely lead to the next breakthrough in medical applications (74).

Another area where advancement will occur is in the realm of distant anesthetic management of trauma and

critically ill patients. Indeed a recent report from Virginia Commonwealth University (VCU) shared anesthetic management decision-making between the home institution and Ecuador (75). Airway management, dysrhythmias, and oxygen saturation-related decision-making was made from the distant location over a 64 kbps satellite linked data line.

Public and health care perception must also improve, especially for the application of remote care systems in emergency situations such as trauma and critical care. Additional studies are needed. These studies should include standard outcomes as well as patient, family, and provider satisfaction data.

Regulations will continue to limit advancement of this field. Federal and private reimbursement issues will need to be continually addressed. In order to promote that change in mentality, more research needs to be done to study the cost-effectiveness of the application of telemedicine techniques when compared to conventional trauma and critical care.

The gaps between bench discovery and bedside application must continue. Those who focus on implementing the enormous capabilities of digital technologies in the realm of trauma and critical care will close an important technology gap. It must be recognized that initial systems will require significant capital outlay, but will return a priceless dividend of lives and limbs saved.

## SUMMARY

Optimal care to trauma and critically ill patients requires an organized approach with dedicated resources delivered by specialty-trained professionals. Telemedicine applications in trauma and critical care are being developed and studied. At present, limited research exists to support a wholesale adoption of this technology. Based on presently available data, telemedicine has incredible untapped potential for augmenting care in emergency circumstances, especially in the areas of trauma in critical care and in the follow-up of that care. Regionalization of care and application of these technologies is beginning to demonstrate significant advantages to remote locations and those that are otherwise understaffed with specialized health care providers. It is quite encouraging that the presently limited available data from application of these technologies into the ICU has been able to demonstrate improvement in the quality of care while reducing costs and resource utilization. These improvements have been realized despite the usual steep learning curve and, in many circumstances, limited resources.

Telemedicine has been used in many instances for education, image transfer, second opinions, consultative care, and direct acute care. In these domains there is growing evidence that these systems are effective at improving care to patients located in remote areas. Clearly, more work needs to be done to improve not only the technological aspects of telemedicine but also the human aspects of delivering this type of care, at the practitioner, organizational, and governmental levels.

Some have likened the use of outside physicians for night-time coverage (e.g., NightHawk radiological oversight) of patients as a form of outsourcing (73). Yet, in many cases the doctors serving in foreign countries are U.S. trained, or possess a similar level of certification. American radiology departments will likely rely in increasing numbers on NightHawk services from foreign countries, because as one hemisphere of the globe sleeps

the other is awake; hence, a natural reciprocation of responsibilities avails itself. The next critical element in wider utilization of these services rests in the realm of certification and credentialing. Providing levels of training and oversight (quality control) are similar within institutions; distant radiologists or other physicians should be capable of providing the same level of care. A system of reciprocity is being developed to confirm that levels of expertise are at a high level for those making diagnosis from distant shores.

The establishment of accepted standards including medico-legal and regulatory issues need to be accomplished in order to have a working and efficient system. The future of these systems seems to grow in potential importance given the shortage of specialty-trained physicians like intensivists and the present trend for fewer surgical trainees to enter specialty training tracks. Given the lack of availability of specialty-trained physician groups in remote areas, health care decision makers should be strongly embracing telemedical approaches to better leverage care by such highly skilled and trained individuals.

## KEY POINTS

- ✦ The regionalization of trauma care has improved overall outcome, but not solved the significant problem of providing high-level trauma and critical care services to remote locations where organized trauma systems do not exist.
- ✦ A potential solution to delivering trauma and critical care to remote locations and to address shortages of subspecialty-trained physicians is the use of telemedicine.
- ✦ Military research has helped develop many aspects of telemedicine, and the direct applications to both military and civilian care are enormous.
- ✦ Computer-assisted surgical robotics is a technological area whose immense potential will likely facilitate telemedicine applications for trauma in the near future.
- ✦ Telemedicine connects two physically separated locations (which can be positioned anywhere on the globe), and facilitates the sharing of clinical information between health care providers (or between patient and provider) for the diagnosis and or management of medical and surgical conditions.
- ✦ Telemedicine can be used in a variety of situations from consultative care, triage, and direct patient care, to image transfer and continuing medical education.
- ✦ The specific computer-based elements needed for each telemedicine application varies, but when dealing with trauma or critically ill patients, the system requires capability to handle real-time, synchronous interactive videoconference.
- ✦ The main characteristic that defines the quantity of data that can be transmitted over a line or other medium is bandwidth.
- ✦ The role of trauma leader can be safely provided by a traumatologist not physically present in the TRS in locations where the trauma training of individuals is insufficient, but telecommunication understanding is adequate (36).
- ✦ The application of telepresence in trauma surgery has evolved to include use of the *Da Vinci*<sup>®</sup> system computer-assisted robotics.
- ✦ The theoretical goal of minimally invasive computer-assisted robotic techniques in trauma is that they will be applied in resuscitative (including damage-control) surgery as a potential method to stabilizing selected patients.
- ✦ The addition of supplemental, telemedicine-based, remote intensivist programs has been associated with both improved clinical outcomes and hospital financial performance.
- ✦ Effective as of October 2001, Medicare has expanded its coverage of telemedicine services to include broader geographical areas and physician services (70).
- ✦ The Joint Commission on Accreditation of Hospitals (JCAHO) has recently dictated a requirement of credentialing in hospitals, which are establishing telemedicine care.
- ✦ Much more can and must be done to utilize current technological capabilities to improve medical communication between levels of care.

## Hyperbaric Oxygen Therapy in Trauma and Critical Care

Enrico M. Camporesi

Department of Anesthesiology and Critical Care, University of South Florida College of Medicine, Tampa, Florida, U.S.A.

Irving "Jake" Jacoby

Hyperbaric Medicine Center, Department of Emergency Medicine, UC San Diego Medical Center, San Diego, California, U.S.A.

### INTRODUCTION

Hyperbaric oxygen (HBO<sub>2</sub>) therapy is a growing specialty in medicine that overlaps many other specialties due to the ever-increasing understanding of the numerous physiologic effects of O<sub>2</sub> under pressure. The increasing elucidation of HBO<sub>2</sub> mechanisms of action has increased the therapeutic application of this treatment by specially trained physicians around the globe. This chapter provides an overview of HBO<sub>2</sub> therapy, including the basic science, physiology, and the clinical indications relevant to the fields of trauma and critical care.

Hyperbaric medicine is a relatively new field of medicine that has been recently reviewed from a historical perspective (1). However, a couple landmark developments deserve special note. Its beginnings were in non-scientific-based air compression chambers, starting in the 17th century. Initial treatments for Caisson's Disease during the construction of underwater tunnels in New York City and in Europe were with compressed air. Several unusual large chambers were built in the early 20th century, including the 6-story high "Steel Ball Hospital," built by Cunningham in Cleveland (1,2). This edifice did not survive, however, due to lack of scientific grounding in indications and procedures at that time.

Modern HBO<sub>2</sub> therapy had its beginnings in 1955 with the work of Churchill-Davidson, who attempted to use HBO<sub>2</sub> to potentiate radiation therapy in cancer patients (3), and with Boerema, at the University of Amsterdam, who during that same year proposed using HBO<sub>2</sub> in cardiac surgery to prolong tolerance of circulatory arrest by patients (4). It was a logical step for Brummelkamp at the University of Amsterdam to consider the possibility of inhibiting anaerobic infections with O<sub>2</sub> under pressure, and the first published report of use of HBO<sub>2</sub> for gas gangrene was reported in 1961 (5). Treatment of carbon monoxide (CO) poisoning was also first reported in 1961 (6).

Since that time, hyperbaric medicine has developed into a full-fledged medical discipline, with specialty journals, fellowships, and board certification for physicians within the last decade. The Hyperbaric Therapy Committee of the Undersea and Hyperbaric Medical Society (UHMS) meets and reviews all submitted indications for HBO<sub>2</sub> therapy, and that list is updated approximately every three years (7). There are currently 13 UHMS-approved indications for HBO<sub>2</sub> therapy (Table 1).

### GENERAL PRINCIPLES

**HBO<sub>2</sub> therapy is defined as the therapeutic administration of O<sub>2</sub> at pressures greater than one atmosphere at sea level.** One atmosphere of pressure, expressed in millimeters of mercury (mmHg), corresponds to 760 mmHg, and in units of atm abs, "atmospheres absolute," units commonly used in HBO<sub>2</sub> therapy, is 1 atm abs. The concentration of O<sub>2</sub> in air is approximately 21%, therefore, the partial pressure of dry O<sub>2</sub> (PO<sub>2</sub>) is 160 mmHg at 1 atm abs ( $0.21 \times 760 \text{ mmHg} = 160 \text{ mmHg}$ ). The remaining component (79% of air) is mainly Nitrogen (N<sub>2</sub>) and other trace inert gases. Together, they exert a partial pressure of approximately 600 mmHg at 1 atm abs ( $0.79 \times 760 \text{ mmHg} = 600 \text{ mmHg}$ ). The partial pressure of water vapor (P<sub>H<sub>2</sub>O</sub>) in air is variable and depends on both temperature and humidity. At 37°C and 100% humidity, conditions commonly found in the lung, P<sub>H<sub>2</sub>O</sub> is 47 mmHg. This value is unchanged at 2 and at 3 atm.

The PO<sub>2</sub> in dry air is increased to approximately 479 mmHg when the pressure is raised to 3 atm abs ( $3 \times 760 \text{ mmHg} \times 0.21 = 479 \text{ mmHg}$ ). If the concentration of O<sub>2</sub> is then increased to 100%, PO<sub>2</sub> at 3 atm abs increases approximately to 2280 mmHg ( $3 \times 760 \text{ mmHg} \times 1.00 = 2280 \text{ mmHg}$ ).

In the alveoli, carbon dioxide (CO<sub>2</sub>) as well as H<sub>2</sub>O vapor is added to inspired gases, reducing the initial partial pressure of any inspired gas to the alveolar level. The typical alveolar partial pressure of CO<sub>2</sub> (P<sub>ACO<sub>2</sub></sub>) is 40 mmHg and is usually closely regulated by subjects and patients around this value, despite changing the ambient pressure. The alveolar P<sub>H<sub>2</sub>O</sub>, as mentioned above, is unchanged at 47 mmHg. By using the "alveolar gas equation" one can calculate approximate alveolar partial pressures of O<sub>2</sub> (P<sub>AO<sub>2</sub></sub>), at various chamber pressures:

$$P_{AO_2} = (P_B - P_{H_2O}) F_{IO_2} - P_{ACO_2}$$

where P<sub>B</sub> = ambient pressure or chamber pressure, F<sub>IO<sub>2</sub></sub> = fractional concentration of inspired O<sub>2</sub> and the approximation is represented by the assumption that the respiratory quotient is equal to 1. P<sub>AO<sub>2</sub></sub> is usually 110 mmHg while breathing air at 1 atm abs [ $P_{AO_2} = (760 - 47)0.21 - 40 = 110$ ] and increases to 2193 mmHg while breathing 100% O<sub>2</sub> at 3 atm abs [ $P_{AO_2} = (2280 - 47)1.00 - 40 = 2193$ ].

While the P<sub>AO<sub>2</sub></sub> increases in proportion to the increase in ambient pressure, the arterial PO<sub>2</sub> (P<sub>aO<sub>2</sub></sub>) will vary according

to the degree of pulmonary dysfunction present. The [a/A] O<sub>2</sub> ratio has been utilized and verified in healthy subjects and in patients with varying pulmonary problems as a predictor of arterial oxygenation at increased inspired oxygen concentrations up to 2.8 atm abs (8). When arterial O<sub>2</sub> tension (PaO<sub>2</sub>) approaches 1200 mmHg, about 4% vol of O<sub>2</sub> are dissolved in plasma and can provide for the total metabolic requirements of the tissues. The oxygen dissolved in plasma diffuses first from the capillaries, and constitutes the majority of the (a-v) difference required by tissue consumption.

✎ **Treatment with HBO<sub>2</sub> is empirically limited to a maximum tolerated inspired PO<sub>2</sub> and the total time of exposure.** ✎ Normally 100% O<sub>2</sub> is administered at pressures no greater than 3 atm abs (PO<sub>2</sub> = 2280) and only for intervals no longer than 20–25 min. “Air breaks,” intermittent periods of air breathing, of 5 to 10 min, are administered between intervals if therapy is required to exceed these times. Air breaks reduce periodically the inspired PO<sub>2</sub>, thereby minimizing the acute onset of central nervous system O<sub>2</sub> toxicity and delaying the development of pulmonary O<sub>2</sub> toxicity. Some typical values commonly found in a hyperbaric environment are summarized in Table 2.

## MULTIPLACE VS. MONOPLACE HYPERBARIC CHAMBERS

The traditional method of administering HBO<sub>2</sub> therapy is with a multiplace chamber that accommodates two or more individuals. Size may vary from small, often portable two-man chambers used for transporting patients in the field, to several feet in diameter, in which up to a dozen or more patients may be comfortably admitted, in addition to tenders, nurses, and physicians. This type of multiplace chamber is usually compressed with air, while the patient breathes oxygen either with a head tent, facemask, or through a tracheal tube. ✎ **Because of the immediate access to the patient by accompanying personnel, monitoring is commonly simplified with multiplace HBO<sub>2</sub> chambers.** ✎ Intravenous lines can be inserted at any time during treatment and airway control can be provided. Surgery has even been performed inside multiplace hyperbaric chambers. On the other hand, setting up and

**Table 2** Approximate Values of Alveolar Oxygen Pressure, After Correction for Water Vapor Pressure and CO<sub>2</sub> Pressure, Assuming a Respiratory Quotient of 0.8

Environmental pressure (atm abs)	Alveolar PO <sub>2</sub> (mmHg) breathing air (21% O <sub>2</sub> )	Alveolar PO <sub>2</sub> (mmHg) breathing 100% O <sub>2</sub>

2	262	1433
3	422	2193

maintaining these chambers is complex. They have a large space requirement for installation and are costly.

The other type of chamber is the monoplace. This type of chamber is large enough to accommodate only one patient. The chamber wall in several types is manufactured of clear plastic, facilitating close observation of the patient. The chamber is compressed with 100% O<sub>2</sub>. The advantage of monoplace chambers is their relatively low cost and ease of installation. The chamber may be put into use by connecting the oxygen inlet to the hospital supply, with modification to accommodate large flow rates. Operation of the chamber is relatively simple. The disadvantage is the lower flexibility and the treatment pressure range, which most often cannot exceed 3 atm abs. Inside a monoplace chamber monitoring is more remote, and emergency care of the airway cannot be provided. ✎ **Development of a tension pneumothorax, although rare, could be fatal in a monoplace chamber because of the impossibility of inserting a chest tube prior to decompression.** ✎ Nevertheless, monoplace technology now permits intravenous fluid administration from the outside of the chamber, invasive intravascular monitoring, and mechanical ventilation. Most chambers are now equipped with a mask system (called BIBS or “built in breathing system”) from which the patient may breath air and receive air breaks. Critically ill patients can routinely be treated in monoplace chambers if the experience of the personnel warrants it.

## TRAUMA AND HBO<sub>2</sub>

HBO<sub>2</sub> can be utilized in the treatment of several clinical situations associated with acute trauma. Therapy with HBO<sub>2</sub> is effective by elevating total pressure in body compartments in gas embolic disease and increasing oxygen tensions in blood and tissues. Of particular note is the possibility of pulmonary venous emboli that can occur following both penetrating and severe blunt thoracic trauma. The institution of HBO<sub>2</sub> therapy in this patient population is complicated due to the other common competing problems. However, in the case of severe pulmonary venous air entry and subsequent systemic arterial embolization to important structures (e.g., brain, heart, and other viscera), HBO<sub>2</sub> therapy can be life saving.

In addition, HBO<sub>2</sub> exposure has been associated with intense vasoconstriction, resulting in reduction or resolution of edema in compartment syndrome, while nutrient blood flow is preserved (7). Several post-traumatic infectious syndromes appear to benefit from HBO<sub>2</sub>, as elevated O<sub>2</sub> tension is bactericidal toward a variety of micro-organisms (5).

## AIR AND GAS EMBOLISM

Air or gas can gain entry into the intravascular spaces more often than is currently recognized. Embolism can occur as a complication during a medical diagnostic or therapeutic procedure (9) or during accidental rapid decompression (10). The latter has been traditionally associated with scuba divers, but it can also occur in aviators, typically pilots of high performance military aircraft (11). During scuba dives, and usually in an inexperienced diver, embolism can happen with a rapid ascent from a dive, while breathing compressed gas and while breath-holding during ascent.

Pulmonary barotrauma can then occur, forcing gas into pulmonary capillaries, producing an arterial gas embolus (AGE). An iatrogenic embolism can occur during almost any invasive medical procedure penetrating tissue and bone and can produce either an AGE and/or a venous gas embolus (VGE). Included in such procedures are head, neck, or thoracic surgery; cardiopulmonary bypass (12); penetrating chest injury; needle or catheter placement for monitoring (13), diagnostic (14–16), or therapeutic purposes (17–21); renal dialysis (22); obstetric or gynecologic manipulation (23); and urologic procedures (24). In recent years several reports of forced air embolism have been published following use of rapid infusers, and steps have been taken to better detect the potentially lethal air bubbles in an effort to decrease the embolic risk (25).

Venous gas embolism occurs when the partial pressure of the intravascular offending gas exceeds the ambient pressure. As little as 5 cmH<sub>2</sub>O pressure difference between the atmosphere and the intravascular space is enough to entrain large volumes of air (26). Many of these bubbles are clinically “silent” as they cause no symptoms to the patient. These are however detectable by Doppler ultrasound (27). The technology has been applied clinically to study decompression sickness and monitor cardiopulmonary bypass and intracranial surgery.

However, the ability of the pulmonary vasculature to eliminate venous air emboli is limited (28). Transpulmonary passage of venous air emboli seems to be related to air infusion rates; if they are kept below a threshold value, the lungs can clear gaseous emboli. It also appears that vascular pressures have an important role in the passage of gas emboli through the pulmonary circulation. An infusion rate of 0.30 ml/kg/min in dogs is a threshold above which the lung capillaries can no longer clear the air embolus to the alveoli (29).

Intravascular gas can produce injury by two mechanisms. Intravascular bubbles cause a mechanical obstruction to blood flow and induce intravascular thrombosis through platelet aggregation and activation of other hemostatic mechanisms, mainly fibrin deposition. Manifestations of gas emboli are varied and depend on their size and location, the volume of gas entrained, speed of the event, position of the patient, and whether the main location is intra-arterial or intra-venous. These undesirable occlusive processes inevitably result in organ or tissue ischemia (30). AGE commonly produce clinical symptoms in the cerebral and spinal cord circulations as well as in the coronary circulation. Usual CNS symptoms include sudden dizziness, nausea, sensory or motor deficits, visual disturbances, confusion, coma, and seizures. Cardiac symptoms include ischemic chest pain and

electrocardiographic changes associated with ischemia. VGE may produce pulmonary symptoms such as chest pain, coughing, dyspnea, and hemodynamic instability, including hypotension, tachypnea, pulmonary edema, or cardiac arrest. Elevation of CPK enzyme levels is reportedly a very frequent accompaniment to air emboli (31).

Mortality and morbidity can be significant. The diagnosis of air or gas embolism may be difficult, unless air entry is actually witnessed, or gas is found on aspiration from a central line, or the bubbles are visualized via ultrasonic imaging. Rarely is the diagnosis made by auscultation alone through the classic “millwheel murmur.” New Doppler and neuroimaging modalities, particularly magnetic resonance imaging (MRI), have greatly added to the diagnostic armamentarium; however, both have limitations. The Doppler devices can alert that air emboli are occurring, but in general are more qualitative than quantitative. In addition, these devices do not determine the precise target tissue, or the severity of ischemia affecting that tissue. **☞ MRI is the most sensitive in detecting focal cerebral ischemia due to air embolism. ☞** A study by Warren et al. has determined that MRI is more sensitive than computed tomography scanning in this situation (27).

HBO<sub>2</sub> therapy has the ability to increase both tissue perfusion and tissue O<sub>2</sub> tensions and is therefore the treatment of choice for air or gas embolism. Rapidly increasing the ambient pressure decreases bubble volume immediately via the reduction in actual bubble volume, improving blood flow to the affected area. Increasing pressure by only 760 mmHg or to 2 atm abs decreases bubble volume by 50%; increasing pressure to 3 atm abs decreases bubble volume to 33% of the original volume. As the patient is also ventilated with 100% O<sub>2</sub>, the largest gradient is created for inert gases present in the bubble (N<sub>2</sub> if the embolus is air) to be reabsorbed. In cases involving emboli to the cerebral and spinal cord circulations, hyperoxic vasoconstriction may decrease edema and improve the survival of marginally viable or ischemic tissue. Various treatment protocols have been used. These include the use of O<sub>2</sub> at 2.8 atm abs or compressed air or Nitrox (50% O<sub>2</sub> and 50% N<sub>2</sub>) at 6 atm abs utilizing U.S. Navy Table 6 or 6A, repeating the treatment until no further improvement can be demonstrated (32).

## DECOMPRESSION SICKNESS

**☞ Decompression sickness (DCS), also known as caisson disease, or the bends, is the clinical syndrome occurring during decompression. ☞** Bubbles of N<sub>2</sub> form intravascularly and in tissues. The details on formation and growth of these bubbles are still unknown. However, bubbles form when the speed of decompression exceeds the rate at which perfusion can carry the dissolved gas to the lungs for exchange. Bubbles may form in any part of the body, producing a variety of signs and symptoms. Table 3 identifies the “no decompression” time limits for divers breathing compressed air and provides a frame for decompression-free limits in human diving at sea level.

The clinical presentation of DCS can vary widely from patient to patient; therefore a high index of suspicion and a history of decompression are essential to making a diagnosis. Correct diagnosis is vital; without treatment, permanent

**Table 3** No-Decompression Limits for Sport Divers Breathing Compressed Air

Depth	No decompression limit
40 feet	200 min
50 feet	100 min
90 feet	30 min
100 feet	25 min
130 feet	10 min

neurological deficits can ensue in previously healthy patients. So-called Type I DCS or the "bends" occurs in over 90% of cases and includes joint pain and cutaneous rashes. Typically this syndrome is characterized by deep, dull pain occurring in any joint. Type II DCS occurs in over 25% of cases and is characterized by primarily CNS effects with a predominance of spinal cord involvement. Dizziness, nausea, behavioral changes, visual disturbances, seizures, and coma are common presentations. Motor and/or sensory deficits, paraplegia, bowel or bladder incontinence, and loss of sexual function usually indicate spinal cord involvement.

A more careful neurological exam and a more attentive physician can often elicit significant subtle symptoms early in the disease.

In approximately 22% of all the sport divers presenting with DCS, peripheral nervous system symptoms are present. These may include low back pain, paresthesias, weakness, or proprioceptive deficits. Rarely do labyrinthine effects such as nystagmus, vertigo, nausea, and vomiting occur. When they do, treatment should be initiated as soon as possible to prevent permanent damage. More serious cardiorespiratory symptoms, pulmonary edema, shock, and death depict a wide spectrum of problems (33).

Various factors predispose to decompression sickness. Included are: cramped position during or after decompression, a recent strain or sprain of a muscle or a joint, hard exercise during or after decompression, hyperthermia, postalcoholic state, age over 40, and hypercarbia. One study found that in 23 divers with serious decompression sickness the incidence of a patent foramen ovale was 40% as compared to 5% in 176 normal volunteers. It has been hypothesized that the presence of a patent foramen ovale allowed otherwise innocuous venous gas bubbles to enter the arterial circulation and produce symptoms (33).

**✎ The definitive treatment for DCS is recompression in a HBO<sub>2</sub> chamber, and is the standard of care for patients suffering from decompression sickness and arterial gas embolism.** ✎ Often there is a need to transport a patient a long distance to the nearest hyperbaric chamber. The ambient pressure during transport should be maintained as high as possible by utilizing pressurized or low-flying aircraft (best at less than 1000 feet). In the meantime 100% O<sub>2</sub> should be administered via a tight-fitting face mask or endotracheal tube to hasten the elimination of N<sub>2</sub>. Fluid resuscitation with intravenous crystalloid or colloid solutions are used also to aid in the elimination of N<sub>2</sub> as well as to maintain tissue perfusion. Hypotonic fluids should be avoided in cases of pulmonary involvement because they will add to any pulmonary edema present.

Whenever cerebral or spinal cord edema is suspected, the use of steroids should be considered, even if it may take several hours to be effective. Though steroids have been

shown in animal studies to increase the risk of oxygen toxicity this has not been proven to be clinically significant in human studies. Also, hyperglycemia has been shown to augment neurologic injury due to ischemia (34). Therefore, glucose-containing fluids should not be used for resuscitation.

The clinical severity of the illness, clinical response to treatment, and residual symptoms after HBO<sub>2</sub> treatments will dictate the choice of treatment tables and the number of such treatments required. U.S. Navy Table 6 is most often used to treat severe DCS symptoms (with compression to 2.8 atm abs), whereas, U.S. Navy Table 5 is utilized for less severe symptoms (32).

Multiple treatments may be given until there is no further clinical improvement. Best results occur when the patient is treated as soon as possible. This is especially true when treating labyrinthine DCS. However, even after a delay of several days, treatment can still be effective. Finally, treatments are continued until no further improvement is seen in the patient. Altitude DCS is similar to diving DCS in pathophysiology and clinical presentation. Return to sea level and oxygen breathing are usually sufficient to treat mild cases. Compression in a hyperbaric chamber may be required with more serious presentations.

**✎ HBO<sub>2</sub> treatment of decompression sickness and arterial gas embolism is very cost-effective in today's medical climate of cost control given the alternative of permanent spinal cord, brain or peripheral nerve damage, or death.** ✎

## CARBON MONOXIDE TOXICITY

Toxicity due to CO occurs commonly during traumatic events when patients are exposed to fire, explosions, or the emission of gases from combustion engines. The presentation is often nonspecific, as a variety of symptoms can manifest. Exposure is most often accidental, occurring in the absence of other trauma, during cold weather. Sources of CO toxicity include motor vehicle exhaust, space heaters, industrial furnaces, and house fires. Increasing recognition of CO poisoning is occurring following disasters, particularly in the recovery phase after floods (35,36) and hurricanes (37-39), generally due to powered pressure washers and generators used indoors or in proximity to open doors or windows.

Classic presentation includes headache, nausea, vomiting, hypotension, syncope, vasomotor collapse, behavioral abnormalities, seizures, and coma. In acute exposures carboxyhemoglobin (Hb-CO) levels of 10% to 20% are often asymptomatic, while levels of 50% to 60% are found frequently in comatose victims. In chronic exposure, as measured in hours, Hb-CO levels that are normally survivable can become lethal, and the initial values do not correlate well with clinical findings or outcome. This is because blood levels do not accurately reflect the amount of intracellularly bound CO. This was observed in a study by Norkool and Kirkpatrick, who found, in patients admitted to care after a prolonged exposure, that the mean Hb-CO levels in those who survived (29.3%) did not differ significantly from those who died (30.8%) (40). Neuropsychiatric abnormalities are often present, but may be subtle and may require psychometric testing for detection (41). **✎ In judging the severity of CO intoxication it is important to account for the duration of exposure, the activity of the victim during exposure, and the time from exposure to**

**assessment.** Recently it has been shown that intracellular binding of carbon monoxide to cytochrome oxidase in mitochondria may occur in vivo (42). This may contribute to tissue hypoxia by causing a persistent disruption of intracellular respiration.

Oxygen therapy either via hyperbaric or via face mask/endotracheal route is the therapy of choice in CO intoxication. It improves tissue oxygenation by decreasing the half-life of Hb-CO, by increasing the amount of oxygen physically dissolved in solution, and by hastening the liberation of CO from cytochromes. The half-life of Hb-CO is inversely related to the inspired oxygen partial pressure. Thus HBO<sub>2</sub> causes carboxyhemoglobin dissociation faster than normobaric oxygen (43). Prior to instituting HBO<sub>2</sub>, patients should receive 100% O<sub>2</sub> via a tight-fitting face mask or an endotracheal tube. Transfer to a hyperbaric chamber should be accomplished as soon as possible. In patients with the history of exposure, with Hb-CO levels greater than 25%, therapy should be guided by the presence of neurologic symptoms, circulatory or respiratory collapse, and ischemic changes on the electrocardiogram. The recommended therapy is at 2.5 to 3.0 atm abs for up to 90 min. Treatment is guided by the severity of symptoms and response to therapy. Follow-up treatments may be administered 12 to 24 hrs later in those who presented with severe manifestations or in those with persistent symptoms. This treatment paradigm is supported by an excellent randomized clinical study (44).

The use of HBO<sub>2</sub> for CO intoxication during pregnancy has been described. Recent literature presented a case of maternal CO intoxication leading to signs of fetal distress, reviewed the pertinent literature, and concluded that short hyperoxic exposures during therapy can be well tolerated by the fetus in all stages of development. Therefore, HBO<sub>2</sub> may reduce the risk of death to the mother and deformity or death to the fetus. **HBO<sub>2</sub> therapy is not only safe to use during pregnancy but is very beneficial, when used for standard indications (45).**

## ACUTE INFECTIONS

### Clostridial Myonecrosis

Clostridial myonecrosis, commonly known as gas gangrene, is a dramatic necrotizing infection characterized by rapidly spreading muscle necrosis (46). Diabetic or debilitated patients with traumatic, contaminated, or ischemic wounds are particularly at risk. Compound fractures and the presence of foreign bodies in the wound also increase risk. The most common organism implicated in causing clostridial myonecrosis is *Clostridium perfringens*. *Clostridium novii*, *C. septicum*, *C. histolyticum*, *C. fallax*, *C. sordellii*, and *C. bifermentans* have also been cultured from involved wounds. *C. perfringens* is an anaerobic, spore-forming, gram positive rod found abundantly in the soil and in the normal flora of the gastrointestinal tract. Despite being an anaerobic organism it can grow freely in O<sub>2</sub> tensions up to 30 mmHg (similar to body tissue oxygen tensions) and under certain conditions up to 70 mmHg. By providing an area of low O<sub>2</sub> tension, the clostridial spores can develop into a major infectious threat.

The pathophysiology of clostridial myonecrosis is related to the production of exotoxins of which 20 types have now been identified. Nine of these are seen in clinical clostridial myonecrosis and myositis (47). It also causes serious side effects via cytolytins and promotes

direct vascular injury at the site of infection. Usually in the area immediately surrounding the infected wound the patient complains of extreme pain, and exaggerated swelling, brownish skin discoloration, gas production, and a brownish sweet-smelling drainage are present. Some systemic effects of alpha-toxin include septic shock, hemolysis-causing anemia, renal failure, disseminated intravascular coagulation, cardiotoxicity, and neurologic abnormalities. The clinical course is characterized by rapid deterioration if early treatment is not initiated.

The rationale for HBO<sub>2</sub> in this type of infection is based on the fact that anaerobic organisms lack antioxidant enzymes (superoxide-degrading enzyme, dismutase; and hydrogen peroxide-degrading enzyme, catalase). This enables oxygen to be lethal for anaerobic organisms (48). HBO<sub>2</sub> at 2 to 3 atm abs by increasing tissue oxygen tensions above 30 mmHg has been demonstrated to stop spore germination and to inhibit bacterial growth in a bacteriostatic fashion. In an inoculum of tissues from rats exposed to 3 atm abs for one and one-half hours it was found that the production of alpha-toxin could be inhibited but the toxin already produced was still stable in this environment (49). HBO<sub>2</sub> also induces hyperoxic-vasoconstriction that has also been demonstrated to decrease edema and improve perfusion to swollen ischemic tissue. HBO<sub>2</sub> is recommended as adjuvant therapy in addition to surgical debridement and broad spectrum antibiotics. Mortality rates with gas gangrene have ranged as high as 30% to 50% prior to the addition of HBO<sub>2</sub>. However, since the addition of HBO<sub>2</sub>, both mortality and morbidity have decreased significantly. In 1983 a study covering 20 years of experience found the overall mortality rate to be 20% (50). Mortality directly attributed to gas gangrene was reported to be 10.6%. Therapy with HBO<sub>2</sub> produced the best results when begun within 24 hrs of diagnosis. HBO<sub>2</sub> decreased the amputation rate when surgery was the primary therapy from 50% to 24% when used in addition to surgery. Similar findings have been supported in other studies.

### Other Necrotizing Infections

Although clostridial myonecrosis is the most common and lethal of the necrotizing infections, other anaerobic and aerobic gas-forming organisms are capable of causing clinical syndromes similar to gas gangrene. Most often these infections occur in debilitated patients with either traumatic or surgical wounds. These conditions favor local tissue hypoxia and encourage bacterial growth. Prognosis with these infections is closely related to any coexisting disease present. Crepitant anaerobic cellulitis is a gas-producing infection involving the soft tissues without muscle involvement. This disease is neither a cellulitis produced by anaerobes nor a Clostridial toxin-induced disease. The onset of infection after a traumatic injury, usual to the lower extremities, is gradual. Systemic involvement is low. Mortality is lower than in other disease entities in this group at 10% to 15%. Bacteroides, Peptostreptococcus, Enterobacteriaceae, and Clostridium species are frequently isolated from the wounds. Progressive bacterial gangrene begins as an indurated site slowly progressing to painful ulcerating lesions involving the skin and subcutaneous tissues of the abdominal and thoracic walls. Usually it takes about two weeks to develop after a traumatic injury or surgery. Mortality ranges between 10% and 25%.

The synergistic action of anaerobic streptococci with *Staphylococcus aureus* or Enterobacteriaceae is the cause of

this syndrome. Necrotizing fasciitis was first described by Meleny in 1924. It was called hemolytic Streptococcal gangrene. It is a common clinical entity involving deep infection of subcutaneous tissues (51). It has a high mortality, averaging 40%. Necrotizing fasciitis is characterized by extensive necrosis of the superficial and deep fascia, and in the pure form does not involve muscle. However, it is not uncommon to have spread to ischemic muscles (myonecrosis) in numerous clinical settings.

The necrotizing fasciitis infection spreads through tissue planes. The sine qua non of necrotizing fasciitis is the rapid spread of the disease along fascial planes with ensuing necrosis of the superficial skin above. Fournier's Gangrene is a necrotizing fasciitis involving the perineum or scrotal areas. Systemic toxicity is marked. Anaerobic organisms (*Bacteroides*, *Peptostreptococcus*, and *Fusobacterium* species) as well as aerobic organisms (*S. aureus*, *Streptococcus pyogenes*, and *Enterobacteriaceae*) have been isolated from these infections.

☞ **HBO<sub>2</sub> is recommended as adjuvant therapy following emergency surgical debridement and antibiotics for most necrotizing infections.** ☞ HBO<sub>2</sub> is effective because of the direct lethal effect of O<sub>2</sub> on anaerobic and microphilic aerobic organisms. Also, the neutrophil myeloperoxidase-hydrogen peroxide-halide system that is postulated to aid in bacterial cell wall destruction may be another important oxygen dependent system contributing to the success of HBO<sub>2</sub>. Prophylactic antibiotics in addition to HBO<sub>2</sub> produced an additive effect in the reduction of infectious necrosis (52). The recommended therapy involves twice daily treatments at 2.0 to 2.5 atm abs for 90 to 120 min until the patient's condition stabilizes. After that, treatments can be reduced to once a day.

## ACUTE ISCHEMIC PROCESSES

☞ **Acute ischemic processes that are amenable to HBO<sub>2</sub> include crush injury and compartment syndrome.** ☞ Crush injury is defined as a severe diffuse trauma involving two or more different tissues. Various degrees of tissue and microvascular damage occurs producing edema and swelling. The result is ischemia from poor perfusion to the involved area. Compartment syndrome occurs commonly in the anterior compartment of the leg and volar aspect of the forearm. Ischemia is produced by a similar mechanism in that edema and swelling, confined by fascia compartments leads to decreased perfusion. Vasodilation from local tissue hypoxia leads to further swelling and decreased perfusion.

Muscle necrosis can occur ultimately causing fibrous tissue deposition and contractures. HBO<sub>2</sub> promotes hyperoxic-vasoconstriction which reduces swelling and edema and improves local blood flow and oxygenation. It also increases tissue oxygen tensions and improves the survival of marginally viable tissue. At the time of surgical debridement, prior treatment with HBO<sub>2</sub> aids in the demarcation of nonviable tissue. Best results, again, are obtained when therapy is begun early. Twice daily treatments at 2.0 to 2.5 atm abs for 90 to 120 min are recommended for five to seven days with frequent examinations of the affected area.

## MASSIVE BLOOD LOSS

Only when blood transfusion is unavailable (usually due to a major blood typing incompatibility) or has been refused (due

to religious reasons as with a Jehovah's Witness) should HBO<sub>2</sub> be used to treat exceptional anemia. The rationale for using HBO<sub>2</sub> is based on the fact that life can be supported solely by O<sub>2</sub> physically dissolved in plasma when 100% O<sub>2</sub> at 3 atm abs is administered. HBO<sub>2</sub> used in this rare circumstance can only sustain a patient temporarily until compatible blood is available or until there is sufficient time for erythropoiesis. A summary of several treatments spanning several years of practice has been published by Hart et al. (53).

## THERMAL BURNS

☞ **HBO<sub>2</sub> therapy in the treatment of burns in the absence of CO intoxication is controversial.** ☞ The rationale is that burn wounds are often characterized by edema, increased vascular permeability, stasis of circulation, and intravascular coagulation. Thus tissue surrounding a burn is prone to hypoxia, infection, poor wound healing, and scar formation. HBO<sub>2</sub>, by several mechanisms described above, can decrease tissue hypoxia surrounding a burn, correcting many of these shortcomings directly. HBO<sub>2</sub> therapy can maintain microvascular integrity, minimize edema and provide the vital oxygen needed for tissues to heal and become viable once again (54). HBO<sub>2</sub> therapy minimized white blood cell adherence to endothelial cell walls, preventing the cascade causing vascular damage (55). Thus HBO<sub>2</sub> has a beneficial effect on the microcirculation. Also, burns are often complicated by smoke inhalation, CO intoxication, and cyanide toxicity. These complications should be suspected in all unconscious patients rescued from fires.

## EYE TO THE FUTURE

Many effects of HBO<sub>2</sub> therapy remain to be elucidated. As time goes on, it is expected that additional studies will clarify the effects of HBO<sub>2</sub> therapy for additional clinical situations.

In the field of diving medicine, newer areas of interest include exploration of whether the addition of adjunctive drugs might enhance the response of Type II decompression sickness to HBO<sub>2</sub>. Drugs currently under investigation for this application include lidocaine and steroids (56,57).

The use of HBO<sub>2</sub> for chronic refractory osteomyelitis raises the question of whether there are other roles for HBO<sub>2</sub> in bone healing. Hyperbaric oxygen affects the activity levels of both osteoblasts and osteoclasts, and there might be a role for HBO<sub>2</sub> in accelerating bone healing, particularly for nonunions. One particular area that is intriguing is in the setting of open fractures of the tibia, which have a predilection for developing osteomyelitis. Could there be a role for HBO<sub>2</sub>, for instance, in prophylaxis to prevent osteomyelitis and mal-union in the setting of trauma?

The addition of brain abscess as an approved indication in the last UHMS hyperbaric therapy committee report also suggests the issue of whether enough data can be acquired to demonstrate effectiveness in other infectious diseases, such as mucormycosis (58), actinomycosis, anaerobic liver abscesses, and other infections. Although several case reports of activity in some of these clinical scenarios exist, true randomized controlled studies to demonstrate effectiveness are still lacking, but are sorely needed. A case registry for cases of mucormycosis is currently attempting

to track cases of mucormycosis for further outcome study. A recent evidence-based report on the benefits and risks of HBO<sub>2</sub> therapy for brain injury, cerebral palsy, and stroke has been issued (59), also demonstrating the need for further studies.

Although hyperbarics has a demonstrated beneficial effect on many nonhealing diabetic and other hypoxic wounds, current Medicare coverage limits reimbursement to Wagner 3 or greater wounds in diabetics, thus limiting the physician's ability to get appropriate treatment for their patients with recalcitrant wounds. Better, more definitive studies, especially cost-effectiveness studies, are still needed in this arena to justify appropriate medical treatment in this particular patient population. Progress is being made at the cellular level in understanding the mechanisms affecting white blood cell adhesion (60).

Hyperbaric medicine remains a fertile ground for augmenting medical care in many specialties, and opportunities for significant contributions in basic and clinical studies abound. Future demonstration of additional physiologic effects of clinical importance is likely.

## SUMMARY

This chapter reviews basic physical and physiological principles of HBO<sub>2</sub> therapy. Specifically reviewed are traumatic syndromes that are amenable to therapy with HBO<sub>2</sub>. Included are: bubble-mediated diseases (air and gas embolism, decompression syndrome), toxicosis (CO toxicity), acute infections (clostridial myonecrosis and other necrotizing infections), acute ischemic processes (crush injury, compartment syndrome), and syndromes requiring special considerations (exceptional blood loss, thermal burns). Basic physiological considerations and practical issues of clinical treatment in the hyperbaric environment are discussed.

## KEY POINTS

- ✍ HBO<sub>2</sub> therapy is defined as the therapeutic administration of O<sub>2</sub> at pressures greater than atmospheric at sea level.
- ✍ Treatment with HBO<sub>2</sub> is empirically limited to a maximum tolerated inspired PO<sub>2</sub> and the total time of exposure.
- ✍ Because of the immediate access to the patient by accompanying personnel, monitoring is commonly simplified with multiplace HBO<sub>2</sub> chambers.
- ✍ Development of a tension pneumothorax, although rare, could be fatal in monoplace chamber because of the impossibility of inserting a chest tube prior to decompression.
- ✍ MRI is the most sensitive in detecting focal cerebral ischemia due to air embolism.
- ✍ Decompression sickness (DCS), also known as caisson disease, or the bends, is the clinical syndrome occurring during decompression.
- ✍ The definitive treatment for DCS is recompression in a hyperbaric chamber, and is the standard of care for patients suffering from decompression sickness and arterial gas embolism.
- ✍ HBO<sub>2</sub> treatment of decompression sickness and arterial gas embolism is very cost-effective in today's medical

climate of cost control given the alternative of permanent spinal cord, brain or peripheral nerve damage, or death.

- ✍ In judging the severity of CO intoxication it is important to account for the duration of exposure, the activity of the victim during exposure, and the time from exposure to assessment.
- ✍ HBO<sub>2</sub> therapy is not only safe to use during pregnancy but is very beneficial, when used for standard indications (45).
- ✍ HBO<sub>2</sub> is recommended as adjuvant therapy following emergency surgical debridement and antibiotics for most necrotizing infections.
- ✍ Acute ischemic processes that are amenable to HBO<sub>2</sub> include crush injury and compartment syndrome.
- ✍ HBO<sub>2</sub> therapy in the treatment of burns in the absence of CO intoxication is controversial.

### INTRODUCTION

The management of trauma and critical care consumes a significant portion of the healthcare budget and has become progressively more complex. Numerous conditions remain associated with high mortalities despite intensive resource allocation. Accordingly, traumatologists and intensivists are increasingly challenged to measure and improve outcomes. Governmental agencies, accrediting bodies, and third-party payers increasingly evaluate performance for quality outcomes as well as cost-effectiveness. Consumers seeking quality healthcare have greater access than before to hospital quality data and performance indicators (mortality rates, lengths of stay, complication rates, volumes etc.), which compare outcomes across institutions and providers. Accordingly, clinicians and researchers want to evaluate and improve the quality of care delivered and identify “best practices” in the treatment of their patients.

Two of the early pioneers of trauma and critical care scoring research, Champion (1) and Knaus (2), were instrumental in forming many of the initial ideas. These early investigators developed and tested scoring and mortality prediction models that have proven valid in outcomes studies and serve as the foundations for the tools that are used currently. Subsequent contributions to their creative visions have helped promote injury severity and critical illness scoring models into increasingly refined and accurate measurement devices.

This chapter begins by reviewing the purpose of scoring systems in terms of their utility in clinical decision-making, and for facilitating comparisons between various treatment units and institutions. Trauma scoring systems are only briefly surveyed, because the topic is extensively reviewed in Volume 1, Chapter 4, of this textbook along with trauma triage. Critical care scoring systems are presented in greater detail with an effort to illuminate the clinically relevant elements of the most commonly utilized scoring instruments.

Because multiple organ dysfunction (MOD) syndrome is responsible for a large fraction of the morbidity that occurs in critically ill patients and also represents the most common scenario for irrecoverable states (i.e., futile therapy) from which medical therapy is withheld or withdrawn, organ injury scoring is also reviewed.

A comparison between the various scoring systems is provided as a mechanism to further amplify their strengths and weaknesses. The Eye to the Future section provides some provocative ideas about the future of scoring systems and emphasizes the need for unification of these schemes; the first steps of which have been taken by the American College of Surgeons National Trauma Databank (NTDB) (3), the Society of Critical Care Medicine’s “Project Impact” (4), and the Intensive Care Audit and Research Centre (INARC) in the United Kingdom (5).

### PURPOSE AND UTILITY OF SCORING SYSTEMS

Prior to the implementation of critical illness scoring systems, it was difficult to determine if mortality outcome variance across surgical intensive care units (SICUs) and Trauma Units was related to treatment effects or a difference in the patient case mix. Mortality rate (MR) and length of stay (LOS) as single indices used to assess SICU performance offered only a rudimentary analysis for comparison and demonstrated the need for case-adjusted data for accurate quantitative risk assessment and outcome comparisons (6).

Trauma scoring systems were developed for both triage purposes and outcomes research (as fully described in Volume 1, Chapter 4), whereas, SICU scoring systems are designed to estimate the probability of in-hospital death of patients admitted to an SICU, based on severity-adjusted mortality measures.

☞ **All scoring systems represent quantitative classification schemes and most use multiple logistic regression methodology applied to prospectively collected data sets of demographic, physiological, and clinical variables.** ☞ From this, standard mortality ratios (SMRs) can be calculated by dividing the observed mortality rate by the mortality rate predicted using the specific patient-related variables. The SMR can be used as a risk-adjusted measure for probability estimates and for comparisons of SICU performance over time, as well as for cross-comparative analyses. These tools provide reasonably accurate prediction in acutely ill patients of the severity, prognosis, and expected course of disease, with mortality outcomes

usually measured as death before discharge from hospital after intensive care (7,8).

Although their primary purpose is to predict mortality, scoring systems have been used on broader scales to research and analyze other outcomes (e.g., LOS, readmission rates etc.), address cost-benefit analyses, evaluate resource utilization, and improve care through comparative evaluation of treatment effectiveness and benchmarking for continuous quality improvement. Predictions of mortality or prolonged stay in the ICU are also of potential benefit for triage, resource allocation, and patient-family counseling as adjuncts (not substitutes) to clinical judgment. Severity scores are frequently used in research trials to stratify patients and establish group similarities (9).

✎ **While scoring systems are useful for research and comparing SICU performance with respect to endpoints such as mortality and LOS, their usefulness is less clear in medical decision-making or prognostic estimations for individual patients.** ✎ Controversy exists about the utility of mortality prediction models as decision support tools due to differences in the accuracy in probability estimates for group versus individual outcomes. Other limitations of models which may result in under- or overestimations of probability include: (i) degradation of reliability over time due to changes in population characteristics and/or advances in treatment, (ii) "goodness of fit" calibration and discrimination issues affecting internal and external validation, (iii) errors in data collection (manual or electronic) and/or misinterpretation of scoring rules (human factors), (iv) lag time issues, (v) statistical problems related to sample size, selection, weighting of variables and so on, and (vi) individual patient-related confounds (e.g., presence of outliers) (10,11).

Although mortality outcome predictions will never be entirely accurate, ICU scoring systems, as with trauma scoring systems, are nevertheless extremely useful tools to classify and quantify severity of illness and to predict outcomes for groups of patients. The use of common terminology (e.g., SMR) enables comparisons between patient groups, individual units, and among ICUs. Such outcome comparisons are essential to research and in the evaluation and improvement of ICU care and organization.

## TRAUMA SCORING SYSTEMS

Numerous well-functioning trauma scoring systems and prediction models based on anatomical injury and physiological impairment (or combinations thereof) are in current use (1,12–17). These tools are useful for: (i) triage and pre-hospital treatment, (ii) injury severity description, (iii) assessment and documentation using common terminology, (iv) quality of care and patient outcome evaluation, (v) trauma system evaluation and comparison, (vi) trauma epidemiology, and (vii) trauma research and funding. The most commonly used trauma scoring tools are highlighted in this section.

### Trauma Score and Revised Trauma Score (TS, RTS)

The coefficient values assigned reflect each parameter's ability to affect outcome, with the highest assigned weight given to the GCS, reflecting increased impact that head injuries have on outcome compared to the initial SBP or RR. The RTS values range from 0 to 7.8, with a higher value indicating increased probability of survival ( $P_s$ ) (12).

The RTS is limited by exclusion of age and other comorbidities that affect outcome (13). The TS and the RTS are simple to use, accurate, and have been incorporated into the trauma score-injury severity score (TRISS) methodology (described in Volume 1, Chapter 4).

### Organ Injury Scale

The Organ Injury Scale (OIS) was developed by the American Association for the Surgery of Trauma (AAST) in 1987 (14) as a tool to devise injury severity scores (ISSs) for individual organs using common nomenclature to describe injuries. The classification scheme provides detailed anatomic descriptions, scaled from one to six [one representing the least, and five the most severe that is salvageable; the value of six denotes the organ is nonsalvageable (in the case of a liver or cardiac trauma this also connotes lethality)] (14). Injuries may also be divided by mechanism (blunt versus penetrating) or by injury description (e.g., hematoma, laceration, and contusion), and grades are advanced for multiple injuries to the same organ.

The first OIS version covered liver, spleen, and kidney injuries. Since 1987, several revisions have occurred and other organs were added. There now exist OIS characterizations for lung, heart, chest wall, diaphragm, abdominal, vascular, ureter, bladder, and urethra, as well as the original three organs. These OIS schemes continue to be updated periodically. These scales are provided throughout this text in other chapters covering the affected organs. The OIS differs from the AIS, which is also anatomically based, but is designed to reflect the impact of a specific organ injury on patient outcome.

### Abbreviated Injury Scale

The abbreviated injury scale (AIS) is an anatomically based global scoring system that classifies each injury in various body regions, using a six-point ordinal scale to rank injury severity (15). The AIS was initially developed in 1969 as a uniform tool to categorize and quantify blunt injuries sustained in motor vehicle collisions (MVCs) by a consortium of automobile insurance firms along with the American Medical Association (15). The AIS has since expanded considerably and is revised and updated every five to ten years.

The AIS is the most frequently modified and commonly used anatomical scoring system, and continuously expands to accommodate changing clinical demands. The AIS is a component of the ISS described subsequently. Limitations of AIS are mainly related to describing physiologically based injuries and in specifying wounds. It cannot accurately describe all fractures and locations (e.g., anterior, posterior, bilateral), contusions commonly seen together in the same region (e.g., rib fractures and pulmonary contusions), near drowning, hypo- and hyperthermia, or inhalation injuries. Despite their limitations, both the AIS and the OIS provide reasonably accurate rankings of injury severity in trauma patients.

### Injury Severity Score

The Injury Severity Score (ISS) is an anatomical scoring system introduced by Baker et al. in 1974 (16). It was developed as an extension of AIS as an ordinal summary severity score for patients with multiple injuries. ✎ **ISS correlates with hospital stay, morbidity, mortality, and other measures of trauma severity and is the most widely accepted severity of injury index in use today.** ✎

Each injury is assigned an AIS code and classified in one of six body regions, as follows: (i) head/neck, (ii) face, (iii) thorax, (iv) abdomen, (v) extremities (including pelvis), and (vi) external (15). The highest scores from the three most severely injured regions are squared, and then added together to provide the ISS score (i.e.,  $ISS = a^2 + b^2 + c^2$ ) (16). Any injury assigned the AIS score six is automatically given the maximal ISS score of 75. ISS values range from zero (no injuries) to 75 (incompatible with life). An example ISS calculation and expected outcomes based upon the ISS encountered are provided in Volume 1, Chapter 4 (Tables 4–6).

Limitations of the ISS include its one-dimensional representation of wide varieties of injuries of the polytrauma patient. Equal (correctly evaluated) AIS scores in different body regions can give the identical ISS scores, but represent a wide range of injuries with vastly different outcomes. Furthermore, multiple injuries in the same body region are (by convention) not taken into consideration, as ISS uses only the highest, rather than the overall, score from the body region (18). Any error in AIS scoring decreases the subsequent ISS precision (19–21). Age and comorbidity are not taken into account, and severe neurological trauma is undervalued (22).

Despite these shortcomings, the ISS remains the most widely accepted severity of injury index for multiple trauma, and its value correlates with mortality. When the  $ISS \leq 15$  there is less than 10% risk of mortality;  $ISS = 17$  is critical with values greater than 17 denoting severe injury; and mortality increases linearly with  $ISS > 25$  (Volume 1, Chapter 4). Although ISS has not incorporated multiple injuries in the same region, a modified version, the “new ISS” (NISS), statistically outperforms the ISS, is easier to use, and provides a more accurate prediction by calculating the three highest AIS scores regardless of body regions (17,23–25).

## CRITICAL CARE SCORING SYSTEMS

The most commonly used mortality prediction models in critical care include the acute physiology and chronic health evaluation (APACHE) score, and the subsequent upgrades, APACHE II\*, APACHE III, and APACHE IV. Other clinically useful scoring systems for critical care include the simplified acute physiology score (SAPS), SAPS II\*, SAPS III, and the mortality probability model (MPM) and MPM II\*. The most commonly used versions are signified by the affixed asterisk\* (6,9).

The primary differences in scoring systems are based on the number and types of patient characteristics selected and the assignment of their relative weights as covariates, as well as the inclusion/exclusion criteria and timing of assessment. In general, these instruments use clinical and physiological data collected on the first day of ICU admission to predict mortality risk. **☞ The APACHE II/III/IV, SAPS II/III, and MPM II are considered “third generation” scoring systems based on their use of multiple regression statistical techniques (7,8). ☞**

### Acute Physiology and Chronic Health Evaluation

The first widely used severity of illness classification system for critical care was the APACHE score, published in 1981 by Knaus and colleagues at the George Washington University Medical Center (2). The APACHE score was developed based on the evaluation of 805 patient admissions in two

U.S. ICUs, taking into account three patient factors: disease, reserve, and severity, all of which were treatment independent. The original APACHE consisted of two parts: the acute physiology score (APS), which indicated the degree of physiologic derangement, and a chronic health evaluation (CHE), which was considered an indicator of physiologic reserve before the acute illness onset. Thirty-four physiological variables were selected (by expert panel) and assigned relative weights, using the worst value for each variable within the first 32 hours following ICU admission. The CHE component classified patients into four categories (A for excellent health, to D for severely failing health). Results from the initial study population and others demonstrated high correlations between APS scores and the probability of death; however, with the CHE, only class D was found to be an independent predictor of mortality. Despite its relatively good correlation with mortality, criticisms of the APACHE included the large number of variables (34) needed to calculate scores, making it difficult to use clinically, as well as the restrictive time frame of 32 hours allowed for data collection. Use of APACHE is no longer recommended because of its outdated database (26).

APACHE II was found to be easier to use than the original APACHE and soon became the most widely utilized and studied prediction tool worldwide. The current criticisms of APACHE II are: (i) its risk predictions are based on old data from 1979 to 1982, (ii) the system was not designed to predict outcome for individual patients and particular diseases, (iii) variations in timing of ICU admission (e.g., ED vs. floor transfer) cause errors in prediction, (iv) the included diagnostic categories do not accurately account for the diversity of conditions that lead to ICU admissions, and most importantly, (v) the predictive database includes relatively few surgical and trauma patients. Indeed there is widespread agreement that APACHE II underestimates mortality in surgical patients (27,28). APACHE II also lacks a component to assess accurately the full extent of acute trauma-related illness in formerly healthy individuals, as opposed to patients with more chronic conditions.

**☞ APACHE III is more predictive than APACHE II due to modifications (increased size and representativeness of the database, and expansion of diagnosis to include more complex injury characterizations). ☞** APACHE III (Table 1) was released in 1991 to address many of the above detailed shortcomings of its predecessor. APACHE III has numerous additional advantages over APACHE II scoring as it controls for selection and lead-time bias (difference between hospital/ICU admit dates) through the inclusion of weights for ICU readmissions as well as patient location and LOS prior to ICU admission. In addition, APACHE III has a proprietary “clinical support package” which includes the ability to derive ICU core measure outcomes [e.g., deep venous thrombosis (DVT), ventilator associated pneumonia (VAP), and stress ulcer disease (SUD) prophylaxis], as well as software linkages to the Society of Critical Care Medicine’s *Project Impact* (Cerner Corporation, Kansas City, MO) (4). With the release of the third version, Knaus and colleagues (developers of the various APACHE versions) recommended that APACHE II, with its outdated reference data (based on 1979–1982) be abandoned, and that APACHE III (based on 1988–1990 reference data) be utilized instead (29).

Major drawbacks to APACHE III relate to its complexity, user difficulty, and cost. APACHE III has not gained wide acceptance because it is less freely available (licensing fees)

**Table 1** Acute Physiology and Chronic Health Evolution III Variables and Definitions

Acute physiology score (0–252 points)	Points
Mean blood pressure	0–23
Respiratory rate adjusted for mechanical ventilation	0–18
Temperatures	0–20
Pulse	0–17
Neurologic status	0–48
24-hrs urine output	0–15
Hematocrit	0–3
White blood cell count	0–19
Arterial pH adjusted for PCO <sub>2</sub>	0–12
Arterial PO <sub>2</sub> or A-aDO <sub>2</sub> if ventilated	0–15
Serum sodium	0–4
Serum albumin	0–11
Serum glucose	0–9
Serum creatinine	0–10
Blood urea nitrogen	0–12
Serum bilirubin	0–16
<i>Age, in years (0–24 points)</i>	
≤44	0
45–59	5
60–64	11
65–69	13
70–74	16
75–84	17
≥85	24
<i>Chronic health condition<sup>a</sup> (0–23 points)</i>	
AIDS	23

than APACHE II (in public domain). It has, therefore, been slow to receive validation studies (although this is beginning to change). Several large population studies have shown APACHE III to underestimate mortality (30). Like APACHE I & II, version III lacks specificity with trauma patients and has not been convincingly validated in trauma populations (31). Another problem with APACHE scoring is that 24-hour physiological data used to derive APACHE II and APACHE III scores can be treatment-dependent and therefore may reflect poor clinical management rather than sicker patients (32).

☞ **APACHE IV was released in 2005 using data from 116,209 admissions to 104 ICUs at 45 hospitals during 2002 and 2003.** ☞ While predictor variables are similar to APACHE III, new variables have been added including impact of sedation on the GCS, ventilator status, thrombolysis and so on. In addition, different statistical modeling techniques are used (33).

### Simplified Acute Physiology Score

In 1984, another predictive scoring system was created in France, based on the evaluation of 679 consecutive patients

in eight French ICUs. Named the SAPS, it promoted a simplified version of APACHE taking into account 14 biologic and clinical variables (34).

SAPS II (Table 2) was updated in 1993 by Le Gall et al. based on a large European/North American multicenter study with a cohort of almost 13,000 patients from 137 hospitals (110 in Europe; 27 in N.A.). SAPS II includes 17 variables: 12 physiologic (weighted according to their degree of deviation from normal), as well as age, type of admission (medical and scheduled/unscheduled surgery), and three variables related to particular diseases (acquired immunodeficiency syndrome, metastatic cancer, and hematologic malignancy). SAPS II scores range from 0 to 163 points (up to 16 for physiology, up to 17 for age, and up to 30 for underlying diagnosis). As with APACHE II, summed scores are converted to probability scores using logistic regression to predict mortality. ☞ **SAPS II is the most widely used mortality prediction tool in European ICUs (35).** ☞

One major problem with this scoring system is that sedated patients do not have their GCS calculated. While many ventilated patients are sedated, the neurological evaluation is not considered for the calculations (36). SAPS II has also been shown to underestimate mortality in trauma patients (37). A recently published paper has described an expanded and updated version of SAPS II (with updated statistics and inclusion of more routine data variables), which has shown better calibration and discrimination in SMR calculations across populations (38).

The main advantage of the SAPS II score is the ease of data collection. Furthermore, this scoring system is calculated directly from the logistic regression equation without needing to add points or make other corrections (6). Overall SAPS II has shown reasonable accuracy in stratifying the risk of death in a wide range of disease states and clinical settings and is predictive in nontrauma surgical patients (39). In comparison studies with APACHE II, SAPS II showed good overall linear correlation on aggregate data; however, significant disparities exist with predicted mortalities on individual patients (40).

☞ **A latest version (SAPS III) has been recently released with 2002 data from 22,791 patients in 309 participating ICUs worldwide.** ☞ SAPS III conceptually dissociates evaluation of the individual patient from evaluation of the ICU. For individual patient assessment, the system separates the relative contributions of chronic health status or previous therapy, circumstances related to ICU admission, and degree of physiologic dysfunction. Equations are also customized to four areas of the world (North America, Europe, Australia, and South America) for regional and/or global reference comparisons. No comparison between SAPS III and other scores are available to date (41,42). As with the APACHE versions, trauma patients are generally under scored.

### Mortality Prediction Model

The first model developed using multiple regression techniques was the Mortality Prediction Model (MPM), published in 1985 by Stanley Lemeshow, Professor of Biostatistics at the University of Massachusetts (Table 3) (43–45).

The MPM system, unlike the APACHE and the SAPS systems, was designed to measure mortality risk at later times after ICU admission (i.e., at 24, 48, and 72 hrs) (46). Major advantages of the MPM system are that multiple diagnoses can be included (rather than a single, most severe condition) and adjustments can be made in conditions

**Table 2** Simplified Acute Physiology Score II Variables and Definitions

Variable	Definition	Points
Age	Age (in years) at last birthday	0–18
Heart rate	Use the worst value in 24 hrs, either low or high heart rate: if it varied from cardiac arrest (11 points) to extreme tachycardic (7 points), assign 11 points	0–11
Systolic blood pressure	Use the same method as for heart rate: e.g., if it varied from 60 mm Hg to 205 mm HG, assign 13 points	0–13
Body temperature	Use the highest temperature	0–3
PaO <sub>2</sub> /FIO <sub>2</sub>	If ventilated or continuous pulmonary artery pressure, use the lowest value of the ratio	0–11
Urinary output	If the patient is in the intensive care unit for <24 hrs, make the calculation for 24 hrs: e.g., 1 L in 8 hrs = 3 L in 24 hrs	0–11
Serum urea or serum urea nitrogen level	Use the highest value in mmol/L for serum urea and in mg/dL for serum urea nitrogen	0–10
WBC count	Use the worst (high to low) WBC count	0–3
Serum potassium level	Use the worst (high or low) value in mmol/L	0–3
Serum sodium level	Use the worst (high or low) value in mmol/L	0–5
Serum bicarbonate level	Use the lowest value in mEq/L	0–6
Bilirubin level	Use the highest value in $\mu\text{mol/L}$ or mg/dL	0–9
Glasgow Coma Scale	If the patient is sedated, record the estimated Glasgow Coma Scale score before sedation	0–26
Type of admission	Unscheduled surgical <sup>a</sup> , scheduled surgical <sup>b</sup> , or medical <sup>c</sup>	8, 0, or 6
AIDS	Yes, if HIV-positive with clinical complications such as <i>Pneumocystis carinii</i> pneumonia, Kaposi's sarcoma, lymphoma, tuberculosis, or <i>Toxoplasma</i> infection	17
Hematologic malignancy	Yes, if lymphoma, acute leukemia, or multiple myeloma	10
Metastatic cancer	Yes, if proven metastatic by surgery, CT, or any other method	9

<sup>a</sup>Patients added to operating room schedule within 24 hrs of the operation.

<sup>b</sup>Patients whose surgery was scheduled at least 24 hrs in advance.

<sup>c</sup>Patients having no surgery within 1 week of admission to intensive care unit.

*Abbreviations:* AIDS, acquired immunodeficiency syndrome; CT, computed tomography; FIO<sub>2</sub>, fraction of inspired oxygen; HIV, human immunodeficiency virus; SAPS, simplified acute physiology score; WBC, white blood cells.

**Table 3** Mortality Probability Models Variables and Definitions

MPM II Model at admission (MPM0)	MPM II Model at 24 (MPM24), 48 (MPM48), and 72 (MPM72) hrs
Age	Variables obtained at admission
Coma or deep stupor	Age
Heart rate	Cirrhosis
Systolic blood pressure	Intracranial mass effect
Chronic renal insufficiency	Metastatic neoplasm
Cirrhosis	Medical or unscheduled surgery admission
Metastatic neoplasm	Variables obtained in 24 hrs
Acute renal failure	Coma or deep stupor
Cardiac dysrhythmia	Creatinine > 2.0 mg/dL
Cerebrovascular incident	Confirmed infection
Gastrointestinal bleeding	Mechanical ventilation
Intracranial mass effect	PaO <sub>2</sub> < 60 mm Hg
Cardiopulmonary resuscitation	Prothrombin time > 3 secs above standard
Mechanical ventilation	Urine output < 150 mL in 8 hrs
Medical or unscheduled surgery admission	Vasoactive drugs > 1 hrs intravenously

*Source:* From Ref. 44.

considered and in weightings which can be altered from admission to other time points, reflecting differing impacts on mortality. As a result of timing intervals, however, treatment-related factors can significantly influence mortality predictions.

### Therapeutic Intervention Scoring System

The Therapeutic Intervention Scoring System (TISS) was developed in 1974 by Cullen et al. (47). It is based on the fact that therapeutic interventions are more common and extensive in patients with more advanced disease (48). TISS was developed to quantify severity of illness among intensive care patients based on the type and amount of treatment received. The underlying philosophy is that the sicker the patient, the greater the number and complexity of treatments. By quantifying this, a (rough) measure of illness severity can be obtained. Initially the system scored 76 therapeutic interventions. However, due to its complexity, the TISS-28 was proposed, reducing the variables from 76 to 28 (49). This score considers seven main parameters: basic activities, ventilatory (e.g., mechanical ventilation), cardiovascular (e.g., vasoactive drugs), renal (e.g., dialysis), neurologic (e.g., ICP monitoring), and metabolic support (e.g., parenteral nutrition), in addition to specific interventions, with each of the variables divided in subitems (Table 4). In a comparison between patients in a surgical ICU, the simplified version (TISS-28) was shown to be easier and more accurate than the TISS-76.

**Table 4** Therapeutic Intervention Scoring System Variables and Definitions

	Points
<i>Basic activities</i>	
Standard monitoring. Hourly vital signs, regular registration and calculation of fluid balance	5
Laboratory, biochemical, and microbiological investigations	1
Single medication. Intravenously, intramuscularly, subcutaneously, and/or orally (e.g., gastric tube)	2
Multiple intervention medication. More than one drug, single shots, or continuously	3
Routine dressing changes. Care and prevention of decubitus and daily dressing change	1
Frequent dressing changes. Frequent dressing change (at least one time per each nursing shift) and/or extensive wound care	1
Care of drains. All (except gastric tube)	3
<i>Ventilatory support</i>	
Mechanical ventilation. Any form of mechanical ventilation/assisted ventilation with or without positive end-expiratory pressure, with or without muscle relaxants; spontaneous breathing with positive end-expiratory pressure	5
Supplement ventilatory support. Breathing spontaneously through endotracheal tube without positive end-expiratory pressure; supplementary oxygen by any method, except if mechanical ventilation parameters apply	2
Care of artificial airways. Endotracheal tube or tracheostomy	1
Treatment for improving lung function. Thorax physiotherapy, incentive spirometry, inhalation therapy, intratracheal suctioning	1
<i>Cardiovascular support</i>	
Single vasoactive medication. Any vasoactive drug	3
Multiple vasoactive medications. More than one vasoactive drug, disregard type and doses	4
Intravenous replacement of large fluid losses. Fluid administration $>3L/m^2/day$ , disregard type of fluid administered	4
Peripheral arterial catheter	5
Left atrium monitoring. Pulmonary artery flotation catheter with or without cardiac output measurement	8
Central venous line	2
Cardiopulmonary resuscitation after arrest; in the past 24 hrs (single precordial percussion not included)	3
<i>Renal support</i>	
Hemofiltration techniques. Dialytic techniques	3
Quantitative urine output measurement (e.g., by urinary catheter à demeure)	2
Active diuresis (e.g., furosemide $>0.5\text{ mg/kg/day}$ for overload)	3
<i>Neurologic support</i>	
Measurement of intracranial pressure	4
<i>Metabolic support</i>	
Treatment of complicated metabolic acidosis/alkalosis	4
Intravenous hyperalimentation	3
Enteral feeding. Through gastric tube or other gastrointestinal route (e.g., jejunostomy)	2
<i>Specific interventions</i>	
Single specific interventions in the intensive care unit. Naso or orotracheal intubation, introduction of pacemaker, cardioversion, endoscopies, emergency surgery in the past 24 hrs, gastric lavage. Routine interventions without direct consequences to the clinical condition of the patient, such as radiographs, echography, electrocardiogram, dressings, or introduction of venous or arterial catheters, are not included	3
Multiple specific interventions in the intensive care unit. More than one, as described above	5
Specific interventions outside the intensive care unit. Surgery or diagnostic procedures	5

Source: From Ref. 49.

TISS scores, though not widely used to quantify severity of illness, have shown usefulness in identifying ICU acuity, staffing needs, and cost (50).

## ORGAN DYSFUNCTION SCORING SYSTEMS

The idea of developing an organ-dysfunction score was first reported by Baue in 1975 (51). Most organ dysfunction scores include the evaluation of six organ systems: the central nervous, cardiovascular, respiratory, hepatic, renal, and hematological systems.  **The advantage of organ dysfunction scores is that they allow the analysis of the function of**

**different and specific organs, making possible comparisons between patients with the same disease processes.** 

In addition, these scores can be used to assess response to treatment and monitor recovery or deterioration of specific organs during the evolution of the patient's disease process in ICU, with data collected on admission and usually daily thereafter. The three most widely utilized organ injury scoring systems are reviewed subsequently.

### Sequential Organ Failure Assessment (SOFA) Score

The sepsis-related organ failure assessment (SOFA) was developed by the European Society of Intensive Care Medicine in 1994 (52). It was renamed to Sequential Organ Failure

**Table 5** Sepsis-Related Organs Variables and Definitions

	Score				
	0	1	2	3	4
Respiration PaO <sub>2</sub> /FiO <sub>2</sub> (Torr)	>400	301–400	201–300	101–200 with respiratory support	≤100 with respiratory support
Coagulation Platelets (x10 <sup>3</sup> /mm <sup>3</sup> )	>150	101–150	51–100	21–50	≤20
Liver Bilirubin (mg/dL)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	≥12.0
Cardiovascular Hypotension	No	MAP <70 mmHg	Dopamine ≤5 or dobutamine (any dose)	Dopamine >5 and ≤15 or epi ≤0.1 or norepi ≤0.1	Dopamine >15 or epi >0.1 or norepi >0.1
Central nervous system Glasgow Coma Scale Score	15	13–14	10–12	6–9	3–5
Renal Creatinine (mg/dL) or urinary output	<1.2	1.2–1.9	2.0–3.4	3.5–4.9 or 200–500 mL/day	≥5.0 or <200 mL/day

Source: From Ref. 53.

Assessment (SOFA), which remains the current terminology (Table 5), after the verification that it could be also used for nonseptic patients. This scoring system includes six organ systems (central nervous, cardiovascular, pulmonary, hepatic, renal, and hematological system) and takes into account the worst values on each day using a scoring system that ranges from 0 (normal) to 4 (most abnormal). The aggregate score [total maximum SOFA score (TMS)] is calculated by summing the worst scores for each of the organ systems during the ICU stay. TMS scores can be used to quantify and evaluate the patient's organ dysfunction over time. Janssens et al. demonstrated that the SOFA score is a valid and reliable tool to access the severity of organ dysfunction not only in septic patients, but also in surgical, trauma, and medical cardiovascular patients (53).

SOFA is a simple and effective instrument for use in the evaluation of organ dysfunction/failure and the effects of cumulative insult by assessing degree of dysfunction already present on admission, as compared to maximum and delta SOFA scores. Serial assessment of organ dysfunction during

the first few days of ICU admission may be a particularly good indicator of prognosis (54).

### Multiple Organ Dysfunction (MOD) Score

The MOD score is another system based on organ dysfunction that was published in 1995 by Marshall and colleagues (Table 6) (55). This system evaluates the same six organ systems as the SOFA score. Raw values for each of the component variables are obtained daily. The range of the most representative values for each organ system is graded from 0 (normal function) to 4 (markedly deranged function) on a daily basis. Scores are calculated at the same point in time each day (first morning values) to avoid capturing momentary changes in physiologic variables. The overall score varies from 0 to 24 points and correlates well with ICU mortality. The major difference between the SOFA and MOD scores lies in the variables used to define cardiovascular dysfunction.

The MOD and SOFA scores have been used to assess and document specific organ function, taking into account

**Table 6** Multiple Organ Dysfunction Variables and Definitions

	Score				
	0	1	2	3	4
Respiration PaO <sub>2</sub> /FiO <sub>2</sub> (Torr)	>300	226–300	151–225	78–150	≤77
Coagulation Platelets (x10 <sup>3</sup> /mm <sup>3</sup> )	>120	81–120	51–80	21–50	≤20
Liver Bilirubin (μmol/L)	≤20	21–60	61–120	121–240	>240
Cardiovascular (Pressure adjusted rate)	≤10	10.1–15.0	15.1–20.0	20.1–30.0	>30
Central nervous system Glasgow Coma Scale Score	15	13–14	10–12	7–9	3–6
Renal Creatinine (μmol/L)	≤100	101–200	201–350	351–500	>500

Source: From Ref. 55.

the time and course of a patient's condition during an entire ICU stay, and to correlate these to expected outcome. The SOFA score incorporates both physiologic measures and measures of therapeutic intervention (e.g., need for mechanical ventilation, inotropic or vasopressin support), whereas MOD scoring is independent of treatment. Most comparison studies have shown little practical difference between SOFA and MOD scores; however, in most studies the SOFA cardiovascular score has shown better performance.

### Logistic Organ Dysfunction (LOD) Score

The Logistic Organ Dysfunction (LOD) scoring system was published in 1996 by LeGall and colleagues using methodology similar to that used with SAPS II. The LOD score takes into account both the relative severity among organ systems and the degree of severity within a system. The LOD is a global score that can be calculated to summarize the combined effect of dysfunction among several organs. Logistic regression techniques are used to determine severity levels and relative weights (according to prognostic significance) for the LOD score and its conversion to a probability of mortality (56).

## INTENSIVE CARE UNIT SCORING SYSTEM COMPARISONS

☞ **Third generation ICU scoring systems (APACHE II/III, SAPS II, and MPM II use statistical modeling techniques to select and weigh variables and generate prognostic information.** ☞ APACHE and SAPS collect data within 24 hours of admission and, with MPM II, data is collected serially to 72 hours post admission. These tools are comparable and produce similar results with regard to discrimination (identifying survivors versus nonsurvivors). Wide variations exist, however, in calibration (difference between observed and predicted mortality).

Several large U.S. and European comparative studies with third generation models have shown that each of the models provide reasonable discrimination. Large discrepancies were found across the models evidenced by significant variations in SMR. Studies on sub-groups of patients confirm these findings. Though these models clearly show better performance than earlier generations, their discriminative accuracy (sensitivity/specificity) remains inconsistent across populations (31,57,58).

A study comparing APACHE II, MPM II, and SAPS II demonstrated that MPM II and APACHE II models presented very similar mean predicted mortality and were closer to the observed mortality than SAPS II (59). Another comparison of four scores: APACHE II, SAPS II, MPM0 and MPM24 in 969 patients showed that prediction of mortality was good in all four scoring systems, although it was better with APACHE II and MPM0. When divided into disease sub-groups, MPM0 and MPM24 overestimated mortality in the nonoperative trauma group, whereas SAPS II underestimated mortality in medical patients other than those admitted for cardiovascular, respiratory, and neurological problems (60).

Due to several scoring systems available, there is a need to evaluate these scores to determine which is more accurate to a specific ICU population. In the past 10 years, the APACHE II was the system most commonly used and evaluated (Fig. 1) (31).

In a comparison between five scores including APACHE II, APACHE III, a U.K. version of APACHE II, SAPS II, and MPM II at admission (MPM0) and at 24 hrs

**Figure 1** Severity of illness scoring systems: frequency of use and evaluation. *Abbreviations:* APACHE, acute physiology and chronic health evolution; MPM, multiple organ dysfunction; SAPS, simplified acute physiology score; SOFA, sepsis-related organs; TISS, therapeutic intervention system.

(MPM24), data on 10,393 patients in 22 ICUs in Scotland was analyzed (Table 7). It was concluded that SAPS II demonstrated the best overall performance, but APACHE II was the most appropriate model for comparisons of mortality rates between ICUs. APACHE III underestimated the mortality (Table 1) (31).

Each of the three organ scoring systems has generally been shown to have reasonable discrimination and calibration; in one study all three were also comparable to APACHE III in predicting mortality (61–63). However, in a recent large Canadian study by Zygun et al. comparing SOFA with MODS, it was found that neither discriminated or calibrated well with multisystem patients (12% were trauma patients), questioning the ability to use these scoring system predictively in patients with multisystem organ dysfunction at their current level of development (64). Differences between prognostic and organ dysfunction scores are summarized in Table 8 (61).

## EYE TO THE FUTURE

Recent years have shown significant improvement in the sophistication, accuracy of illness, injury scoring tools, and mortality prediction models. However, given the rapid changes in the treatment of critically ill and injured patients, many challenges remain in the evaluation of outcomes aimed at improving the quality and consistency of ICU care. ☞ **Innovations in managing the magnitude of data necessary for predictive accuracy in risk adjustment (essential to the performance of prognostic models) will parallel a continually increasing ability to automatically capture and retrieve demographic and clinical data.** ☞ Statistical techniques utilizing “artificial intelligence” or neural networks are proceeding to the next level of development, whereby continuous updating of databases and “real time” recalibration of variables is possible. Multicenter linkages with updated national databases (e.g., NTDB, “Project Impact,” and INARC) and global data collaboration efforts are one step in this direction whereby information from multiple institutions can be analyzed centrally and strengthened through data volumes and wider geographic inputs. Recently, newer disease-specific and customized mortality prediction models have been utilized which show better “goodness of fit” than generic models when applied to

subgroups of ICU patients. This trend of adapting models to unique patient populations is likely to continue and improve their value as benchmarks. While specificity and qualification of variables improve accuracy, there remains a need for uniform and compatible reporting methods and languages for research, and broader comparison across ICUs. The expanded utilization of multiple models and combinations, as well as integration with other disease-specific classification measures and with ICD-10 codes, will enhance predictive capabilities and help to identify the most clinically relevant variables and endpoints.

Restricting parameters to measures of mortality and LOS do not, for trauma and ICU survivors, address many of the patient-centered outcomes of ICU performance such as quality of life and functional status following illness or injury. A greater focus on multidimensional outcomes is emerging, and the evaluation methodologies to assess these outcomes must be broad enough to capture these constructs without losing precision. In other words, our tools need continual refinement in order to capture the complex and meaningful variables associated with illness and injury and their consequences.

Lastly, comparative information about ICU and trauma outcomes is critical, but in and of itself insufficient, if not matched by methods to determine the structures and practice patterns that ultimately influence and contribute to improving the quality of patient care (65).

## SUMMARY

Characterization of injury and illness severity are essential to the scientific study of trauma and critical care. A number of severity scoring systems and prediction models have been developed which are designed to quantify severity, prognosis, and course of disease. They also serve the purposes of assessing therapies, comparing quality outcomes, and of evaluating performance within and across centers and patient populations.

Accuracy of injury scoring tools reflects their ability to describe the patient's anatomic and physiologic injury. With the increasing sophistication of these measures they have assumed a major role in trauma practice and outcomes studies.

Critical care prognostic scoring systems are used to characterize ICU patient populations and predict (albeit imperfectly) mortality (9). Although increasingly sophisticated, prognostic models exhibit a level of

uncertainty, and an understanding of their limitations is essential for their appropriate selection and use in individual ICUs. ⚡ **Clearly no single "gold standard" model exists which can be applied to all populations and types of ICUs.** ⚡ Currently these systems should not be used to prognosticate individual patients or used solely in decisions regarding futility of care.

Scoring models for organ dysfunction such as the SOFA, MOD, and LOD systems are utilized to assess risk in patients with severe illnesses (e.g., sepsis and ARDS) and those with several impaired organ systems. Although methodological differences exist between the various organ dysfunction scales (Table 8), each of these has shown predictability within its realm of evaluation. In addition, these are easy to use, relying on objective and easily accessible clinical data to evaluate patient outcomes. Yet, none of these organ dysfunction scoring systems is specific for the trauma patient.

Other scores can be utilized to assess the severity of specific disease processes. Examples include the Hunt-Hess classification of subarachnoid hemorrhage, the GCS (also a component of other scores), the Murray lung injury severity score for ARDS, NYHA classification, and Child's classification of chronic liver disease (66). These scores have the advantage of focusing on a specific aspect of each disease, and can be used to supplement the overall severity score to evaluate that particular organ for a patient.

## KEY POINTS

- ⚡ All scoring systems represent quantitative classification schemes, most of which use multiple logistic regression methodology applied to prospectively collected data sets of demographic, physiological, and clinical variables.
- ⚡ While scoring systems are useful for research and comparing SICU performance with respect to endpoints such as mortality and LOS, their usefulness is less clear in medical decision-making or prognostic estimations for individual patients.
- ⚡ ISS correlates with hospital stay, morbidity, mortality, and other measures of trauma severity, and is the most widely accepted severity of injury index in use today.
- ⚡ The APACHE II/III/IV, SAPS II/III, and MPM II are considered "third generation" scoring systems based on their use of multiple regression statistical techniques.

- 9 APACHE III is more predictive than APACHE II due to modifications (increased size and representativeness of the database, and expansion of diagnoses to include more complex injury characterizations).
- 9 APACHE IV was released in 2005 using data from 116,209 admissions to 104 ICUs at 45 hospitals during 2002–2003.
- 9 SAPS II is the most widely used mortality prediction tool in European ICUs.
- 9 A latest version (SAPS III) has been recently released with 2002 data from 22,791 patients in 309 participating ICUs worldwide.
- 9 The advantage of organ dysfunction scores is that they allow the analysis of the function of different and specific organs, making possible comparisons between patients with the same disease processes.
- 9 Third generation ICU scoring systems (APACHE II/III, SAPS II, and MPM II) use statistical modeling techniques to select and weigh variables and generate prognostic information.
- 9 Innovations in managing the magnitude of data necessary for predictive accuracy in risk adjustment (essential to the performance of prognostic models) will parallel a continually increasing ability to automatically capture and retrieve demographic and clinical data.
- 9 Clearly no single “gold standard” model exists which can be applied to all populations and types of ICUs.

# TRAUMA

## Critical Care

### about the book . . .

This multi-authored textbook is offered as a two-volume set, covering the entire spectrum of trauma management.

**Volume 1** reviews initial management considerations beginning in the pre-hospital phase, continues through the primary and secondary surveys of the hospital-based evaluation process, and proceeds to the perioperative management of trauma, burns, and associated conditions.

**Volume 2** discusses the entire gamut of critical care management of the trauma patient and also covers common complications and conditions treated in Surgical Intensive Care Units that are not specifically unique to trauma (e.g. sepsis, renal failure, liver failure, etc).

The latest developments in each area of trauma management are addressed, and evidence based guidelines are emphasized where such data exists. The book is written in a readable clinically focused fashion, while at the same time providing abundant up-to-date citations for all recommendations and guidelines.

### about the editors . . .

**WILLIAM C. WILSON** is Clinical Professor of Anesthesiology and Critical Care Medicine at the University of California San Diego Medical School, as well as Director of Anesthesiology Critical Care and Associate Director of the Surgical Intensive Care Unit at the University of California, San Diego Medical Center. He is also Associate Editor of the journal *TraumaCare*. Dr. Wilson has published extensively and lectured nationally and internationally on nearly every topic related to trauma resuscitation anesthesia and critical care. Notably, Dr. Wilson is an internationally recognized expert on trauma airway management, respiratory gas exchange, thoracic anesthesia, and monitoring. Dr. Wilson, has authored nearly 100 peer reviewed papers, abstracts, and book chapters. He has edited 2 textbooks, and numerous monographs. Dr. Wilson received the M.D. degree from Temple University, Philadelphia, Pennsylvania, and completed three years of general surgical training and a critical care fellowship at the University of California, San Francisco, in addition to a residency in anesthesiology and a fellowship in cardiothoracic anesthesia at the University of California, San Diego.

**CHRISTOPHER M. GRANDE** is Executive Director of the International TraumaCare (ITACCS), Baltimore, Maryland. Dr. Grande has directed numerous large-scale international symposia, and has been an active member of the scientific and organizing committees of many national and international meetings of other learned societies. He has been invited to testify before committees of the U.S. Senate and the U.S. House of Representatives, and at the National Academy of Sciences, Institute of Medicine. Dr. Grande has published extensively in the area of trauma anesthesia and critical care, having authored more than 100 articles, chapters, and reviews, and has edited more than 20 books and monographs.

**DAVID B. HOYT** is the John E. Connolly Professor and Chairman, Department of Surgery, at the University of California, Irvine Medical Center, Irvine, California. He is a member of many prestigious surgical organizations including the American Surgical Association, the Surgical Biology Club, the Western Surgical Association, and the Society of University Surgeons. He served as President of the American Association for the Surgery of Trauma, the Society of General Surgeons of San Diego, and the Shock Society. He is the Past Chairman of the American College of Surgeons Committee on Trauma, and is currently the President of the Panamerican Trauma Society. He has been a visiting professor at a large number of institutions nationally and internationally and is an editorial board member of six journals. Dr. Hoyt has consistently received significant public research funding throughout his career. He received the M.D. degree from Case Western Reserve University, Cleveland, Ohio, and completed surgical training at the University of California, San Diego Medical Center. He is the author of over 420 publications.
