Contents

Volume I

Section I. Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of software applications computing. Chapters found within these pages provide an excellent framework in which to position software applications within the field of information science and technology. Individual contributions provide overviews of open source software, software testing, social software, and software quality, while also exploring critical stumbling blocks of this field. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring the research and application of software applications.

Section II. Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of software systems and applications. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing successful software applications.

Volume II

Section III. Tools and Technologies

This section presents extensive coverage of the technology that both derives from and informs software applications. These chapters provide an in-depth analysis of the use and development of innumerable devices and tools, while also providing insight into new and upcoming technologies, theories, and instruments that will soon be commonplace. Within these rigorously researched chapters, readers are presented with examples of the tools that facilitate and support software design and engineering. In addition, the successful implementation and resulting impact of these various tools and technologies are discussed within this collection of chapters.

Volume III

Section IV. Utilization and Application

This section introduces and discusses the ways in which information technology has been used to shape the realm of software applications and proposes new ways in which IT-related innovations can be implemented within organizations and in society as a whole. These particular selections highlight, among other topics, intelligent software agents in e-commerce and utilizing open source software in organizations. Contributions included in this section provide excellent coverage of today's changing environment and insight into how evolutions in software applications impact the fabric of our present-day global village.

Volume IV

Section V. Organizational and Social Implications

This section includes a wide range of research pertaining to the social and organizational impact of software applications. Chapters introducing this section analyze open source software communities, while later selections discuss organizational modeling and the analysis of user interfaces. The inquiries and methods presented in this section offer insight into the implications of software applications at both a personal and organizational level, while also emphasizing potential areas of study within the discipline.

Volume V

Section VII. Critical Issues

This section addresses conceptual and theoretical issues related to the field of software applications, which include ethics in software engineering, software piracy, and morality in free and open source software. Within these chapters, the reader is presented with analysis of the most current and relevant conceptual inquires within this growing field of study. Overall, contributions within this section ask unique, often theoretical questions related to the study of software applications and, more often than not, conclude that solutions are both numerous and contradictory.

Volume VI

Section VIII. Emerging Trends

This section highlights research potential within the field of software applications while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight evolutions in social software, state-of-the-art agile software methods, and modeling large software systems. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

Preface

Since the introduction of von Neumann architecture in the 1940s, which stipulated the critical division between hardware and software, engineers and programmers alike have been striving to build bigger, faster and cheaper software applications. This end goal of creating the most elegant program utilizing the least resources while performing the most work has seen a plethora of developments over the last several decades. Every innovation from the early programming languages of COBOL and FORTRAN to the more recent move toward the agile programming method has informed the creation of software applications designed to meet increasing demands and to answer a greater number of needs in the most efficient way possible.

Now, with an entire generation of computer users who have come to expect the integration of software applications in their everyday lives, there is a call for greater research and development and more efficient programming in an ever widening spectrum of disciplines from business, government, and education to everyday use and recreation. To keep up with the demand for newer and better software, practitioners and researchers must thrive within a fluid environment. They need be cognizant of constant advances that must be considered and responded to in order to ensure the success of developing software applications.

Due to the ever changing landscape of software applications, it is a constant challenge for researchers and experts in the development of software applications to absorb the volume of innovations which will inform and quickly outdate current software applications. Information Science Reference is pleased to offer a six-volume reference collection on this rapidly growing discipline, in order to empower students, researchers, academicians, and practitioners with a comprehensive understanding of the most critical areas within this field of study. This collection provides the most comprehensive, in-depth, and recent coverage of all issues related to the development of cutting-edge software applications, as well as a single reference source on all conceptual, methodological, technical and managerial issues, and the opportunities, future challenges and emerging trends related to the development of software applications,

Entitled **"Software Applications: Concepts, Methodologies, Tools, and Applications,"** this collection is organized in eight distinct sections, providing the most wide-ranging coverage of topics such as: 1) Fundamental Concepts and Theories; 2) Development and Design Methodologies; 3) Tools and Technologies; 4) Utilization and Application; 5) Organizational and Social Implications; 6) Managerial Impact; 7) Critical Issues; and 8) Emerging Trends. The following provides a summary of what is covered in each section of this multi-volume reference collection:

Section I, ***Fundamental Concepts and Theories***, offers an extensive view of the foundational theories and concepts which inform the development of software applications. This section begins with the chapter "A Historical Analysis of the Emergence of Free Cooperative Software Production," by Nicolas Jullien which describes the vacillation of open source programming from its popularity in the 1950s to its near disappearance in the 1980s up through its most recent boom in popularity. Other chapters in the section

such as, "Software Modernization of Legacy Systems for Web Services Interoperability" by Chia-Chu Chiang and "Intelligent Analysis of Software Maintenance Data" by Marek Reformat, Petr Musilek and Efe Igbide, deal with the critical issue of analysis and adaptation for the maintenance of software applications. "Malicious software" by Thomas M. Chen and Gregg W. Tally discusses the problematic topic of malware. In this chapter, Chen and Tally present malware as one of the most costly and widespread types of virtual attacks on organizations. This section also contains chapters such as David Lo and Siau-Cheng Khoo's "Mining Software Specifications" which discusses the emerging area of data mining, focusing on drawing out software specifications based on the behavior of a software application.

In Section II, ***Development and Design Methodologies,*** the creative stages of software application design are explored through developmental strategies and design methodologies. This section opens with "Ontology Based Object-Oriented Domain Modeling: Representing Behavior" by Jeorg Evermann and Yair Wand. Evermann and Wand describe the usefulness of the object-oriented software modeling language to the early conceptual stage of application domain analysis for which no specific language is accepted. More application specific chapters, such as "Building an LMS with Ubiquitous Software" by Michael Rees and Charles Herring, can be found later in the section. In their chapter, Rees and Herring present their experience during the development and trial run of an off-the-shelf learning management system that utilized Microsoft Office Systems at its core. In addition, this section contains selections like "Bug Fixing Practices within Free/Libre Open Source Software Development Teams" by Kevin Crowston and Barbara Scozzi which examines the success of debugging in open source software despite the fact that it is primarily developed by distributed teams.

Section III, ***Tools and Technologies,*** begins with Kerstin Fink and Christian Plodder's chapter "Knowledge Management Toolkit for SMEs" which presents four knowledge processes designed to help small and medium enterprises take advantage of their intellectual capital. Additional tools for free software projects are presented in "Tools for the Study of the Usual Data Sources found in Libre Software Projects" by Gregorio Robles, Jesús M. González-Barahona, Daniel Izquierdo-Cortazar and Israel Herraiz. Several chapters, such as "A Software Tool for Reading DICOM Directory Files" by Ricardo Villegas, Guillermo Montilla and Hyxia Villegas and "LOGIC-Minimiser: A Software Tool to Enhance Teaching and Learning Minimization of Boolean Expressions" by Nurul I. Sarkar and Khaleel I. Petrus discuss individual tools with specific uses in mind. This overview of various tools and technologies for software applications comes to a close with "A Pliant-Based Software Tool for Courseware Development" by Marcus Vinicius dos Santos, Isaac Woungang and Moses Nyongwa. In this chapter, the authors discuss the use of the Pliant software framework for web-based courseware development.

Section IV, ***Utilization and Application***, describes the implementation of technologies, methodologies, and theories related to software applications. This section contains chapters such as "Online Synchronous vs. Asynchronous Software Training Through the Behavioral Modeling Approach: A Longitudinal Field Experiment" by Charlie C. Chen and R. S. Shaw which compares and contrasts the implementation of a particular modeling approach in three different learning environments. "Patchwork Prototyping with Open Source Software" by M. Cameron Jones, Ingbert R. Floyd and Michael B. Twidale proposes the utilization of a prototype which has been patched together from existing open source resources to provide real life feedback for software application development. Lawrence R. LaForge's chapter, entitled "Teaching Operations Management with Enterprise Software" rounds out the section describing the use of enterprise software to provide operations management students with an understanding of how operations management decisions affect various aspects of a manufacturing enterprise.

Section V, ***Organizational and Social Implications***, delves into the vital conversation surrounding the issues that arise from developments in software design. "The Impact of Ideology on the Organizational Adoption of Open Source Software" by Kris Ven and Jan Verelst begins the discussion of how ideology

can factor into the pragmatic decisions of open source software adoption. In their article "Volunteers in Large Libre Software Projects: A Quantitative Analysis Over Time," Martin Michlmayr, Gregorio Robles, and Jesus M. Gonzalez-Barahona investigate the effectiveness of drawing participants to open source software. Jennifer Papin-Ramcharan and Frank Soodeen offer their perspective on the use of open source software in developing countries in "Open Source Software: A Developing Country View." Other important social issues are also presented in "Facilitating E-Learning with Social Software: Attitudes and Usage from the Student's Point of View," by Reinhard Bernsteiner, Herwig Ostermann, and Roland Staudinger, and "Planning and Managing the Human Factors for the Adoption and Diffusion of Object-Oriented Software Development Processes," by Magdy K. Serour.

This section illuminating the interaction of human beings and software is completed by "Mental Contents in Interacting with a Multiobjective Optimization Program" by Pertti Saariluoma, Katja Kaario, Kaisa Miettinen, and Marko M. Mäkelä, which uses a specific psychological theory to analyze interaction with professional software.

Section VI, ***Managerial Impact,*** presents contemporary coverage of the managerial applications and implications in the field of software. "Combining Tailoring and Evolutionary Software Development for Rapidly Changing Business Systems" by Jeanette Eriksson and Yvonne Dittrich begins this section with the analysis of a case study performed to evaluate the usability of software for business systems. The principles of management in software development projects and optimization tools for managerial decision making, especially in the environment of small IT companies, are thoroughly discussed in "Computer-Aided Management of Software Development in Small Companies," by Lukáš Pichl and Takuya Yamano. Also included in this section is the chapter "A Survey of Competency Management Software Information Systems in the Framework of Human Resources Management," by Alfonso Urquiza, which shows the Competency Management Software evolution from a previous fragmented market situation to a much more integrated scenario in which best of breed single-function oriented product preferences are now swiftly moving to the Enterprise Resource Planning (ERP) type of architecture. The many tools available to managers are also explored through selections such as "Channel Optimization for On Field Sales Force by Integration of Business Software on Mobile Platforms" by Rishi Kalra and Amit Nanchahal, "Revenue Models in the Open Source Software Business" by Risto Rajala, Jussi Nissilä and Mika Westerlund, and "Knowledge Management and organizational Performance in the egyptian software Firms," by Ahmed Seleim and Omar Khalil. The chapters in this section provide a comprehensive survey of the many intersections between software and management.

Section VII, ***Critical Issues,*** surveys some of the most important considerations that impact software development and are in turn influenced by software. Dave Yeats offers his research on the subtle philosophical differences represented in two open source software movements in "Morality and Pragmatism in Free Software and Open Source." The more technical issues are also discussed in selections such as "A Graphical User Interface (GUI) Testing Methodology," by Zafar Singhera, Ellis Horowitz and Abad Shah, "A Metamorphic Testing Approach for Online Testing of Service-Oriented Software Applications," by W. K. Chan, S. C. Cheung and Karl R. P. H. Leung, and "A Formal Verification and Validation Approach for Real-Time Databases," by Pedro Fernandes Ribeiro Neto, Maria Lígia Barbosa Perkusich, Hyggo Oliveira de Almeida and Angelo Perkusich, which raise issues surrounding testing. The issues raised in this section are, in many ways, the crux of software engineering today, giving the reader a full understanding of the research surrounding the most pressing questions found in this discipline.

The concluding section of this authoritative reference tool, ***Emerging Trends,*** highlights research potential within the field of software while exploring uncharted areas of study for the advancement of the discipline. "Bridging the Gap between Agile and Free Software Approaches: The Impact of Sprinting" by J. Paul Adams and Andrea Capiluppi presents an analysis of the effect of sprinting—commonly used

in the agile programming method—on the free software approach to programming. In addition, this section highlights future trends related to social software in chapters such as "Social Software and Language Acquisition" by Sarah Guth and Corrado Petrucco and "Social Software Trends in Business" by Peter Burkhardt. The trends highlighted in this section present a broad range of topics for future research and implementation leading the continued advancement of software application development.

Although the primary organization of the contents in this multi-volume collection is based on its eight sections, offering a progression of coverage of the important concepts, methodologies, technologies, applications, social issues, and emerging trends, the reader can also identify specific contents by utilizing the extensive indexing system listed at the end of each volume. Furthermore to ensure that the scholar, researcher and educator have access to the entire contents of this multi-volume set as well as additional coverage that could not be included in the print version of this publication, the publisher will provide unlimited multi-user electronic access to the online aggregated database of this collection for the life of edition, free of charge when a library purchases a print copy. This aggregated database provides far more contents than what can be included in the print version in addition to continual updates. This unlimited access, coupled with the continuous updates to the database ensures that the most current research is accessible to knowledge seekers.

Advances in software applications have been both immense and pervasive in the last several decades as the discipline has continued to grow and thrive with each new development. From the early days, through the "software crisis" of the late 60s and early 70s and on to the present day, software applications have become increasingly vital to the everyday user. As software applications become a ubiquitous part of everyday life, the demand for larger, faster, and more cost effective software applications continues to grow. This ever increasing demand will lead to greater improvements in this burgeoning discipline. Access to the most up-to-date research findings and firm knowledge of established techniques and lessons learned from other researchers or practicing software developers will facilitate the discovery and invention of more effective methodologies. This will allow for a greater range of applications and the creation of better software to serve a greater number of users.

The diverse and comprehensive coverage of software applications in this six-volume authoritative publication will contribute to a better understanding of all topics, research, and discoveries in this developing, significant field of study. Furthermore, the contributions included in this multi-volume collection series will be instrumental in the expansion of the body of knowledge in this enormous field, resulting in a greater understanding of the fundamentals while fueling the research initiatives in emerging fields. We at *Information Science Reference*, along with the editor of this collection and the publisher, hope that this multi-volume collection will become instrumental in the expansion of the discipline and will promote the continued growth of all aspects of software applications.

Section I
Fundamental Concepts and Theories

This section serves as the foundation for this exhaustive reference tool by addressing crucial theories essential to the understanding of software applications computing. Chapters found within these pages provide an excellent framework in which to position software applications within the field of information science and technology. Individual contributions provide overviews of open source software, software testing, social software, and software quality, while also exploring critical stumbling blocks of this field. Within this introductory section, the reader can learn and choose from a compendium of expert research on the elemental theories underscoring the research and application of software applications.

Chapter 1.1
A Historical Analysis of the Emergence of Free Cooperative Software Production

Nicolas Jullien
LUSSI TELECOM Bretagne-M@rsouin, France

INTRODUCTION

Whatever its name, **Free/Libre or Open Source Software** (FLOSS), diffusion represents one of the main evolutions of the Information Technology (IT) industry in recent years. Operating System Linux, or Web server Apache (more than 60% market share on its market), database MySQL or PHP languages are some examples of broadly-used FLOSS programs. One of the most original characteristics of this movement is its collective, cooperative **software development** organization in which a growing number of firms is involved (some figures in Lakhani & Wolf (2005)). Of course, programs, because they are codified information, are quite easy to exchange, and make the **cooperation** easier than in other industries. But, as pointed out by Stallman (1998), if sharing pieces of software within firms was a dominant practice in the 1950's, it declined in the 1970's, and almost disappeared in the 1980's, before regaining and booming today.

This article aims at explaining the evolution (and the comeback) of a cooperative, non-market production.

In the first part, we explain the decrease of cooperation as a consequence of the evolution of the computer users, of their demand, and of the industrial organization constructed to meet this demand. This theoretical and historical framework is used in the second part to understand the renewal of a cooperative organization, the FLOSS phenomenon, first among computer-literate users, and then within the industry.

SOFTWARE IN THE HISTORY OF THE COMPUTER INDUSTRY

Among the few works of reference existing on the evolution of the **computer industry**, we use the following as our basis: Mowery (1996), Genthon (1995), and Dréan (1996). Richardson (1997) and

Horn (2004) have analyzed the specificities of the software industry.

If these authors do not agree on the number of periods that this industry has gone through since its birth at the end of World War II, they agree on two main ruptures:

- The arrival of the IBM 360 series, in the early 1960's, opening the mainframe and mini period when, thanks to the implementation of an operating system, a standard machine could be sold to different clients, but also a program could be used on a family of computers, of different power, and not abandoned when the machine was obsolete; and
- The arrival of the PC, and specifically the IBM PC, in the early 1980's, when the computer became a personal information management tool, produced by different actors.

Each of these periods is characterized by a technology which has allowed firms to propose new products to new consumers, changing the dominant producer-user relations. This has had an impact on the degree of cooperation in the **software production**.

Period 1: The Industry of Prototypes – Start: Mid-1940's

As pointed out by Langlois and Mowery (1996), there was no real differentiation between hardware and software in that period, and computers were "unique" products, built for a unique project. They were computing tools, or research tools, for research centers (often military in nature, like H-bomb research centers). Each project allowed producers and users to negotiate the characteristics of the machine to be built. Also, the software part was not seen as an independent source of revenue by firms.

Production is Research

Thus, computer and software development were a research activity, conducted by high-skilled users, or Von Hippel (VH) users, in reference to Von Hippel's (1988) user who has the competences to innovate, and being the one who knows best his needs, is the best to do so (Dréan, 1996; Genthon, 1995).

Research is Cooperation

In that non-profit, research environment, we think that cooperation was rather natural, allowing firms to decrease their research costs and better answer to users' requirements. But this cooperation was mainly bilateral cooperation, between the constructor and the user. There was no network to exchange punch cards.

Period 2: Industrialization – Start: Early 1960's

Thanks to technological progress (miniaturization of transistors, compilers, and operating systems), the scope of use extended in two directions in that period: the reduction in size and in the price of computers. This raised the number of organizations that were able to afford a computer.

According to Genthon (1996), the main evolution characterizing the period was that the same program could be implemented in different computers (from the same family), allowing the program to evolve, to grow in size, and to serve a growing number of users. The computer had become a tool for centralized processing of information for organizations (statistics, payment of salaries, etc.).

The Emergence of a Software Industry

In this period, some pieces of software became strategic for producers, especially the operating

system, which was the element allowing them to control the client. In fact, as a program was developed for and worked with one single operating system, it became difficult for a client to break the commercial relation, once initiated, with a producer.

In "exchange," this client no longer even needed to understand the hardware part of the machine and could clearly (increasingly, throughout the period) evaluate the cost of its investments in the software part. This client, increasingly companies, was also more and more reluctant to publish in-house developed programs, for competitive reasons, and because most of the time these programs were so specific that few contributions could be expected.

Increased Cooperation, but for R&D Only

So we can say that the cooperative and open source development of software, and especially of innovative software was very strong in universities (it was during this period that Unix BSD, TCP/IP Internet protocol, etc., were developed), but also in some private research centers, like the Bell Labs (which actually invented the Unix operating system and licensed it very liberally). But this diffusion did not extend beyond the area which Dasgupta and David (1994) called "open science."

Period 3: Specialization – Start: Late 1970's

With the arrival of the micro-processor, the scope of use extended again in two directions: increase in power, and reduction in size and price of low-end computers. The dominant technological concept of this period was that the same program can be packaged and distributed to different persons or organizations, in the same way as for other tangible goods.

The third period was that of personal but professional information processing. As explained by Mowery (1996), this period was dominated by economy of scope thanks to the distribution of standardized computers (PC), but principally because of the development of standardized programs.

Research and Innovation are Strategic Assets to be Valorized

The willingness to close software production and to sell it as product was reinforced, in industry as well as in universities:

- In industry, thanks to the adoption of copyright protection, allowing the closure of the source code, but also because of the growing demand for standard programs, as already explained, and the decreasing skills of PC users; they were unable to develop or to modify their programs, nor to be innovators, and thus unable to cooperate with the producers (Jullien & Zimmermann, 2006); and
- In universities, because of the will at the beginning of the 1980's, due to the feeling of economic and industrial decline in the U.S., to better exploit scientific production, reinforcing its legal protection (see Coriat & Orsi (2002) for a complete analysis of intellectual property (IP) evolution during that period); Coriat and Orsi (2002) have shown that the consequence has been a segmentation of production, and a decrease in the exchange of IP, because of the increased fee to be paid for access to this IP, but also because of the transaction costs that this system has created.

Consequence: Decrease of Cooperation?

Cooperation decreased at the institutional level, but remained vivid and growing between researchers and VH users (especially those using Unix workstations) via mailing lists, or "news" services (Mowery, 1996). We could say that, alongside these increasingly-closing practices, this period (especially the 1980's) led to the structure of cooperative practice, and also its ideology, when Richard Stallman created the GNU project (1983) and the Free Software Foundation to support it, and Linus Torvalds started his Linux project (1991).

The point is thus not to understand why cooperation has come back, as actually it has always existed, but why it has returned to the forefront, and especially to the industrial agenda.

THE FLOSS MOVEMENT AS A NEW FRAMEWORK TO ORGANIZE (INDUSTRIAL) COOPERATION

The creation of the FLOSS movement, in opposition to the closing trend, has been advocated by Stallman (1998). We understand his arguments as the response of a profession (software developers) to an institutional trend (the closure of the sources) opposed to their culture, practices, and productivity. They organized themselves, creating a structured organization of cooperative production. With the diffusion of the Internet, FLOSS products spread, making firms involved in FLOSS production.

Developers' Motivations for a FLOSS Organization

As explained in Lakhani and von Hippel (2003), Lakhani and Wolf (2005), Demazière et al. (2004), individual motivations for initiating a Free software project or for collaborating in an existing project are numerous:

- For high-skilled developers, it sometimes costs less to develop a program from scratch than to use one which does not exactly meet its needs. Once developed, a free publication allows a quicker diffusion and, thus, quicker feedback, which is very useful to track bugs and to improve functionalities; and
- Following the same principle, which guided Stallman's initiative, such developers find it very interesting to use FLOSS products that they can adapt to their needs. The return of the bug found, the correction of those bugs, or the modifications, once done, is relatively inexpensive. And as for freeing a program, the developer knows that this problem solution or program modification will be integrated and maintained in the next versions.

It is clear that the social capital that a hacker can earn participating in a FLOSS project (the "carrier concerns"), pointed out by Lerner and Tirole (2002), is also a factor for keeping these persons motivated to do this task. However, this does not seem to have been anticipated by the developers who were interviewed (Demazière et al., 2004; Lakhani & Wolf, 2005).

In addition to this, the movement appears in an historical context:

- Computer science courses were (and are) partly based on the principle that it is more efficient to reuse what exists than to redevelop from scratch. Raymond (2000) has "codified" it as the hacker philosophy. Mainly concentrated in public and private research centers, this professional culture spread at the same time that students in computer science were being hired by firms;
- A personality, Richard Stallman, has made the difference between a vague feeling of

resentment towards the closure of programs in the IT professional community and the construction of a coordinated "riposte." His convictions in this regard have led him to give up his professional situation to defend them, by creating the Free Software Foundation (FSF). And his charisma allows him to be respectfully heard and followed by his "co-developers"; and

- New technical tools, especially the Internet services (and, before that, the ARPANET/ Usenet), have made this campaign possible and have largely facilitated the diffusion of FSF production and of Stallman's arguments against the closure of sources.

The consequence of this initiative and of the use of the Internet network has been the creation of a structured, organized way of producing software cooperatively.

The Creation of a Structured Organization for Cooperative Production

These voluntary contributions are organized and coordinated as Raymond (1999) advocated. Some in-depth studies of such communities have been conducted, such as the one by Mocus et al. (2000) on the Apache development organization, confirming this point.

Kogut and Metiu (2001) show that each project is led by a core group of developers (the "kernel") which develop the majority of the source code. A larger group follows the development, sometimes reports bugs, and proposes corrections ("patches") or new developments. And an even larger group just uses the program and sometime posts some questions on the use of this program on user mailing lists. If, in details, the organizations differ from one project to another, there are always mechanisms to select the contributions and the questions, so the main developers should not be inundated by peripheral problems. If there were not such mechanisms, the risk is that the most productive developers would progressively dedicate more and more time to addressing basic problems, thus losing interest in the development or even withdrawing from it.

Another very important characteristic is that big projects are split in coordinated, small, easier-to-manage subprojects. Baldwin and Clark (2003) show how this modularity reinforces the will to participate as developers can concentrate on the part/functionalities which interest them the most.

As far as FLOSS production was limited to the community of developers, apart from the commercial sphere, it only met a very small part of the users' needs and had no actual economic significance. Actually, this was close to the cooperation existing in the research/Unix world that we presented in the Increased Cooperation subsection. Things changed with the diffusion of the Internet and the consequent evolution of demand.

According to Porterfield (1999), the Internet and FLOSS are closely linked; the diffusion of the Internet, in non-U.S. research centers first and to the public later, has increased the number of users and developers of Free software, as the Internet tools are free software programs. This diffusion explains the diffusion of FLOSS products within firms, and the involvement of producers in FLOSS development.

When Cooperation Comes Back to Firms

At the beginning of the diffusion of the Internet within organizations (firms, administrations), in the early 1990's, servers were installed by engineers who had discovered these tools when they were students at a university. Additionally, as they often did not have any budgets, they installed what they knew at the lowest cost: "free" software. We can consider that the base installed in universities has initiated the "increasing return to adoption".

Actually, the first "FLOSS" firms entered the market selling Internet applications (Operating System, Web server, e-mail servers), like RedHat in 1994, Sendmail Inc. in 1998, and so forth, and to serve VH users (for instance, RedHat's Linux distributions on CdRom were interesting at that period because of low speed connectivity).

Today, since the announcement made by IBM in 2001 of investing $1 billion in Linux development, free software has been adopted in many commercial offers (Novell, buying Ximian and SuSE, Sun open-sourcing its operating system, IBM open-sourcing its development tool software Eclipse, even Microsoft[1]). Lakhani and Wolf (2005) notice that "a majority of (... the) respondents (of their survey) are skilled and experienced professionals working in IT-related jobs, with approximately 40 percent being paid to participate in the FLOSS project."

This can be explained by the evolutions in demand induced by this diffusion.

Following Steinmueller (1996), we see the generalization of computer networking, both inside and outside organizations, as the main technical evolution in information technology of today, in conjunction with miniaturization which has allowed the appearance of a new range of "nomad" products like Personal Digital Assistants (PDA, such as Psion and Palm), mobile phones, and music players. Network communications and exchanges between heterogeneous products and systems are nowadays crucial and require appropriate standards. Network externalities are becoming the dominant type of increasing return to adoption. According to Zimmermann (1999), to this aim, open solutions are probably the best guarantee for users and producers for product reliability throughout time and the successive releases of the products.

A second aspect stems from the wide diversity of users and users' needs that require software programs (and more particularly, software packages) to be adapted to the needs and skills of every individual without losing the economies of scale. Zimmermann (1998) explains that what characterizes this evolution of demand and the technological evolution of software is the increasing interdependence between software programs built from basic components and modules that have to be more and more reused, thus becoming increasingly refined and specialized. Furthermore, as pointed out by Horn (2004), the related demand for software customization generates a renewed services activity for the adaptation of standard-component software programs.

The split of the FLOSS project into different subprojects makes them quite modular and easier to adapt than monolithic programs, generating commercial offers from new entrants (like RedHat), especially toward those who do not have the skills to adapt the programs by themselves. In return, these adoptions reinforced the product, accelerating the increasing return to adoption phenomenon.

Considering that, incumbent producers have adapted their strategies, integrating the use of FLOSS products when necessary:

- Some of these programs, like Apache, were dominant in the Internet market. It was rational and less expensive to adopt the dominant design. These firms used the standard and contributed to it to make sure that the programs that they produced would certainly be taken into account by the standard; and
- In some markets, challengers saw opportunities to sponsor a standard in competition with the dominating standard. This is the case, for instance, in operating systems: Some competitors (IBM, HP, Novell now), of SUN in the Unix market, or of Microsoft in the operating systems for the servers' market, had strong incentives to support Linux to create a competitor to these firms at a very low cost. Being GPL protected, this program could not be appropriated by a single firm, which would mean coming back to the situation that they resisted by using Linux.

We think that FLOSS and especially GPL-protected software, when standardization effects are important, appears to be a way to solve the "wedding-game" situation: Actors want to impose their view, but less than to see a competitor imposing its own. So when you are not the leader, it can be interesting to favor an open, non-"privatizable" solution. Such "open" organization allows such creation of "public industrial goods" (Romer, 1993) and explain the renewal of cooperation in the software industry.

CONCLUSION

So, we could say that a series of convergent interests in the industrial domain has relayed the professionals' initiative to "revive" cooperation in software production, made easier at the beginning of the 1990's by the diffusion of a new information exchange network (the Internet).

This leads to two questions:

- Is that system transposable to another knowledge or information production industry, such as biotechnologies, increasingly based on database analysis and bio-computing, or hardware design, which uses a computer language, VHDL?

This could be the case if users and producers could find more efficient, less costly ways to share a part of their intellectual property, and if a structure, like FSF, could help to organize this cooperation.

- Are we witnessing the emergence of a new period for software ecology, with new technology, new dominant use (the network), and a new system of production (FLOSS-based production)?

This would be the case if the FLOSS production succeeds in matching the interests of computer professionals, users-innovators, and firms. This means succeeding in constructing a model, granting that these actors should contribute in the long run, and not just free-ride using the product. Developing Ousterhout's (1999), Bessen's (2002), Dahlander's (2004), Feller, Finnegan, and Hayes's (2005), Dahlander and Wallin's (2006), and Jullien and Zimmermann's (2006) works, there is a growing need for studies on business models assuring returns for firms and incentives to contribute, but also for studies on the impact of corporate involvement and agenda on the stability of the open cooperative organization of production.

KEY TERMS

The ARPANET: "The Advanced Research Projects Agency NETwork developed by ARPA of the United States Department of Defense (DoD) was the world's first operational packet switching network, and the predecessor of the global Internet" (extract from Wikipedia article). It has been designed to connect the U.S. universities working with the DoD to facilitate cooperation.

Free/Libre Open Source software (FLOSS): This is software for which the licensee can get the source code, and is allowed to modify this code and to redistribute the software and the modifications. Many terms are used: *free*, referring to the freedom to use (not to "free of charge"), *libre*, which is the French translation of Free/freedom, and which is preferred by some writers to avoid the ambiguous reference to free of charge, and *open source*, which focuses more on the access to the sources than on the freedom to redistribute. In practice, the differences are not great, and more and more scholars are choosing the term FLOSS to name this whole movement.

Free Software Foundation: "Free software is a matter of liberty, not price. The Free Software Foundation (FSF), established in 1985, is dedicated to promoting computer users' rights to use, study, copy, modify, and redistribute computer programs. The FSF promotes the development and use of free software, particularly the GNU operating system, used widely in its GNU/Linux variant" (presentation of the Foundation, http://www.fsf.org)

The GNU project: "The GNU Project was launched in 1984 to develop a complete Unix-like operating system which is free software: the GNU system. Variants of the GNU operating system, which use the kernel called Linux, are now widely used [...] (GNU/Linux systems). GNU is a recursive acronym for "GNU's Not Unix"; it is pronounced *guh-noo*, approximately like *canoe*" (definition by the FSF, http://www.gnu.org/)

The GPL (General Public Licence): The best-known and the most-used FLOSS license; according to the FSF, "the core legal mechanism of the GNU GPL is that of "copyleft," which requires modified versions of GPL'd software to be GPL'd themselves". For an analysis of FLOSS licenses, see Clément-Fontaine (2002).

Hacker: In this text, this term is used in its original acceptation, i.e., a highly-skilled developer.

Increasing return to adoption, defined by Arthur (1988): This means that the more a product is adopted, the more new adopters have an incentive to adopt this product. Arthur (1988) distinguishes five type of increasing returns:

- **Learning effect**: Investment in time, money, and so forth, to learn to use a program, as well as a programming language, makes it harder to switch to another offer;
- **Network externalities:** The choices of the people you exchange with have an impact on the evaluation you make for the quality of a good. For instance, even if a particular text editor is not the one which is most appropriate to your document creation needs, you may

choose it because everybody you exchange with sends you text in that format, and so you need this editor to read the texts;

- **Economy of scale:** Because the production of computer parts involves substantial fixed costs, the average cost per unit decreases when production increases. This is especially the case for software where there are almost only fixed costs (this is a consequence of the fact that it presents the characteristics of a public good);
- **Increasing return to information:** One speaks more of a technology since it is widely distributed; and
- **Technological interrelations:** A piece of software does not work alone, but with other pieces of software. What makes the "value" of an operating system is the number of programs available for this system. And the greater the number of people who choose an operating system, the wider the range of software programs for this very system, and vice versa.

Public Good: This is good which is:

- Non-rivalrous, meaning that it does not exhibit scarcity, and that once it has been produced, everyone can benefit from it; and
- Non-excludable, meaning that once it has been created, it is impossible to prevent people from gaining access to the good. (definition taken in http://www.investordictionary.com/definition/public+good.aspx)

The Usenet (USEr NETwork): "It is a global, distributed Internet discussion system that evolved from a general-purpose UUCP network of the same name. It was conceived by Duke University graduate students Tom Truscott and Jim Ellis in 1979" (extract from Wikipedia article).

Chapter 1.2
Free Software Philosophy and Open Source

Niklas Vainio
University of Tampere, Finland

Tere Vadén
University of Tampere, Finland

ABSTRACT

This chapter introduces and explains some of the most relevant features of the free software philosophy formulated by Richard M. Stallman in the 1980s. The free software philosophy and the free software movement built on it historically preceded the open source movement by a decade and provided some of the key technological, legal and ideological foundations of the open source movement. Thus, in order to study the ideology of open source and its differences with regard to other modes of software production, it is important to understand the reasoning and the presuppositions included in Stallman's free software philosophy.

INTRODUCTION

The free software (FS) movement is the key predecessor of the open source (OS) community. The FS movement, in turn, is based on arguments developed by Richard M. Stallman. In crucial ways, Stallman's social philosophy creates the background for the co-operation, co-existence and differences between the two communities. Stallman started the FS movement and the GNU project prompted by his experiences of the early hacker culture and subsequent events at the MIT artificial intelligence lab in the 1980s. The project was founded on a philosophy of software freedom, and the related views on copyright or the concept of *copyleft*. After the creation of the open source movement in 1998, debates between the two movements have erupted at regular intervals. These

debates are grounded in the different ideological perspectives and sociopsychological motivations of the movements. The FS movement has laid technological, legal and ideological cornerstones that still exist as part of the open source movement.

THE SOCIOHISTORICAL BACKGROUND OF THE FREE SOFTWARE PHILOSOPHY

The first computer systems were built in the 1940s and 1950s mainly for military and scientific purposes. One of the earliest research institutes to use and study computers was the Massachusetts Institute of Technology (MIT). The artificial intelligence (AI) lab at MIT was founded in 1958 and became one of the birthplaces of computer science and computer culture.

In *Hackers* (1984), Steven Levy describes the subculture around the AI lab computers in the 1960s. Young male electronics hobbyists devoted their time to programming and studying these machines. They called themselves *hackers*, a word denoting a person who enjoys exploring computer systems, being in control of the systems, and facing the challenges they present. For a hacker, a computer is not just a tool, it is also an end in itself. The computer is something to be respected and programming has an aesthetics of its own (Hafner & Lyon, 1996; Levy, 1984; Turkle, 1982).

A subculture was created among the MIT hackers with traditions and social norms of its own. Important values for the community were freedom, intelligence, technical skills, and interest in the possibilities of computers while bureaucracy, secrecy, and lack of mathematical skills were looked down on. The six rules of this *hacker ethic* as later codified by Levy were:

1. *Access to computers—and anything which might teach you something about the way the world works—should be unlimited and total. Always yield to the hands-on imperative!*
2. *All information should be free.*
3. *Mistrust authority—promote decentralization.*
4. *Hackers should be judged by their hacking, not bogus criteria such as degrees, age, race, or position.*
5. *You can create art and beauty on a computer.*
6. *Computers can change your life for the better.* (Levy, 1984, pp. 40-45)[1]

Computer programs were treated like any information created by the scientific community: Software was free for everyone to use, study, and enhance. Building on programs created by other programmers was not only allowed, but encouraged. On one hand, nobody owned the programs, and on the other, they were common property of the community.

In the early 1980s, a conflict arose in the AI lab when some of the hackers formed a company called Symbolics to sell computers based on technology originally developed in the lab. Symbolics hired most of the hackers, leaving the lab empty. This, together with the fact that the software on Symbolics machines was considered a trade secret, caused a crisis. The community and its way of life had been destroyed and Stallman later described himself as "the last survivor of a dead culture" (Levy, 1984, p. 427; see also Williams, 2002).

Stallman saw an ethical problem in the growing trend of treating software in terms of property. In the AI lab, there was a strong spirit of co-operation and sharing, making the code, in a way, a medium for social interaction. Thus restrictions in the access to code were also limitations on how people could help each other.

In 1984, Stallman published *The GNU Manifesto* announcing his intention to develop a freely available implementation of the Unix operating system. He explained his reasons in a section titled *Why I Must Write GNU*:

I consider that the golden rule requires that if I like a program I must share it with other people who like it. Software sellers want to divide the users and conquer them, making each user agree not to share with others. I refuse to break solidarity with other users in this way. I cannot in good conscience sign a nondisclosure agreement or a software license agreement…So that I can continue to use computers without dishonor, I have decided to put together a sufficient body of free software so that I will be able to get along without any software that is not free. (Stallman, 2002d, p. 32)

The project gained interest and Stallman started receiving code contributions from developers. During the 1980s, major components of an operating system were developed, including a system library, shell, C compiler, and a text editor. However, a core component, the kernel, was still missing until Linus Torvalds began to work on the Linux kernel in 1991. During the 1990s, free software systems based on the Linux kernel gained in popularity, media hype, and venture capital investments.

STALLMAN'S ARGUMENTS IN *THE GNU MANIFESTO* AND THE *FREE SOFTWARE DEFINITION*

Stallman's main argument in *The GNU Manifesto* (1984) is the "golden rule" quoted previously: A useful program should be shared with others who need it. Stallman started GNU in order to "give it away free to everyone who can use it" (Stallman, 2002d, p. 31) in the spirit of co-operation, sharing and solidarity. He criticizes proprietary software sellers for wanting to "divide the users and conquer them" (Stallman, 2002d, p. 32). Stallman's intention here is not anti-capitalist or anti-business. He gives suggestions on how software businesses can operate with free software. The fundamental ethical problem Stallman sees in proprietary software is the effect it has on community and co-operation. For Stallman, himself a master programmer, the "fundamental act of friendship among programmers is the sharing of programs" (Stallman, 2002d, p. 32). Restrictions on sharing would require programmers to "feel in conflict" with other programmers rather than feel as "comrades" (Stallman, 2002d, pp. 32-33).

Stallman suggests that software businesses and users could change the way they produce and use software. Instead of selling and buying software like any other commodity, it could be produced in co-operation between users and companies. Although the software would be free, users would need support, modifications and other related services which companies could sell. Stallman argues this would increase productivity by reducing wasteful duplication of programming work. Also it would make operating systems a shared resource for all businesses. If the business model of a company is not selling software, this would benefit the company. Being able to study source code and copying parts of it would increase the productivity of the programmer.

An important goal in the manifesto is increasing the users' independence from software sellers. When software is free, users are no longer at the mercy of one programmer. Because anyone can modify a free program, a business can hire anyone to fix the problem. There can be multiple service companies to choose from.

For Stallman, the main reason for rejecting software ownership is good civil spirit, but he also argues against the concept of copyright and authorship: "Control over the use of one's ideas' really constitutes control over other people's lives; and it is usually to make their lives more difficult," Stallman (2002d, p. 37) notes. He denies the idea of copyright as a natural, intrinsic right and reminds us that the copyright system was created to encourage literary authorship at a time when a printing press was needed to make copies of a book. At the time, copyright restrictions did little harm, because so few could invest in the equipment required to make a copy. Today, when copies

of digital works can be made at practically zero cost, copyright restrictions cause harm because they put limits on the way the works can benefit society. Stallman (2002d, p. 37) notes that copyright licensing is an easy way to make money but is "harming society as a whole both materially and spiritually." He maintains that even if there was no copyright, creative works would be created because people write books and computer programs on other grounds: fame, self-realization, and the joy of being creative.

Depending on the context, four different meanings of the term *community* can be found in Stallman's argument. The first one is that of a *hacker community* like the one at MIT's AI lab. The second is the *computer-using community* interested in business, wasted resources, and independence from software sellers. The third community is the *society* that will benefit from co-operation and face costs from complicated copyright and licensing mechanisms and enforcement. The fourth level of community Stallman mentions is *humanity*. He argues that because of the copyright restrictions on computer programs, the "amount of wealth that humanity derives" is reduced (Stallman, 2002d, p. 36). In these four meanings of the term, we can see community grow from a small group of friends to an interest group, then to society and finally to humanity as a whole. As the communities grow in size, the temporal perspective is expanded: for hacker friends, the benefits are direct and immediate whereas in the case of humanity change may require decades.

In *The GNU Manifesto*, Stallman mentions that "everyone will be permitted to modify and redistribute GNU, but no distributor will be allowed to restrict its further redistribution. That is to say, proprietary modifications will not be allowed" (Stallman, 2002d, p. 32). In *Free Software Definition* (Stallman, 2002a), he lists the *four freedoms* which a piece of software must meet in order to be free software. The freedoms are:

- **Freedom 0:** The freedom to run the program, for any purpose
- **Freedom 1:** The freedom to study how the program works, and adapt it to your needs; access to the source code is a precondition for this
- **Freedom 2:** The freedom to redistribute copies so you can help your neighbor
- **Freedom 3:** The freedom to improve the program, and release your improvements to the public, so that the whole community benefits; access to the source code is a precondition for this (Stallman, 2002a, p. 41)

Freedom of software is defined by referring to the rights of the computer user, who may run the program for any purpose, good or evil, study and adapt the software, and distribute copies of the program, modified or original. It should be noted that the definition assumes sharing is always beneficial and desired. It does not matter if the neighbor or the community has any use for the software or the skills to use it.

For a piece of software to be free, it would not be enough to abolish the copyright system. Because a user needs the source code in order to effectively exercise freedom 3, the author must actively promote software freedom by releasing the source code. Therefore, a co-operative community is already needed for software freedom.

Stallman makes an important distinction between *free as in free speech* and *free as in zero price*. The concept of free software is not against selling software, it is against restrictions put on the users. Free software can be sold but the seller may not forbid the users to share or modify it.

COPYLEFT: THE GPL AS LEGAL AND SOCIAL DEVICE

Because Stallman was the copyright holder of the GNU programs that he wrote, he could have handed the programs to the public domain. Thus

the programs would have been free. However, releasing the programs to the public domain would have meant that people would have been able to distribute the programs in ways which would have restricted the freedom of users, for instance, by distributing them without the source code. A free program would have become non-free. Stallman wanted the distribution of his programs or any other free software to stay free forever, and together with Free Software Foundation (FSF) legal counsel Eben Moglen, they devised the GNU General Public License (GPL) for this purpose (Stallman, 1989; Stallman, 2002b). The main idea of the GPL is that anyone is free to use, modify and redistribute a GPLed program on the condition that the same freedom of use, modification, and redistribution is also given to the modified and redistributed program. The easiest way to fulfill the condition is to release the redistributed and modified program under the GPL. The GPL is in this sense "viral": a GPLed program can be unified with other code only if the added code is compatible with the GPL. The purpose of the GPL is to keep free software free and to stop it ever becoming a part of proprietary software (Stallman, 2002a, pp. 89-90; Stallman, 2002c, pp. 20-21). The GPL is called a *copyleft* license, because in a sense it turns around the copyright by giving the user, not only the author, the freedom to use and to continue to build on the copylefted work. In this sense, copyright law and the GPL license built on it are the artifices that make the free software movement possible. There is some irony to the fact that the movement in this sense needs the copyright law in order to function. This is also the reason why it is not correct to describe the movement as being against copyright. Consequently, the GPL has to function well. The original GPL version 1 has been modified into version 2, under which, for instance, the Linux kernel is released. Currently, in 2006, a new version, GPLv3, is being prepared by Stallman and the FSF. The somewhat unorthodox twist that GPL gives to copyright law has sometimes aroused suspicion over whether the GPL is a valid and enforceable license. As Moglen (2001) notes, most often GPL violations are settled without much publicity in negotiations between the FSF and the violator. As the FSF seeks only the freedom of software, a violator can easily rectify the situation by starting to comply with the GPL. It is sometimes argued that the fact that code under GPL can not lose the property of being free does not give the user maximum freedom with the code: the user is not permitted to "close" the code and release it under a proprietary software license. For instance, a typical Berkeley Software Distribution (BSD) license does not require that modifications or derivative works be free. Proponents of BSD see this as a good thing, maybe even as a benefit over the GPL, because the BSD license gives the developer more possibilities. However, for Stallman this is not desired, as closing the source tramples on the possible future uses of the code: "It is absurd to speak of the 'freedom to take away others' freedom'" (Stallman cited in Butler, 2005).

FREE SOFTWARE AS A POLITICAL PHILOSOPHY

As described above, Stallman's free software philosophy goes beyond the freedom and needs of an individual programmer. In Stallman's work, we find a political philosophy that has roots both in the liberalist and the communitarian traditions but accepts neither as such.

Stallman's ideas on user's freedom have roots in the liberalist political philosophy of Thomas Hobbes, John Locke, John Stuart Mill and others. In the *Second Treatise of Government* (1690), Locke argued that societies are built on a social contract in which people agree to give away some of their personal liberty to escape the cruel reality of the "state of nature" and receive protection for the fundamental rights which are life, liberty, and property. Locke's influence on political philosophy can be seen, for example, in the formulation of

the U.S. Declaration of Independence and in the Constitution.

Stallman describes his relation to the liberalist tradition as follows:

The philosophy of freedom that the United States is based on has been a major influence for me. I love what my country used to stand for. ... Science is also an important influence. Other campaigns for freedom, including the French and Russian revolutions, are also inspiring despite the ways they went astray. (Stallman, 2004)

The four freedoms of free software were named after the influential speech given by the U.S. President Franklin D. Roosevelt during the Second World War in 1941, called *The Four Freedoms* (Roosevelt, 1941).

For Locke, freedom means "to be free from restraint and violence from others" (Locke, 1690, para. 57). For Stallman, software freedom means the freedom to run, study, modify, and distribute the program Locke described the time before organized society as a natural state where everybody had complete freedom but had to live in constant danger. Stallman has described the American society as a "dog-eat-dog jungle" where antisocial behavior like competition, greed and exclusion is rewarded instead of co-operation (Levy, 1984, p. 416; Stallman, 2002e). Because sharing of software is forbidden, freedom is restricted in such a society.

The tension between individualism and communitarianism is constant in Stallman's philosophy. He started the GNU project because of his own moral dilemma, but he also argues for it on a collectivist basis. In the first announcement of the GNU project (Stallman, 1983), the perspective was individualist: "So that I can continue to use computers without violating my principles, I have decided to put together a sufficient body of free software so that I will be able to get along without any software that is not free." In *The GNU Manifesto* (Stallman, 2002d), the words "violating my principles" were replaced with the word "dishonor," indicating a move towards a more communal view. The tension also arises if we ask for what and for whom software freedom is intended. Isaiah Berlin (1969) has introduced a distinction between the notions of negative and positive freedom: negative freedom means freedom from obstacles and restrictions while positive freedom means control over one's life and positive opportunities to fulfill a goal. Both the liberalist tradition and Stallman mainly use the negative concept of freedom, but in his emphasis on community we can also see aspects of positive freedom.

Freedom 0, the freedom to run the program, is a pure example of the negative concept of freedom. The user has the right to use the software, whatever the purpose might be. Freedom 1 has two components: having permission to study the program and having the source code. In this sense freedom 0 is not only about absence of restraints, it is also about presence of the source code and in this sense a positive freedom. Likewise, freedom 2 is not only an individualist or negative freedom: the freedom to redistribute copies is necessary to help the neighbour. Freedom 3 to improve the program and release the improvements to the community is also of a positive nature: It is required to build a community.

For a programmer, freedom of software is a fundamental issue related to a way of life, to the identity of a hacker. Is the freedom relevant only for programmers? Bradley Kuhn and Richard Stallman reply:

We formulated our views by looking at what freedoms are necessary for a good way of life, and permit useful programs to foster a community of goodwill, cooperation, and collaboration. Our criteria for Free Software specify the freedoms that a program's users need so that they can cooperate in a community. We stand for freedom for programmers as well as for other users. Most of us are programmers, and we want freedom for

ourselves as well as for you. But each of us uses software written by others, and we want freedom when using that software, not just when using our own code. We stand for freedom for all users, whether they program often, occasionally, or not at all. (Kuhn & Stallman, 2001)

This freedom is for everyone, whether they need it, use it, or not, just like freedom of speech. But freedom of software is just a means to a more important end, which is a co-operative, free society. Stallman wants to contribute to a society that is built on solidarity and co-operation, not exclusion and greed. In a communitarian way, the argument sees morality and the good of the individual co-dependent on the good of the community.

POLITICAL MOVEMENT OR DEVELOPMENT MODEL? A COMPARISON OF FS AND OS IDEOLOGIES

One of the motivations for launching the Open Source Initiative (OSI) was the perception that the ideology and concepts used by the FS movement, in general, and Richard Stallman, in particular, were putting off potential collaborators, especially business partners. Eric S. Raymond explains his motivations as tactical, rather than principal:

The real disagreement between the OSI and the FSF, the real axis of discord between those who speak of "open source" and "free software," is not over principles. It's over tactics and rhetoric. The open source movement is largely composed not of people who reject Stallman's ideals, but rather of people who reject his rhetoric. (Raymond, 1999)

Thus, the aim of the term *open source* is to emphasize the practical benefits of the OS development model instead of the moral philosophy behind the free software ideal. For the actors in the OS movement, the creation of OS software is an utilitaristic venture of collaboration, based on individual needs. According to Eric S. Raymond, "Every good work of software starts by scratching a developer's personal itch" (Raymond, 1999). This is in clear contrast with the intentional, systematic, and collective effort described by Stallman: "essential pieces of GNU software were developed in order to have a complete free operating system. They come from a vision and a plan, not from impulse" (Stallman, 2002c, p. 24).

The main ideological shift was in the professed motivation for writing code. The software itself often stayed the same: by definition, free software is a subset of open source software. For the outside world this ideological shift may present itself as relatively minor, so that in the name of simplification a common name such as FOSS (free/open source software) or FLOSS (free/libre and open source software) is often used. Initially the two communities also overlapped to a large degree, but lately some polarization has been in evidence. For instance, in a recent survey a large majority of Eclipse developers reported that they identify with the OS movement, while a clear majority of Debian developers reported identification with the FS movement (see Mikkonen, Vainio, & Vadén, 2006). This development may be expected to continue, as companies are increasingly taking part and employing programmers in OS development.

A crucial difference between OS and FS has to do with the political economy of software production. However, this distinction is best described as the difference between *business friendly* open source and *ideological/political* free software, or *capitalist* open source and *communist* free software. These are not the correct levels of abstraction. For instance, sometimes the GPL license is more *business friendly* than a given non-GPL-compatible open source license. The fact that the OS community treats code as a *public good* might be perceived as odd in certain types of market economies, while in others such public goods are seen as necessary drivers

of capitalism. By making software a non-scarce resource, OS has an effect on where and how a revenue stream is created. However, this merely reorganizes production and labour, instead of changing their mode.

Schematically put, FS is a social movement, while OS is a method for developing software. Whatever the definitions of systems of economical production—such as capitalism, communism, market economy, and so on—may be, OS is non-committal with regard to the current issues of political economy, such as copyright, intellectual property rights and so on. Individual members of the OS community may or may not have strong views on the issues, but as a community OS is mostly interested in the benefits of openness as a development model. This attitude is well exemplified in the views expressed by Linus Torvalds: "I can't totally avoid all political issues, but I try my best to minimize them. When I do make a statement, I try to be fairly neutral. Again, that comes from me caring a lot more about the technology than about the politics, and that usually means that my opinions are colored mostly by what I think is the right thing to do technically rather than for some nebulous good" (quoted in Diamond, 2003). This pragmatic or "engineering" view on FOSS is intended to work better than ideological zealotry in advancing the quality and quantity of code. In contrast, in order to change a political system one needs a social movement. As noted previously, the FS movement is a social movement based on shared values. While these values are close to the loosely interconnected values of the anti-globalization movement (see Stallman, 2005, 2002f), they are not the defining values of socialist or communist parties or movements. For instance, the FS movement does not have a stand on class relations or on how to treat physical property, and so on. In this sense the FS movement as a social movement is a specialized, one-cause movement like many other post-modern social movements. Again, here lies a crucial distinction: the ethical principles of FS concern only information, and only information that is a tool for something. Typically, a socialist or communist set of values would emphasize the importance of material (not immaterial) things and their organization.

Ideologically proximate groups often behave in a hostile manner towards each other in order to distinguish themselves; the public controversies between the FS and OS communities are a good example. Extra heat is created by the different perspectives on the politics of freedom. The Torvaldsian view of "no politics" is tenable only under the precondition that engineering can be separated from politics and that focusing on the engineering part is a non-political act. Stallman, for one, has consistently rejected this precondition, and claims that the allegedly non-political focus on the engineering perspective is, indeed, a political act that threatens the vigilance needed for reaching freedom.

A good example of these controversies is the one over the name (Linux or GNU/Linux) of the best known FOSS operating system. Since the mid 1990s, Stallman and the FSF have suggested that developers use the name GNU/Linux, arguing that "calling the system GNU/Linux recognizes the role that our idealism played in building our community, and helps the public recognize the practical importance of these ideals" (FSF, 2001). However, true to their pragmatical bent, OS leaders such as Raymond and Torvalds have replied that the name Linux has already stuck, and changing it would create unnecessary inconvenience. Some of the distributions, such as Debian, have adopted the naming convention suggested by the FSF.

CONCLUSION: FS AS A HISTORICAL BACKDROP OF OS

The FS movement initiated by Stallman predates the OS movement by over a decade and the latter was explicitly formed as an offshoot of the former. Consequently, the definition of OS soft-

ware was developed in the context of an ongoing battle between the FS and proprietary software models. Arguments presented by Stallman in the early 1980s still form some of the most lucid and coherent positions on the social and political implications of software development. Most importantly, the polarization of the FOSS community into the FS and OS camps has been only partial. All of these facts point out how FS has acted as a necessary background for OS. This background can roughly be divided in technological, legal and ideological parts.

On the technological side, FS code often forms a basis and ancestry for OS projects. The formation of the operating system Linux or GNU/Linux is one of the examples where the functions of the FS movement form an essential cornerstone of existing OS software. Typically Linux distributions include major technological components (such as glibc [the GNU C Library], Coreutils, and gcc) from the GNU project.[2] It is uncontroverted that without the systematic and prolonged effort by the FSF the development and adoption of Linux (the operating system) would not have been as rapid or widespread as it has been. However, it is equally clear that several key OS projects, such as Apache or Eclipse, are not technologically dependent on GNU.

The legal cornerstone provided to the OS community by the FSF and Stallman is the GPL license, under which Linux (the kernel) and several other key OS projects were developed. The GPL is concurrently clearly the leading FOSS license, comprising over 50% of the code in projects maintained at SourceForge and of major GNU/Linux distributions (Wheeler, 2002). The GPL as a license and the ideal of freedom that it embodies are the legal lifeblood of both the FS and the OS communities, even though several other families of licenses are crucially important.

The ideological foundation provided by the FS movement is difficult to gauge quantitatively. Suffice it to say the OS movement is, according to its own self-image, a tactical offshoot of the FS movement. Many of the sociocultural arguments (openness for reliability, longevity of code, and user control) and ways of functioning (collaborative development based on the GPL) that the OS community uses were spearheaded by the FS community. Moreover, now that OS is moving outside its niche in software production and gaining ground as a *modus operandi* in other fields (such as open content, open medicine, open education, open data, and so on), the OS movement finds itself again in closer proximity to the ideals expressed by the FS movement. However, there are also trends that tend to emphasize the neutral, engineering point of view that created the need for the separation of OS from FS in the first place: as OS software becomes more commonplace and even omnipresent, the ideological underpinnings are often overlooked with or without purpose.

KEY TERMS

Communitarianism: A philosophical view holding that the primary political goal is the good life of the community.

Copyleft: The practice of using copyright law in order to remove restrictions on the distribution of copies and modified versions of a work for others and require the same freedoms be preserved in modified versions.

Free Software (FS): Software that can be used, copied, studied, modified, and redistributed without restriction.

General Public License (GPL): A widely used free software license, originally written by Richard M. Stallman for the GNU project.

Hacker Community: A community of more or less likeminded computer enthusiasts that developed in the 1960s among programmers working on early computers in academic institutions, notably the Massachusetts Institute of Technology. Since then, the community has spread throughout the world with the help of personal computers and the Internet.

Liberalism: A philosophical view holding that the primary political goal is (individual) liberty.

ENDNOTES

1 For alternative formulations of the hacker ethos, see the entry "hacker ethic" in *The Jargon File*, edited by Raymond (2003) and *The Hacker Ethic* by Himanen (2001), who gives the concept a more abstract scope.

2 For a view of the complexity of a GNU/Linux distribution (see Wheeler, 2001).

Chapter 1.3
Open Source Software Basics:
An Overview of a Revolutionary Research Context

Eirini Kalliamvakou
Athens University of Economics and Business, Greece

ABSTRACT

The open source software (OSS) development area of research presents a fresh and generous domain for analysis and study. In line with this, it is important to have a high-level understanding of the "open source phenomenon" before being able to delve deeper into specific niches of research. OSS presents a rich picture and because of that, both academics and practitioners have shown intense interest in producing high-quality literature. This chapter provides an initial understanding of what OSS is and how it has come to be the exciting research platform that it is today, attracting attention from various sources. In addition, we take an overview of the research streams that have formed in recent years, and the basic findings of attempts made to transfer lessons from OSS to other research areas.

OPEN SOURCE SOFTWARE AT A GLANCE

Open source software (OSS) has received growing attention in recent years from various perspectives. The thriving numbers behind OSS adoption and contribution have captured the attention of academic research that, in the past years, has been trying to decipher the phenomenon of OSS, its relation to already-conducted research, and its implications for new research opportunities.

OSS has a definition that focuses on specific characteristics that software has to serve in order to be labeled as "open source." The Open Source Initiative (OSI) is a nonprofit corporation dedicated to managing and promoting the OSS definition for the good of the community; thus, acting as the official organization behind OSS. Based on the OSS definition provided by OSI, any software that has the characteristics listed below is considered to be OSS, and vice versa:

- Free redistribution
- Access to source code
- Derived works allowed under the same license
- Integrity of the author's source code
- No discrimination against persons or groups
- No discrimination against fields of endeavor
- Distribution of license
- License must not be specific to a product
- License must not restrict other software
- License must be technology-neutral

The current OSS landscape presents a very interesting picture. Although the idea behind OSS dates back to the 1960s and the UNIX era in the 1980s, the official term of OSS was coined in 1998 and, at the same time, the OSI was created. Since then, the OSS movement has evolved at a very fast pace. Prime examples of successful OSS projects include operating systems (Linux, FreeBSD, OpenBSD, NetBSD), Web browsers (Firefox, Konqueror), graphical environments (KDE, Gnome), productivity applications (OpenOffice), programming languages and infrastructure (Apache, MySQL), and development tools (GNU toolchain, Eclipse). These widely accepted OSS endeavors show that, today, a wide range of OSS applications are available and they present a viable and robust alternative to proprietary software solutions.

In addition to the presence of prime examples in the OSS environment, the plethora of OSS projects is impressive. Project support sites are online environments that provide tools for listing and managing OSS projects while supplying information such as developer teams, maturity stage, latest versions, and so forth. Two of the biggest and most well-known support sites, *Sourceforge.net* and *Freshmeat*, have reported to have more than 125,000 and 40,000 listed projects in the summer of 2006, respectively. Although many of these projects are still in designing stages, these numbers reveal the dynamics behind OSS and its evolution/adoption. Furthermore, this striking progress of OSS provides an intricate motive for conducting research in such a context.

OPEN SOURCE SOFTWARE AS A RESEARCH CONTEXT

Open source software is developed in a way different than proprietary software. Development is done inside communities of developers that work on code for their personal satisfaction or need. However, lately, a trend has formed inside large companies, that pay their employees to contribute to OSS projects, using this as a platform that enables them to affect the introduction of new software features so that the final OSS product is better aligned with the company's interests and needs. An open question remains as to how expanded this trend currently is, and whether the "paid volunteers" are involved in the process of developing OSS software primarily out of their own satisfaction or are assigned to it exclusively by their employers.

Independent of this fact, the community-oriented development leads to the efficient production of high-quality software available for use by anyone interested. This is an important element of OSS, the prime motivation for developers is not to "make software" as requested by clients or employers, but mainly to satisfy their own software needs, which cannot be fulfilled by vendor-supplied software. After the software is prototyped, it can be made public for anyone who wishes to use, modify, and redistribute.

OSS communities have significant similarities with professional software engineering teams utilized by software houses. However, these two organizational structures also portray critical differences that show that they stand quite far apart. It is important to note that since not all companies organize their software development efforts in the same mode, and also, there is a wide variety

Table 1. Differences between OSS and proprietary software projects (Based on Crowston & Howison, 2005)

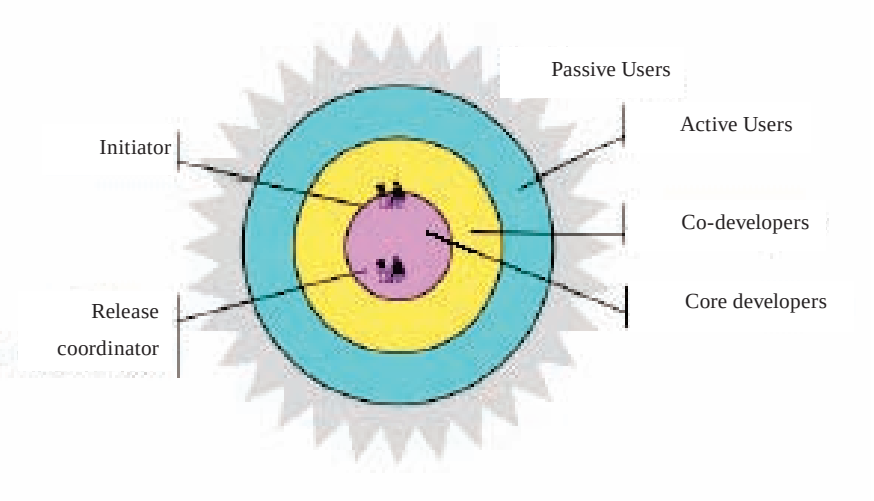
	OSS projects	**Proprietary software projects**
Release planning process	Own ideals about quality and features	Time-to-delivery pressure
Quality assurance	Developers do not have write access to the repository	Developers have write access to the repository
Leadership	Leaders are required to have proven competence via previous contributions	Project leadership is a hierarchical level where people are promoted by other than technical criteria
Tools and standards	Use of standardized tool chains (not modern modeling tools and techniques)	Each project may opt for another technology leading to different set of tools (code re-use between projects is limited)
Motivation of developers	Desire to learn and establish new skills (fun-to-code)	Typical task assignment by hierarchical superiors or salary incentives (not as efficient)
Roles of members	Members assume roles according to personal interests	Tasks are assigned

of organizational structures inside OSS projects, similarities and differences between them can be valid upon different occasions. The most basic differences are pictured in Table1.

Inside OSS communities, there are rules to be accepted and respected by both the developers and the users. Also, there is always some hierarchy of roles, although this hierarchy can take many forms, depending on the internal organization of each project and the profiles of its developers and owners. Through various case studies (Cox, 1998; Gacek et al., 2004; Moon & Sproull, 2000; Mockus, Fielding, & Herbsleb, et al., 2002; Moon & Sproull, 2000), a hypothesized model of OSS project structure is suggested. The model consists of concentric circles of persons that serve different roles within the project and have different responsibilities. At the center of this onion-like form, we find the team of core developers that contribute most of the code, and also have the role of overseeing the project's evolution and design. Core developers also review and check-in the patches submitted by co-developers that belong to the consecutive circle. In the next circle, we find active users of the project's product that do not write code but provide bug reports, testing of new releases, and also use-cases. Finally, in the outer circle (for which there is no specific border), we find the software's passive users that do not have an active presence in the project's mailing lists and forums. This onion-like structure is shown in Figure 1.

What is surprising and initially hard to explain in the case of OSS is *how it is possible to build software of top quality that, in many cases, outperforms the products of multimillion-dollar companies with a vast amount of resources.* The answer seems to lie beyond issues of money and resources and closer to self-organizing communities and networks between developers. The OSS phenomenon has brought forth a different perspective in the way software is created. New paradigms regarding technical, legal, team formation, and organization and knowledge dissemination issues have converted OSS development into an interesting and intriguing research topic.

Figure 1. The OSS onion-like model of organization (Crowston & Howison, 2005)



Although the majority of studies, at least at the beginning of the spread of OSS, were mostly concerned with the technical elements behind its success, some other aspects related to OSS soon presented interesting research questions. Hence, concepts like *community* and *social interaction* are currently under investigation and reveal their great importance when interpreting and understanding many questions.

Since OSS is presenting such an interesting research area with useful conclusions and implications also for other domains of research, it is important that a researcher has at least a brief overview of discussions and studies that have formed the OSS literature. In the next section, we will take a look of at a limited number of very influential studies that portray the multidisciplinary approach to OSS research and the intriguing results that it can provide. Through this approach, we will be able to gain a deeper understanding of the research context offered by OSS.

OSS LITERATURE

As it is expected, the core of researchers of open source software, at the beginning, mostly consisted of software engineers with the basic aim to understand the processes associated with OSS development and get a global picture of it. However, as it is evident now, along with the technical aspects of OSS, also social, economic, organizational, and other issues form its rich picture. This is why in the last few years the "OSS phenomenon" has attracted the attention of not only software engineers, but also researchers from many other disciplines and backgrounds.

OSS became a matter of study in the late 1990s, although it can be traced back to the 1980s and even earlier (Salus, 2005). The first studies came from individuals actively involved in OSS development communities (rather than academic researchers) who published results regarding the OSS development processes and outcomes as well as its economic implications for the software development industry/scenery in general. Also, popular voices at that time were those of OSS advocates that discussed ethical and philosophical aspects of OSS (Stallman, 1999), although published later, is a good example). A third group of references regarded the use of applications, with little attention to the development process itself. Academic papers related to OSS began to appear around 2000 in workshops and in conferences and

a little later in scientific journals and magazines. After extensive research on the literature on OSS development, we have found almost no significant references before 1998.

Early Works Try to Decipher the Development Process

The most widely-known, representative and influential text of that time is the well-known essay by Eric S. Raymond "The Cathedral and the Bazaar" (Raymond, 1998). Although the text is not supported by an empirical study of many projects (only the *Linux kernel* and *fetchmail* projects are discussed), "The Cathedral and the Bazaar" made an important contribution by establishing a metaphor. Traditional software development projects were modeled as cathedrals, where the development process is centralized and highly dependent on just a few persons whose roles are clearly defined. Release management follows a closed planning, user feedback is limited, and contributions by external developers are not fostered. In opposition to the cathedral we find the bazaar, where there is lack of planning (at least in the first stages of the project) and everything starts with the need of a developer and his/her ability to create software that meets that need. Developers publish often and users are regarded as co-developers under the bazaar model. Obviously, the bazaar model represents a more flexible and open way for the software development process that stands contrary to the cathedral model. It is important to note that the cathedral model should not be mistaken as representing only proprietary software; some OSS projects from the GNU project (such as the GNU Compiler Collection and the GNU Emacs editor) fall under the cathedral model of development although they are OSS.

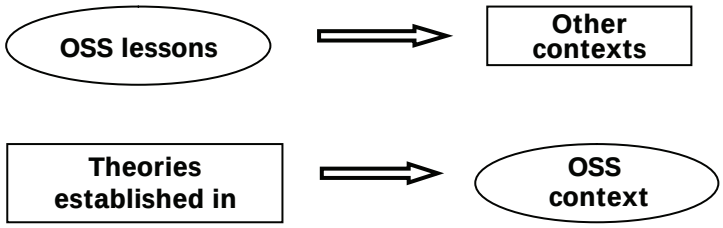
Almost immediately after "The Cathedral and the Bazaar" was released (first through the Internet, later published), other authors started either to build on top of it or severely criticize it. One well-known follow-up came from Bezroukov (Bezroukov, 1997), who made a point saying that the bazaar development model is not some revolutionary phenomenon, but just a different form of "scientific community." Bezroukov considered Raymond's ideas as too simple to match reality, and proposed other models based on academic research that could better explain the phenomenon.

As far as development models for OSS are concerned, Vixie compared the classical waterfall model with the processes used in the production of OSS (Vixie, 1999). According to Vixie, the waterfall model is composed of a set of a complete and logical sequence of steps aiming at obtaining a final product, while the OSS development model relies on the absence of formal methods. Such methods prove unsatisfactory for programmers who voluntarily devote time to program. This lack of formality, Vixie argues, is compensated for by user feedback and by the introduction of software engineering methods (developers define a methodology to face a specific problem for which they are experienced enough). Therefore, it is obvious through Vixie's argument that no ad hoc development model exists for OSS; the methods and practices evolve with the project and usually show a tendency to formalization of tasks.

Identifying Research Streams in OSS

Although, as it is evident above, the early works in OSS literature were concerned with the development model of OSS, this picture quickly changed. This coincided with, and was the result of, the rapid expansion of OSS and its successful use and adoption by a growing mass of interested parties. This success needed both to be explained and also to investigate whether it could prove useful for other research areas (related or not to software engineering that was the principal environment for the birth of OSS). Therefore, the extensive review of literature for OSS led us to discover and reveal two main research streams that confirm these inherent needs. These two research streams can be visualized in Figure 2.

Figure 2. Research streams in OSS literature



Applying OSS Research Conclusions to Other Domains

The first research stream uses the conclusions drawn from OSS case studies and the lessons learned via studying and investigating OSS, and tries to identify whether these successful lessons can be utilized in other contexts. One of the first concerns has been whether for-profit organizations could profit by adopting the seemingly effective practices of OSS. Seeing how the OSS development model proves to be successful (judging from the results it achieves). it would useful for organizations to follow similar models to make their own software development models more efficient. Several studies point that such a shift (from "traditional" to OSS model of development) can be achieved given that the organizations will be willing to change in terms of processes, internal organization, and philosophy.

Sharma et al. (Sharma, Sugurmaran, & Rajagopalan, 2002) argued that the success of the OSS model is setting the stage for a structural change in the software industry, transforming it from manufacturing to a service industry. Therefore, they explored how for-profit organizations can foster an environment similar to OSS in order to reap its numerous advantages to manage their own software development efforts. After examining the OSS environment using a framework based on dimensions of structure, process, and culture (Galbraith, 1973; Miles & Snow, 1978; Robey, 1991) from organizational theory literature, Sharma et al. (2002) offered their own framework for creating hybrid-OSS communities inside organizations. Their proposed framework included properties of community building, community governance, and community infrastructure. It appears from this work that the ability of organizations to move to a hybrid-OSS environment will depend on:

1. The ability of management and workers to understand the OSS philosophy
2. The development of mutual trust between management and workers
3. The workers' perception of being involved in challenging and innovative projects
4. The motivation of workers to participate in such projects

The arguments of Sharma et al. (2002) concerning the internalization of OSS development model characteristics by organizations is also asserted by another study published a little earlier. In a technical report by the Software Engineering Institute of Carnegie Mellon University, it is stated that "industries, specifically those in the software-development business, are beginning to support the idea of development in the style of OSS." The report analyses several OSS case studies and provides useful conclusions, as well as a set of guidelines for organizations that consider adopting a model of development or internal structure similar to an OSS project.

The organizations' interest to incorporate the successful OSS mechanisms in their own practices was also discussed by Cook (2001), who described the motivators for those involved in OSS, and then defined the problems that need to be overcome for this incorporation to happen.

OSS motivators, according to Cook, are the same factors that appear as contradictions between OSS and CSS (closed-source software). The different "organizational structure" (the benevolent dictatorship), the pool of resources, the level of talent, the motivations for contribution, and the fact that OSS is not attempting to redesign the wheel are the contradictions that are cited as separating OSS projects from commercial organizations. As a result, Cook proposes the features that can be imbibed from OSS environments to traditional organizations:

1. Interacting with customers in certain domains
2. Rewarding talent
3. Allowing individuals to register as potential contributors

Following the same line of thought, several studies have been concerned with whether the successful patterns of online and offline collaboration, team building, and coordination can be utilized in other contexts besides the OSS development environment, for example in organizations. Yamauchi, Yokozawa, Shinohara, and Ishida (2000), based on observation, interviews, and quantitative analysis of two OSS projects (FreeBSD Newconfig Project and GNU GCC Project), found evidence that suggests that spontaneous work coordinated afterward is effective, rational organizational culture helps achieve agreement among members, and communications media moderately support spontaneous work.

These findings could imply a new model of dispersed collaboration. Although the same argument is shared by other researchers as well, like Crowston and Howison (2005), Gallivan (2001) seems to counter this belief by proposing that trust and effective online collaboration of OSS developers is not a critical factor to a project's success, but that it is "various control mechanisms [that] can ensure the effective performance of autonomous agents who participate in virtual organizations" (OSS projects are viewed as virtual organizations by the author). However, Gallivan's study is not backed by empirical data to support this claim, but rather a content analysis of already published OSS case studies and the literature that they are based on.

The general effects of OSS on software engineering have been the subject of considerable analysis. Jorgensen (2001) studied the incremental software development model followed in the FreeBSD project where a stream of contributions goes into a single branch in the repository and is required to preserve the software in a working state. This is a process that creates a succession of development releases, akin to the practices of OSS that utilize frequent releases, but different from the commercial software development line of thought. This fact was also mentioned in "The Cathedral and the Bazaar," where the "release early, release often" (Raymond, 1998) principle of the bazaar model was discussed for its superiority and more effective results. This incremental model has had its effects on more and more commercial software development efforts that have incorporated it.

Scacchi (2002) described and analyzed four OSS development communities to understand the requirements for OSS development efforts, and how the development of these requirements differs from those traditional to software engineering and requirements engineering. He discovered eight kinds of *software informalisms* (software development processes that do not follow the typical route of software development companies) that play a critical role in the elicitation, analysis, specification, validation, and management of requirements for developing open source software systems. This enables considering a reformulation of the requirements engineering process, having a large effect on software engineering in general.

All studies presented in this section share the common characteristic of investigating the applicability of OSS principles and conclusions to other areas of research and practice. In the

following section, we will review studies that belong to the second of the two research streams mentioned earlier.

Investigating how Other Disciplines Apply to the OSS Context

The second research stream is interested in almost the opposite approach. Here we see studies that build on theories established in various disciplines, and review their applicability in the context of OSS. The main disciplines accounting for the majority of the studies of this type are economics, sociology/psychology, software engineering, and network analysis.

Lerner and Tirole (2004) acknowledged the initial puzzlement that OSS causes to an economist. However, they argued that existing economic frameworks can explain OSS- related activities. In their study, they draw on labor and industrial organization literature to give alternative views to the OSS trend. Here, programmers are seen as incurring opportunity costs of time, and the long-term benefits of participating in OSS projects are shown. These long-term incentives are further empowered under three conditions: (a) the more visible the performance to the relevant audience, (b) the higher the impact of effort on performance, and (c) the more informative the performance about talent, for example, Holmström (1999). As a result, Lerner and Tirole conclude that there are economic incentives entangled in the OSS processes, although they are different from the incentives in software development companies and hence may not be directly recognizable.

In a study by Johnson (2002), OSS development is modeled as the private provision of a public good. Such models of public good provision have been studied by many researchers (Bergstrom, Blume, & Varian, 1986; Bliss & Nalebuff, 1984; Chamberlin, 1974; Palfrey & Rosenthal, 1984; Bergstrom, Blume, & Varian, 1986; Bliss & Nalebuff, 1984) and are at the center of economic theory. Based on that, Johnson shows that the superior ability of the open source method to access the Internet talent pool, and to utilize more private information, provides an advantage over the closed source method in some situations. Nonetheless, free riding (which is a crucial problem when discussing public goods) implies that some valuable projects will not be produced, even when the community of developers becomes large.

Bitzer, Wolfram, and Schroder (2004) adapted a dynamic private-provision-of-public-goods model to reflect key aspects of the OSS phenomenon. In particular, instead of relying on extrinsic motives for programmers (e.g., signaling), his model was driven by intrinsic motives of OSS programmers, arguing that since programming software is associated with the risk of failure (e.g., in terms of the development of the software is not successful or the project does not become famous), extrinsic motives (signaling) are unable to explain the OSS phenomenon in full, and can rarely be linked to the motives of initiators of OSS projects. This approach, in a sense, challenges earlier views that analyzed the economic aspects of OSS based on extrinsic motives. According to Bitzer et al., the motives for a programmer to initiate a project are the mix of:

1. The need for a particular software solution
2. Fun or play
3. Gift culture, social standing

Motivation of OSS developers has been a recurrent theme for studies either from an economic (Torvalds & Diamond, 2001; Hars & Ou, 2002; Hertel, Nieder, & Herrmann, et al., 2003; Krishnamuturthy, 2002; Lakhani & Wolf, 2003) or a sociological/psychological perspective (Weber, 2004).

In discussing a framework for analyzing OSS, Feller and Fitzerald (2000) study and use two previous frameworks which that have been very influential in the IS field: Zachman's IS architecture (ISA) and Checkland's CATWOE framework from soft systems methodology (SSM).

Furthermore, Lawrie and Gacek (2002) use basic software engineering principles and metrics to discuss dependability issues regarding OSS. There is a large number of studies discussing technical or evaluation issues in OSS that draw on the software engineering scientific area, but their technicality does not support our analysis, and thus they are not presented in this literature review.

Through this overview, it became evident that the area of OSS-related research spans a number of disciplines and contexts. Researchers of OSS today are not strictly software engineers, and issues of interest are not limited to development and engineering principles. A lot of different perspectives have been considered in order to explain OSS expansion and philosophy and, at the same time, a lot of different domains of research have stepped up with the desire to utilize all the successful practices that OSS development has to offer. It is a collective aim for the research and analysis of OSS development to continue, and for knowledge and best practices to be transferred to other areas as well.

CONCLUSION

The purpose of this chapter was really introductory. Many of the FOSS historical issues as well as research topics will be covered in detail in the next chapters, where special emphasis will be paid to the knowledge and learning management context. From this point of view, it is really exciting to reveal the mutual beneficial relationships of FOSS and knowledge and learning management and their linkages that support sustainable performance and development.

Chapter 1.4
Open-Source Software Issues

Sofiane Sahraoui
American University of Sharjah, UAE

INTRODUCTION

Two major research publications have recently dedicated special issues to the emerging field of OSS (Research policy, 2003; Management Science, 2006). Likewise, major information systems conferences are starting to list OSS as a research track (IRMA 2004, Working IFIP 8.6) translating the heightened importance of this phenomenon in the business world. Undoubtedly, OSS has been admitted as a legitimate field of study in the realm of business academics, but OSS research remains largely trailing the gigantic developments in the open-source industry. For instance, there are recurrent speculations in specialized IT magazines that Microsoft will go down the drain with the OSS phenomenon (Fontana, 2003); Oracle will have a hard time maintaining its supremacy in the database market (Bank, 2003); and Apple might come out the big winner by latching on to OSS (Brockmeire, 2003). However, there is hardly any solid piece of academic research to forecast the outlook of the IT industry in light of the surging OSS phenomenon. Existing research, including the two special issues mentioned above, is focusing on validating models of innovation in a virtual environment (Franke, 2003; Von Krogh, Spaeth, & Lakhani, 2003; Hippel, 2001); tracking project management dynamics in OSS development (Hertel, Neidner, & Herrmann, 2003; O'Mahony, 2003); examining the intellectual property, ethical and legal implications of OSS (Evers, 2000; Faldetta, 2002); or reworking the economics underlying software development in the case of OSS (Zeitlyn, 2003). Much less has been done in critical areas pertaining to the new competitive game introduced by OSS; the sustainability of the OSS business model or models; the strategies for OSS licensing; the economic and business viability of OSS in light of potential challenges and opportunities; and the nascent national and government IT strategies centered on OSS; plus

a variety of other issues that are beyond the scope of this short article.

This article seeks to clarify the critical factors that will increasingly determine the success of OSS in becoming a mainstream choice for software procurement processes. Along with a definition of each of these factors, potential research avenues are indicated. However, these factors are not meant to be exhaustive in any fashion.

OSS: A BRIEF DEFINITION

The most basic definition of open source software is software for which the source code is distributed along with the executable program, and which includes a license allowing anyone to modify and redistribute the software.

Actual licenses for OSS vary between different companies and development projects, but they have certain characteristics in common. The Open Source Initiative, a group of developers who disseminate information on the benefits of open source (see www.opensource.org) has posted on its Web site a "meta-definition" of basic conditions they feel should be included in an OSS license. These include:

- Allowing free redistribution of the software without royalties or other fees to the author.
- Requiring that source code be distributed with the software or otherwise made available for no more than the cost of distribution.
- Allowing anyone to modify the software or derive other software from it, and to redistribute the modified software under the same license terms.
- Any software distributed under a license that conforms to these requirements is open-source software, according to the Open Source Initiative.

Although OSS solutions are increasingly available for an increasing number of business applications, it is very unlikely, however, that users are currently undertaking comparisons between alternative solutions. Nonetheless, it is a matter of time—and probably a short time—until open-source solutions become a must-consider item in software procurement decisions.

OPEN-SOURCE LICENSING

Many different types of OSS licenses are in use, almost as many as 50. The increasing number of license types under which open-source software is distributed could prove damaging to the overall development of OSS. Nonetheless, as a group OSS licenses could be clearly distinguished from conventional proprietary licenses. The latter are generally designed to take away the user freedom to share and change the software, which is the object of the license. By contrast, open-source licenses explicitly guarantee the freedom to share and change software without any permission from its original owner (Evers, 2000).

The General Public License (GPL; see www.opensource.org/licenses/gpl-license.html is the most important license, as key open-source software solutions are distributed under its terms; most notably, the Linux kernel (Evers, 2000). Not only does the GPL guarantee the freedom to share and change software, but it also requires that anything linked with the concerned software be distributed as free software, as well. This is known as the "virus" effect (Evers, 2000). A consequence of this is that any software developed based on the Linux Kernel, for example, has to be shared back with the open-source community, hence released under a GPL itself. This has had a very positive consequence on the development of Linux as a major player in the server open-source market and even as a potential contender to unsettle Windows desktop hegemony. Conversely, other operating systems distributed under open-source licenses

that do not require re-channeling changes, such as the BSD license, have led to dispersed programming efforts and even an appropriation of open-source code by proprietary vendors. Apple's latest version of its proprietary operating system (i.e., Mac OS X) is heavily based on Darwin, a code that is freely available under the BSD license.

One major research avenue would be to analyze the open-source strategies that proprietary vendors are currently undertaking and the opportunities offered by various licensing schemes to further such strategies. Such a study will survey the existing or potential open-source strategies of proprietary vendors and match them to appropriate licensing schemes, hence performing a competitive outlook of the OSS industry. The study would also cover the competitive alternatives, if any, of proprietary vendors that will not likely go the open-source way.

BUSINESS MODEL

When users acquire software through an open-source license, they truly become owners of the software, which means they inherit the right to modify it, share it, redistribute it and even resell it if they have made significant additions, which they can license themselves. Software in the open-source licensing model, hence, is treated like a commodity rather than intellectual property that has to be traced back to its original author. Indeed, major applications in open source and databases are in widespread use (i.e., mass market); the industry has settled on common standards, and new features are less important than price and performance, hence reducing the importance of the intellectual content of the software and turning it more into a commodity, just like what generic drugs have done for branded ones (Karp, 2003). Proprietary licensing restrictions would not allow any of this.

While the concept is appealing from an intellectual and maybe an ethical point of view, it raises questions about the sustainability of its business model (Zieger, 2003). As software is steadily turning into a commodity, will sales volume be enough to secure the survival and growth of OSS vendors, especially software that can be virtually replicated for free? How can OSS vendors make money from software that is essentially free and does not require much servicing, then?

Besides pinning down the business model for OSS, this line of research would analyze existing OSS business models, both successful and unsuccessful, and speculate on an industry structure for the OSS market in the long term.

SECURITY AND MARKET OPPORTUNITIES FOR OSS

OSS would be less susceptible to hackers than proprietary software. OSS transparency allegedly increases security because "back doors" used by hackers can be exposed and programmers can root out bugs from the code (The Economist Group, 2003). On the other hand, security, a top concern for software users, is increasingly proving to be the Achilles' wheel of proprietary software, and especially for Windows. A number of governments around the world are wary of repeated computer-virus attacks that target Microsoft's Windows operating system (Yamada, 2003). The latest attacks by the Blaster and SoBig viruses have indeed increased concerns about Windows security (The Economist Group, 2003).

At this level, one can investigate the magnitude of the security problem with proprietary software and the opportunities that OSS could present in this respect. Along with other factors such as cost, performance and service support among others, such a study could give a clear indication on the true potential of OSS in a particular market or region.

GOVERNMENT AND NATIONAL IT STRATEGIES

Security has yet another aspect that is important for government clients especially. They usually try to avoid relying on a single open source, vendor or center of operation. For instance, the ministry of interior in Germany justified the country's decision to adopt OSS by the need to raise the level of IT security by avoiding monocultures (Rajani, 2003). Likewise, the government of China has been working on a local version of Linux, on the grounds of self-sufficiency, security and to avoid being too dependent on a single foreign supplier (The Economist Group, 2003). OSS is being increasingly used in politics as an extension of nationalist discourses advocating national sovereignty, the right to access to knowledge and national security. The free software movement in Brazil, for example, has gained momentum since the Leftist Workers Party took office in January 2003 (Karp, 2004). The governments of Japan, China and South Korea will collaborate with major high-tech companies to develop open-source software products that will offer an alternative to the Windows operating system (Yamada, 2003). Already, 60 countries around the world are either considering or have passed legislation that encourages—or requires consideration—of free software. Even in the United States (U.S.), where proprietary software giants like Microsoft and Oracle yield massive lobbying power, the U.S. Congress has established an entity called the National Technology Alliance to give agencies guidance on how to contract with vendors using open source, and what kind of technology is available (Zieger, 2003).

Research is needed to determine the motives and configurations of national OSS strategies that have sprung up worldwide. Security is probably only one element of the equation, alongside cost, reducing the digital divide and so forth.

TOTAL COST OF OWNERSHIP (TCO)

Several studies have been done or are under way and have reported conflicting findings. Studies tend to favor those who paid for them (Maguire, 2003) and findings are generally disputed (Varghese, 2003).

TCO means the total amount of money that the decision of introducing new software costs, which can exceed the selling price of the software. Other cost factors include system preparation, including hardware and other necessary software; man-hours to handle the software installation, operation and maintenance; user training; updates; cost of migration to the new software, including any changes to business processes; and so forth (Evers, 2000). The general argument of proprietary software vendors is that the cost of software itself does not exceed 20% to 30% of the TCO, and even much less than that for organizations such as schools benefiting from special pricing schemes (Maguire, 2003b). Beyond that, the OSS show is allegedly dismal and carries a heavier cost than proprietary software. Unfortunately, no methodologically sound research is available to corroborate or deny such findings. Research is urgently needed to sift the debate on TCO and develop costing models for various contexts.

THE ETHICAL ARGUMENT

From an academic point of view, the ethical debate surrounding OSS is likely to revive the conventional and overheated debate of software piracy and its ethical connotation. The OSS model is indeed throwing the debate open about the legitimacy and even the ethics of restricting the "free flow of software." Many have questioned the proprietary model of software development and distribution and deemed it unethical (see www.netaction.org/msoft/world/). Microsoft and its allies have counter attacked and sought to discredit OSS,

likening its challenge of proprietary ownership to communism and suggesting that its openness makes it insecure and therefore vulnerable to terrorism (Fontana, 2003). Microsoft-supported lobby groups, such as the Initiative for Software Choice and the Business Software Alliance, have been staging major campaigns worldwide to confuse the public about the OSS phenomenon and have blocked legislation supporting the adoption of OSS by governments in different countries of the world (Adelstein, 2003).

The ethical argument extends beyond the issue of copying software, however. The City of Munich, for instance, did not wish to place the functioning of government in the hands of a commercial vendor with proprietary standards that is accountable to shareholders rather than to citizens (Fontana, 2003). Besides security, OSS seems to provide an alternative to governments not to lock their citizens onto the technology of one overpowering vendor. Bridging the digital divide, another ethical imperative for governments worldwide, seems to be more attainable with free software.

The issues are many and are worth debating. Research is first needed to delineate the most pressing items, lay out the stakes and unfold rational discourses to engage long-held and perhaps erroneous perceptions and beliefs. Deconstructing the classical argument underlying the ethics of software piracy should be a thrilling endeavor for any researcher.

CONCLUSION

This outline of a research agenda makes no claim of starting a new research stream that is well underway. It simply summarizes the author's newfound interest and perceptions of the issues surrounding the OSS phenomenon. In addition, many important avenues for research have not been indicated here, simply because the work is at its inception phases and is based on a limited number of readings in the area. This shall be expanded while issues are uncovered and more research is published. Finally, only business-related issues have been addressed; issues relating to software engineering, standards, architecture and so forth have been purposefully left out.

KEY TERMS

Linux Kernel: Basic programming code for the Linux operating system.

Linux: Open source operating system.

Open Source Community: Community of developers that interact virtually to write code collaboratively.

Open Source Initiative: Group of developers who disseminate information on the benefits of open source.

Open Source License: Guarantees the freedom to share and change software without any permission from its original owner.

Open Source Software (OSS): Software for wish the source code is distributed along with the executable program.

Proprietary Software: Its source code is not available.

Source Code: Programming code prior to execution.

TCO: Total Cost of Ownership (TCO): The total amount of money that the decision of introducing new software costs.

Chapter 1.5
Open Source Software:
Strengths and Weaknesses

ABSTRACT

The philosophy underlying open source software (OSS) is enabling programmers to freely access the software source by distributing the software source code, thus allowing them to use the software for any purpose, to adapt and modify it, and redistribute the original or the modified source for further use, modification, and redistribution. The modifications, which include fixing bugs and improving the source, evolve the software. This evolutionary process can produce better software than the traditional proprietary software, in which the source is open only to a very few programmers and is closed to everybody else who blindly use it but cannot change or modify it. The idea of open source software arose about 20 years ago and in recent years is breaking out into the educational, commercial, and governmental world. It offers many opportunities when implemented appropriately. The chapter will present a detailed definition of open source software, its philosophy, its operating principles and rules, and its strengths and weaknesses in comparison to proprietary software. A better understanding of the philosophy underlying open source software will motivate programmers to utilize the opportunities it offers and implement it appropriately.

INTRODUCTION

Open source software (OSS) has attracted substantial attention in recent years and continues to grow and evolve. The philosophy underlying OSS is to allow users free access to, and use of, software source code, which can then be adapted, modified, and redistributed in its original or modified form for further use, modification, and redistribution. OSS is a revolutionary software development methodology (Eunice, 1998) that involves developers in many locations throughout

the world who share code in order to develop and refine programs. They fix bugs, adapt and improve the program, and then redistribute the software, which thus evolves. Advocates of OSS are quick to point to the superiority of this approach to software development. Some well-established software development companies, however, view OSS as a threat (AlMarzouq, Zheng, Rong, & Grover, 2005).

Both the quality and scope of OSS are growing at an increasing rate. There are already free alternatives to many of the basic software tools, utilities, and applications, for example, the free Linux operating system (Linux Online, 2006), the Apache Web server (Apache Software Foundation, 2006; Mockus, Fielding, & Herbsleb, 2000), and the Sendmail mail server (Sendmail Consortium, 2006). With the constant improvement of OSS packages, there are research projects, even complex ones, that entirely rely on OSS (Zaritski, 2003). This opens new research and educational opportunities for installations and organizations with low software budgets.

Incremental development and the continuity of projects over long periods of time are distinctive features of OSS development. The software development processes of large OSS projects are diverse in their form and practice. Some OSS begins with releasing a minimal functional code that is distributed for further additions, modification, and improvement by other developers, as well as by its original authors, based on feedback from other developers and users. However, open source projects do not usually start from scratch (Lerner & Tirole, 2001). The most successful OSS projects, like Linux and Apache, are largely based on software provided by academic and research institutions. In recent years, more and more OSS has been derived from original software provided by for-profit companies.

A large potential-user community is not enough to make an OSS project successful. It requires dedicated developers. In Raymond's (1998) words, "The best OSS projects are those that scratch the itch of those who know how to code." For example, the very successful Linux project attracted developers who had a direct interest in improving an operating system for their own use. Similarly, webmaster developers contributed to the development of the Apache Web server project.

Despite the characterization of the OSS approach as ad hoc and chaotic, OSS projects appear, in many cases, to be highly organized, with tool support that focuses on enhancing human collaboration, creativity, skill, and learning (Lawrie & Gacek, 2002). The good initial structural design of an OSS project is the key to its success. A well-modularized design allows contributors to carve off chunks on which they can work. In addition, the adoption of utility tools and the use of already existing OSS components are necessary if an OSS project is to succeed.

The growing interest of commercial organizations in developing and exploiting OSS has led to an increased research focus on the business-model aspects of the OSS phenomenon. There are a number of business models for OSS, all of which assume the absence of traditional software licensing fees (Hecker, 2000). The economics of OSS projects is different from that of proprietary projects (Lerner & Tirole, 2002). Models of effort and cost estimation in the development of projects involving OSS are needed (Asundi, 2005).

In the past, most OSS applications were not sufficiently user friendly and intuitive, and only very knowledgeable users could adapt the software to their needs. Although the use of OSS is growing, OSS is still mainly used by technically sophisticated users, and the majority of average computer users use standard commercial proprietary software (Lerner & Tirole, 2002). The characteristics of open source development influence OSS usability (Behlendorf, 1999; Nichols, Thomson, & Yeates, 2001; Raymond, 1999), which is often regarded as one of the reasons for its limited use. In recent years, the open source community has shown increased awareness of

usability issues (Frishberg, Dirks, Benson, Nickell, & Smith, 2002). Existing human-computer interface (HCI) techniques and usability improvement methods appropriate for community-based software development on the Internet can be used to leverage distributed networked communities to address issues of usability (Nichols & Twidale, 2003). Some OSS applications, such as the Mozilla Web browser (Mozilla, 2006; Reis & Fortes, 2002) and OpenOffice (OpenOffice, 2006), have made important advances in usability and have become available for both Windows and Linux users.

As the stability and security of open source products increase, more organizations seem to be adopting OSS at a faster rate. There are many open source community resources and services online. When implemented appropriately, OSS offers extensive opportunities for government, private-sector, and educational institutions. OSS appears to be playing a significant role in the acquisition and development plans of the U.S. Department of Defense and of industry (Hissam, Weinstock, Plakosh, & Asundi, 2001).

For many organizations, integrating the revolutionary OSS developmental process into traditional software development methods may have a profound effect on existing software development and management methodologies and activities.

The remainder of this chapter will review the history of OSS and define some key terms and concepts. It will discuss the incentives to engage in OSS and its strengths and weakness. Finally, it will review some OSS business models.

BACKGROUND

Software source code that is open has been around in academic and research institute settings from the earliest days of computing. Feller and Fitzgerald (2002) provide a detailed historical background to open source since the 1940s. The source code of programs developed in universities, mainly as learning and research tools, was freely passed around. Many of the key aspects of computer operating systems were developed as open source during the 1960s and 1970s in academic settings, such as Berkeley and MIT, as well as in research institutes, such as Bell Labs and Xerox's Palo Alto Research Center, at a time when sharing source code was widespread (Lerner & Tirole, 2002).

The free software (FS) movement began in the 1980s in academic and research institutes. The Free Software Foundation (FSF) was established by Richard Stallman of the MIT Artificial Intelligence Laboratory in 1984. The basic idea underlying the foundation was to facilitate the development and free dissemination of software. It is important to note that free in this case relates not to price, but to freedom of use. The developers of the Linux operating system bought in to the FS concept. Linux, initiated by Linus Tovalds in 1991, was the first tangible achievement of the FS movement (Stallman, 1999). This successful operating system has, through the collaboration of the global FS community, grown into the second most widely used server operating system.

The OSS movement evolved from the FSF during the 1990s. OSS has more flexible licensing criteria than the FSF. The widespread use of the Internet led to acceleration in open source activities. Numerous open source projects emerged, and interaction between commercial companies and the open source community became commonplace. Unlike the FS community, the OSS movement does not view itself as a solution for proprietary software, but rather as an alternative to it (Asiri, 2003). This has led to the acceptance of selective open sourcing, in which companies may elect to make specific components of the source code, rather than the entire code, publicly available, an approach which appeals to the business community. This allows companies to package available OSS products with other applications and extensions, and sell these to customers. Profit can also be made on the exclusive support pro-

vided with the retail packages, which may include manuals, software utilities, and support help lines. For example, Red Hat Software (Red Hat, 2006), the leading provider of the Linux-based operating system, founded in 1995, based its business model on providing Linux software for free and selling extras such as support, documentation, and utilities, making it easy for users to install and use the software.

Definitions: FS and OSS

According to the FSF, FS involves users' freedom to run, copy, distribute, study, change, and improve software. The FSF defined four kinds of freedom for software users (Free Software Foundation, 2006).

1. The freedom to run the program for any purpose
2. The freedom to study how the program works, and adapt it to one's needs; access to the source code is a precondition for this
3. The freedom to redistribute copies so one can help a neighbor
4. The freedom to improve the program and release improvements to the public so that the whole community benefits; access to the source code is a precondition for this

The FSF recommends the GNU (a Unix-compatible operating system developed by the FSF) General Public License (GPL; Free Software Foundation, 1991) to prevent the GNU operating system software from being turned into proprietary software. This involves the use of "copyleft," which Stallman (1999) defines as follows:

The central idea of copyleft is that we give everyone permission to run the program, copy the program, modify the program, and distribute modified versions—but not permission to add restrictions of their own. Thus, the crucial freedoms that define "free software" are guaranteed to everyone who has a copy; they become inalienable rights.

The GPL permits the redistribution and reuse of source code for unfettered use and access as long as any modifications are also available in the source code and subject to the same license.

The term OSS was adopted in large part because of the ambiguous nature of the term FS (Johnson, 2001). On the most basic level, OSS simply means software for which the source code is open and available (Hissam et al., 2001), and that anyone can freely redistribute, analyze, and modify while complying with certain criteria (AlMarzouq et al., 2005). However, OSS does not just mean access to source code. For a program to be OSS, a set of distribution terms must apply.

A comprehensive Open Source Definition (OSD) was published by the Open Source Initiative (OSI). The OSD differentiates itself from FS by allowing the use of licenses that do not necessarily provide all the freedoms granted by the GPL. According to the updated version of the OSD (1.9), the distribution terms of OSS must comply with all 10 of the following criteria (Open Source Initiative, 2005).

1. **Free redistribution:** The license shall not restrict any party from selling or giving away the software as a component of an aggregate software distribution containing programs from several different sources. The license shall not require a royalty or other fee for such sale.
2. **Source code:** The program must include source code, and must allow distribution in source code as well as compiled form. Where some form of a product is not distributed with source code, there must be a well-publicized means of obtaining the source code for no more than a reasonable reproduction cost—preferably, downloading via the Internet without charge. The source code must be the preferred form in which a programmer would modify the program. Deliberately obfuscated source code is not allowed. Intermediate forms such as the

output of a preprocessor or translator are not allowed.

3. **Derived works:** The license must allow modifications and derived works, and must allow them to be distributed under the same terms as the license of the original software.
4. **Integrity of the author's source code:** The license may restrict source code from being distributed in modified form only if the license allows the distribution of patch files with the source code for the purpose of modifying the program at build time. The license must explicitly permit distribution of software built from modified source code. The license may require derived works to carry a different name or version number from the original software.
5. **No discrimination against persons or groups:** The license must not discriminate against any person or group of persons.
6. **No discrimination against fields of endeavor:** The license must not restrict anyone from making use of the program in a specific field of endeavor. For example, it may not restrict the program from being used in a business, or from being used for genetic research.
7. **Distribution of license:** The rights attached to the program must apply to all to whom the program is redistributed without the need for execution of an additional license by those parties.
8. **License must not be specific to a product:** The rights attached to the program must not depend on the program's being part of a particular software distribution. If the program is extracted from that distribution and used or distributed within the terms of the program's license, all parties to whom the program is redistributed should have the same rights as those that are granted in conjunction with the original software distribution.
9. **License must not restrict other software:** The license must not place restrictions on other software that is distributed along with the licensed software. For example, the license must not insist that all other programs distributed on the same medium must be open source software.
10. **License must be technology neutral:** No provision of the license may be predicated on any individual technology or style of interface.

Although there are some differences in the definitions of OSS and FS, the terms are often used interchangeably. Neither OSS nor FS pertains to the source code and its quality, but rather to the rights that a software license must grant. Various licensing agreements have been developed to formalize distribution terms (Hecker, 2000). Open source licenses define the privileges and restrictions a licensor must follow in order to use, modify, or redistribute the open source software. OSS includes software with source code in the public domain and software distributed under an open source license. Examples of open source licenses include the Apache license, Berkeley Source Distribution (BSD) License, GNU GPL, GNU Lesser General Public License (LGPL), MIT License, Eclipse Public License (EPL), Mozilla Public License (MPL), and Netscape Public License (NPL).

Table 1 provides a comparison of several common licensing practices described in Perens (1999).

The OSI has established a legal certification for OSS, called the OSI certification mark (Open Source Initiative, 2006b). Software that is distributed under an OSI-approved license can be labeled "OSI Certified."

Incentives to Engage in OSS

A growing body of literature addresses the motives for participation in OSS projects. Lerner and Tirole

Table 1. Comparison of licensing practices (Source: Perens, 1999)

License	Can be mixed with non-free software	Modifications can be made private and not returned	Can be relicensed by anyone	Contains special privileges for the original copyright holder over others' modifications
GPL				
LGPL	X			
BSD	X	X		
NPL	X	X		X
MPL	X	X		
Public Domain	X	X	X	

(2001) describe incentives for programmers and software vendors to engage in such projects:

Programmers' Incentives

- Programmers are motivated by a desire for peer recognition. Open source programmers' contributions are publicly recognized. By participating in an OSS project, programmers signal their professional abilities to the public.
- Programmers feel a duty to contribute to a community that has provided a useful piece of code.
- Some programmers are motivated by pure altruism.
- Some sophisticated OSS programmers enjoy fixing bugs, working on challenging problems, and enhancing programs.
- OSS is attractive to computer science students who wish to enter the market as programmers in higher positions.

Software Vendors' Incentives

- Vendors make money on OSS complementary services such as documentation, installation software, and utilities.
- By allowing their programmers to get involved in OSS projects, vendors keep abreast of open source developments, which allows them to better know the competition.
- Vendors benefit from efficient use of global knowledge. Many companies can collaborate on a product that none of them could achieve alone.

MAIN FOCUS OF THE CHAPTER

OSS Strengths and Weaknesses

OSS has a number of strengths and weaknesses compared to traditional proprietary software.

Strengths

The strengths of OSS can be classified into five main categories: freedom of use; evolution of software; time, cost, and effort; quality of software; and advantages to companies and programmers.

Freedom of Use

- It allows free access to the software source code for use, modification, and redistribution in its original or modified form for further use, modification, and redistribution.
- OSS users have fundamental control and flexibility advantages by being able to modify and maintain their own software to their liking (Wheeler, 2005).

- OSS allows independence from a sole source company or vendor. It provides users with the flexibility and freedom to change between different software packages, platforms, and vendors, while secret proprietary standards lock users into using software from only one vendor and leave them at the mercy of the vendor at a later stage (Wong & Sayo, 2004).
- It eliminates support and other problems if a software vendor goes out of business.
- It prevents a situation in which certain companies dominate the computer industry.
- Users can get free upgrade versions of the software, switch software versions, and fix and improve software (Perens, 1999).

Evolution of Software

- OSS contributes to software evolution due to the parallel process of many developers being simultaneously involved rather than a single software team in a commercial proprietary software company (Feller & Fitzgerald, 2002).
- It enables programmers all over the world to fix bugs.
- It evolves continuously over time as opposed to proprietary software whose development takes place in a series of discrete releases under the control of the authors.
- OSS represents a viable source of components for reuse and to build systems.

Time, Cost, and Effort

- It involves a joint effort by contributors from countries all over the world, collaborating via the Internet.
- There is a lower cost of software development in comparison to proprietary software.
- Open source initiatives allow software to be developed far more quickly and permits bugs to be identified sooner.
- The OSS approach is not subject to the same level of negative external process constraints of time and budget that can often undermine the development of dependable systems within an organizational setting (Lawrie & Gacek, 2002).
- OSS reduces the cost of using the software as the licensing is not limited compared to the limited licensing of proprietary software. The licensing cost, if any, is low, and most OSS distributions can be obtained at no charge. On a licensing cost basis, OSS applications are almost always much cheaper than proprietary software (Wong & Sayo, 2004). Open source products can save not-for-profit organizations, such as universities and libraries, a lot of money.
- It reduces development time, cost, and effort by reusing and building on existing open source code.
- It reduces maintenance and enhancement costs by sharing maintenance and enhancements among potential users of the same software application.

Quality of Software

- OSS reduces the number of bugs and enhances software quality by using the feedback of many users around the world and other qualified developers who examine the source code and fix the bugs.
- OSS is under constant peer review by developers around the world. Linus' law states the following: "Given enough eyeballs, all bugs are shallow" (Raymond, 1998).
- Programmers, knowing in advance that others will see the code they write, will be more likely to write the best code they can possibly write (Raymond, 1998).
- Security vulnerabilities are more quickly solved when found in OSS than in proprietary software (Reinke & Saiedian, 2003).

- OSS represents an alternative approach to distributed software development able to offer useful information about common problems as well as possible solutions (Johnson, 2001).

Advantages to Companies and Programmers

- There is an efficient use of global knowledge.
- Programmers learn from existing source code how to solve similar problems.
- Students, especially computer science students, can gain excellent programming experience and make contributions to open source software by becoming involved in open source projects (Zaritski, 2003).
- OSS allows groups of companies to collaborate in solving the same problem.
- Companies gain leverage from developers who contribute free improvements to their software.
- Companies using OSS benefit from its very rapid development, often by several collaborating companies, much of it contributed by individuals who simply need an improvement to serve their own needs (Perens, 1999).

Weaknesses

OSS weaknesses are mainly related to management, quality, and security.

Management

- Given the difficulty in managing resources in closed source proprietary software projects, planning and delivering projects based on an open source community can be a much bigger challenge (Asundi, 2005). The separation between distributed developers creates difficulties in coordination and collaboration (Belanger & Collins, 1998; Carmel & Agarwal, 2001).
- Some OSS projects are developed without concern for the process of accepting or rejecting changes to the software.
- Resource allocation and budgeting are more complex than in proprietary software projects.
- There is higher fluidity in the membership of the development team. OSS developers are not bound to projects by employment relationships and therefore may come and go more often (Stewart, Darcy, & Daniel, 2005).
- Existing effort and cost models for proprietary projects are inadequate for OSS projects, and there is a need to develop new models.
- Commercial proprietary projects generate income and thus enable companies to hire high-quality and motivated programmers. This is not the case in open source projects.

Quality and Security

- OSS programmers are not always enthusiastic about providing and writing documentation, therefore some OSS have inadequate documentation, far below commercial standards.
- Some OSS applications are not sufficiently intuitive and user friendly, and are thus accessible only to very knowledgeable users.
- It appears that there is sometimes a race among many current OSS projects, which often results in rapid releases with the software consequently containing many bugs (Hissam et al., 2001).
- The OSS movement has made the life of cyberterrorists somewhat easier. Since the source code is open and available, cyberterrorists can learn about vulnerabilities in both OSS and proprietary closed source software

(CSS) products. The knowledge that some components of CSS are descendants of similar OSS components, or share the same root code base or the same architecture, design, or specification provides clues as to what attacks could be possible against such software (Hissam et al., 2001).

- There is less variety of applications as compared to proprietary applications.

OSS Business Models

The open source model has a lot to offer the business world. For a company considering adopting an open source strategy, open source needs to be evaluated from a business point of view. It requires being clear on the advantages and disadvantages of open source relative to the traditional proprietary model. There are a number of business models for OSS, all of which assume the absence of traditional software licensing fees. As published by the Open Source Initiative (2006a), there are at least four known business models based on OSS.

1. **Support sellers:** In this model, the software product is effectively given away, but distribution, branding, and after-sales service are sold. This is the model followed by, for example, Red Hat (2006).
2. **Loss leader:** The open source is given away as a loss leader and market positioner for closed software. This is the model followed by Netscape.
3. **Widget frosting:** In this model, a hardware company (for which software is a necessary adjunct but strictly a cost rather than profit center) goes open source in order to get better drivers and cheaper interface tools. Silicon Graphics, for example, supports and ships Samba (2006).
4. **Accessorizing:** This involves selling accessories such as books, compatible hardware, and complete systems with open source software preinstalled. It is easy to trivialize this (open source T-shirts, coffee mugs, Linux penguin dolls), but at least the books and hardware underlie some clear successes: O'Reilly Associates, SSC, and VA Research are among the companies using this model.

So far, the exemplars of commercial success have been service sellers or loss leaders. Nevertheless, there is good reason to believe that the clearest near-term gains in open source will be in widget frosting. For widget makers (such as semiconductor or peripheral-card manufacturers), interface software is not even potentially a revenue source. Therefore, the downside of moving to open source is minimal. (Hecker, 2000, proposes more models potentially usable by companies creating or leveraging OSS products.)

CONCLUSION

OSS is an alternative method of development that makes efficient use of global knowledge. It has captured the attention of academics, software practitioners, and the entire software community. Some OSS products have proven to be as reliable and secure as similar commercial products, and are a viable source of components from which to build OSS and CSS systems. Unfortunately, through OSS products, cyberterrorists also gain additional information about these components and discover vulnerabilities in products based on them.

There are a number of business models for OSS. Software development companies are beginning to support OSS-style development. They tend to try to profit through providing additional value to OSS products, such as value-added software, professional documentation, packaging, and support.

Both the quality and scope of OSS are growing at an increasing rate and there are already free alternatives to many of the fundamental software

tools, utilities, and applications that are able to compete with traditional proprietary software. However, there is still controversy about whether OSS is faster, better, and cheaper than proprietary software. Adopters of OSS should not enter the realm blindly and should know its benefits and pitfalls. Further empirical and theoretical research is needed on developing and managing OSS projects. Identifying and explicitly modeling OSS development processes in forms that can be shared, modified, and redistributed appears to be an important topic for future investigation (Jensen & Scacchi, 2005). The open development process can provide a suitable environment for investigation of software development processes.

LIST OF ACRONYMS

BSD: Berkeley Source Distribution
CSS: Closed source software
FS: Free software
FSF: Free Software Foundation
GNU: GNU Not Unix (recursive acronym)
GPL: General Public License
LGPL: Lesser General Public License
MPL: Mozilla Public License
NPL: Netscape Public License
OSD: Open Source Definition
OSI: Open Source Initiative
OSS: Open source software

KEY TERMS

Closed Source Software (CSS): Non-OSS for which the source code is not available and not open. It is closed to modification and distribution by licenses that explicitly forbid it. The term CSS is typically used to contrast OSS with proprietary software.

Copyleft: Permission for everyone to run, copy, and modify the program, and to distribute modified versions, but no permission to add restrictions of one's own.

Free Software (FS): Free relates to liberty and not to price. It is similar to OSS but differs in the scope of the license. FS does not accept selective open sourcing in which companies may elect to make publicly available specific components of the source code instead of the entire code.

General Public License (GPL): License that permits the redistribution and reuse of source code for unfettered use and access as long as any modifications are also available in the source code and subject to the same license.

Open Source Software (OSS): Software for which the source code is open and available. Its licenses give users the freedom to access and use the source code for any purpose, to adapt and modify it, and to redistribute the original or the modified source code for further use, modification, and redistribution.

Proprietary Software (PS): Software produced and owned by individuals or companies, usually with no provision to users to access to the source code, and licensed to users under restricted licenses in which the software cannot be redistributed to other users. Some proprietary software comes with source code—users are free to use and modify the software, but are restricted by licenses to redistribute modifications or simply share the software.

Source Code: The original human-readable version of a program, written in a particular programming language. In order to run the program, the source code is compiled into object code, a machine-readable binary form.

This work was previously published in Handbook of Research on Open Source Software: Technological, Economic, and Social Perspectives, edited by K. St.Amant and B. Still, pp. 184-196, copyright 2007 by Information Science Reference (an imprint of IGI Global).

Chapter 1.6
Open Source Software Evaluation

Karin van den Berg
FreelancePHP, The Netherlands

ABSTRACT

If a person or corporation decides to use open source software for a certain purpose, nowadays the choice in software is large and still growing. In order to choose the right software package for the intended purpose, one will need to have insight and evaluate the software package choices. This chapter provides an insight into open source software and its development to those who wish to evaluate it. Using existing literature on open source software evaluation, a list of nine evaluation criteria is derived including community, security, license, and documentation. In the second section, these criteria and their relevance for open source software evaluation are explained. Finally, the future of open source software evaluation is discussed.

INTRODUCTION

The open source software market is growing. Corporations large and small are investing in open source software. With this growth comes a need to evaluate this software. Enterprises need something substantial to base their decisions on when selecting a product. More and more literature is being written on the subject, and more will be written in the near future.

This chapter gives an overview of the available open source evaluation models and articles, which is compounded in a list of unique characteristics of open source. These characteristics can be used when evaluating this type of software. For a more in-depth review of this literature and the characteristics, as well as a case study using this information, see van den Berg (2005).

OPEN SOURCE SOFTWARE EVALUATION LITERATURE

The name already tells us something. Open source software is open—not only free to use but free to change. Developers are encouraged to participate in the software's community. Because of this unique process, the openness of it all, there is

far more information available on an open source software package and its development process. This information can be used to get a well-rounded impression of the software. In this chapter we will see how this can be done.

Though the concept of open source (or free software) is hardly new, the software has only in recent years reached the general commercial and private user. The concept of open source evaluation is therefore still rather new. There are a few articles and models on the subject, however, which we will introduce here and discuss more thoroughly in the next section.

Open Source Maturity Models

Two maturity models have been developed specifically for open source software.

The first is the Capgemini Expert Letter open source maturity model (Duijnhouwer & Widdows, 2003). The model "allows you to determine if or which open source product is suitable using just seven clear steps." Duijnhouwer and Widdows first explain the usefulness of a maturity model, then discuss open source product indicators and use these in the model. The model steps start with product research and rough selection, then uses the product indicators to score the product and determine the importance of the indicators, combining these to make scorecards. Finally it ends with evaluation.

Second, there is the Navica open source maturity model, which is used in the book *Succeeding with Open Source* (Golden, 2005). This model uses six product elements in three phases: assessing element maturity, assigning weight factors, and calculating the product maturity score.

Open Source Software Evaluation Articles

Aside from the two models, a number of articles on open source software evaluation have been written.

Crowston et al. (2003) and Crowston, Annabi, Howison, and Masango (2004) have published articles in the process of researching open source software success factors. In these articles, they attempt to determine which factors contribute to the success of open source software packages.

Wheeler's (n.d.) *How to Evaluate Open Source/Free Software (OSS/FS) Programs* defines a number of criteria to use in the evaluation of open source software, as well as a description of the recommended process of evaluation. Wheeler continues to update this online article to include relevant new information.

Another article defining evaluation criteria for open source software is *Ten Rules for Evaluating Open Source Software* (Donham, 2004). This is a point-of-view paper from Collaborative Consulting, providing 10 guidelines for evaluating open source software.

Finally, Nijdam (2003), in a Dutch article entitled "Vijf Adviezen voor Selectie van OSS-Componenten" ("Five Recommendations for Selection of OSS Components"), gives recommendations based on his own experience with selecting an open source system.

Literature Summary

Table 1 summarizes the criteria derived from the literature mentioned in the previous two sections and how they are discussed.

EVALUATING OPEN SOURCE SOFTWARE

The open source software market is in some ways very different from the traditional software market. One of the differences is that there is an abundance of information available concerning the software and its development process that is in most cases not available for traditional software.

The evaluation of traditional software is usually focused on the functionality and license cost of the software. In the open source world, the

Table 1.

Criterion	Duijnhouwer and Widdows (2003)	Golden (2005)	Crowston et al. (2004)	Wheeler, (2005)	Donham (2004)	Nijdam (2003)

Security	Y	In risk	-	Y	Y	-
Functionality	Features in time	Y	-	Y	Y	Y
Integration	Y	Y	-	In functionality	In infrastructure	-

evaluation includes information from a number of other resources, giving a well-rounded picture of the software, its development, and its future prospects.

Using the existing evaluation models and articles discussed in the previous section, an overview is given here of the characteristics of open source software relevant to software evaluation and the information available on an open source software project concerning these characteristics.

Community

According to Golden (2005, p. 21), "One of the most important aspects of open source is the community."

The user community for most open source projects is the largest resource available. The community provides developers, user feedback, and ideas, and drives the project team. An active community helps the project move forward. It also shows the level of interest in the project, which can provide a measurement of quality and compliance with user requirements. A well-provided-for community also shows the team's interest in the user, allows the user to participate, and gives voice to the user's wishes and requirements.

The user community of an open source project consists of the people that use the software and participate in some way, from answering user questions to reporting bugs and feature requests. Users in the community sometimes cross the line into the developer community, which is often a line made very thin by encouraging participation and making the developer community accessible to anyone who is interested. In some cases, the user and developer community interact fully in the same discussion areas.

The community of an open source project is very important because it is the community that does most of the testing and provides quality feedback. Instead of using financial resources to put the software through extensive testing and quality assurance (QA), like a proprietary vendor will do, the open source projects have the community as a resource. The more people that are interested in a project, the more likely it is that it will be active and keep going. A large and active community says something about the acceptance of the software. If the software was not good enough to use, there would not be so many people who cared about its development (Duijnhouwer & Widdows, 2003).

The community is mostly visible in terms of the following (Crowston et al., 2004; Duijnhouwer & Widdows, 2003; Golden, 2005; Nijdam, 2003):

- **Posts:** Number of posts per period and number of topics
- **Users:** Number of users and the user-developer ratio in terms of the number of people and number of posts; if only users post, the developers are not as involved as they should be
- **Response time:** If and how soon user questions are answered
- **Quality:** The quality of posts and replies; are questions answered to the point, and are the answers very short or more elaborate? Is there much discussion about changes and feature additions?
- **Friendliness:** How friendly members are toward each other, especially to newcomers, also known as "newbies"; the community should have an open feel to it, encouraging people to participate

The depth of conversations, as mentioned in the fourth item, gives a good impression of how involved the community is with the ongoing development of the project. Much discussion about the software, in a friendly and constructive manner, encourages the developers to enhance the software further. The community activity is also reflected in other areas such as support and documentation.

Release Activity

The activity level of a project consists of the community activity and the development activity. The community was discussed above. The development activity is reflected in two parts:

- The developer's participation in the community
- The development itself—writing or changing the source code

The latter activity is visible mostly in the release activity. All software projects release new versions after a period of time. The number of releases per period and their significance, meaning how large the changes are per release (i.e., are there feature additions or just bug fixes in the release), illustrates the progress made by the developers. This gives a good indication of how seriously the developers are working on the software.

The open source repositories SourceForge[1] and FreshMeat[2], where project members can

share files with the public, provide information that could be useful to evaluate the release activity (Wheeler, n.d.).

An open source project often has different types of releases:

- **Stable releases:** These are the most important type for the end user. They are the versions of software that are deemed suitable for production use with minimal risk of failure.
- **Development versions:** These can have different forms, such as beta, daily builds, or CVS (Concurrent Version System) versions, each more up to date with the latest changes. These versions are usually said to be used "at your own risk" and are not meant for production use because there is a higher possibility of errors. A project that releases new versions of software usually publishes release notes along with the download that list all the changes made in the software since the previous release. Other than the release notes, the project might also have a road map, which usually shows what goals the developers have, how much of these goals are completed, and when the deadline or estimated delivery date is for each goal. Checking how the developers keep up with

this road map shows something about how well the development team can keep to a schedule.

Though a project might stabilise over time as it is completed, no project should be completely static. It is important that it is maintained and will remain maintained in the future (Wheeler, n.d.).

The project's change log can give the following information (Chavan, 2005):

- **The number of releases made per period of time:** Most projects will make several releases in a year, sometimes once or twice a month. A year is usually a good period in which to count the releases.
- **The significance of each release:** The change log or release notes explain what has changed in the release. These descriptions are sometimes very elaborate, where every little detail is described, and sometimes very short, where just large changes are listed. A good distinction to make is whether the release only contains bug fixes or also contains enhancements to features or completely new features. One thing to keep in mind here is that fewer, more significant releases is in most cases better than a large number of less significant releases leading to the same amount of change over time since the users will have to upgrade to new versions each time a release is made, which is not very user friendly. There should be a good balance between the number of releases and the releases' significance. If the project is listed on SourceForge and/or FreshMeat, some of the release activity information is available there.

Longevity

The longevity of a product is a measure of how long it has been around. It says something about a project's stability and chance of survival. A project that is just starting is usually still full of bugs (Golden, 2005). The older a project, the less likely the developers will suddenly stop (Duijnhouwer & Widdows, 2003). However, age is not always a guarantee of survival. First of all, very old software may be stuck on old technologies and methods, from which the only escape is to completely start over. Some software has already successfully gone through such a cycle, which is a good sign in terms of maturity. One thing that needs to be taken into account when products are not very young is whether or not there is still an active community around it.

The age and activity level of a project are often related. Young projects often have a higher activity level than older ones because once a project has stabilised and is satisfactory to most users, the discussions are less frequent and releases are smaller, containing mostly bug and security fixes. This does not mean that the activity should ever be slim to none. As mentioned before, no project is ever static (Wheeler, n.d.). There is always something that still needs to be done.

Longevity is checked using the following criteria (Golden, 2005; Nijdam, 2003):

- **Age of the product:** The date of the first release
- **Version number:** A 0.x number usually means the developers do not think the software is complete or ready for production use at this time.

If the project is very old, it is worthwhile to check if it has gone through a cycle of redesign, or if it is currently having problems with new technology.

Keep in mind that the version number does not always tell the whole story. Some projects might go from 1.0 to 2.0 with the same amount of change that another project has to go from 1.0 to 1.1. The fast progression of the version number might be used to create a false sense of progress.

Other software products are still in a 0.x version even after a long time and after they are proved suitable for production use (Nijdam, 2003).

License

The licenses in the open source world reflect something of the culture. The most important term in this context is "copyleft," introduced by Richard Stallman, which means that the copyright is used to ensure free software and free derivative works based on the software (Weber, 2004). In essence, a copyleft license obligates anyone who redistributes software under that license in any way or form to also keep the code and any derivative code under the license, thus making any derivatives open source as well.

The most well-known example of a copyleft license is the GNU GPL (General Public License; Weber, 2004). This is also one of the most used licenses. On SourceForge, a large open source public repository where over 62,000 projects reside, almost 70%[3] of projects use the GNU GPL as their license. There are some large and well-known products that do not use SourceForge, and some of these have their own license, such as Apache, PHP, and Mozilla (Open Source Initiative [OSI], 2005).

Because copyleft in the GNU GPL is very strong, an additional version was made called the LGPL (library GPL, also known as lesser GPL), which is less restrictive in its copyleft statements, allowing libraries to be used in other applications without the need to distribute the source code (Weber).

A non-copyleft license that is much heard of is the BSD (Berkeley source distribution) license. It has been the subject of much controversy and has had different versions because of that. Components that are licensed under the BSD are used in several commercial software applications, among which are Microsoft products and Mac OS X (Wikipedia, 2005a). The license of the software in use can have unwanted consequences depending on the goal of the use. If the user plans to alter and redistribute the software in some way but does not want to distribute the source code, a copyleft license is not suitable. In most cases, however, the user will probably just want to use the software, perhaps alter it to the environment somewhat, but not sell it. In that case, the license itself should at least be OSI approved and preferably well known. The license should fit with the intended software use.

As just mentioned, the license should preferably be an OSI-approved license. If it uses one of the public licenses, the better known the license, the more can be found on its use and potential issues (Wheeler, n.d.).

Support

There are two types of support for a software product:

- **Usage support:** The answering of questions on the installation and use of the software
- **Failure support or maintenance:** The solving of problems in the software

Often, the two get mixed at some level because users do not always know the right way to use the product. Their support request will start as a problem report and later becomes part of usage support (Golden, 2005).

The way support is handled is a measure of how seriously the developers work on the software (Duijnhouwer & Widdows, 2003). One way to check this is to see if there is a separate bug tracker[4] for the software and how actively it is being used by both the developers and the users. When the developers use it but hardly any users seem to participate, the users may not be pointed in the right direction to report problems. Aside from community support, larger or more popular projects may have paid support options. The software is free to use, but the user has the option to get professional support for a fee, either on a

service-agreement basis where a subscription fee is paid for a certain period of time, or a per-incident fee for each time the user calls on support. The project leaders themselves may offer something like this, which is the case for the very popular open source database server MySQL (2005).

There are companies that offer specialised support for certain open source software. This is called third-party support. For example, at the Mozilla support Web page, it can be seen that DecisionOne offers paid support for Mozilla's popular Web browser FireFox, the e-mail client Thunderbird, and the Mozilla Suite (Mozilla, 2005). The fact that paid support exists for an open source product, especially third-party support, is a sign of maturity and a sign the product is taken seriously.

Support for open source software is in most cases handled by the community. The community's support areas are invaluable resources for solving problems (Golden, 2005). Mature products often have paid support options as well if more help or the security of a support contract is required.

Community Support

The usage support is usually found in the community. Things to look for include the following (Golden, 2005):

- Does the program have a separate forum or group for asking installation- and usage-related questions?
- How active is this forum?
- Are developers participating?
- Are questions answered adequately?
- Is there adequate documentation (see the documentation section)?

Responses to questions should be to the point and the responders friendly and helpful. In the process of evaluating software, the evaluator will probably be able to post a question. Try to keep to the etiquette, where the most important rule is to search for a possible answer on the forum before posting a question and to given enough relevant information for others to reproduce the problem (Golden, 2005; Wheeler, n.d.).

The way the community is organised influences the community support's effectiveness. A large project should have multiple areas for each part of the project, but the areas should not be spread to thin. That way, the developers that are responsible for a certain part of the project are able to focus on the relevant area without getting overwhelmed with a large amount of other questions. If the areas are too specialised and little activity takes place in each, not enough people will show interest and questions are more likely to remain unanswered.

Failure support within the project is often handled by a bug tracker by which problems are reported and tracked. Statistical studies have shown that in successful projects, the number of developers that fix bugs in open source software is usually much higher than the number of developers creating new code (Mockus, Rielding, & Herbsleb, 2000).

Paid Support

Paid support might be available from the project team itself (Golden, 2005). There may have been people who have given their opinion about the quality of this support.

One of the strong signs of the maturity of open source software is the availability of third-party support: companies that offer commercial support services for open source products (Duijnhouwer & Widdows, 2003). Some companies offer service contracts, others offer only phone support on a per-incident basis. Check for paid support options whether they will be used or not (Duijnhouwer & Widdows). How the situation may be during actual use of the software is not always clear and it can give a better impression of the maturity of the software.

Documentation

There are two main types of documentation (Erenkratz & Taylor, 2003):

- User documentation
- Developer documentation

User documentation contains all documents that describe how to use the system. For certain applications, there can be different levels in the user documentation, corresponding with different user levels and rights. For example, many applications that have an administrator role have a separate piece of documentation for administrators. Additionally, there can be various user-contributed tutorials and how-tos, be it on the project's Web site or elsewhere. The available documentation should be adequate for your needs. The more complex the software, the more you may need to rely on the user documentation.

The other main type of documentation, which plays a much larger role in open source software than in proprietary applications, is developer documentation. A voluntary decentralised distribution of labour could not work without it (Weber, 2004). The developer documentation concerns separate documents on how to add or change the code, as well as documentation within the source code by way of comments. The comments usually explain what a section of code does, how to use and change it, and why it works like it does. Though this type of documentation may exist for proprietary software, it is usually not public.

If it is possible that you may want to change or add to the source code, this documentation is very valuable. A programmer or at least someone with some experience in programming will be better able to evaluate whether this documentation is set up well, especially by the comments in the source code. It is a good idea to let someone with experience take a look at this documentation (n.d., 2005).

A third type of documentation that is often available for larger server-based applications is maintainer documentation, which includes the install and upgrade instructions. These need to be clear, with the required infrastructure and the steps for installing the software properly explained. This documentation is needed to set up the application. For this type, again, the complexity of the application and its deployment determines the level of documentation that is needed. Documentation is often lagging behind the status of the application since it is often written only after functionality is created, especially user documentation (Scacchi, 2002). It is a good idea to check how often the documentation is updated, and how much the documentation is behind compared to the current status of the software itself.

The documentation for larger projects is often handled by a documentation team. A discussion area may exist about the documentation, giving an indication of the activity level of that team.

Security

Security in software, especially when discussing open source software, has two sides to it. There are people who believe security by obscurity is better, meaning that the inner workings of the software are hidden by keeping it closed source, something that open source obviously does not do. The advocates of security by obscurity see the openness of open source software as a security hazard. Others argue that the openness of open source actually makes it safer because vulnerabilities in the code are found sooner. Open source software gives both attackers and defenders great power over system security (Cowan, 2003; Hoepman & Jacobs, 2005).

Security depends strongly on how much attention the developers give to it. The quality of the code has much to do with it, and that goes for both proprietary and open source software. If the code of proprietary software is not secure, the vulnerabilities may still be found. There are

plenty of examples where this occurs, such as the Microsoft Windows operating system (OS). The vulnerabilities are often found by hackers who try to break the software, sometimes by blunt force or simple trial and error. In this case, a vulnerability might get exploited before the vendor knows about it. The attack is the first clue in that case. The open source software's vulnerabilities, however, could be found by one of the developers or users just by reviewing the code; he or she can report the problem so it can be fixed (Payne, 2002). It is important that the developers take the security of their software seriously and respond swiftly to any reported vulnerabilities.

There are various security advisories to check for bugs in all types of software that make it vulnerable to attacks. A couple of well-known advisories are http://www.securityfocus.com and http://www.secunia.com. Keep in mind that more popular software will have a higher chance of having vulnerability reports, so the mere lack of reports is no proof of its security. On the project's Web site, it can be seen, for instance in the release notes, how serious the project is about security.

Functionality

Though functionality comparison is not specific to open source software evaluation and is properly covered in most traditional software evaluation models, there are some points to take into consideration. Open source software often uses the method described by the phrase "release early and often" (Raymond, 1998). This method enables faster error correction (Weber, 2004) by keeping the software up to date as much as possible. It also encourages people to contribute because they see the result of their work in the next release much sooner (Raymond). However, this often means that the software is incomplete during the first releases, at least more so than is customary with proprietary software. Where vendors of proprietary software will offer full functionality descriptions for their software, open source projects might not have the complete information on the Web site (Golden, 2005). Just like with documentation, the information on the Web site might be lagging behind the actual functionality. Other means of checking the current functionality set might be needed. Fortunately, open source software that is freely available gives the added option of installing the software to enable the full testing of the functionality, an option that is mostly not available with proprietary software, for which at most only limited versions, in terms of functionality or time, are given freely for trying it out.

One problem with open source projects is that the documentation is not always up to date with the latest software. Look beyond the feature list on the Web site to find out what features the software has. Two options are to query the developers and ask the user community (Golden, 2005). Eventually the software itself should be investigated. If it is a Web-based application, an online demo might be available, though installing it on a test environment could be useful because it also gives insight on how well the software installs.

A list of functional requirements for the goal of the software can be used to check if the needed functionality is available. If such a list is not given, there may be one available from technology analyst organisations (Golden, 2005). It is wise to make a distinction in the list between features that are absolutely necessary, where the absence would lead to elimination, and those that would be a plus, which results in a higher score. If there is something missing, there is always the option to build it or have it built.

When comparing functionality, those features that are part of the functional requirements should take priority, but additional features may prove useful later. The features used or requested by the users in the future are not really predictable. While evaluating the software, features may be found in some of the candidates that are very useful for the goal. These can be added to the functional requirements.

Part of the functionality is localisation. The languages to which the interface and documentation are translated are a sign of the global interest taken in the software.

Integration

Duijnhouwer and Widdows (2003) mention three integration criteria. These are most important for software that is being used in collaboration with other software, and for people who are planning on adapting the software to their use, such as adding functionality or customising certain aspects so that it fits better in the organisation's environment. The three criteria are discussed in the next three subsections.

Modularity

Modularity of software means that the software or part of the software is broken into separate pieces, each with its own function. This type of structure has the following advantages:

- Modular software is easier to manage (Garzarelli, 2002; Mockus, Fielding, & Herbsleb, 2002).
- With a base structure that handles the modules well, people can easily add customised functionality without touching the core software.
- Modular software enables the selection of the needed functionality, leaving out those that are not necessary for the intended use. This way, the software can be customised without the need for a programmer.
- Modular software can be used in commercial applications. By making software modular, not everything needs to be given away as open source. It is can be used to give away only parts of software as open source while the add-on modules are sold as proprietary software (Duijnhouwer & Widdows, 2003). This is also called the razor model, as in giving away the razor for free and charging for the blade (Golden, 2005).

Evidence of a modular structure can often be found in several places, such as the source code, the developer documentation, or the download section, where modules might be available for download separate from the core software.

Standards

In the software market, more and more open standards emerge to make cooperation between software easier (Golden, 2005). If the software vendors use these standards in their software, it makes it easier to communicate between different software packages, and to switch between software packages. In some industries, standards are far more important than in others. For some software, there may not even be an applicable standard.

The use of current and open standards in open source software is a sign of the software's maturity (Duijnhouwer & Widdows, 2003). The feature list of the software usually lists what standards are used and with which the software complies.

Collaboration with Other Products

Closely connected to standards is the collaboration with other products. As mentioned before, not every software type has applicable standards, and sometimes the formal standards are not used as much as other formats. Examples of such formats are the Microsoft Word document format, and Adobe's PDF (portable document format). The office suite OpenOffice.org (2005) has built-in compatibility for both formats.

Software Requirements

Most software is written for a specific OS, for example, Microsoft Windows or Linux (Wheeler, n.d.). Certain types of software also rely on other

software, such as a Web server or a database. The requirements of the software will state which software and which versions of that software are compatible. If these requirements are very specific, it could lead to problems if they are incompatible with the organisation's current environment.

THE FUTURE OF OPEN SOURCE SOFTWARE EVALUATION

Open Source Software Evaluation Literature

More is being written on open source software evaluation at the time of writing. For example, another model called the business readiness rating (OpenBRR, 2005), aimed at open source software, was released recently. The research of Crowston and others is still ongoing, so there will be more results in the near future to include in the open source software evaluation process. Given how recent the rest of the literature discussed in this chapter is, it is likely that more will be published on the subject in the next few years.

The Future of Open Source Software

Open source software is being used increasingly by corporations worldwide. There is now some literature available to help with the evaluation of open source software, and the number of articles and models is increasing. With this growth in the field comes more attention from companies, especially on the enterprise level, which will cause more demand for solid evaluation models. Because open source software and the process around it provide much more information than traditional software, there is certainly a need for such models.

This literature will help justify and solidify the position of open source software evaluation in a corporate setting, giving more incentive to use open source software. Most likely, more companies will be investing time and money in its development, like we are seeing today in examples such as Oracle investing in PHP and incorporating this open source Web development language in its products (Oracle, 2005), and Novell's acquisition of SUSE Linux (Novell, 2003). The open source software evaluation literature can help IT managers in adopting open source.

CONCLUSION

The field of open source software evaluation is growing, and with that growth more attention is gained from the large enterprises. With this attention comes more demand for evaluation models that can be performed for these corporations, which will give more growth to the open source software market as well. In this chapter, an overview is given of the current literature and the criteria derived from that literature that can be used in open source software evaluation. For each of the criteria—community, release activity, longevity, license, support, documentation, security, and functionality—this chapter explains why it is important in the market and what to do to evaluate it. This information can be used on its own or in conjunction with more traditional evaluation models and additional information referenced here by companies and individuals that wish to evaluate and select an open source software package. It helps to give insight into the open source software sector.

KEY TERMS

Community: A group of people with shared interests that interact. In case of open source software, the community is the group of developers and users that come together, mostly on a Web site, to discuss, debug, and develop the software.

Documentation: The documents that are associated with a piece of software. There is usually user documentation, in the form of help files, tutorials, and manuals, and there can be developer documentation, such as programming guidelines and documents explaining the structure and workings of the software (source code). In some cases there is administrator documentation, which explains how to install and configure the software. The latter is more important for large pieces of software, where one installation will be used by many users, such as Web applications.

License: An agreement that is attached to the use of a product. In case of software, the software license agreement defines the terms under which you are allowed to use the software. For open source software, there are a number of common licenses, not bound to a specific piece of software, that can be used for almost any type of open source software. These licenses are well known so users and developers usually know the conditions of these licenses.

Maturity Model: Not to be confused with the capability maturity model (CMM), a maturity model as discussed in this chapter is a model that can be used to assess the maturity of a software package, evaluating the software using several criteria.

Software Longevity: The life expectancy of software, measured by various factors among which is its age.

Software Release Activity: The number and significance of releases that are made for a certain software package. A release can be a minor

change such as a bug fix, or a major change such as added functionality.

Software Security: How well a piece of software is built in terms of vulnerabilities and defense against them. Any software will have some type of security hole in it that allows a person, often with hostile intentions, to break into the software and use it for purposes that are unwanted. It is necessary for developers to minimize these holes and fix them if they are discovered. In case of open source software, because the source is public, the users may help in discovery by examining the source code. This, however, also means that a person with hostile intentions can also find these holes by examining the source code. Thus, it is always important to keep a close eye on security.

Chapter 1.7
On the Role of Public Policies Supporting Free/Open Source Software

ABSTRACT

Governments' interest in free/open source software is steadily increasing. Several policies aimed at supporting free/open source software have been taken or are currently under discussion all around the world. In this chapter, we review the basic (economic) rationales for such policy interventions and we present some summary statistics on policies taken within the European countries. We claim that in order to evaluate correctly the consequences of such interventions one has to consider both the role and the administrative level at which such decisions are taken as well as the typology of software that is involved. Moreover, we argue that the level playing field cannot be taken for granted in software markets. Therefore, non-intrusive public policies that currently prevail at the European level in terms, for instance, of the promotion of open standards or in terms of campaigns aimed at informing IT decision-makers, are likely to be welfare enhancing.

INTRODUCTION

Governments' interest in free/open source (F/OS) software is steadily increasing. In Europe, this interest has become visible in the Lisbon Strategy and in the corresponding eEurope Action Plans 2002 and 2005 approved by the European Commission where it has been clearly stated the key role of open source software and open standards in pursuing the general objective of giving all citizens the opportunity to participate in the global information society.[1]

All over the world governments are considering various policies to support F/OS software; these policies go from the provision of "best practices" for the usage of open source to information cam-

paigns aimed at making markets participants aware of all software alternatives, from simple expressions of preference towards F/OS software to large scale adoption of open source solutions in governments' offices and schools.

The role of the public sector in the software market is of primary importance. Governments not only set the legal and regulatory framework where economic agents interact, but they are also big software purchasers;[2] this double role makes governments key players in determining the future evolution of software markets and it is therefore of crucial interest to understand both the motivations and the effects of governments' interventions in this sector.

This chapter critically reviews the main arguments in favor or against public intervention supporting F/OS; we also provide some empirical evidence about the various public interventions that are already in place in Europe. The chapter is structured in three parts: in the first part, we provide a general analytical framework; public interventions may occur at different administrative levels (i.e., from municipalities to national or supra-national level), and they may have different motivations. These complexities have not received enough attention in the previous analyses on public interventions towards F/OS; the aim of this section is to offer a possible taxonomy for governmental policies in the software market and to discuss the many rationales for intervention but also the counterarguments that often have been put forward. In the following section, we present some evidence concerning the main public initiatives in Europe. Rather than focusing on any specific case study, we have collected information from the European IDABC, the program documenting the major initiatives supporting F/OS within the European Union. In this way, we have been able to draw some general considerations on the motivations and the characteristics of governments interventions implemented all across the EU. The subsequent section concludes by bridging the theoretical discussion with the empirical analysis.

We claim that, if one considers that the largest share of the software market is represented by self-developed or customized products, the existing literature has placed too much emphasis on packaged software and arguments against public support of F/OS might be improperly grounded. Moreover, we believe that the level playing field cannot be taken for granted in software markets. Therefore, non-intrusive public policies that currently prevail at the European level in terms, for instance, of the promotion of open standards or in terms of campaigns aimed at informing IT decision makers, are likely to be welfare enhancing.

BACKGROUND: A GENERAL FRAMEWORK

It is useful to start our analysis by providing a general framework for discriminating the large heterogeneity of public interventions in the software market. In particular, we claim that, in order to judge correctly rationales, motivations, and consequences of public interventions, it is important to distinguish between the various roles played by policy makers and the various categories of software involved. We argue that many existing contributions, both in the scholarly and in the practitioners' debate, have not clearly taken into account these distinctions.

Public administrations, institutions, and governments play a double role in the software industry. On the one side, being big spenders for software licenses and software development, their adoption/use decisions represent a significant share of the demand thus having a major impact on market equilibrium. On the other side, by acting as legislators and regulators, governments do in various ways determine the evolution of the market; for instance, it is quite evident that the legislation towards intellectual property rights, either based on strong patent protection as in the U.S. or on weaker copyright legislations as it is within the EU, has a major influence on the functioning of

the market and the diverging experiences on the two sides of the Atlantic stand as a clear example of this role. Similarly, as we discuss later in the chapter, governments frequently intervene mandating the adoption of open standards/interfaces; these policies are usually aimed at promoting compatibility and interoperability between different software platforms, thus creating a level playing field between different competitors; this kind of intervention clearly affects the efficiency of the market and therefore suggests a regulatory intention of the proponents.[3]

Obviously, it is often difficult to disentangle interventions of public authorities as adopters/users from those motivated on regulatory scopes; being large users, the decision to adopt a certain software package taken by public bodies affects the dynamic evolution of the industry and the equilibrium outcome, thus having regulatory consequences on the overall functioning of the market.

Irrespectively of the role played by a public administration, interventions may produce different consequences depending on the nature of the product involved. Software is not a commodity and the industry is extremely heterogeneous; indeed, the vast majority of software is either self-developed or custom while packaged software represents a minor share of the market.[4] The structure, the players, and the dynamics of mass-market and custom segments of the software industry are very different as well as different are likely to be the effects induced by the various public interventions.

In Table 1 we provide four examples of interventions distinguishing among different roles of public administrations and different typologies of software: three of these interventions are directly related to the promotion of F/OS, while the fourth refers to the well-known Microsoft European antitrust case. This last example relates to the F/OS world since, as a consequence of the antitrust action, Microsoft has recently announced its decision to allow access to some parts of the source code of its operating system.[5]

Rationales for Intervention: Review of the Literature

The literature on F/OS software in public administrations is quite substantial. Supporters of F/OS software have mainly focused on adoption of such technologies in the public sector and have based their arguments on technical, cost-efficiency or political-idealistic grounds. Regulatory scopes and therefore those rationales based on the consequences of F/OS public adoption on the overall functioning of the market have been receiving a much more limited attention by this stream of research.

Conversely, most of the critical voices in this

Table 1. Examples of public interventions supporting F/OS or regulating the market[10]

	Adoption/Development	Market Regulation
Custom	August 2005: the French Ministry of Foreign Affairs starts developing an open source architecture in order to integrate its computing system.[6]	October 2004: the Belgian administration published its white book concerning the use of open standards and open specifications for public sector purchased software.[7]
Packaged	September 2004: the Education Council of Castilla - La Mancha signed an agreement with Sun Microsystems to distribute Star Office 6.0 to the region's schools.[8]	EU's 2004 antitrust decision: Microsoft is required to disclose complete and accurate interface documentation which would allow non-Microsoft work group servers to achieve full interoperability with Windows PCs and servers. This will enable rival vendors to develop products that can compete on a level playing field in the work group server operating system market.[9]

debate have warned against detrimental consequences of both direct support/intervention and adoption of F/OS by public administrations on market performance.

In what follows, we briefly summarize the debate on F/OS software in the public sector; we devote the first subsection to provide a general overview of the most frequent motivations that have been proposed to justify public support towards open source. In the second subsection we look at the issue from a more critical viewpoint and we present the (often) skeptical view held by some economists and closed source practitioners.

Why Supporting F/OS?

Advocates of the F/OS movement put forward several rationales for public policies in the software market. Leaving aside pure idealistic-philosophical motives,[11] governments should support F/OS because of its intrinsic superiority with respect to closed source software. F/OS is considered to outperform proprietary software in terms of, for instance, higher reliability, security, flexibility, and maintainability of the code.[12] These superior features stem both from the organizational mode of F/OS which is characterized by the presence of a community of developers that continuously reviews the source code and fixes possible bugs, as well as from the fact that the availability of the source code makes it possible for the user to adapt the software to her/his own personal needs and to check every possible defect. Cost-efficiency is a second common rationale for policy interventions which is especially important for those public administrations that are pressured by budget concerns. The public sector would benefit from F/OS because of a number of reasons: net savings due to the reduced or non-existing licensing fees, the opportunity of freely contracting with software developers for subsequent code maintenance/upgrade without being locked into the relationship with the initial provider, or the possibility of profiting from economies of reuse/collaborative development.[13] Similarly, a further beneficial effect would follow from a more efficient employment of public resources that would be shifted from license costs towards human capital investments.

With respect to the issue of innovation dynamics in the software industry, F/OS advocates also stress the importance and benefits of public intervention. Open source licenses guarantee the availability of the source code and the same legal rights as those of the original developer to every individual who is interested in a certain software product. This wide availability of the "updated state-of-art," within an industry characterized by cumulative generation of knowledge, is perceived to be of crucial importance to spur innovation. In this respect, Varian and Shapiro (2003) argue that, being typically based on open interfaces, F/OS encourages third-party innovation in terms of development of, for instance, adds-on and complementary products.[14] Similarly, Benkler (2002) considers self-organization in the distributed peer production model more efficient in "acquiring and processing information about human capital available to contribute to information production projects" than traditional institutions, such as markets and hierarchies. Henkel and von Hippel (2004) push this argument further, claiming that "user innovation," a fundamental trait in F/OS software development, is welfare enhancing.

From the national perspective, those countries, whose software industry is lagging behind or is not competitive in the international markets, may consider public support to F/OS a viable way to cultivate a domestic software industry, therefore reducing their dependency from foreign suppliers; this rationale for public intervention seems to be ranked particularly high in the agenda of both emerging[15] and developed[16] countries. Varian and Shapiro (2003) sponsor this opinion and emphasize that the GNU/Linux operating system is "an open platform on which commercial or open source applications can be built, thereby spurring the development of a robust domestic

industry."[17]

Another common motivation for intervening in support of the F/OS movement is the stimulus of competition in the software market; this motive seems particularly relevant for those segments of the market characterized by the presence of dominant firms such as in the packaged software segment[18] and, more generally, in software procurement markets where dominant proprietary systems tie users to single suppliers, thus restricting competition.[19]

A More Critical View

During the last few years, several economists and other scholars have scrutinized the possible role of public policies in support of F/OS software. Apart from some relevant exceptions, the majority of authors seem to be rather skeptical about the welfare benefits that would accrue from governments directly stimulating F/OS.[20] One leading argument is that open source has emerged and, in many cases, has been extremely successful even without any intervention in place; therefore, there seems to be no need for public policies in order for F/OS to flourish. On top of that, focusing on closed source software, many authors claim that there is no clear evidence of significant failures in the software market and, consequently, there is no urge for governments' intervention. Evans (2002) and Evans and Reddy (2002) point out that the software industry is highly competitive[21] and also its performances in terms of growth, productivity, and R&D expenditures have been impressively high.[22] In other terms, software markets appear to be an example of well-functioning markets and, therefore, public funding to stimulate the emergence of alternatives to closed source software are prone to pick the "wrong winner." Moreover, a strong support to F/OS software may seriously undermine the incentives of commercial firms to innovate or to improve the quality of their software (Schmidt & Schnitzer, 2003).

One of the main arguments in favor of F/OS is that it guarantees to public administrations significant reductions in software expenses; various authors point out that cost savings obtainable by adopting F/OS rather than proprietary software are by far smaller that those expected. The licensing fees represent only a minor part of software costs and a meaningful comparison between F/OS and commercial software has to be done in terms of the total cost of ownership (TCO) which also includes user training, technical support, maintenance, and possible upgrades of the software. On these grounds, the overall cost advantage of F/OS is less evident.[23]

The higher degree of innovativeness that, according to supporters, characterizes the F/OS development mode is also a strongly debated issue. Smith (2002) acknowledges the brilliant performances of proprietary software companies in terms of R&D expenditures and resulting innovation and declares himself rather skeptical about F/OS being able to replicate such figures.[24] Evans (2002) and Evans and Reddy (2002) go even further and claim that the theoretical argument according to which open source implies more innovation completely lacks of solid empirical evidence, given that many successful F/OS software projects draw strong inspiration from already existing closed source counterparts.

This discussion reveals a widespread skepticism among economists and closed source advocates about direct government policies in favor of F/OS software; nonetheless, there is a general consensus on the need of a broader set of interventions that somehow ensure the level playing field in the software market. In particular, various authors are making strong arguments against the current system of protection of intellectual property rights. A long series of decisions taken by U.S. courts during the last twenty years has extended software patent protection and has made it easier for applicants to obtain patents even for obvious inventions. These facts have induced large firms to accumulate sizable numbers of software patents, the so-called patent thickets, that can be

strategically used in order to block competitors' innovation. As Bessen (2002, p. 13) points out, U.S. patent legislation may actually "sabotage the otherwise healthy open source movement" therefore potentially undermining competition from F/OS solutions.[25]

Finally, an issue that has drawn the attention of several contributors relates to the public funding of software R&D based on open source solutions. In this case, the non-rival and non-excludable nature of software goods, largely due to negligible replication costs, may induce policy makers to sponsor F/OS software projects as a means to increase social welfare.[26] While there is some consensus on the beneficial effects of this kind of interventions, the usage of restrictive licensing schemes (such as the GPL), is still very much debated: the software developed within publicly funded R&D projects should be made available to the widest possible audience but such restrictive licensing terms may undermine private appropriation of publicly funded basic science efforts.[27] In particular, closed source firms may be prevented from adopting and developing complementary applications for software distributed under GPL-like licensing schemes. Lessig (2002) suggests that governments should employ a non-discriminatory approach: publicly funded code should be released in the public domain or employing non-restrictive open source licenses (such as BSD-like ones).

MAIN FOCUS OF THE CHAPTER

Major Interventions in the EU

All across Europe, governments and public agencies are intervening in the software market in various ways; since September 2003, the major initiatives are registered on the Open Source Observatory, a dedicated Web site compiled by the European Commission within the IDABC program.[28] For each intervention registered on this Web site a brief abstract and, usually, a series of official documents and press releases describing the content of the policy are available. In order to derive useful information, we have reviewed the existing documentation focusing on the most important interventions registered on the IDABC site, therefore disregarding public initiatives taken by very small municipalities. The dataset we have compiled starting from the IDABC documentation has been complemented with the information recovered from an independent investigation by the Center for Strategic and International Studies (see Lewis, 2004).

It should be noted that given the methodology used within the IDABC program, the information we have gathered does not represent the complete set of initiatives taken in the European public sector. Some typologies of policies or some countries might be underrepresented in the sample. However, we believe that our effort to summarize the existing policies in favor of F/OS software represents a useful starting point to analyze the major European initiatives within a unified setting.

Overall, we have collected information about 105 interventions, distributed across 14 European countries; France is by large the most active country with more than 28% of the interventions in our sample.[29] Around 8.5% of the policies have been taken at the EU level and therefore they should be common to all European countries.

To summarize the information derived from our dataset, we have grouped policies according to:

- **Type of software involved by the intervention:** We have distinguished between *custom*, *packaged* software, and broader interventions aimed at supporting the use of *open standards*/*interfaces.*
- **Political and administrative levels at which the intervention is taken:** We have applied a two-tier classification distinguishing both between *government* and *public agencies*/bureaus (e.g., central government

vs. postal services) and between *central* and *local*/regional level of intervention (e.g., central government vs. local municipality).

- **Type of intervention:** We have grouped interventions into three broad categories: *adoption* when the government/agency has decided to adopt a certain software, *advisory* when the policy consists of a general claim of preference towards open source and/or encourages the use of F/OS or it is aimed at informing potential adopters of the existence and characteristics of open source and, finally, *development* when the government actively promotes the creation of new software.
- **Rationale for intervention:** We have classified policies into seven non-exclusive broad categories: *cost-efficiency,* that pools together motivations such as savings in license fees, economies of reuse of the software, savings from collaborative development of projects, and more efficient employment of public resources (e.g., shift from license fees to investment in human capital); *code availability,* combining motivations connected to the technical advantages assured by transparency, security, robustness, and quality of the code; *interoperability,* in which the rationale for intervention lies in stimulating the diffusion of open standards and in promoting interoperability in the software market; *flexibility,* in which motivations are linked to flexibility advantages assured by, for instance, the possibility of tailoring the code to the user's needs, to assure integration and compatibility with existing systems, and so on; *enhanced competition*, combining interventions motivated by levelling the playing field, creating alternatives to proprietary companies, supporting domestic industries, stimulating technical independence from dominant vendors, introducing competition in support, maintenance, and upgrade of systems and so forth; *efficiency in the public sector*, gathering motivations specifically related to the diffusion of best practices in public administration bodies; and, finally, *information diffusion*, a category representing those interventions motivated by the aim of increasing the available information and of raising consciousness about F/OS in the general public or, more specifically, in public administrations.

Table 2 shows the sample distribution of the various policies with respect to their type. F/OS adoption and advisory are the most common interventions in Europe: together they represent more of the 80% of the whole sample.

In Table 3 we go further into the detail and we present how the three types of policies are distributed between central and local decisional levels and between governmental authorities and public bureaus/agencies. More than 80% of the interventions in our sample are taken at the governmental level (both local and central) while agencies have played a much more limited role. Advisory policies aimed at suggesting and promoting F/OS prevail in central governments while at the other levels adoption is the most common type of intervention. This is not surprising once considered that central governments often provide "guidelines" for action while operative decisions are effectively endorsed at the local level and in agency bodies.

In Table 4 interventions are grouped according to the kind of software they are directed to:

Table 2. Public policies classified in terms of type of intervention

Intervention	Freq.	%
Adoption	47	44.8
Advisory	39	37.1
Development	19	18.1
TOTAL	105	100

Table 3. Policies classified in terms of type of intervention and administrative level

	Intervention			
Level	**Development**	**Adoption**	**Advisory**	**TOTAL**
Central Gov.	8 (17.8%)	9 (20%)	28 (62.2%)	45 (100%)
Central Agency	1 (8.3%)	9 (75%)	2 (16.7%)	12 (100%)
Local Gov.	9 (21.4%)	24 (57.1%)	9 (21.4%)	42 (100%)
Local Agency	1 (16.7%)	5 (83.3%)	0 (0%)	6 (100%)
TOTAL	19 (18.1%)	47 (44.8%)	39 (37.1%)	105 (100%)

Table 4. Policies classified in terms of software type and administrative level

	Software		
Level	**Custom**	**Packaged**	**Open Std.**
Central Gov.	69%	73%	0%
Central Agencies	33%	66%	17%
Local Gov.	38%	78%	5%
Local Agencies	83%	33%	0%
TOTAL	53%	72%	8%

either software custom or packaged or towards the implementation of open standards. Note that in many cases, the intervention is not restricted to a unique type of software but it may involve two or all of them.[30] Table 4 suggests that local governments are more active towards packaged software while central governments do not seem to follow any particular pattern.

Restricting the analysis to central governments and central agencies, we have looked more closely at the motivations behind interventions. According to the available information, only in 37 out of 57 of the cases it was possible to collect official statements explicitly accounting for the rationales for intervention. The information we have gathered is presented in Table 5. Clearly, given the small number of observations, some caution has to be exerted when interpreting these data; however, it is worthwhile to highlight the major trends that characterize European policies.

Total figures in Table 5 show that cost-efficiency motivations are the most popular, followed by interoperability and code availability ones. Regarding specific policies, adoption policies are largely motivated by interoperability (viewed at the level of the single adopter) and cost-efficiency rationales (in particular, savings on license fees) while rationales regarding technical advantages of code availability and flexibility (all subcategories equally represented) are less cited, therefore suggesting that short-term advantages might be more salient than long-term ones in the stated motivations. On the other hand, pure regulatory motivations (such as stimulating market competi-

Table 5. Public policies classified in terms of rationale for intervention (central government and agencies only)

	Type of Motivation							
Intervention	**Total**	**Cost Efficiency**	**Code Availability**	**Interoperability**	**Flexibility**	**Enhanced Competition**	**Efficiency in Public Sector**	**Information Diffusion**
Development	**6 (100%)**	1 (17%)	4 (67%)	1 (17%)	1 (17%)	1 (17%)	0 (0%)	1 (17%)
Adoption	**11 (100%)**	7 (64%)	2 (18%)	6 (55%)	3 (27%)	2 (18%)	1 (9%)	1 (9%)
Advisory	**20 (100%)**	11 (55%)	7 (35%)	11 (55%)	2 (10%)	8 (40%)	5 (25%)	7 (35%)
TOTAL	**37 (100%)**	19 (51%)	13 (35%)	18 (49%)	6 (16%)	11 (30%)	6 (16%)	9 (24%)

tion) are not explicitly accounted for. As far as advisory policies are concerned, interoperability (also considered at the market level) and cost-efficiency (all subcategories equally represented) are still fundamental rationales, but other regulatory motivations are popular as well (in particular, enhancing competition and raising awareness in markets). Finally, technical advantages of code availability represents the major rationale for R&D policies, while, surprisingly, motivation regarding cost-efficiency are rather infrequent.

FUTURE TRENDS

As we have briefly discussed in a prior section, economists are rather critical about intrusive public policies into the software market and, to some extent, we adhere to this skepticism.

Just to mention some arguments, the software industry has really proved to be extremely dynamic, characterized by high rates of growth and, while competition in some software segments might result in "winner-takes-all" outcomes, dominant positions have been frequently displaced by new comers (see Schmalensee, 2000); in a word, markets have performed reasonably well. Moreover, it is not yet clear if the production mode of open source is really more innovative than the proprietary one and empirical evidence on this issue is far from being clear-cut.

However, we believe that looking at the F/OS movement from an economic viewpoint, many relevant aspects have not received so far the attention that they should have deserved and the evidence on the EU experience reported above suggests some of the directions towards which the analysis should look at in order to better understand the actual effects of these policies.

For example, we believe that the distinction between custom and packaged software has not been properly taken into account in the literature. One of the main concerns against public support towards open source is based on the allegation

that such policies would be detrimental for the incentives to innovate by commercial firms. We have already pointed out that almost two thirds of the market is represented by software that has been developed internally or that is customized and, as shown in Table 4, more than half of the interventions in our sample relates to this latter type of software. We are convinced that the above allegation cannot apply to this kind of software: customized software is by definition software "on demand" and the incentives to develop new lines of code arise at the moment of the call for tender, regardless of the open or close nature of the source code.

From the evidence presented in a previous section, it emerges that across the EU, together with cost saving reasons, public interventions in support of F/OS founded their motivations primarily on the desire of stimulating an open standard environment for software applications but also on the relevance of source code availability and on the intention to promote more competitive software markets.

It is recognized that proprietary software is likely to create important lock-in positions; the unavailability of the source code renders adopters dependant on the original software provider for further maintenance/development/upgrade of the code. Moreover, the use of closed standards, a typical solution employed by proprietary vendors, makes it more difficult for adopters to disengage themselves from software vendors. The absence of complete and public documentation regarding file and data storage formats and other communication standards might substantially increase the switching costs thus rendering unprofitable the migration to other software packages. Lock-in is certainly a source of a relevant increase in life-cycle costs but these costs are extremely difficult to evaluate when one wants to compute correctly the total cost of ownership of a given software product.

On the contrary, a relevant feature of both open source code and open standards is that competition may be created in the aftermarket, and this may significantly reduce the cost of service, support, maintenance and interoperability.[31] Moreover, according to this view, fears of picking "wrong winners" through governmental advisory or adoption of F/OS solutions should be lessened if one takes into account that F/OS software is based on open formats that are commonly available and that might be employed by closed source vendors to develop compatible value-added proprietary solutions or interoperable adds-on and complementary products.[32]

While the above arguments apply to custom software in particular, a regulatory policy in support of open standards may found solid justifications also in the context of mass-market software; as a consequence of strong network effects, these segments of the software industry are often characterized by the presence of dominant players whose platforms have the typical features of "essential facilities." Controlling an interface (the key input) allows the dominant firm to protect its position and possibly to extend it to other complementary products. Similarly to the current practice in other industries, also for the case of software the provision of open access to the essential facility should be seriously considered in order to promote competition and to improve market efficiency.

CONCLUSION

The bottom line is to ensure that markets lead to efficient outcomes and therefore to exclude, based on economic grounds, that public interventions might be beneficial relates to the assumption that all potential adopters are properly informed about the alternatives that are available in the market. A recent empirical study on F/OS in the public sector shows that this is not necessarily the case. Ghosh and Glott (2005) show that a large share of IT administrators in the public sector ignore that in their agencies F/OS was actually employed.[33]

More interestingly, the fact of being aware or not about the current usage of open source software has a major impact on the evaluation of the potential benefits of F/OS adoption. Nearly 70% of the "aware IT administrators" finds it useful to extend the use of open source in their agencies. This percentage shrinks to 30% among the IT administrators that were unaware that F/OS software was already employed in their institutions. Clearly, this evidence provides strong support for policies aimed at informing potential adopters about the characteristics and the availability of open source solutions.[34]

ACKNOWLEDGMENT

The authors would like to thank Bruno Caprile, Vincenzo D'Andrea, Sebastian Spaeth, Ruben van Wendel de Joode and two anonymous referees for their helpful comments on earlier drafts of this chapter. The usual disclaimer applies. Financial supports from Progetto di Ateneo 2006—University of Padua (for Stefano Comino and Fabio Manenti) and from MIUR under the projects FIRB03 and PRIN05 (for Alessandro Rossi) are gratefully acknowledged.

KEY TERMS

Customers' Lock-In: A situation in which a customer is so dependent on a vendor for products and services that he/she cannot move to another vendor without substantial switching costs, real and/or perceived.

Economic Regulation: Set of restrictions promulgated by government administrative agencies through rulemaking supported by a threat of sanction or a fine. The main scope for government's regulation is to prevent markets' failures, in

other words, situations in which markets do not efficiently organize production or allocate goods and services to consumers (as in the presence of a monopoly/dominant firm).

Essential Facility: In a vertically related market, it is defined as a facility, function, process, or service that meets three criteria: it is monopoly controlled; a potential competitor requires it as an input to provide services and to compete downstream with the monopoly supplier; and it cannot be economically or technically duplicated. Facilities that meet this definition shall be subject to mandatory unbundling and mandated pricing.

Intellectual Property Rights (IPRs): Intellectual property is a term used to refer to the object of a variety of laws, including patent law, copyright law, trademark law, trade secret law, and industrial design law. These laws provide exclusive rights to certain parties over intangible subject matter or over the product of intellectual or creative endeavor; many of them implement government-granted monopolies.

Proprietary Software (PS): Software products that are designed in such a way that others cannot access or view a product's source coding/the programming that allows the software to perform certain functions.

Source Code: The programming that allows software programs to perform certain actions or functions.

Total Cost of Ownership (TCO): Financial estimate aimed at helping consumers and enterprise managers to assess direct and indirect costs related to the purchase of any capital investment, such as (but not limited to) computer software or hardware.

ENDNOTES

1 Further details are available at: http://europa.eu.int/information_society/eeurope/2005/index_en.htm. All the URLs provided in this chapter are active at the moment of writing the chapter (June 2006).

2 Just to give a relevant example, the Dutch public sector spent around 400 million euros on software in 1997; see http://www.ososs.nl.

3 For an example at the transnational level see the European Interoperability Framework for pan-European eGovernment services, mandating a series of policies, standards and guidelines aimed at "facilitating […] the interoperability of services and systems between public administrations, as well as between administrations and the public" (http://europa.eu.int/idabc/en/document/2319/5644). For an application at the national level the reader may refer to the Dutch manual on open standards and open source software (OSOSS) in the procurement process, encouraging the adoption of open standards in the public sector (http://www.ososs.nl).

4 According to Bessen (2002), packaged software has never accounted for more than a third of software expenses.

5 See, for instance, Microsoft's Jan. 25, 2006 press release available at http://www.microsoft.com/presspass/press/2006/jan06/01-25EUSourceCodePR.mspx and the comments of Neelie Kroes (European Union's antitrust chief), stating that documentation enabling interoperability, rather than mere code disclosure, is at issue in order to meet EU's requirements (http://today.reuters.com/business/newsArticle.aspx?type=technology&storyID=nL26331447).

6 http://europa.eu.int/idabc/en/document/4549/469

7 http://europa.eu.int/idabc/en/document/3336/469.

8 http://europa.eu.int/idabc/en/document/1766/469.

9 http://europa.eu.int/rapid/pressRe-

leasesAction.do?reference=IP/04/382&format=HTML&aged=l&language=EN&guiLanguage=en.

10 For a brief but comprehensive review of various national initiatives and policies on open source software see the links provided by the IDABC Open Source Observatory at http://europa.eu.int/idabc/en/document/1677/471.

11 A notable example of this kind of motivations can be found in the programs and activities of the Free Software Foundation, aimed at affirming the primacy of freedom ideals in the development and diffusion of software.

12 For a comprehensive survey on this topic see Wheeler (2005).

13 Reuse economies are savings due to recycling previously developed code as a basis for a new project; collaborative development economies are strategies of mutualization consisting in partnerships for joint development by the public sector, motivated by the needs of pooling efforts and sharing costs in building, maintaining and upgrading large software projects of common interest. See Schmitz and Castiaux (2002) for an assessment applied to FO/S software.

14 Bessen (2002) holds a similar view.

15 Support to domestic software industry lies at the core of the IT national policies of India and China. See, for instance, the remarks of the Indian President, A.P.J. Abdul Kalam, on the future challenges of information technology for developing countries (http://news.com.com/2100-1016-1011255.htmlnews.com.com/2100-1016-1011255.html) or the speech of the Ministry of Science and Technology at the 2004 International Conference on Strategies for Building Software Industries in Developing Countries (http://www.iipi.org/Conferences/Hawaii_SW_Conference/Li%20Paper.pdf).

16 This occurs both at the national as well as at the local levels. See the statement by the Finnish Ministry Kyösti Karjula (http://www.linuxtoday.com/news_story.php3?ltsn=2002-06-17-011-26-NW-DP-PB) as an example of the first type and the deliberation of the autonomous province of Trento on the adoption of open standards and open source software (http://www.linuxtrent.it/Members/napo/deliberaPAT_n1492.pdf) as an instance of the second type.

17 Smith (2002) contrasts this view arguing that in a large number of countries, not only in the developed ones, a flourishing (proprietary) software industry already exists.

18 Among others, see the statement made by Boris Schwartz, deputy leader of the SPD parliamentary group, during the debate about the transition towards open source systems of the city of Munich (http://www.linuxtoday.com/infrastructure/2003052600126NWSWPB).

19 See, for instance, the recommendations of the Danish Board of Technology (2002) on supporting the emergence of alternatives in custom built software markets as means to foster competition and the recommendations of the Finnish Minister of Finance (2003), suggesting to include the possession of the source code in tender drafts in order to assure competitive bidding in future development and maintenance.

20 One notable exception is represented by Lessig (2002) who claims that government preference towards F/OS is justified by the presence of externalities that market forces do not internalize. For instance, software developed for or adopted by some branches of the government could be employed usefully also by other branches if it is free or open source; the initial development/adoption decision should take into account also the potential benefits for future users.

21 These authors provide several figures to support their argument. In the US the Herfindahl-Hirschman index (HHI) for the

software industry is smaller that the average HHI computed for the US manufacturing industries; furthermore, during the period 1996-2000 there has been a decrease by 27% in the quality-adjusted prices for the packaged software.

22 According to Evans (2002), in the year 2000 the R&D expenditure of software companies represented one tenth of the overall R&D undertaken within the industrial sectors while fifteen years before it accounted for only 1%.

23 The empirical evidence comparing the TCO of open vs. close software solutions does not seem to be conclusive. For a comprehensive overview the reader may refer to the FlossPols report on policy support (Ghosh & Glott, 2005).

24 Smith, Microsoft's senior vice president, also claims that often, in order to bring the software to the market, additional investments have to be done and these can not accrue from the F/OS world but can only come from the commercial one.

25 For an empirical analysis on software patents see Bessen and Hunt (2004). According to these authors, the strategic accumulation of patent thickets seems to be the most convincing explanation for the large increase of software patenting in the US. Similarly, several panelists, according to a recent US Federal Trade Commission (2003) report, support the view that the patent protection system poses threats to innovation in the software industry. Lessig (2002) and von Hippel (2005) argue in favor of lessening the extent of patent protection in the software industry. According to Evans (2002) and Evans and Layne-Farrar (2004), even though some (minor) reform of the patent legislation might be beneficial, software patents should not be banned altogether.

26 See, for instance DeLong and Froomkin (2000) for an application to digital goods markets.

27 Smith (2002) and Lessig (2002) hold the view that government should finance R&D activities but the resulting software should not be distributed under restrictive licensing schemes. On the contrary, Varian and Shapiro (2003) focusing on the Linux case argue that the adoption of GPL does not necessarily prevents the development of complementary applications. Henkel (2006) provides empirical evidence that, despite GPL's strict requirements in releasing derived works, firms can adopt several successful strategies in order to protect their own code enhancements.

28 IDABC stands for Interoperable Delivery of European eGovernment Services to public Administrations, Businesses and Citizens; the information available on the Open source Observatory is collected by a special Web-team from staff members of the European public sector and also by searching the Internet for relevant information. The documentation we have collected is available at the following URL http://europa.eu.int/idabc/en/chapter/491.

29 The large interest of public authorities in France has been documented also in a previous IDABC report, see Schmitz (2001).

30 This fact explains why rows sum up to more than 100%.

31 On these lines, Ghosh, Krieger, Glott, and Robles (2002) suggest that whenever it is feasible governments and public institutions should opt for software open source, for example, by granting unlimited access to the source code, the right to modify the software and that to reproduce and distribute an unlimited amount of copies of the modified version under the same license restrictions. Forge (2005, p. 492) argues that policy-markers should mandate "backward compatibility, open access to program interfaces, and separation between operating

systems and applications".

[32] Moreover, it is worth mentioning that in some cases policies supporting F/OS software are inspired by neutrality principles, therefore suggesting joint use rather than full substitution of closed source software by migrating to F/OS systems.

[33] According to the authors 30% of IT administrators were unaware of F/OS software usage and this figure increases in the case of small budget public agencies.

[34] A welfare analysis of the impact of various policies supporting F/OS in the presence of "unaware" potential adopters can be found in Comino and Manenti (2005).

This work was previously published in Handbook of Research on Open Source Software: Technological, Economic, and Social Perspectives, edited byK. St. Amant; and B. Still, pp. 412-427, copyright 2007 by Information Science Reference (an imprint of IGI Global).

Chapter 1.8
Open Source Survey Software

Jason D. Baker
Regent University, USA

ABSTRACT

One of the significant advances in software design afforded by the Internet has been the open source movement, an effort to collaboratively create software and make it widely and freely available to the online community. Although the open source movement started with Unix-like computer operating systems, it has expanded to include a wide variety of software programs, including tools to publish and analyze online surveys. This chapter introduces the open source movement, and then profiles three leading open source survey programs: php Easy Survey Package (phpESP), PHP Surveyor, and the Moodle course management system.

BACKGROUND

The open source movement has its roots in the Unix community and, in particular, the development of the GNU Project back in 1984. The goal of this idealistic group of software developers was to create an entirely free Unix operating system so users would not be dependent on commercial versions from Sun, IBM, and others. Here is the introduction from the GNU Web page:

The GNU Project was launched in 1984 to develop a complete Unix-like operating system which is free software: the GNU system. (GNU is a recursive acronym for 'GNU's Not Unix'; it is pronounced 'guh-NEW'.) Variants of the GNU operating system, which use the kernel Linux, are now widely used; though these systems are often referred to as 'Linux,' they are more accurately called GNU/Linux systems. (http://www.gnu.org)

Since then, the movement has grown far beyond computer scientists writing operating system code, and has become an ideology in which people freely contribute to content that is made freely available, and where changes are not only acceptable, but encouraged, just as long as the results are offered back to the community. In many ways, it is a sophisticated countercultural response to the limitations of copyrights and patents. As Raymond (1998) declared, "Perhaps in the end the open-source culture will triumph…simply because the commercial world cannot win an evolutionary arms race with open-source communities that can put orders of magnitude more skilled time into a problem."

Not surprisingly, the open source approach has moved beyond computer operating systems into high-demand computer and Internet-based applications, including survey software. For those individuals or organizations unable or uninter-

ested in paying commercial hosting companies to administer online surveys and tests, there are open source equivalents. Popular open source survey programs include the php Easy Survey Package (phpESP) and PHP Surveyor. For educational-style tests, the Moodle open source course management system is one of the more popular.

PROFILES AND COMMENTARY

phpESP, PHP Surveyor, and Moodle are all open source programs that run on Unix Web platforms and make use of the php scripting language and the MySQL database system. Each of these programs can be installed using their respective Web-based installation programs. Additionally, many Web hosting providers offer one-click installation of various open source programs through a menu-driven program called Fantastico De Luxe. Fantastico generally comes bundled with phpESP, PHP Surveyor, and Moodle, along with other useful open source programs. Once installed, all three programs can be administered via a Web-based interface.

phpESP is the older of the survey programs and features a number of basic and advanced online survey functions. To create a survey, one first configures the general survey details, along with the look and feel of the survey template, and then populates the survey with individual questions. A variety of question types are supported including yes/no, multiple choice, check boxes, Likert-style scales, short answer, and even essay (although open-ended questions cannot be tallied the same way as multiple-choice and other fixed questions). Once all of the questions and answer options are entered and ordered, the user can test the survey before publishing it for real. Once activated, the survey administrator can view individual and aggregate results through the management interface, as well as download the results for analysis in Excel, SPSS, or similar programs. The strength of phpESP is its varied features, extensive development history, and simplicity of code modification. The weakness of the program is that it lacks detailed documentation and thus, can be confounding to basic computer users.

PHP Surveyor possesses many of the same survey features as phpESP, but couples them with a significantly richer administration interface that makes the program more accessible to novices. In addition to 20 different question types ranging from multiple choice and checkboxes to Likert-style scales and flexible arrays (which permit custom text descriptors in each point along the scale), PHP Surveyor supports open or closed surveys. Open surveys can be completed by anyone visiting the Web site, while closed surveys require registration or invitation to participate. Furthermore, the survey administrator can preregister selected users and send out e-mails to solicit participation in the online survey. PHP Surveyor also supports branching surveys, which enable different follow-up questions to be presented based on answers to previous questions, and uses a templating feature to change the look and feel of online surveys. Survey responses can be reviewed online or downloaded for more in-depth statistical analysis. While still under heavy development, PHP Surveyor is likely to become a leading open source survey program because of its rich feature set and relative ease of use.

Unlike phpESP and PHP Surveyor, Moodle is not strictly a survey program, but rather is an open source course management system (CMS). Moodle can be considered an open source equivalent to commercial CMSs like Blackboard or WebCT and thus, is designed for instructional purposes. It includes features to post course syllabi, documents, grades, and hold online class discussions. In addition, however, Moodle includes robust online quiz and survey modules that can be used to administer online assessments or surveys. The quiz module enables instructors to set up assessments, along with the correct answers, so students can complete these and have their scores provided instantly. The survey module includes predefined

surveys that can be used with online courses, and also supports the development of custom surveys. Results can be viewed online, or downloaded in Excel or comma-separated value format. Since Moodle is designed for online courses, complete with student accounts and registration, it is less ideal for a public survey than either phpESP or PHP Surveyor, but has many more options if one is integrating such online tests and surveys into coursework.

COST

All three programs are open source and available at no cost. In addition to the free download, the source code is also freely available, and can be changed as desired.

LOCATION

phpESP is available at http://phpesp.sourceforge.net

PHP Surveyor is available at http://www.phpsurveyor.org

Moodle is available at http://www.moodle.org

KEY TERMS

Course Management System: A computer software program designed to support the delivery of online instruction. Popular CMSs include Blackboard, WebCT, and Moodle.

Database: A software package for storing information in a searchable and relational structure. Popular databases include Oracle, MySQL, SQL Server, and Access.

Open Source Software: An approach to software development where multiple individuals collaboratively write code and release both the source code and resulting program to the online community. Anyone is then permitted to freely use the software and modify the code, provided that such modifications are again made available in a public release of the code.

Unix: A popular computer operating system. Many Web servers run on Unix-based systems.

Chapter 1.9
FLOSSmole:
A Collaborative Repository for FLOSS Research Data and Analyses

Megan Conklin
Elon University, USA

Kevin Crowston
Syracuse University, USA

ABSTRACT

This article introduces and expands on previous work on a collaborative project, called FLOSSmole (formerly OSSmole), designed to gather, share, and store comparable data and analyses of free, libre, and open source software (FLOSS) development for academic research. The project draws on the ongoing collection and analysis efforts of many research groups, reducing duplication, and promoting compatibility both across sources of FLOSS data and across research groups and analyses. The article outlines current difficulties with the current typical quantitative FLOSS research process and uses these to develop requirements and presents the design of the system.

INTRODUCTION

This article introduces a collaborative project called FLOSSmole,[1] designed to gather, share, and store comparable data and analyses of free and open source software development for academic research. The project draws on the ongoing collection and analysis efforts of many research groups. Our intent in developing FLOSSmole is to reduce duplication, and to promote compatibility both across sources of FLOSS data and across research groups and analyses.

Creating a collaborative data and analysis repository for research on FLOSS is important because research should be as reproducible, extendable, and comparable as possible. Research with these characteristics creates the opportunity to employ meta-analyses, exploiting the diversity of existing research by comparing and contrasting results to expand our knowledge. Unfortunately, the current typical FLOSS research project pro-

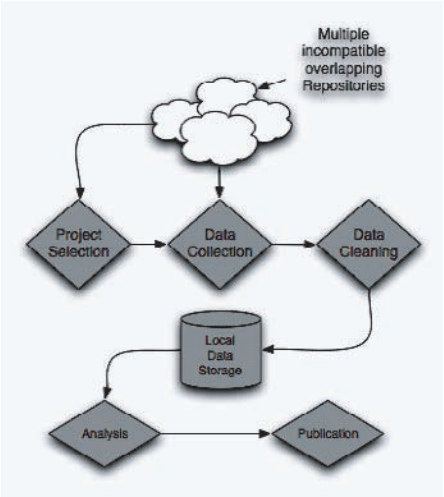
ceeds in a way that does not necessarily achieve these goals. These goals require detailed communal knowledge of the many choices made throughout a research project. Traditional publication prioritizes results, but masks or discards much of the information needed to understand and exploit the differences in our data collection and analysis methodologies. FLOSSmole was originally designed to provide resources and support to academics seeking to prepare the next generation of FLOSS research. Since its inception, FLOSSmole has also been a valuable resource for nonacademics who are also seeking good data about development practices in the open source software industry.

BACKGROUND OF PROBLEM

Obtaining data on FLOSS projects is both easy and difficult. It is easy because FLOSS development utilizes computer-mediated communications heavily for both development team interactions and for storing artifacts such as code and documentation. This way of developing software leaves a freely available and, in theory at least, highly accessible trail of data upon which many academics have built interesting analyses about optimal organization of development teams, economics of building software in the commons, and the like. Yet, despite this presumed plethora of data, researchers often face significant practical challenges in using this data to construct a collaborative and deliberative research discourse. In Figure 1, we outline the research process we believe is followed in much of the quantitative literature on FLOSS.

The first step in collecting online FLOSS data is selecting which projects and which attributes to study, two techniques often used in estimation and selection are census and sampling. (Case studies are also used but these will not be discussed in this article.)

Figure 1. The typical quantitative FLOSS research process (notice its noncyclical and noncollaborative nature)



Conducting a census means to examine all cases of a phenomena, taking the measures of interest to build up an entire accurate picture. Taking a census is difficult in FLOSS for a number of reasons. First, it is hard to know how many FLOSS projects there are "out there," and it is hard to know which projects should actually be included. For example, are corporate-sponsored projects part of the phenomenon or not? Do single-person projects count? What about school projects?

Second, the projects themselves, and the records they leave, are scattered across a surprisingly large number of locations. It is true that many are located in the major general repositories, such as Sourceforge[2] and GNU Savannah.[3] It is also true, however, that there are a number of other repositories of varying sizes and focuses (e.g., CodeHaus,[4] CPAN[5]), and that many projects, including the well-known and much-studied Apache and Linux projects, prefer to use their own repositories and their own tools. This diversity of location effectively hides significant portions of the FLOSS world from attempts at census. Even if a full listing of projects and their locations

could be collated, there is also the practical difficulty of dealing with the huge amount of data — sometimes years and years of e-mails, CVS, and bug tracker conversations — required to conduct certain comprehensive analyses.

Do the difficulties with census-taking mean that sampling would be more effective? By saying sampling we mean taking a random selection of a small (and thus more manageable) subgroup of projects that can, through careful selection, represent the group as a whole. While this will go some way toward solving the manageability problem, sampling FLOSS projects is difficult for the same reason as census-taking: the total population from which to take the sample selection is not well-defined. Perhaps more importantly, sampling open source projects is methodologically difficult because everything FLOSS research has shown so far points to massively skewed distributions across almost all points of research interest (Conklin, 2004; Xu, Yongqin, Christley, & Madey, 2004). Selecting, even at random, from highly skewed distributions does not, in general, produce a representative sample. The difficulty of sampling is demonstrated in the tendency of FLOSS studies to first limit their enquiries to projects using one repository (usually Sourceforge), and often to draw on samples created for entirely different purposes (such as top 100 lists as in Krishnamurthy, 2002), neither of which is a satisfactory general technique. Selection of projects to study is further complicated by the fact that the public repositories contain a large number of projects that are dormant, relocated, or dead.

BACKGROUND: DATA COLLECTION DIFFICULTIES

Once the projects of interest have been identified and located, the actual project data must be collected. There are two techniques that prevail in the FLOSS literature for collecting data: Web spidering and obtaining database dumps.

Spidering data is fraught with practical complexities (Howison & Crowston, 2004). Because the FLOSS repositories are usually maintained using a database back-end and a Web front-end, the data model appears straightforward to reproduce. The central limitation of spidering, however, is that the researcher is continually in a state of discovery. The data model is always open to being changed by whoever is controlling the repository, and there is usually no way that the researcher will know of changes in advance. Spidering is a time-intensive and resource-consuming process, and one that is being unnecessarily replicated throughout the world of FLOSS research.

Getting direct access to the database is clearly preferable, but not all repositories make their dumps available. (Some, such as Freshmeat, provide a nightly build containing several text files with the majority of their information included.) And understandably so because it is not a costless process to make data-dumps available. Dumps can contain personally identifiable and financial information (as with the Sourceforge linked donation system) and so the data must be anonymized or otherwise modified to protect this information. Repositories are facing an increasing number of requests for database snapshots from academics and are either seeking a scalable way to do releases or declining to release the data entirely. It is often unclear whether database dumps obtained by one research project can be shared with other academics, so rather than possibly breach confidentiality or annoy their subjects by asking for signed releases, it is understandable that academics who do get a database dump may not make those dumps easily available. Other projects, such as the Sourceforge dump available from Notre Dame[6], only provide the dumps to qualified academic researchers with editorial restrictions. It is unclear what effect this limitation will have on research efforts in the open source

community, however, since research efforts are certainly not limited to academics.

Even when dumps are available it is necessary to interpret their database schema. This is not always as straightforward as one would expect. After all, the databases were designed to be used to build Web pages quickly, not to conduct academic analyses. Furthermore, they have been built over time and face the complexity that any schema faces when stretched and scaled beyond its original intended use: labels are obscured, extra tables are used, and there are inconsistencies between old and recently added data. The interpretation and transformation of this data into information semantically interesting to researchers is not a trivial process, and there is no reason to think that researchers will do this transformation in a consistent fashion.

Even pristine and labeled data from repositories is not sufficient because different repositories store different data. Different forges can have projects with the same names, different developers can have the same name across multiple forges, and the same developer can go by multiple names. Forges have different terminology for things like developer roles, project topics, and even programming languages. They often have fields which are named the same in multiple forges but which represent different data. Another problematic area is calculated fields, such as activity or downloads, for which there is incomplete publicly available information on their formula or correctness.

BACKGROUND: DATA CLEANING DIFFICULTIES

Once projects have been selected and the available data harvested, researchers must be confident that data adequately represent the activities of a project. For example, projects use repository tools to differing degrees. For example, many projects are listed on Sourceforge, and use the mailing lists and Web hosting provided there. But some of these same projects will shun the notoriously quirky "Tracker" bug-tracking system at Sourceforge, preferring to set up their own tracking systems using, perhaps, Bugzilla or RT software. Other projects host their activities outside Sourceforge but maintain a "placeholder" registration with little used mailing lists and out of date release information. It is very difficult, short of detailed examination of each project, to know whether a project is fully using a tool. Thus, it is difficult to state with confidence that the data collected about that tool is a reasonable depiction of the project's activities.

Complete accuracy is, of course, not required because in large-scale data analysis some "dirty data" is acceptably handled through statistical techniques. At a minimum, though, researchers contemplating the accuracy of their data must have some reason to believe that there are no systematic reasons that the data collected in the name of the group would be unrepresentative. Unfortunately, given the idiosyncrasies of FLOSS projects, confidence on this point appears to require project-by-project verification, a time-consuming process for individual researchers and projects, and one that is too frequently repeated by other researchers.

The conclusion we draw from this analysis is that each step of the typical FLOSS research process introduces variability into the data that underlies any quantitative analysis of FLOSS development. Decisions about project selection, collection, and cleaning are compounded throughout the cycle of research. FLOSS researchers have not, so far, investigated the extent to which this variability affects their findings and conclusions. In addition, the demands of traditional publication also mean that the decisions are not usually fully and reproducibly reported.

Our critique is not against the existence of differences in research methods or even difference in datasets. There is, rightly, more than one way to conduct research, and indeed this richness drives discovery. Rather, our critique is that the

research community is currently unable to begin a meta-analysis phase or a reflective phase because the current process of FLOSS research introduces variability that is difficult to trace. The research process is also hampered by redundant, wasted effort in data collection and analysis. It is time to learn from the free and open source approaches we are studying and develop an open, collaborative solution to this problem.

PROPOSING A SOLUTION: FLOSSMOLE

The previous problem description motivates our attempt to build a system to support research into FLOSS projects. FLOSSmole (formerly OSSmole — the name was changed to reflect our inclusion of Free and Libre software in addition to open source software) is a central repository of data and analyses about FLOSS projects which have been collected and prepared in a decentralized manner. Data repositories have been useful in other fields; the presence of trusted datasets allows research communities to focus their efforts. For example, the TREC datasets have supported a community of information retrieval specialists facilitating performance and accuracy comparisons; the UMI machine learning repositories have been widely used in the development of new machine learning algorithms. There are numerous examples from biology and physics as well. The intention of FLOSSmole is to provide high-quality and widely used datasets, and to share standard analyses for validation, replication, and extension.

REQUIREMENTS OF THE FLOSSMOLE SYSTEM

Below we list some of our initial requirements for an optimal data and analysis clearinghouse for FLOSS data, and we note to what extent FLOSSmole has met each of these requirements. The next section expands on additional specific design attributes of the FLOSSmole system.

An optimal data and analysis repository for FLOSS data should be:

Collaborative. The system should leverage the collective effort of FLOSS researchers to reduce redundancies and to free researchers' time to pursue novel analyses. Thus, in a manner akin to the BSD rather than the GPL licensing model, FLOSSmole expects, but does not require, that those that use data contribute additional data and the analysis scripts that they obtain or use.

Available. The system should make the data and analysis scripts available without complicated usage agreements, where possible through direct unmonitored download or through interactive database queries. This should end the problem of data lockup, and will ease entry of new researchers with novel techniques. Freely available data also lowers the barriers to collegial replication and critique. FLOSSmole scripts and data are open-sourced and available to anyone via the FLOSSmole Sourceforge project page.[7]

Comprehensive and compatible. Given the fragmentation of FLOSS project storage identified previously, the system should cover more than just one repository. The system should be able to pull historical snapshots for purposes of replication or extension of earlier analyses. Compatibility requires that the system should translate across repositories allowing researchers to conduct both comprehensive and comparative analyses. (Currently FLOSSmole contains data from three repositories.) There exists the potential to develop an "interchange" format for FLOSSmole project collateral which projects themselves, which fear data and tool lock-in, might find convenient and

useful as they experiment with new tools and repositories.

Of high quality. Researchers should be confident that the data in the system is of high quality. The origins and collection techniques for individual data-points must be traceable so that errors can be identified and not repeated. Data validation performed routinely by researchers can also be shared (for example, scripts that sanity-check fields or distributions) and analyses validated against earlier analyses. By implementing these requirements, FLOSSmole is potentially a large advantage over individual research projects working with nonvalidated single datasets because it implements the "many eyeballs" FLOSS methodology for quality assurance.

Able to support reproducible and comparable analyses. It is desirable that data extracted from the database for transformation be exported with verbose comments detailing its origins and how to repeat the extraction. The best way to ensure reproducible and comparable analyses is to have as much of the process as possible be script-driven, and in this goal, FLOSSmole excels. Optimally, the system should specify a standard application programming interface (API) for inserting and accessing data via programmed scripts. That would allow analyses to specify, using the API, exactly the data used.

A system that meets these requirements, we believe, will promote the discovery of knowledge about FLOSS development by facilitating the next phase of extension through replication, apposite critique, and well-grounded comparison.

ADDITIONAL DESIGN DETAILS

The FLOSSmole data model is designed to support data collection, storage, and analysis from multiple free and open source forges in a way that meets the previously stated requirements. This section lists some additional design details we have made in implementing our FLOSSmole system.

FLOSSmole is able to take both spidered data and data inserted from a direct database dump. The raw data is time stamped and stored in the database, without overwriting any data previously collected, including data from the same project and from the same forge. Finally, periodic raw and summary reports are generated and made publicly available on the project Web site.

The type of data that is currently collected from the various open source forges includes the full HTML source of the forge data page for the project, project name, database environments, programming languages, natural languages, platforms, open source license type, operating systems, intended audiences, and the main project topics. Developer-oriented information includes number of developers, developer information (name, username, e-mail), and the developer's role on the project. We have also collected issue-tracking data (mainly bugs), such as date opened, status, date closed, and priority. Data has been collected from Sourceforge, GNU Savannah, the Apache foundation's Bugzilla and Freshmeat. We are currently creating mappings between fields from each of these repositories and assessing how comparable the fields are. The forge-mapping task is extensive and time-consuming, but the goal is to build a dataset that is more complete and is not specific to only one particular forge.

FLOSSmole is constantly growing and changing as new forges are added. And because data from multiple collectors are both expected and encouraged, it is important that the database also store information about where each data record originally came from (i.e., script name, version, command-line options used, name and contact information of person donating the data, and date of collection and donation). This process ensures accountability for problematic data, yet encourages collaboration between data collectors. The

information is stored inside the database to ensure that it does not get decoupled from the data.

Likewise, it is a general rule that data are not overwritten when project details change; rather, one of the goals of the FLOSSmole project is that a full historical record of the project be kept in the database. This will enable researchers to analyze project and developer changes over time and enable access to data that are difficult or impossible to access once they are no longer viewable from the repository's front-end interface.

Access to the FLOSSmole project is two-pronged: both data and scripts are continually made available to the public under an open source license. Anyone can download the FLOSSmole raw and summary data for use in their own research projects or just to get information about the state of the art in open source development. The raw data are provided as multiple text file "data dumps" from the FLOSSmole database. Summary files are compiled periodically, and show basic statistics. Examples of summary statistics that are commonly published would be the count of projects using a particular open source license type, or the count of new projects in a particular forge by month and year, or the number of projects that are written using each programming language. It is our hope that more sophisticated analyses will be continually be contributed by researchers, and that the system will provide dynamic and up-to-date results rather than the static pictures that traditional publication unfortunately leaves us.

The scripts that populate the FLOSSmole database are also available for download under an open source license. These scripts are given for two reasons: first, so that interested researchers can duplicate and validate our findings, and second, so that anyone can expand on our work, for example, by modifying a script to collect data from a new forge. Indeed this process has begun with the recent publication of a conference paper comparing and commenting on our spidering and summaries and beginning collaboration (Weiss, 2005). FLOSSmole expects and encourages contributions of additional forge data, and interested researchers should see the FLOSSmole project page and join the mailing list for information on how to contribute.

RESULTS

Because it is a regularly updated, publicly available data repository, FLOSSmole data have been used both for constructing basic summary reports about the state of open source, as well as for more complex social network analyses of open source development teams. For example, summary reports posted as part of the FLOSSmole project regularly report the number of open source projects, the number of projects per programming language, the number of developers per project, and so forth. These sort of descriptive data are useful for constructing "state of the industry" reports, or for compiling general statistical information about open source projects. The FLOSSmole collection methods are transparent and easily reproduced, so FLOSSmole can serve as a reliable resource for these metrics. Having a stable and consistently updated source of this information will also allow metrics to be compared over time. One of the problems with existing analyses of open source project data is that researchers will run a collection and analyze it once, publish the findings, and then never run the analysis again. The FLOSSmole data model and collection methodology was designed to support historical comparisons of this kind.

FLOSSmole data were used in a number of large-scale social network analyses of FLOSS project development. Crowston and Howison (2004) report the results of a SNA centralization analysis in which the data suggest that, contrary to the rhetoric of FLOSS practitioner-advocates, there is no reason to assume that FLOSS projects share social structures. Further FLOSSmole data were used in the preparation of Crowston,

Howison, and Annabi (2006) which, in an effort to avoid the ambiguities of relying on ratings or downloads, develops a range of quantitative measures of FLOSS project success including the half-life of bugs. FLOSSmole makes available the full data and analysis scripts, which make these analyses fully reproducible, and, we hope, extendable.

FLOSSmole data were also used in a recent exploration of whether open source development teams have characteristics typical of a complex network (Conklin, Howison, & Crowston, 2004). This research investigated whether FLOSS development networks will evolve according to "rich get richer" or "winner take all" models, as other self-organized complex networks do. Are new links (developers) in this network attracted to the largest, oldest, or fittest existing nodes (project teams)? The FLOSSmole data were used to determine that there are indeed many characteristics of a complex network present in FLOSS software development, but that there may also be a mutual selection process between developers and teams that actually stops FLOSS projects from matching the "winner take all" model seen in many other complex networks.

Projects of a nonacademic nature are making use of FLOSSmole data as well. The Swik project from SourceLabs[8] is a wiki-driven system for managing facts about other open source software projects. Swik uses FLOSSmole data to populate its initial list of projects. Working independently, the Swik team was able to download FLOSSmole data and put them to use immediately to save time and effort during their development process. By using a dataset that was freely available and for which the provenance of all data was known and validated, Swik was able to accelerate their development cycle.

LIMITATIONS AND FUTURE WORK

There are, of course, limitations in the FLOSSmole project and in our approach. First, we are limited to collecting data available online, and we are limited to collecting data gathered as a direct result of documented project activities. Of course, electronically documented project activities are not the only interactions FLOSS team members have, and even these activities are not always available for perusal by outside parties. Thus while textual data like mailing lists, CVS comments, Forums, and IRC chat logs could be included[9], FLOSSmole does not aim to capture unlogged instant messaging, IRC, Voice-over-IP, or face-to-face interactions of FLOSS developers. Nor do we intend to store interviews or transcripts conducted by researchers that would be restricted by research ethics policies.

There are also dangers in this approach that should be acknowledged. The standardization implied in an academic repository, while valuable, runs the risk of reducing the valuable diversity that has characterized academic FLOSS research. We hope to provide a solid and traceable dataset and basic analyses that will support, not inhibit, interpretative and theoretical diversity. This diversity also means that research is not rendered directly comparable simply because analyses are based on FLOSSmole data or scripts; the hard intellectual work remains and hopefully FLOSSmole, by supporting baseline activities, leaves us more time for such work.

It is quite likely that a functional hierarchy could develop between cooperating projects, something akin to the relationship between FLOSS authors and distributions, such as Debian or Red Hat and their package management systems (i.e., apt and rpm). For example, such an arrangement would allow groups to specialize in collecting and cleaning particular sources of data and others to concentrate on their compatibility. Certainly, we expect that the existing communities of academics

interested in FLOSS, such as opensource.mit.edu, will be a source of data and support.

Finally, we must also consider privacy issues. There is some discussion in the research community about breaching developer privacy in a large system of aggregated data like ours (Robles, 2005), specifically in terms of uniquely identifying developers and analyzing their work products. FLOSSmole should have the ability to hash the unique keys indicating a developer's identity. This effort will have to be researched, implemented, and documented for the benefit of our community.

CONCLUSION

Researchers study FLOSS projects in order to better understand collaborative human behavior during the process of building software. Yet it is not clear that current researchers have many common frames of reference when they write and speak about the open source phenomenon. As we study open software development, we learn the value of openness and accessibility of code and communications; FLOSSmole is a step towards applying that to academic research on FLOSS. It is our hope that by providing a repository of traceable and comparable data and analyses on FLOSS projects, FLOSSmole begins to address these difficulties and supports the development of a productive ecosystem of FLOSS research.

ACKNOWLEDGMENT

This research was partially supported by NSF Grants 03-41475, 04-14468, and 05-27457. Any opinions, findings, conclusions, or recommendations expressed in this material are those of the authors and do not necessarily reflect the views of the National Science Foundation. Chapter 1.10
Free/Libre Open Source Software for Bridging the Digital Divide

Yu-Wei Lin
University of York, UK

INTRODUCTION: THE FORGOTTEN USERS IN SOFTWARE DESIGN

As some scholars claim, the digital divide, referring to the perceived gap between those who have access to the latest information technologies and those who do not, entails that not having access to this information is an economic and social handicap (Compaine, 2001). In software design, structured inequalities operate along the main axes of gender, race/ethnicity and class. Each of these in turn generates its own structure of unequal practices giving rise to institutionalised sexism, racism or class divisions/conflict. "Gender, race and class also crosscut each other in various complex ways, sometimes reinforcing and at other times weakening the impact of existing inequalities" (Cohen & Kennedy, 2000, p. 100). For instance, Webster's research (1996) employing feminist approaches to study computer system designs addresses the issue of a male-dominated system design field, which continuously excludes female users' needs, requirements, interests and values in the innovation process. She criticises that, "Human factors may be bolted onto existing methods of systems design, local and contingent knowledge of work and information handling processes held by users in an amorphous sense may now even be incorporated into the systems design process, but this does not create an awareness of the way in which skills and knowledge are defined in gender-divided terms" (p. 150).

In a similar course, I argue that users' experiences in developing or undeveloped countries are often ignored in mundane software designs led by developed countries. Although localisation of information infrastructure is an eminent issue emerging in current system development, profit-oriented products and services, such as Microsoft's local language program (LLP), do not really comply with local needs. Rather, this type of multi-languages software packages, a software suite fabricated universally for countries around the world, signify the phenomenon, which I term the "MacDonaldisation of Windows-Intel platforms," which in fact alienates users and the local contexts.

FLOSS IN ACTION

In recent years, free/libre open source software (FLOSS) has emerged as an important phenomenon in the information communication technology (ICT) sector as well as in the wider public domain. An increasing number of governments have endeavoured to either convert the public administration infrastructure from Windows to Linux or to adopt FLOSS for similar tasks (e.g., Munich in Germany or Zaragoza in Spain) (c.f., "Linux in Spain" on LWN.net; C|Net News.com August 29, 2001). FLOSS transparentises the often black-boxed software code and allows users to copy, distribute and modify a programme received freely. In making source code available, software technologies can be challenged, adapted, and ameliorated to satisfy diverse user needs. Apart from solving the prolonged usability1 problem in software engineering, implementing FLOSS also helps ground both social and technical knowledge in locales and bridge the digital divide. In other words, implementing FLOSS facilitates technical knowledge (e.g., programming skills and ICT expertise) and social experiences to be transported and transferred through the acclaimed practices of social networking and mutual help noted prominently in many recent community studies (e.g., Wellman, 1999; Rheingold, 2000; Hampton & Wellman, 2003; Jordan et al., 2003; Lin, 2004a).

There have been a number of tactical considerations of implementing FLOSS in countries or organisations devoid of intellectual or financial resources: for economic reasons to save software costs; for educational reasons to improve human resource; for political reasons to stop monopoly proprietary software from expanding their market share as well as to gain digital autonomy, just to name a few. Hence, it is a strategic interplay for local governmental or non-governmental organisations (NGOs), and FLOSS activists to coalesce to tackle these inequalities. Because knowledge transfer is as crucial as infrastructure implementation, hands-on training made available to the local users is essential in the execution. Projects such as the E-Riders2 and Low Income Networking and Communications3, or events such as the Summer Source Camp4 and Africa Source5, all illustrate the transfer of knowledge and technology across cultural boarders. These examples also show how the implementation of FLOSS shapes the lives and identities of local users as well as software developers around the globe (Lin, 2004b). Additionally, there is conspicuous implementation of Linux-based infrastructure in the local educational, NGO and governmental organisations in developing countries or regions (e.g., Washington Post, November 3, 2002). The advents of embedded technologies such as the "Simputer," a Linux handheld applied in India, are believed to enable affordable, sustainable village development in places without phones and power, giving more and more people a voice in the conversation about their future (Cherlin, 2002). Wireless technologies are amongst others to bring the Internet to developing countries or regions to facilitate networking at both local and global levels. Krag, a Danish expert of wireless technologies who I met at the 2003 summer source camp in Croatia, describes wireless technologies as low-cost and decentralised. Here is a quote from his talk at the O'reilly 2004 emerging technology conference6 about the advantage of wireless technologies:

> Billions of people in the world have never been online. The Internet as a technology is an elitist tool, reserved for the few and unreachable by the many. This is a problem not likely to be solved by the commercial interests of existing telecommunications companies and existing ideas about expensive, centralized infrastructure. But low-cost, decentralized wireless technologies could have an important role to play, in this respect. Their low price point and decentralized nature, and the openness of the standards, mean that these technologies are incredibly adaptable to new situations and new uses. (Krag, 2004)

Krag and his colleagues have been working in undeveloped/developing countries around the world, building up and promoting wireless technologies (mainly 802.11b standard, also known as WiFi) for the locals. They bring the Internet and intranet connectivity to those parts of the world not included in the plans of the commercial telecommunications companies. They teach and give hands-on training to the locals about how to use ICT, and at the same time build wireless networks in the countries they visit. In so doing, they hope to "not only raise awareness and heighten skill sets, but also gain the experience necessary to build a central repository of documentation and tools, targeted specifically at the developing world" (ibid.). Krag's words subtly show that working with the locals de facto benefits the legitimate knowledge system of wireless technologies by means of bringing in more empirical cases that illustrate how infrastructure can be turned into applications, and how experiments can be turned into existing proofs. That said, working in undeveloped/developing areas in fact is not a one-way giving episode, rather, it is a reciprocal process that involves mutual help and mutual learning. Sometimes, extra functions are endorsed to the original products or facilities to meet local users' needs or habits ad hoc. The local contingencies entail that products and facilities can be renovated with the new functions and features after being deployed in local environments. This close link with global and legitimate knowledge sets also suggests that local expertise is worth being documented or transcribed in order to understand the construction of a knowledge-based society from both macro and micro levels.

DEMOCRATISING SOFTWARE INNOVATION PROCESS: WHOSE DEMOCRACY?

Given the advantages of FLOSS, it is believed that FLOSS is seen as an effective tool and approach to tackle the digital divide. Although FLOSS provides more flexibility and economic good for local users, solutions are mostly identified and crafted from the point of view of the developed countries. The collaborative episodes between NGO and FLOSS sectors illustrated above show an ambition to mobilise awareness and participation, and build capacity. However, when taking the local requirements into account, the social problem of the digital divide is perceived merely in the eyes of some NGO and FLOSS workers, rather than derived from the locals. Whereas a FLOSS-based solution seems to bridge the digital divide more efficiently than proprietary software, it sometimes still ignores that the political-cultural position of the locals and does not automatically move towards the centre of the global society. The cultural differences between the outsiders and insiders at the locale influence which perspective in a FLOSS implementation (e.g., economical, educational, social, political, technical) should be prioritised. This decision is a tactic because in the decision-making process, NGO and FLOSS activists all identify and interpret the social problem from their point of view. For FLOSS and NGO activists, introducing and implementing FLOSS denotes a cultural shift of networking the local with the global. They believe that ideas and knowledge are the cosmopolitan valuables, and community building and social networking are the most effective means to engage these social capitals that can be amplifiers in an innovation system. However, the social problems have different meanings to the local. In some places, freedom of information is not the priority. Instead, to endorse the local economic purchase power is on top of any other concerns. Without taking the local interests into account, the design of the information infrastructure, which is out of context, is likely to be lost in translation. That said, the social problems addressed, presented and represented differently by NGO and FLOSS activists in each local context, are better seen as articulations of the communication and move-

ments between different forms of knowledge and cultural practice. In short, "who provides what for whom" is a crucial question when studying the implementation of FLOSS. There is a dilemma of "translation from whom?"

This dilemma has gradually been noticed by some FLOSS activists who have devoted much time to implementing FLOSS infrastructure in undeveloped/developing countries. In the case of wireless technologies, it is true that wireless technologies are relatively cheap and have all of the technical advantages of simplicity, openness, decentralisation and autonomy. However, when the digital divide is perceived as a social problem for NGO and FLOSS activists, it has actually produced a subtle prejudice invisible to the digital elite. Indeed, some FLOSS spokespersons have shown different opinions on mainstream media policy that "often take the technological configuration of the new media as a 'given' or prefigured system that needs to become more widely diffused to citizens" (Mansell, 2002, p. 408). However, as Mansell also points out, arguments such as Lessig's research (2000, 2001) "does not examine the rhetorical forms that help to sustain the configurations of the new media that are favoured by an influential minority of technology developers and producers" (op. cit.). It is likely that the implementation of FLOSS conversely deteriorates the opposition between the rich and the poor because the poor cannot perceive the digital divide as an urgent problem. It would be a failure of not being able to correspond the local's interests and encourage their motivations.

Is FLOSS a silver bullet for bridging the digital divide? It could be. Compared with other ICT based on proprietary software, a FLOSS-based implementation does provide a better approach to bridging the digital divide from many aspects, particularly in terms of mapping and incorporating local users' requirements and lowering their ICT purchase cost (Lin, 2004b; Wheeler, 2004). However, the degree of empowerment may be counteracted if local users' interests are not fully included in the implementation agenda. So-called "digital independence" and "participatory democracy" would be just a proclaimed allegation in the FLOSS hype, as they are in most ICT advocacy. Having said that, it is not my intention to deny the advantages of FLOSS and its socio-technical impacts. But I would like to point out some blind points remaining in its world wide implementation and deployment. There has been a tendency in the development of ICT to facilitate human activities with more ubiquitous and efficient infrastructure and interfaces to meet users' needs in various areas. Whilst this vision of civilisation sounds promising, the accentuation on ICT's positivity also leads to all manner of delusions and falsehoods. When a newly invented ICT product is praised for its influential potential to empower consumers, it is yet invalid without asking whether a product is usable and useful to users, or without understanding users situated in different cultural and social contexts. This focus on the infrastructure building has misled both the public and the private sectors to believe a set of dominant and monolithic values, such as "efficiency," "modernity," and "improvement" (in the context of the "state-of-the-art"). Users are imposed to accept explicitly or implicitly these values which are fabricated and fortified to meet interests of specific social groups. A solitary identity and socio-technical class is produced to categorise users: to be connected/wired or to be alienated from the digital world; to be mobile or to be outmoded; to be electronic or to be antediluvian. Diverse meanings of "innovation" thus are muted in this dominant socio-technical context. Modern users of ICT de facto have lost their socio-cultural identities, which are grounded in everyday lives. The digital divide issue is also lost in this hype that ICT is the vehicle for democratic participation.

Whilst the emergence of FLOSS broadens the digital divide issue from a level of access to information facilities (hardware) to information contents (software), this extended scope remains

the preference of a small group of digital elite. In this regard, I share the opinion of Thomas and Wyatt (2000) that access is not the only important issue for understanding inequality. Instead, it is the assumptions on which diffusion of Internet connection is seen as necessarily expanding and beneficial that should be questioned. In a sociological term, it is more essential to understand the meaning of "access" to the Internet that is interpreted and appreciated differently by different social groups across geo-cultural borders. A crucial perspective to be developed while studying the increasingly prominent FLOSS phenomenon is to examine critically the role of the intellectual and their interactions with the local. It requires a careful examination on the conceptualisation and organisation of resistance to taken-for-granted realities and dominant forms of social organisation, which often goes together with a desire for new technologies. The so-called "digital divide" should be understood as a situated digital divide.

CONCLUSION: TRANSFERRING LOCAL EXPERTISE INTO A GLOBAL KNOWLEDGE SYSTEM

This article argues that FLOSS helps developing regional communities by improving ICT capacity and empowering users. FLOSS provides local governments and organisations a shared code base with higher level of security and a dramatic reduction of development costs. FLOSS bridges the digital divide in lessening dependency on proprietary software and securing the potential for developing local relevant software. However, without adequate expertise, after opening up the black box of software technologies, users are still left in a feeble situation and strongly depedent on experts. This is why hands-on training and a well-networked community providing mutual help are necessary in the implementation process, so that participants can learn to read the code, manipulate the code, and work with the code. Here, "the code" does not only indicate software source code, but is more generically referred to the code of knowledge. Whilst open-source code is decoded, so is the formal expertise deciphered. Consequently, software technologies can be challenged, adapted, and ameliorated to satisfy diverse user needs and solve the prolonged usability problem. Nevertheless, this problem will not be solved in a short time. Whilst open source code can be exploited and employed by experts programmers for individual needs, for users, unless they own or access to the expertise as well, the knowledge does not transfer onto them straight away after source code is released. That said, the empowerment of technology is not a natural process. It requires skills and experiences dealing with and translating the rich information into various languages which facilitate wider accessibility to the core of the knowledge system. I suggest that it is crucial to coalesce the local cultures and the technologies and to improve the dialogues between FLOSS developers, implementors and the locals in order to facilitate the implementation process. In so doing, knowledge-deciphering and knowledge-transferring will less likely to get lost in translation. ICT knowledge thus can be more appropriately transferred to and relocated in locals' daily lives. The global problem of usability, hence, can be tackled through the grassroots social networking.

KEY TERMS

Digital Divide: The digital divide is a social issue referring to the differing amount of information between those who have access to computers and the Internet and those who do not.

FLOSS: Free/Libre Open Source Software (FLOSS), generically indicating non-proprietary software, combines the concepts of free software and open source software. It makes it easier to talk about one movement and not ignore the other, and as such, can be used as a compromise term palatable to adherents of either movement. It also emphasises the libre meaning of the word "free" rather than the "free of charge" or gratis meaning which those unfamiliar with the subject

might assume. This all-inclusive acronym has the extra advantage of being non-anglo-centric: the F stands for Frei in German while the L stands for Libre in French and Spanish, Livre in Portuguese and Libero in Italian, showing that the concepts and their implementation are not exclusive to the English-speaking world.

ICT: Information and communication technology (ICT) is the technology required for information processing. In particular the use of electronic computers and computer software to convert, store, process, transmit, and retrieve information.

NGO: A non-governmental organisation (NGO) is an organisation which is not a part of a government. Although the definition can technically include for-profit corporations, the term is generally restricted to social and cultural groups, whose primary goal is not commericial. Generally, although not always, these are non-profit organisations (NPO) that gain at least a portion of their funding from private sources.

Social Networking: Social networking describes the process of connecting individuals via friends, relatives, and acquaintances. These networks can then branch out and allow friends to connect with people inside their accepted social circle.

Usability: Usability addresses the full spectrum of impacts upon user success and satisfaction. Usability is accomplished through user-centreed (not necessarily user-driven) design. The usability engineer provides a point-of-view that is not dependent upon designers' goals because the usability engineer's role is to act as the users' advocate.

User-Centred Design: User Centered-Design (UCD) is a software process that seeks to answer questions about users and their tasks and goals, then use the findings to drive development and designs, and improve the usability and usefulness.

ENDNOTES

1 Here, "usability" serves as an umbrella term that covers generic human-machine interactions (HCI) issues as well as wider accessibility and the digital divide problems.

Chapter 1.11
Community of Production

Francesco Amoretti
Università degli Studi di Salerno, Italy

Mauro Santaniello
Università degli Studi di Salerno, Italy

INTRODUCTION

There is no universal agreement regarding the meaning of the term "social software." Clay Shirky, in his classic speech "A Group is its Own Worst Enemy," defined social software as "software that supports group interaction" (Shirky, 2003). In this speech, this scholar of digital culture also observed that this was a "fundamentally unsatisfying definition in many ways, because it doesn't point to a specific class of technology."

The example offered by Shirky, illustrating the difficulties of this definition, was electronic mail, an instrument that could be used in order to build social groups on the Net, but also to implement traditional forms of communication such as broadcasting, or noncommunicative acts such as spamming. In his effort to underline the social dimension of this phenomenon, rather than its purely technological aspects, Shirky decided to maintain his original proposal, and this enables scholars engaged in the analysis of virtual communities to maintain a broad definition of social software. Heterogeneous technologies, such as instant messaging, peer-to-peer, and even online multigaming have been brought under the same conceptual umbrella of social software, exposing this to a real risk of inflation. In a debate mainly based on the Web, journalists and experts of the new media have come to define social software as software that enables group interaction, without specifying user behaviour in detail. This approach has achieved popularity at the same pace as the broader epistemological interest in so-called emergent systems, those that, from basic rules develop complex behaviours not foreseen by the source code (Johnson, 2002). This definition may be more useful in preserving the specific character of social software, on the condition that we specify this carefully. If we include emergent behaviour, regardless of which Web technologies enter into our definition of social software, we will once again arrive at a definition that includes both everything and nothing. Emergence is not to be sought in the completed product, that may be unanticipated but is at least well-defined at the end of the productive cycle, but rather resides in the relationship between the product, understood as a contingent event, and the whole process of its production and reproduction. A peculiar characteristic of social software is that, while allowing a high level of social interaction on the basis of few rules, it enables the immediate re-elaboration of products in further collective cycles of produc-

tion. In other words, social software is a means of production whose product is intrinsically a factor of production. Combining hardware structures and algorithmic routines with the labour of its users, a social software platform operates as a means of production of knowledge goods, and cognitive capital constitutes the input as well as the output of the process.

If a hardware-software system is a means of production of digital goods, social software represents the means by which those products are automatically reintroduced into indefinitely-reiterated productive cycles. This specification allows us to narrow down the area of social software to particular kinds of programmes (excluding, by definition, instant messaging, peer-to-peer, e-mail, multiplayer video games, etc.) and to focus the analysis on generative interaction processes that distinguish social software from general network software. Moreover, following this definition, it is possible to operate a deeper analysis of this phenomenon, introducing topics such as the property of hosting servers, the elaboration of rules and routines that consent reiterated cycle of production, and the relationships between actors within productive processes.

NORMATIVE EVOLUTION OF THE INTERNET FROM NET95 TO WEB 2.0

At the end of the 1990s, two particular events gained wide social significance in the evolution of global telecommunications networks. First, a deep restructuring of the fundamental architecture of the Internet radically transformed the network which had been born in the ARPA laboratories. Coming out of a rather narrow military and academic sphere, the Internet became at once easier and more complex. Graphical user interface (GUI) principles simplified computer and database management for a growing mass of individuals who were ready to get connected, giving birth to a vigorous codification of intermediate zones between man and machine. Operating systems, appliances, software, automatic updates: the popularisation of the Net has proceeded through a constant delegation of terminal management from the user to the software producer, and in the case of software distributed under the juridical instrument of the "license of use," this delegation consists in the property of parts of the "personal" computer. The American constitutionalist Lawrence Lessig, underlining the social relevance of this phenomenon, describes the original network (Net95) as being completely twisted, subject to the control of those coding authorities that, since 1995, have reconfigured the architecture of cyberspace (Lessig, 1999).

The second event that has contributed to the morphology of the transformation of new information technologies is a direct consequence of the first, and concerns contents, or products, of this new kind of network. The more Internet has been regulated by a wide group of code writers, among which a narrow circle of economic players who have assumed positions of power, the more personal relationship networks based upon it have assumed social significance and cultural reach. Ease of computer management and development of applications that allow social interaction in an intuitive and simple manner have brought blogs, wiki, syndication and file-sharing platforms to the scene. The growing use of these Internet-based applications, a result of the convergence between the regulation and socialisation of cyberspace, has slowly attracted the attention of political and economic organisations due to its capacity to allow a widespread and participative use of digital goods and knowledge. So, the first realisation of Web 2.0 (or semantic Web) was the product of a normative process operated for the most part by software engineers, a product which, arriving later, attracted the attention of the social sciences, which tended to view the means of that production as black boxes. In this period, between the last two centuries, besides more profound reflection on

emerging social systems based on social software platforms, there was scarce interest in the structures and infrastructures of telecommunications networks, understood as plentiful resources, never as a real means of production.

COMMUNITY OF PRODUCTION

The Dual Reality of Social Software

In the second half of 2006, the Web site called YouTube reached popularity and suddenly burst into the Top 10 of most visited Web sites (Alexa, 2006). Just 18 months after its launch, this platform for video-sharing reached an average of 60 million visits per day, with hundreds of thousands of clips being viewed each day in streaming and 65,000 new clips uploaded every 24 hours. YouTube's success may be explained, above all, by reference to the scarce resources that, despite the arguments of "plenty infrastructure" theorists, characterise Internet as another complex system of means of production. Having no resources to host and transmit a great quantity of video information, millions of individuals use YouTube's resources in order to reach the same goal: to share videos. Uploaded clips, moreover, are immediately available for other, undefined forms of production of meaning, that work mainly through three channels. The first involves categorising videos using labels (called tags), which are filled in by the user who uploads them. In this way, both search and correlations between videos are based on a *folksonomy* system that is able to generate bottom-up relationships. Second, users can express a judgement on the video's quality and relevance to the description, providing single clips with a "reputation." Third, a function of the platform is its capacity to supply code that, pasted in a Web page or a blog, executes the corresponding clip in a streaming player. This last function is largely used by publishers who, not having the required resources to afford streaming connections, use YouTube to retransmit their own digital productions. Another social software platform with similar characteristics is Flickr. In contrast to YouTube, this allows photo, not video, sharing. The greater number of visits for YouTube when compared to Flickr (which is estimated to be the 38th most visited site in the world, with 12 million contacts per day), is partly attributable to the greater quantity of data necessary to code videos rather than photos, that is to produce film transmissions rather than photo-galleries over the Web. The more storage and bandwidth resources required, the more users need and use the platform. This kind of service is without charge, but is not without economic relevance for the organisations that manage it. Beside traditional sponsorship, both Flickr and YouTube largely use content-targeting advertisement, a technology that allows one to scan texts and automatically associate them with ads. Advertisers buy keywords, and when a keyword is found in a text, an associated advertisement is displayed near the text. If the announcement is clicked, the advertiser pays a sum divided between the firm that manages the content-targeting technology and the owner of the Web page upon which the ad was hosted. Gathering content-targeted advertisement is substantially a duopoly, provided by Google and Overture, the latter now being fully controlled by Yahoo. Flickr and YouTube, on the other hand, are the owners of Web pages that host texts produced by their users, and receive the remaining part of the share paid by the advertiser. Thousands of dollars daily move toward the bank accounts of social software platform owners thanks to the work of millions of volunteers who produce texts and links which themselves have economic value.

The concept of the user extends from the sphere of service enjoyment to the sphere of production, to the detriment of the concept of the worker. And if industrialisation proceeded via the eradication of workers' communities (Polanyi, 1944), digitalisation today appears to produce value through the creation and management of delocalised communities of volunteers. This phe-

nomenon assumes such an economic importance in the Internet advertisement sector that not long ago Yahoo bought Flickr to deliver its ads by its own, followed by Google, that recently completed the purchase of YouTube, of which it was already a supplier of content-targeted advertisements. The same fate was reserved for del.icio.us, a social software platform for Web site addresses, taken over by Yahoo. This situation means that, rather than sharing the revenues of content-targeting with these platforms, the two key players in the market preferred to tackle multimillion dollar costs in order to implement processes of vertical organisation, in a market that looked increasingly polycentric within a few years' of its opening. This dynamic, moreover, implies that the overall value of digital commodities produced on social software platforms represents a first order economic entity in the so-called new economy.

EVOLVING SCENARIOS: FROM WEB 2.0 TO INTERNET 2

Besides *folksonomies*, social software platforms can be based on another principle: real time collaborative editing (often called *wiki*). Users of this kind of platform can produce text and modify others' texts in real time, generating processes of collective and negotiated production of meaning. The main actor in this particular segment is the Web-based encyclopaedia Wikipedia. Founded in 2001 in the United States, it quickly entered the 20 most-visited Web sites in the world, with an average of just under 60 million visits per day. At the present time, it hosts 5 million definitions in 229 different languages and idioms. In 2005, the scientific magazine Nature conducted a comparative analysis of Wikipedia and Encyclopaedia Britannica, reaching the conclusion that the two are substantially equivalent in accuracy and trustworthiness, as far as the Natural Sciences are concerned (Giles, 2005). Unlike the previously described social software platforms, Wikipedia doesn't use paid advertisements, being funded by donations gathered by the Wikimedia Foundation, a nonprofit American organisation at whose summit is a five-member Board of Trustees. With a quarterly budget that doesn't exceed $400,000, and with the explicit goal of producing independent and free knowledge, Wikipedia expressly refuses the commodification of its knowledge-based output. But rather than representing the ideal type of social software, this constitutes an exception, whose survival is threatened by evolving scenarios of telecommunication infrastructures. Parallel to the bottom-up categorisation project of digital goods in the Web, there is a categorisation project that concerns not only Web content, but even its own infrastructures. AT&T, Verizon, Comcast, and other enterprises that manage global flows of information have been complaining for several years about the lack of return on their investments in telecommunication systems.

So-called *network neutrality*, the principle that Isenberg referred to as "netstupidity" during the early 1990s, does not allow carriers to distinguish between the functions of the bits of information that they transport; that is, whether they are constitutive of video, e-mail, phone calls, Web surfing, or whatever. This prevents them from applying specific fees according to a service typology that varies on the basis of the media goods moved by these actors and the resources employed. Telco's interests, which are also connected with the traditional phone networks, are clearly damaged by the architecture of their own infrastructure, but cannot prevent users from sidestepping traditional communication fees. If we consider how these interests are converging upon those—even wider—of the main owners of intellectual properties, we can understand how the architectural reconfiguration of Net infrastructures have reached an advanced state of both planning and implementation. Attempts to protect network neutrality by legal means, through the introduction of explicit limits in the U.S. telecommunications legislation, have so

far failed, and continue to generate transversal opposition within Congress (Senate Commerce Committee, 2006. HR.5252).

The Internet 2 project, which alongside the semantic Web introduces an intelligent infrastructure that is able to categorise digital commodities in the Net in a top-down manner, evokes a scenario in which Web sites could be obliged to pay for their visitors, and where fees are proportional to bandwidth used, as well as to the typology of enlivened media commodities. This kind of evolution could have a profound impact on those rare social software platforms exclusively supported by donations from civil society, thus likely to augment the probability of a market opening alongside them in the long term.

CONCLUSION

Migration toward cyberspace presents the same dual aspect that Russel King has observed in relation to mass migration. It creates particular forms of social relationships within a space: both social relations of capitalist production and personal social relations that reproduce migration chains over time (King, 1995).

It is of particular significance that, attempting to shed light on the dual nature of migration trends, King sought to recalibrate the analysis of human movements, introducing the theme of personal relations beside the broader one involving relations of production. In the case of migration toward cyberspace, on the other hand, the area of social relationships was the first to attract the interest of the social sciences, leaving political economy themes to the mercy of the theorists of the new economy.

Social software, one of the outcomes of half-century-long innovation processes in the cybernetic area, highlights the connections between social and production relationships implied in the digitalisation of human interactions. Delocalised human resources, mostly constituted by nonworkers, hardware and software means of production, are more and more concentrated in interconnected oligopolies, cycles of production whose routines accumulate value directly from working activities not remunerated, in same cases even paid by *workuser* to means of production's owner.

Social software seems to adhere to a comprehensive process concerning both the infrastructure of the Net, with its digital commodity flows, and relations of production within a system whose peculiarity is to be equipped with a unique space where production, trade, and finance can simultaneously coexist. Bridled in such a net-space, communities producing value produce social behaviours that, beyond their anthropological significance, assume a substantial economic value. Immediate value extraction by processes generated by noneconomic motivations represent one of most important aspects of the market-based reorganisation of information technologies and, from this point of view, social software could become one of the main arenas for the new relations emerging between capital, space, and labour in the current historical conjunction.

KEY TERMS

Cognitive Capital: A concept that represents knowledge as a scarce resource that can be traded with money, social influence, and political power. This concept is derived from Pierre Bourdieu's concept of "cultural capital," and it sheds light on accumulation and exchange processes regarding cognitive skills, knowledge, and information. Cognitive capital is now recognized as a key asset of institutions and economic organizations.

Cybernetics: "Control and communication in the animal and machine," as defined by its founder Norbert Wiener. This discipline studies living beings, machines, and organizations as regulatory feedback systems. The choice of term, "cybernetics," from Greek Κυβερνήτης (kybernetes, steersman, governor), shows Wiener's awareness, extensively argued in diverse works of his, about political and social relevance of interactive communication networks.

Folksnomy: System used in information organization. Rather than providing an ex ante categorizing project as in taxonomy, it exploits an open labeling system generating pertinences through its user cooperation. Assigning a label (tag) to every piece of information (photo, video, text, address, etc.) users contribute by donating a sense to the digital product universe, otherwise

unable to be tracked and used by its own community of production.

Graphical User Interface (GUI): Interface facilitating human-machine interaction, with graphic elements. Rather than inputting data and instruction in text format, GUI's user controls its elaborator directly manipulating objects: graphic images, menus, buttons, boxes, and so forth. The Interface translates user actions into machine commands, thus representing an intermediate normative zone between man and machine, a zone governed by code produced by software houses.

Instant Messaging (IM): Real-time Internet-based system allowing communication between two or more subjects. It represents an evolution of Internet Relay Chat, to whose decline it contributed. It provides a client software that allows synchronous conversations by means of interfaces supplied with many multimedia functionalities (audio, Webcam, file transfer, *animoticons*, etc.). Unlike social software, conversations produced by IM are not immediately reintroduced in cooperative processes of significance production.

Network Neutrality: Technical and political characteristic of those networks not allowing resource discrimination on the basis of their destination, content, and the applicative class of technology to which they belong. Debate on network neutrality initiated in the United States following an increasingly incisive reprojection of networks by Internet service providers (ISP) and telecommunications providers. Opposing this project reformulating Internet architectures, first of all, are content providers who would be obliged to pay, together with users, on the base of gained visits, used bandwidth, and typologies of service delivered.

Software: An unambiguous sequence of instructions that allows a machine to elaborate information. Software, also called program, defines rules and routines by which computer hardware has to act in order to perform its tasks. Combining software with physical resources, a computer can operate as a means of production, creating digital goods by manipulating a user's input.

Chapter 1.12
E-Democracy:
The Social Software Perspective

Pascal Francq
Université Libre de Bruxelles, Belgium

ABSTRACT

The success of the Internet has launched McLuhan's idea of the global village. Over the years, the Internet has become a real political medium which has inspired the emergence of the concept of e-democracy. Despite some successful applications, many limitations prevent its wide expansion. Some of these limitations can be solved with social software, in particular with the emerging Web 2.0 applications. This kind of applications may contribute to a better application of e-democracy processes for local political decisions.

INSIDE CHAPTER

The Internet is today a widely used platform to exchange information and share knowledge. In this chapter, we propose a prospective study of the use of the Internet as support for e-democracy processes. The history of the Internet shows that social software has always been developed to support knowledge sharing among net surfers. Since participating in political issues implies knowledge sharing, the Internet was rapidly used as a political medium. The concept of e-democracy, i.e. the use of information and communication technologies to allow citizens to participate in the democratic process, is a natural evolution of this situation. Several examples demonstrate that e-democracy can be deployed for local decision purposes. The experiences have also shown several limitations, in particular concerning the on-line tools currently offered. We argue that solutions exist to overcome these limitations and that their integration in social software environments may enhance the concept of e-democracy in order to apply it to more complex decision-taking situations.

INTRODUCTION

With the expansion of available information and the diversity of communication and information technologies, the Internet is a medium support that cannot be ignored. Limited to scientists during its early days, the Internet became a platform for knowledge sharing and collaboration for a variety of domains due to the multitude of social software developed. In particular, the political domain was always present on the Internet and political movements have often used this medium to support their actions. Today, with one billion net surfers around the world, many people claim that the idea of "global village" popularized by

Marshall McLuhan in the late 1690s (McLuhan & Fiore, 1967) is a reality. Now that it becomes possible to engage in discussions with everybody around the world across geographical and temporal boundaries, many people believe in the Internet as a virtual place where different cultures may peacefully coexist. From this dream there emerged, in the late 1990s, the concept of **e-democracy**. The main idea is to use the information and communication technologies to make citizens participate more directly in the democratic process. Several examples of the application of this concept for local decision-taking (decisions concerning a part of a city or a town) seem to demonstrate that the idea of e-democracy is no longer utopian. Moreover, with the emergence of the "Web2.0" concept, there is an increased use of social software by net surfers. This chapter proposes a prospective view of the application of social software to support e-democracy processes. In fact, we argue that social software can already be useful in this context. Moreover, we believe that it may be enhanced by integrating existing technologies to overcome certain limitations related to the current tools supporting e-democracy processes. Concretely, the second section proposes a short historical overview to show how the Internet, initially developed to support knowledge networks, was rapidly used as a political medium. The third section presents the concept of e-democracy, some examples and the main limitations of the current applications. The fourth section proposes an overview of how modern social software can be used in the context of e-democracy, and which technologies should be integrated to propose on-line tools enhancing the application of e-democracy processes. Since these evolutions solve some of the e-democracy limitations, the fifth section briefly analyses in which context the concept of e-democracy should be deployed. Finally, the sixth section proposes some conclusions.

FROM KNOWLEDGE NETWORKS TO POLITICAL MEDIA

The history of the Internet studied in section 2.1 shows that new collaboration tools and methodologies were continuously developed to increase knowledge sharing among social networks (scientific ideas, software, electronic resources, ...). Based on these emerging social networks, communities of net surfers have collaborated through the Internet on many different projects (section 2.2). As soon as the Internet allowed net surfers to freely exchange ideas, it was rapidly used to discuss political issues. The result is the evolution of the Internet to a real political medium (section 2.3).

Internet as Knowledge Networks

The Arpanet computer network, the ancestor of today's Internet, was designed to help researchers to collaborate. Tools such as e-mail and newsgroups were developed in the late 1960s to allow researchers to discuss their ideas, present their results and take scientific decisions. Initially limited to the military research area, the access to Arpanet was rapidly extended the whole research community. In the 1980s, Arpanet became the collaboration platform for many research teams around the world. The result of this evolution was the creation in the late 1980s of the Internet as known today. The main problem with the communication tools existing that time was their asynchronous dimension which strongly limits the interactions between people. With the increased use of the Internet during the 1990s, new synchronized communication applications were developed: instant messaging tools and chat rooms. These tools provided a new level of interactions in the communication process between net surfers. As studied by Rheingold (2000), this technology has permitted the emergence of **virtual communities** of net surfers sharing similar interests. Once

communities have emerged, it is possible to make them live through all modern communication supports. With the evolution of communication tools, in particular the net meeting applications, it has become possible to efficiently organize discussions involving participants that are not presented at the same place[1]. Initially developed at the beginning of 1990s as simple diffusion tools for scientific results at CERN, Web sites have become over the years real knowledge dissemination tools. Today, the number of Web sites containing interesting information has exploded making the localization of the relevant information a crucial issue. Since several technologies have increased the interactivity between Web sites and net surfers, the Web can be considered as a social environment and many modern Web sites have become real social software.

The Internet as Collaboration Platform

With the increasing number of net surfers and the availability of synchronous communication tools, the Internet evolves to a collaboration platform. Built upon virtual communities, net surfers have started to collaborate, in particular to build freely available artefacts (software, books, music tunes, ...). Emerging in the early 1980s, the free and open source software movements are the best examples of free collaboration through the Internet. By combining social software with specific collaboration tools, such as source code managing tools, complex software projects[2], comparable in quality and features to well established commercial software, were successfully developed (Raymond, 2001). One surprising aspect of these projects is their ability to manage long-term decisions and to self-organize the work division across a dozen of individual developers. Most of the time, when conflicts appear concerning important decisions in a given project, such as the choice of a project leader, a democratic approach is privileged by the community. This new production process has been successfully applied to other domains than software development. Founded in 2001, Wikipedia[3], the free content encyclopaedia project, is the best known example of the application of the concept of open source to other content than source code. Despite some problems concerning the control of the quality of part of the content[4], everybody agrees that Wikipedia demonstrates that high quality knowledge can be built in a collaborative way. In particular, on-line writers must sometimes reach a comprise as they elaborate articles discussing controversial issues. Since the early 2000s, and the emergence of the "Web2.0" applications[5], a new dimension in on-line collaboration is proposed. In fact, the role of the net surfer has dramatically changed: he or she has been transformed from a "passive consumer of information" to an active organizer of the Internet content. The new paradigm behind this social software is that net surfers should collaborate to manage shared resources (such as bookmarks, contacts, videos, ...) they find relevant. Since current search tools have difficulties treating the amount of available information on the Internet, this approach proposes a sort of "human indexing" of its content and its users.

The Internet as Political Medium

Since it is possible to communicate and collaborate through the Internet, it seems natural that it is a place where political issues may be discussed. A close look at the history of the Internet shows that its use as a political medium is as old as the Internet itself. In fact, as pointed out by Rosenzweig (1998), it is hard to believe that the creators of the Arpanet were unaware of the political context on the late sixties in the USA, in particular the protests against the Vietnam War mobilizing the American universities campuses. Moreover, some authors claim that the success of the Internet can only be understood if we consider that the first net surfers have adopt it as a democratic and interactive communication platform (Hauben &

Hauben, 1997). This latest theory finds an echo with an analysis of the content of the messages exchanged in newsgroups carried out in 1998. This study showed that 12% of the total number of messages on Usenet were dedicated to political subjects (Hill & Hughes, 1998). The fact that political issues were discussed in newsgroups is not surprising since it was certainly the first virtual place where any kind of subjects were discussed. But, the amount dedicated to politics reveals of the political awareness of many net surfers at that time and the existence of politically-oriented virtual communities. With the growing popularity of the Web as mass communication and diffusion medium, many "politically-oriented" organizations have understood the potential of the Internet as an internal and external communication tool. Internally, it provides a collaboration platform and is a source of information for members and sympathizers. Externally, the goal is to spread their ideas on the Net and to sensitize net surfers to their points of view. With the multiplication of blogs, it becomes very easy for everybody to publish their political ideas and to create a new genre of journalism (Wall, 2005). Conscious that the Internet is becoming widely used among the population in some countries, in the late 1990s, different public authorities deployed **e-government** projects, i.e. using information and communication technologies to better communicate with their citizens. Today, in some countries, citizens can use the Internet to access the debates of parliament, to ask for administrative documents or to fill their tax returns. In the e-government approach, the Internet is only used as a communication medium for governments, but there are no real interactions between citizens and public authorities.

E-DEMOCRACY: APPLICATIONS AND LIMITS

If the Internet was used very early to discuss political issues, it took some time before these discussions were transformed into real political actions. The concept of e-democracy emerged from Internet in the late 1990s (section 3.1) and was successfully applied to several situations (section 3.2). But, as analysed in section 3.3, there are actually some important limitations.

Concept of E-Democracy

There exist several definitions in the literature for the concept of e-democracy (sometimes called cyber-democracy). Nevertheless, all authors agree that it is related to the use of information and communication technologies to involve citizens, sometimes called **e-citizens**, in the political decision-making processes. If the idea of using technologies to build a better and more humane society is not new (Wiener, 1965), the actual development of the Internet in our modern societies makes its realization partially possible. Besides the multiple theoretical definitions, it is also possible to define e-democracy as a wide range of actions that should be available for citizens through the Internet: voting for people, participating in online referendums, intervening in public debates, etc. Since we are discussing e-democracy applications rather than the concept itself, we will adopt this approach. In particular, we choose the definition proposed by Vedel (2003) suggesting that the concept of e-democracy includes three levels of interactions between e-citizens and public authorities:

1. Access to information to ensure transparency in political decisions.
2. Build debates and discussion places between citizens in order to coordinate political actions.
3. Participate in public deliberations and decision-making.

Today, the concept of e-democracy is quite successful in Northern countries. Two elements may explain this:

1. Many citizens in these countries are petitioning for a more participative democracy.
2. In the collective conscience of these countries, the Internet is widely accessible for most citizens, even through if the reality is somewhat different.

Some Examples

The Public Electronic Network (PEN), which started in Santa Monica in 1989 (Rogers, Collins-Jarvis & Schmitz, 1994) is often cited as the first example of e-democracy application. By providing a network of terminals, the American city gave the opportunity to its citizens to discuss problems together. One of the results of these discussions was a project to help the homeless people of the city. Since this experience, several other cities or regions have deployed some of the principles of e-democracy (OECD, 2003). Most of these experiences can be categorized into two types of democratic interactions:

1. The creation of Internet portals where citizens can not only consult information (already available with e-government applications), but also interact directly with politicians, for example by sending e-mails or commenting on proposals.
2. The use of electronic consultations to get the opinion of citizens. Nevertheless, in most cases, there is not always an obligation for public authorities to take the results of these consultations into account.

If most of e-democracy applications were organized by public authorities, new situations emerge today where the e-democratic initiatives are directly launched by citizens themselves. The fact that Internet is more and more used to promote e-petitions (electronic petitions) is certainly the visible part of this for most net surfers. Successful uses of e-petitions in the context of local politics were already pointed out (Macintosh, Malina & Farrell, 2002). Moreover, some e-petitions have influenced more global political decisions, such as during the debate on software patents at the level of the European Parliament where it was one of the methods used by the opponents to sensitize the parliamentarians. Despite the criticism concerning the electronic vote[6], several initiatives have been successfully organized. For example, during the primary votes of the Democrats in Arizona in 2002, nearly 50% of the votes were cast using the Internet (Solop, 2002). The important point of such initiatives is that Internet should never be the only way to interact, but one of the possible ways. In fact, since people can participate from "their homes", the Internet may support the participation of people who would not participate without it. Some initiatives were more ambitious and aim to influence global political stakes. During the 2004 US presidential campaign, a Web site allowed net surfers all over the world "to vote" for their candidate[7]. 500.000 net surfers participated in this virtual election with, of course, no influence at all on the final results. But, this can be seen as an interesting experience of e-democracy at a global level.

Main Limitations

Despite some successful e-democracy applications, there are several important limitations that impede a generalized deployment. The main limitation is, of course, the reality of the digital divide. Many people have not (or rarely) access to the Internet. This makes e-democracy, in practice, a preserve for "rich" populations. If this difference is evident between the South and the North (geographical digital divide), among the Northern countries, many people cannot use, at least regularly and correctly, the Internet (social digital divide). Besides, several authors claim that e-democracy will only be available for a small part of the population which can then control the political choices (Barber, 2004). Apart from these

problems "outside of the technological sphere", the current examples of e-democracy are always related to very specific issues due to the lack of adequate integrated solutions. Of course, everybody would agree that deploying technologies will never solve all the real problems. Our point is that some of these problems are directly related to the underlying tools. To illustrate this, we propose to study the main limitations associated to the different levels of interactions proposed by Vedel (2003). The first category of interactions is related to the access of the relevant information for citizens. If the e-government initiatives can be seen as a first attempt to offer an access to public information, most of the time, e-government portals are not well structured. The consequence is a difficulty in finding all the relevant information related to a given problem. Moreover, all necessary information to build a real political culture is not available on e-government portals. It is also useful to access studies in universities, documents of political parties, citizens' testimonies, etc. Accessing other sources of information, such as the Internet, is an important issue. But the Internet is characterized by an increased quantity of available information, and current search solutions, in particular search engines, cannot face this complexity (Fogarty, & Bahls, 2002). Beside this problem of quantity of information, the quality of the proposed information is also problematic, in particular for search engines which are the most popular search tools. Most Internet search engines rank highly the documents which are the most pointed by hyperlinks on the Web (Brin & Page, 1998). Since hyperlinks can be interpreted as human assessments on a given document, i.e. assessments on the ideas defended by a "politically-oriented" document, search engines have a tendency to always propose the documents containing ideas shared by the majority of net surfers. This problem explains the frequent criticism that the Internet acts as support for a certain form of single thought. We believe that the current search methods should be enhanced, in particular to ensure the diversity of the points of view presented to net surfers. The second category of interactions is related to the creation of places where citizens can debate over political issues. As explained earlier, newsgroups and chat rooms are powerful tools for discussions. Participating in on-line discussions can make communities emerged (Rheingold, 2000), in particular net surfers sharing similar ideas and collaborating with a unique political goal. In fact, newsgroups were already successfully used for public on-line consultations (Rosen, 2001). But, the multiple existing communication channels where such communities may exist are a brake for the emergence of large communities of organized citizens, which is the core of the e-democracy concept. Of course, if there is a fixed political reference for a group of people, such as the Web site of a party or any politically-oriented organization, a community exists *de facto*. On the other hand, limiting the communities built around existing entities is somewhat reductive. We believe that networking tools should help people build new communities and that political portals should be used to coordinate political actions around specific subjects. The third category is related to participating in public debates and decision-making. For simple decision-making, such as answer a simple question (yes/no, for/against) or choose a candidate, Internet technologies can be used without any major technical problems. But, for more complex decision-taking, such as drawing up a budget for a town or writing a bill, there is a real lack of well-established on-line tools. We believe that existing methods managing complex decision-taking should be integrated in political portals.

BUILDING AND ORGANIZING POLITICAL NETWORKS

In the previous section, the short overview of the concept of e-democracy has shown the main actual limits of its application and some possible

directions for enhancement to solve some of these limitations. These enhancements should support the building and organization of political networks not only to group net surfers sharing the same ideas, but also to provide a discussion environment where people having different points of view on a same topic can hold a debate. Today, there is a need for independent **political portals**. Such portals should be sources for information related to specific political subjects (environment, democratic participation, education, ...). They should reference information coming from e-government applications (since many official political documents are public) but also from alternative sources. They should be build upon content management systems to provide an environment for debates and collaborative writing of documents. We argue that a combination of these political portals with other social software, in particular in the context of the emerging Web2.0 applications, may contribute to solve three major problems:

1. Ensure diversity of points of view.
2. Create political networks.
3. Organize complex decision-taking.

Diversity of Points of View

One of the main stakes behind the concept of e-democracy is to access to information representing different points of view on a given problem. As already explained, the e-government portals currently developed by several countries should help to make official information more accessible. But, it is also necessary for e-citizens to read information coming from other sources and comment this information with other people, which is the role of the political portals. Since they must reference relevant information concerning a particular political subject, they should be combined with applications helping to access to interesting information available on the Internet. Several emerging Web2.0 applications propose some solutions to the access of information by providing a platform for a **social indexing** of the Web. Social bookmarking applications, such as del.icio.us, are well known examples. When net surfers find interesting documents on the Web, they tag them with keywords. It is then possible to find all the documents tagged, thus humanly assessed as relevant, with a given set of keywords. We already know that applying the social bookmarking principle can help net surfers (citizens) to access relevant (political) content. But this principle can also help citizens to have a more open mind. In fact, since political issues are characterized by a diversity of points of view, it is evident that a given document, a law or a study for example, may be interpreted in several ways depending on its readers. This diversity of points of view on a given document will probably correspond to different keywords used to tag this document. So, since net surfers will see all the keywords used by others to tag the same documents, it will be possible for them to have an overview of the different points of view by analysing the different sets of keywords used. Once these documents are tagged, they could be discussed on political portals. Everyone would agree that the major problem concerning Internet is related to the quality of the on-line content. For example, many Web sites around the world diffuse racist ideas. Currently, there is no technology that proposes a real solution to this problem, but several approaches have been proposed to limit its impact. One of them, used by several portals such as Internet marketplaces, is to propose a rating system of users (Chen & Singh, 2001). This system gives the opportunities to users to express a degree of trust to others based on their experiences of the interactions with them (for example buying something from them). This approach could be used in another way in our context: users would rate the people whom they do not trust. The idea of rating the non-trusted people rather than rating the trusted people is to avoid the limitation of the diversity of points of view. In fact, if users rated people

by trust, it is probable that they would rate well people sharing the same points of view, and the consequence would be to connect with people that reinforce their opinions rather than open them to diversity. By rating non-trusted people, it will be possible to identify groups of people who are never considered as trusted by most users. This information will be used to filter the information proposed or, at least, to inform net surfers that some political contributions were written by very untrustworthy people and should be taken with caution.

Building Political Networks

The e-democracy concept claims that e-citizens should be able to act on political decisions. It seems therefore evident that they must coordinate their actions. Such a coordination can be built upon "politically-oriented" virtual communities through political portals. If several tools exist to make these communities live (for example newsgroups) and could be integrated in portals, building these **political networks** remains a challenge. In the previous section, we have explained how social bookmarking applications may be used in the context of e-democracy. Moreover, some researchers have shown that it is possible to cluster the net surfers based on the keywords they used to tag documents (Paolillo, & Penumarthy, 2007). But, as already explained, the tags used represent a certain points of view of the tagged document. There is therefore a risk that doing a clustering on a tag-basis will lead to regroup people sharing the same point of view on a particular topic, which will reduce the access to a diversity of points of view. In fact, we need to build communities of people sharing the same interests on a given topic and not sharing the same points of view on a given topic. The clustering of net surfers into communities must therefore be based on the content of the information. The GALILEI platform is one of the solutions that proposes a solution for this problem (Francq, 2007). This platform implements an approach based on **social browsing**. In this approach, the net surfers define different interests, called profiles, and assess the documents they consider as relevant for their profiles. The system computes descriptions for the different profiles of the net surfers based on the relevance assessments on documents and a content analysis. The profiles are then clustered on the basis of their descriptions: similar profiles are grouped together in order to define a number of communities of interests. If this approach is applied with a corpus of political documents, the communities will group people sharing common interests on different political subjects.

Organize Complex Decision-Making

One of the main ideas behind the concept of e-democracy is to make citizens participate in political decisions-making. In the different examples existing today, this participation is limited to making a "simple choice", such as voting for a candidate. For more complex decision-making, there is a lack of on-line tools. A good example of complex decision-making process is to decide how to organize the allocations of a given budget. To solve this problem it is not only necessary to evaluate the priorities of each citizen, but also several constraints influence the choice such as the total budget available. In fact, within a given budget, a situation may occur where two choices can be financed: either project with priority 1 or projects with priority 2 and 3. Choosing between these two possibilities is not as easy as choosing a unique candidate for an election. Another complex problem is for several people to reach a compromise. The collaborative writing of a local policy is a typical example of this kind of problem. A first approach for dealing with complex decision-making is to gather more information from the participants and to integrate this information in the final decision. The domain of operations research has provided a huge number of methods that help take decisions (Winston, 2003), in

particular computer-aided methods for multiple criteria decision-making. But, in the context of e-democracy, these computer-aided decision systems have nevertheless several drawbacks. Since most citizens do not have the competences to understand the methods implemented in these systems, they will probably not correctly understand how their information will be used to take the final decision. This means that these systems can favour the small number of citizens that know which information they have to give to defend their points of view, which is one of the criticisms often made against e-democracy. Moreover, these systems cannot solve every form of complex decision-making, such as agreeing to a comprise. A second approach is to integrate in political portals methods developed to help a group of people dealing in complex decision-making. One of the known method is Delphi (Linstone & Turoff, 1975). This method structures the group communication process of a group of individuals in order to make them solve a complex problem as a single entity. This method was successfully applied in several contexts, including:

- building a common interpretation of historical events.
- evaluating possible budget allocations.
- delineating the pros and cons associated with potential policy options.

An on-line Web system implementing the Delphi approach was already developed (Kenis, 1995). It organizes the communication between a set of users using an interactive process:

1. Each user gives its opinion to a question asked.
2. A moderator proposes a compromise based on the different answers.
3. The compromise is submitted to every user. They can accept it or reject it (and give their comments).
4. If a given majority does not accept the proposition, the process is reiterated beginning from the second step.

Many problems remain for this type of approach, in particular the role of the moderator of the process, the authentication of the net surfers participating in the debate or the democratic control of the process. But, we believe that integrating such a system can propose a new democratic approach for solving some complex problems.

E-DEMOCRACY: WHICH CONTEXT?

It is difficult to evaluate the status of e-democracy. The paradigms of the global village (McLuhan & Fiore, 1967) and the capacity of computers to help human beings (Wiener, 1965) have created many hopes in the Internet to solve the problem of the confidence crisis of most modern democracies. Since the information and communication technologies have demonstrated their capacities to make people exchange and collaborate, many people believe that the e-democracy concept must be promoted. On the one hand, several different initiatives of this concept have been successfully applied, in particular to local political decisions. Moreover, the previous sections have shown that a combination of specific social software and political portals may solve some of the limitations of the application of e-democracy. On the other hand, many limitations cannot currently be solved. Firstly, technologies cannot best organize all forms of decision-making. Secondly, it is necessary to build new control mechanisms to ensure that the way technologies are used respects the democratic process. But, the main limitation is without doubt the (geographical and social) digital divide. To think that, from now to the middle of the twenty-first century, applications of e-democracy will be widely used seems nowadays utopian. Knowing that the geographical digital divide will not be

solved rapidly, it is yet possible to limit locally the social digital divide. Therefore, two main categories of applications of e-democracy will probably be developed in the future:

1. For political local choices related to problems concerning small socially homogeneous communities of citizens, typically the management of a town. If e-citizens have a similar level of access and mastering of the Internet, on-line collaboration tools can increase the commitment of the citizens to final political decisions.
2. For decision-making in organizations where most members have a regular access to the Internet, such as the free and open source community. For nongovernmental organizations, it may also help since most of their decisions centres are located in Northern countries.

We can therefore fear to see in the next decades an asymmetrical deployment of e-democracy applications.

CONCLUSION

The Internet was originally built as a knowledge sharing platform for scientists. Its decentralized schema and the increased facility of content creation and information access have contributed to its use as political medium. The concept of e-democracy was born with the idea of using information and communication technologies to help citizens to interact more directly in political decision-making. In fact, if some examples of e-democracy processes have successively been applied in local areas, despite some utopian attempts, the actual on-line solutions have limitations. Today, some of these limitations can be solved by using and enhancing political portals and social software. Firstly, the emerging Web2.0 applications propose collaboration solutions to manage the information on the Internet. If applied to political content, it may help people to find information on their political interests as well as ensure the diversity of points of view. Moreover, community creation approaches can be used to link people sharing similar political interests. Finally, by integrating on-line methods for complex decision-making on political portals, it is possible to organize on-line collaboration for a group of people in order to take complex decisions. The e-democracy concept has emerged because of the increased use of the Internet. With the digital divide existing today, it is impossible to apply this approach to a wide range of applications. If all democratic constraints must be respected, only specific local or social contexts exist where a real e-democracy process can be applied. Despite the unsolved limitations, this approach proposes a real participative democratic process and should be developed wherever it is possible.

CASE STUDY

BetaVote.com—What if the Whole World could Vote in the U.S. Presidential Election?

During the 2004 US presidential elections, two Americans, Daniel Young and Kevin Frost, claimed that since the decisions of the United States influence the whole world, every citizen in the world should participate to the vote of its

president. They have therefore created a Web site where net surfers could choose between John Kerry and George W. Bush. Around 500,000 net surfers participated in this virtual election, and 88% of them chose senator Kerry as US president. Also, although these Internet results did not influence the real results, this initiative can yet be seen as an experience in e-democracy at a global level. Nevertheless, it illustrates the problem of the digital divide. The percentage of voters is relatively low in comparison to the total number of net surfers (evaluated to one billion). Beyond the digital divide, the low number of participants also illustrates the lack of relay for such initiatives on the Internet. Secondly, in the US, the results of the on-line vote (around 70,000 net surfers participated) gave the victory to John Kerry while the real vote gave the victory to George W. Bush. Since some studies have shown that the Americans who voted for John Kerry were mostly "highly educated", the results of the e-democracy approach seem to confirm that using the Internet as a political medium may be the preserve of a given "elite", which is one of the criticisms against e-democracy. It will be interesting to reiterate this experience during the next US presidential campaign and make comparisons with the one of 2004. In particular, the total number of net surfers participating should be analyzed as well as their geographical distribution.

ENDNOTES

1 The digital divide is, of course, a problem since every participant should have an access to the Internet, a sufficient bandwidth and the corresponding hardware (microphone, webcam, etc.).

2 Linux, Mozilla, OpenOffice.org, Apache or K Desktop Environment are well known examples of software deployed on millions of computers today.

3 Wikipedia project: http://www.wikipedia.org

4 The main criticism concerning Wikipedia is the difference of quality between the articles. Some of them may be written by a team of experts of the corresponding domain, while others can be written by people without a real expertise. Many net surfers do not verify which authors have written which articles, and suppose that all articles have the same level of quality.

5 Many "Web2.0" applications appear on the Internet such as del.ico.us, LinkedIn, etc.

6 The democratic control of how technologies are deployed in the context of the electronic vote is an important issue. We believe that this is an "organisational" problem, since it is possible to control how the information is gathered and how the software manages this information. In democracies, independent commissions should organize this control and ensure the necessary transparency.

INTRODUCTION

Technology Affecting CBISs

As computer technology continues to leapfrog forward, CBISs are changing rapidly. These changes are having an enormous impact on the capabilities of organizational systems (Turban, Rainer, & Potter, 2001). The major ICT developments affecting CBISs can be categorized in three groupings: hardware-related, software-related, and hybrid cooperative environments.

Hardware-Related

Hardware consists of everything in the "physical layer" of the CBISs. For example, hardware can include servers, workstations, networks, telecommunication equipment, fiber-optic cables, hand-held computers, scanners, digital capture devices, and other technology-based infrastructure (Shelly, Cashman, & Rosenblatt, 2003). Hardware-related developments relate to the ongoing advances in the hardware aspects of CBISs.

Software-Related

Software refers to the programs that control the hardware and produce the desired information or results (Shelly et al., 2003). Software-related developments in CBIS are related to the ongoing advances in the software aspects of computing technology.

Hybrid Cooperative Environments

Hybrid cooperative environments developments are related to the ongoing advance in the hardware and software aspects of computing technology. These technologies create new opportunities on the Web (e.g., multimedia and virtual reality) while others fulfill specific needs on the Web (e.g., electronic commerce (EC) and integrated home computing).

These ICT developments are important components to be considered in the development of CBIS's. As new types of technology are developed, new standards are set for future development. The advent of hand-held computer devices is one such example.

BACKGROUND

A Software Engineering View

In an effort to increase the success rate of information systems implementation, the field of software engineering (SE) has developed many techniques. Despite many software success stories, a considerable amount of software is still being delivered late, over budget, and with residual faults (Schach, 2002).

The field of SE is concerned with the development of software systems using sound engineering principles for both technical and non-technical aspects. Over and above the use of specification, and design and implementation techniques, human factors and software management should also be addressed. Well-engineered software provides the service required by its users. Such software should be produced in a cost-effective way and should be appropriately functional, maintainable, reliable, efficient, and provide a relevant user interface (Pressman, 2000a; Shneiderman, 1992; Whitten, Bentley, & Dittman, 2001).

There are two major development methodologies that are used to develop IS applications: the traditional systems development methodology and the object-oriented (OO) development approach.

The traditional systems approaches have the following phases:

- Planning: this involves identifying business value, analysing feasibility, developing a work plan, staffing the project, and controlling and directing the project.
- Analysis: this involves information gathering (requirements gathering), process modeling and data modeling.
- Design: this step is comprised of physical design, architecture design, interface design, database and file design, and program design.
- Implementation: this step requires both construction and installation.

There are various OO methodologies. Although diverse in approach, most OO development methodologies follow a defined system development life cycle. The various phases are intrinsically equivalent for all of the approaches, typically proceeding as follows:

•OO Analysis Phase (determining what the product is going to do) and extracting the objects (requirements gathering), OO design phase, OO programming phase (implemented in appropriate OO programming language), integration phase, maintenance phase and retirement (Schach, 2002).

One phase of the SE life cycle that is common to both the traditional development approach and the OO approach is requirements gathering. Requirements' gathering is the process of eliciting the overall requirements of the product from the customer (user). These requirements encompass information and control need, product function and behavior, overall product performance, design and interface constraints, and other special needs. The requirements-gathering phase has the following process: requirements elicitation; requirements analysis and negotiation; requirements specification; system modeling; requirements validation; and requirements management (Pressman, 2000a).

Despite the concerted efforts to develop a successful process for developing software, Schach (2002) identifies the following pitfalls:

- Traditional engineering techniques cannot be successfully applied to software development, causing the software depression (software crisis). Mullet (1999) summarizes the software crisis by noting that software development is seen as a craft rather than an engineering discipline. The approach

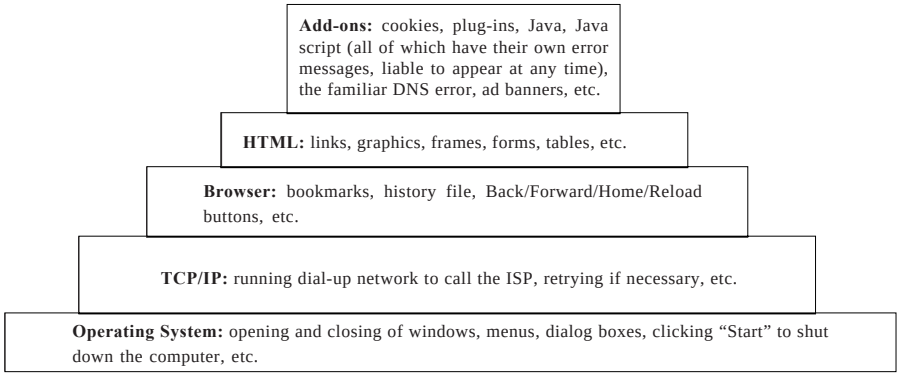
to education taken by most higher education institutions encourages that "craft" mentality; lack of professionalism within the SE world (e.g., the failure of treating an operating system's crash as seriously as a civil engineer would treat the collapse of a bridge); the high acceptance of fault tolerance by software engineers (e.g., if the operating system crashes; reboot hopefully with minimal damage); the mismatch between hardware and software developments. Hardware and software developments are both taking place at a rapid pace but independently of each other. Both hardware and software developments have a maturation time to be compatible with each other, but by that time everything has changed. The final problem for software engineers is the constant shifting of the goalposts. Customers initially think they want one thing but frequently change their requirements.

Notwithstanding these pitfalls, Pressman (2000b) argues that SE principles always work. It is never inappropriate to stress the principles of solid problem solving, good design, thorough testing, control of change, and emphasis on quality.

The Web is an intricate and complex combination of technologies (both hardware and software) that are at different levels of maturity. Engineering Web-based EC software, therefore, has its own unique challenges. In essence, the network becomes a massive computer that provides an almost unlimited software resource that can be accessed by anyone with a modem (Pressman, 2000a). We illustrate these intricacies in Figure 1, which is a representation of a home computer that is attached to the Internet. It depicts the underlying operating system (the base platform), the method of connection to the Internet (dial up, the technology that supports Web activities), browser, an example of a Web communication language (HTML), and additional technology that may be required to be Web active.

All the aspects of Figure 1 will support EC software in some way or another. An SE defect in any of these five layers would create a problem. For example, if the operating system is poorly engineered, the technology that sits on this platform will give piecemeal functionality at best. The problem is further complicated by piecemeal "patch" solutions. These piecemeal solutions can severely affect the usability of the Web, for example by giving cryptic error messages, installing add-ons that affect some unknown setting that the users do not understand, or installing add-ons that require a particular bit of hardware or software to be present.

Figure 1. EC Web application platform (adapted from Hurst & Gellady, 2000)



The View of HCI Advocates

Human-computer interaction is concerned with the way in which computers can be used to support human beings engaged in particular activities. HCI thus involves the specification, design, implementation, and evaluation of interactive software systems in the context of the user's task and work (Preece, Rogers, & Sharp, 2002; Preece, Rogers, Sharp, Benyon, Holland, & Carey, 1994; Shneiderman, 1998).

An aspect related to HCI is interaction design. Interaction design is the process of designing interactive products to support people in their everyday and work lives. In particular, it is about creating user experiences that enhance and extend the way people work, communicate, and interact (Preece et al., 2002).

As stated earlier, it is the users' experience that affects their activities on the Web. The advocates of HCI are intent on discovering the key to successful user experiences and so the concept of usability is intensively investigated in HCI. The ISO 9241-11 standard (1999) defines usability as the following: the extent to which a product can be used by a specified set of users, to achieve specified goals (tasks) with effectiveness, efficiency, and satisfaction in a specified context of use.

INTEGRATED USABILITY

Several researchers have produced sets of generic usability principles, which can be used in improving software (e.g., Mayhew, 1999; Preece et al., 1994; Shneiderman, 1998, 2000). Some of these usability principles are: learnability, visibility, consistency and standards, flexibility, robustness, responsiveness, feedback, constraints, mappings, affordances, stability, simplicity, help, and documentation. Unfortunately, the definitions of such design and usability principles are mostly too broad or general, and, in some cases, very vague. Some of these principles have been adapted for EC (see for example Badre, 2002). It has been shown repeatedly that general usability advice is not effective on its own when designing systems for a context-specific environment. Therefore, it is generally difficult for a non-usability expert or a novice to apply these principles in a particular domain and situation, taking into account the unique factors that give rise to problems in that domain.

We argue that usability advice should be linked to a context-specific environment. For example, if a designer is interested in enticing surfers to stop browsing and engage in transactions, the designer would be well advised to make different design choices for an Internet banking site than for an online library. So, the design of a site for Pick 'n Pay (supermarket chain), ABSA (commercial bank), and the University of South Africa's library should therefore be approached differently.

The HCI proponents also propose certain life cycle models. Williges, Williges, and Elkerton (1987), for example, have produced a model of development to rectify some of the problems in the "classic" life cycle model of SE. In this approach, HCI principles and interface design drive the whole process. Other such life cycle models include the Star model of Hartson and Hix (1989), the Usability Engineering life cycle of Mayhew (1999), and the Interaction Design model of Preece et al. (2002). These methods also introduce various strategies for the development of effective user interfaces. The argument for putting forward these alternative development models is that by spotting user requirements early on in the development cycle, there will be less of a demand for code generation and modification in the later stages of systems development.

FUTURE TRENDS

Standards can serve as good anchor points to focus the dialogues and collaborative activities. However, the existing standards are rather incon-

sistent and thus confusing. More efforts should be invested to render these tools more usable and useful. Specifically, it is worthy to develop implementation strategies for situating or localizing the standards so that they can be applied effectively in particular contexts (Law, 2003).

CONCLUSION

Both the SE proponents and the HCI proponents have a point with regard to their approach. SE proponents try to produce a workable solution and HCI proponents try to develop a usable solution. The two approaches are not mutually exclusive. A workable solution may not be a usable solution, and a usable solution may not be a workable solution. The problem is that the HCI advocates are isolated from their SE colleagues, who in turn ignore the HCI advocates. The HCI advocates use a "blinder approach" in their attempt to develop software by only focusing on the HCI aspects of the design of software, while the SE developers are concerned with a satisfactory solution. The aspects of Figure 1 will in effect influence the HCI advocates' approaches as well as the SE advocates' approaches for designing software for the Web. The uncertainty aspect has to be factored into the design process.

KEY TERMS

Information Systems: First known as business data processing (BDP) and later as management information systems (MIS). The operative word is "system" because it combines technology, people, processes, and organizational mechanisms for the purpose of improving organizational performance.

Interaction Design: The process of designing interactive products to support people in their everyday and work lives.

ISO 9241-11: This part of ISO 9241 introduces the concept of usability but does not make specific recommendations in terms of product attributes. Instead, it defines usability as the "extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use."

Requirements' Gathering: The process of eliciting the overall requirements of a product from the customer.

Software Engineering: Concerned with the development of software systems using sound engineering principles for both technical and non-technical aspects. Over and above the use of specification, design and implementation techniques, human factors and software management should also be addressed.

Usability: The ISO 9241-11 standard definition of usability identifies three different aspects: (1) a specified set of users, (2) specified goals (asks) which have to be measurable in terms of effectiveness, efficiency, and satisfaction, and (3) the context in which the activity is carried out.

Chapter 1.14
Software Agent Technology: An Overview

Chrysanthi E. Georgakarakou
University of Macedonia, Greece

Anastasios A. Economides
University of Macedonia, Greece

ABSTRACT

This chapter provides an overview of the rapidly evolving area of software agents and presents the basic aspects of applying the agent technology to virtual enterprises (VE). As the field of software agents can appear chaotic, this chapter briefly introduces the key issues rather than present an in-depth analysis and critique of the field. In addition to, this chapter investigates the application of agent technology to virtual enterprises and presents current research activity that focuses on this field serving as an introductory step. Furthermore, this chapter makes a list of the most important themes concerning software agents and the application of agent technology to virtual enterprises apposing some order and consistency and serve as a reference point to a large body of literature.

INTRODUCTION

The aim of this chapter is to survey some key research issues in the software agents' area. It annotates several researchers' opinions on many areas concerning software agents trying to give a more documentary point of view of each argued subject. Its main goal is to provide an overview of the rapidly evolving area of software agents serving as a reference point to a large body of literature and outlining the key aspects of software agent technology. While this chapter does not act as an introduction to all the issues in the software agents' field, it intends to point the reader at the primary areas of interest. In addition to, this chapter investigates the application of agent technology to virtual enterprises. It presents basic aspects of applying agent technology to virtual enterprises serving as an introductory step.

First of all, this overview chapter attempts to answer the question of what a software agent is. Secondly, it analyzes the three technologies that distributed artificial intelligence (DAI) has evolved: (1) multi-agent system (MAS), (2) distributed problem solving (DPS), and (3) parallel AI (PAI). Thereinafter, it makes the distinction between single agent and multi-agent systems analyzing their dimensions. In addition to, it goes through the broad spectrum of agent properties.

Furthermore, it discusses the most acknowledged classification schemes or taxonomies (typologies) of software agents proposed in the agent research community. Moreover, it presents the most well known agent architecture classification schemes arguing about each distinct architecture. Besides, it explores the two most important agent communication approaches: (1) communication protocols, and (2) evolving languages. It also discusses about a number of languages for coordination and communication that have been proposed. It argues about possible implementations of agent transportation mechanisms as well. Further, it annotates prominent ontology specification languages and editors for ontology creation and maintenance. Then, it lists and argues standard languages and several prototype languages for implementing agent-based systems that have been proposed for constructing agent-based systems. Afterwards, it presents a number of tools and platforms that are available and support activities or phases of the process of agent-oriented software development. Next, it examines several agent oriented software engineering (AOSE) methodologies that have been proposed to assist engineers to create agent-based systems. At the end, it investigates the application of the agent technology to virtual enterprises, answering the question of why to use agents in virtual enterprises and presenting the current research activity that focuses on the agent technology applied to virtual enterprises.

BACKGROUND

As software agents comprise a prominent scientific area of research activity, a plethora of researchers have investigated them and stated their own point of view. Nwana and Ndumu (1996) mention that software agent technology is a rapidly developing area of research. According to Wooldridge and Jennings (1995), the concept of an agent has become important in both artificial intelligence (AI) and mainstream computer science. Oliveira, Fischer, and Stepankova (1999) observe that for some time now agent-based and multi-agent systems (MASs) have attracted the interest of researchers far beyond traditional computer science and artificial intelligence (AI).

Although software agent technology demonstrates expeditious advancement, there is a truly heterogeneous body of work being carried out under the "agents" banner (Nwana & Ndumu, 1996). Nwana and Ndumu (1996) introduce software agent technology by overviewing the various agent types currently under investigation by researchers. Nwana (1996) largely reviews software agents, and makes some strong statements that are not necessarily widely accepted by the agent community. Nwana (1996) presents a typology of agents, next places agents in context, defines them and overviews critically the rationales, hypotheses, goals, challenges, and state-of-the-art demonstrators of the various agent types of the proposed typology. Besides, Nwana (1996) attempts to make explicit much of what is usually implicit in the agents' literature and proceeds to overview some other general issues which pertain to all the types of agents in the typology.

Agent-based and multi-agent systems (MASs) have attracted the researchers' interest to great extents. Oliveira et al. (1999) try to identify focal points of interest for researchers working in the area of distributed AI (DAI) and MAS as well as application oriented researchers coming from related disciplines, for example, electrical and mechanical engineering. They do this by presenting key research topics in DAI and MAS research and by identifying application domains in which the DAI and MAS technologies are most suitable.

Sycara (1998) presents some of the critical notions in MASs and the research work that has addressed them and organizes these notions around the concept of problem-solving coherence. Sycara (1998) believes that problem-solving coherence is one of the most critical overall characteristics that an MAS should exhibit.

Jennings et al. (1998) provide an overview of research and development activities in the field of autonomous agents and multi-agent systems. They aim to identify key concepts and applications, and to indicate how they relate to one another. Some historical context to the field of agent-based computing is given, and contemporary research directions are presented. Finally, a range of open issues and future challenges are highlighted.

Wooldridge and Jennings (1995) aim to point the reader at what they perceive to be the most important theoretical and practical issues associated with the design and construction of intelligent agents. For convenience, they divide these issues into three areas (agent theory, agent architectures, and agent languages). Their paper is not intended to serve as a tutorial introduction to all the issues mentioned and includes a short review of current and potential applications of agent technology.

Wooldridge (1998) provides an introductory survey of agent-based computing. The article begins with an overview of micro-level issues in agent-based systems: issues related to the design and construction of individual intelligent agents. The article then goes on to discuss some macrolevel issues; issues related to the design and construction of agent societies. Finally, the key application areas for agent technology are surveyed.

An article that should not be omitted at this point is Weiß's (2002) paper. Weiß (2002) offers a guide to the broad body of literature of agent-oriented software engineering (AOSE). The guide, which is intended to be of value to both researchers and practitioners, is structured according to key issues and key topics that arise when dealing with AOSE: methods and frameworks for requirements engineering, analysis, design, and implementation; languages for programming, communication and coordination, and ontology specification; and development tools and platforms.

On the other hand, considering the agent technology application to virtual enterprises, Jennings, Norman and Faratin (1998) exhibit considerable concepts. They argue the case of the agent-based approach showing how agent technology can improve efficiency by ensuring that business activities are better scheduled, executed, monitored, and coordinated.

According to Camarinha-Matos (2002), multi-agent systems represent a promising approach to both model and implement the complex supporting infrastructures required for virtual enterprises and related emerging organizations. The current status of application of this approach to industrial virtual enterprises, virtual communities, and remote supervision in the context of networked collaborative organizations is presented (Camarinha-Matos, 2002). Examples of relevant projects are provided and major challenges and open issues identified as well (Camarinha-Matos, 2002).

Petersen, Divitini, and Matskin (2001) describe how virtual enterprises can be modeled using the AGORA multi-agent architecture, designed for modelling and supporting cooperative work among distributed entities. They underline that the distributed and goal-oriented nature of the virtual enterprise provides a strong motivation for the use of agents to model virtual enterprises. They also mention the main advantages of their approach.

This chapter provides an overview of research activity regarding the scientific domain of software agents. As the field of software agents can appear chaotic, this chapter briefly introduces the key issues rather than present an in-depth analysis and critique of the field. References to more detailed treatments are provided. The purpose of this chapter is to make a list of the most important themes concerning software agents, apposing some order and consistency and serve as a reference point to a large body of literature. In addition to, this chapter makes an introduction of applying agent technology to virtual enterprises and describes current research activity that addresses the above-mentioned issue.

A BRIEF OVERVIEW OF SOFTWARE AGENT TECHNOLOGY

What is a Software Agent?

Software agent technology is a rapidly developing area of research and probably the fastest growing area of information technology (IT) (Jennings & Wooldridge, 1996; Nwana & Ndumu, 1996). Application domains in which agent solutions are being applied or researched into include workflow management, telecommunications network management, air-traffic control, business process reengineering, data mining, information retrieval/management, electronic commerce, education, personal digital assistants (PDAs), e-mail filtering, digital libraries, command and control, smart databases, and scheduling/diary management (Nwana & Ndumu, 1996).

Over the last years, many researchers in the area of agents have proposed a large variety of definitions for the "agent" term. It is stated that it is difficult to give a full definition for the note of agency. Nwana (1996) predicates there are at least two reasons why it is so difficult to define precisely what agents are. Firstly, agent researchers do not "own" this term in the same way as fuzzy logicians/AI researchers, for example, own the term "fuzzy logic"—it is one that is used widely in everyday parlance as in travel agents, estate agents, and so forth. Secondly, even within the software fraternity, the word agent is really an umbrella term for a heterogeneous body of research and development (Nwana, 1996). Concerning the agent definition, Nwana (1996) states:

When we really have to, we define an agent as referring to a component of software and/or hardware which is capable of acting exactingly in order to accomplish tasks on behalf of its user. Given a choice, we would rather say it is an umbrella term, meta-term or class, which covers a range of other more specific agent types, and then go on to list and define what these other agent types are. This way, we reduce the chances of getting into the usual prolonged philosophical and sterile arguments which usually proceed the former definition, when any old software is conceivably recastable as agent-based software. (p. 6)

Bradshow (1997) identifies two approaches to the definition of an agent as follows: (1) agent as an ascription—this approach is based on the concept that "agency cannot ultimately be characterized by listing a collection of attributes but rather consists fundamentally as an attribution on the part of some person," and (2) agent as a description: agents are defined by describing the attributes they should exhibit.

Jennings and Wooldridge (1996) offer a relatively loose notion of an agent as a self-contained program capable of controlling its own decision-making and acting, based on its perception of its environment, in pursuit of one or more objectives will be used here.

Wooldridge (1998) defines an intelligent agent as a system that enjoys the following four properties: autonomy (agents operate without the direct intervention of humans or others, and have control over their actions and internal state), social ability (agents are able to cooperate with humans or other agents in order to achieve their tasks), reactivity (agents perceive their environment, and respond in a timely fashion to changes that occur in it), and pro-activeness (agents do not simply act in response to their environment, they are able to exhibit goal-directed behavior by taking the initiative).

According to Hayes (1999), an agent is an entity (either computer or human) that is capable of carrying out goals, and is part of a larger community of agents that have mutual influence on each other. Agents may co-exist on a single processor, or they may be constructed from physically, but intercommunicating processors (such as a community of robots) (Hayes, 1999). The key concepts in this definition are that agents can act autonomously to some degree, and they are

part of a community in which mutual influence occurs (Hayes, 1999).

Distributed Artificial Intelligence (DAI) Technologies

Distributed artificial intelligence (DAI) is a subfield of artificial intelligence (AI) which is concerned with a society of problem solvers or agents interacting in order to solve a common problem: computers and persons, sensors, aircraft, robots, and so forth (Green, Hurst, Nangle, Cunningham, Somers, & Evans, 1997). Such a society is termed a multi-agent system, namely, a network of problem solvers that work together to solve problems that are beyond their individual capabilities (Green et al., 1997). Software agents have evolved from multi-agent systems (MAS), which in turn form one of three broad areas which fall under DAI, the other two being distributed problem solving (DPS) and parallel AI (PAI) (Nwana, 1996). Therefore, agents inherit potential benefits from both DAI, for example modularity, speed, reliability and AI (e.g., operation at knowledge level, easier maintenance, reusability, platform independence) (Nwana, 1996).

Agent Systems

Jennings et al. (1998) state that an agent-based system is a system in which the key abstraction used is that of an agent. In principle, an agent-based system might be conceptualized in terms of agents, but implemented without any software structures corresponding to agents at all (Jennings et al., 1998). A parallel with object-oriented software can be drawn, where it is entirely possible to design a system in terms of objects, but to implement it without the use of an object-oriented software environment (Jennings et al., 1998). But this would at best be unusual, and at worst, counter-productive (Jennings et al., 1998). According to Jennings et al. (1998), a similar situation exists with agent technology and they therefore expect an agent-based system to be both designed and implemented in terms of agents.

An agent-based system may contain one or more agents (Jennings et al., 1998). There are cases in which a single agent solution is appropriate (Jennings et al., 1998). However, the multi-agent case—where the system is designed and implemented as several interacting agents—is arguably more general and more interesting from a software engineering standpoint (Jennings et al., 1998). Multi-agent systems are ideally suited to representing problems that have multiple problem solving methods, multiple perspectives and/or multiple problem solving entities (Jennings et al., 1998). Such systems have the traditional advantages of distributed and concurrent problem solving, but have the additional advantage of sophisticated patterns of interactions (Jennings et al., 1998). Examples of common types of interactions include: cooperation (working together towards a common aim), coordination (organizing problem solving activity so that harmful interactions are avoided or beneficial interactions are exploited), and negotiation (coming to an agreement which is acceptable to all the parties involved) (Jennings et al., 1998).

As the technology matures and endeavors to attack more complex, realistic, and large-scale problems, the need for systems that consist of multiple agents that communicate in a peer-to-peer fashion is becoming apparent (Sycara, 1998). The most powerful tools for handling complexity are modularity and abstraction (Sycara, 1998). Multi-agent systems (MASs) offer modularity (Sycara, 1998). If a problem domain is particularly a complex, large, or unpredictable, then the only way it can reasonably be addressed is to develop a number of functionally specific and (nearly) modular components (agents) that are specialized at solving a particular problem aspect (Sycara, 1998). In MASs, applications are designed and developed in terms of autonomous software entities (agents) that can flexibly achieve their objectives by interacting with one another

in terms of high-level protocols and languages (Zambonelli, Jennings, & Wooldridge, 2003). An MAS can be defined as a collection of, possibly heterogeneous, computational entities, having their own problem solving capabilities and which are able to interact among them in order to reach an overall goal (Oliveira et al., 1999).

Agent Properties

A software agent is a computer system situated in an environment that acts on behalf of its user and is characterised by a number of properties (Chira, 2003). Most researchers agree that autonomy is a crucial property of an agent. Alonso (2002) states about agents that it is precisely their autonomy that defines them. Furthermore, cooperation among different software agents may be very useful in achieving the objectives an agent has (Chira, 2003). According to the weak notion of agency given by Wooldridge and Jennings (1995) the most general way in which the term agent is used is to denote hardware or (more usually) software-based computer system that enjoys the following properties: autonomy, social ability, reactivity and pro-activeness (Wooldridge & Jennings, 1995). Jennings et al. (1998) identify three key concepts in their definition that they adapt from (Wooldridge & Jennings, 1995): situatedness, autonomy, and flexibility (by the term flexible they mean that the system is responsive, pro-active and social). For Wooldridge (1998), an intelligent agent is a system that enjoys autonomy, social ability, reactivity, and pro-activeness. He also refers to the fact that other researchers argue that different properties, such as mobility, veracity, benevolence, rationality and learning, should receive greater emphasis.

An agent may possess many properties in various combinations. In continuance, we enumerate and define all the properties that we adopt for the purposes of this research:

1. **Autonomy:** It means that the agent can act without direct intervention by humans or other agents and that it has control over its own actions and internal state (Sycara, 1998).
2. **Reactivity or situatedness or sensing and acting:** It means that the agent receives some form of sensory input from its environment, and it performs some action that changes its environment in some way (Chira, 2003; Sycara, 1998).
3. **Proactiveness or goal directed behavior:** It means that the agent does not simply act in response to its environment; it is able to exhibit goal-directed behavior by taking the initiative (Chira, 2003; Odell, 2000; Wooldridge & Jennings, 1995).
4. **Social ability:** It means that the agent interacts and friendliness or pleasant social relations mark this interaction; that is, the agent is affable, companionable or friendly (Odell, 2000).
5. **Coordination:** It means that the agent is able to perform some activity in a shared environment with other agents (Odell, 2000). Activities are often coordinated via plans, workflows or some other process management mechanism (Odell, 2000).
6. **Cooperation or collaboration:** It means that the agent is able to coordinate with other agents to achieve a common purpose; non-antagonistic agents that succeed or fail together (Odell, 2000).
7. **Flexibility:** It means that the system is responsive (the agents should perceive their environment and respond in a timely fashion to changes that occur in it), pro-active and social (Jennings et al., 1998).
8. **Learning or adaptivity:** It means that an agent is capable of (1) reacting flexibly to changes in its environment; (2) taking goal-directed initiative, when appropriate; and (3) learning from its own experience, its

environment, and interactions with others (Chira, 2003; Sycara, 1998).

9. **Mobility:** It means that the agent is able to transport itself from one machine to another and across different system architectures and platforms (Etzioni & Weld, 1995).
10. **Temporal continuity:** It means that the agent is a continuously running process, not a "one-shot" computation that maps a single input to a single output, then terminates (Etzioni & Weld, 1995).
11. **Personality or character:** An agent has a well-defined, believable personality and emotional state (Etzioni & Weld, 1995).
12. **Reusability:** Processes or subsequent instances can require keeping instances of the class agent for an information handover or to check and to analyze them according to their results (Horn, Kupries, & Reinke, 1999).
13. **Resource limitation:** An agent can only act as long as it has resources at its disposal (Horn et al., 1999). These resources are changed by its acting and possibly also by delegating (Horn et al., 1999).
14. **Veracity:** It is the assumption that an agent will not knowingly communicate false information (Wooldridge, 1998; Wooldridge & Jennings, 1995).
15. **Benevolence:** It is the assumption that agents do not have conflicting goals and that every agent will therefore always try to do what is asked of it (Wooldridge, 1998; Wooldridge & Jennings, 1995).
16. **Rationality:** It is the assumption that an agent will act in order to achieve its goals, and will not act in such a way as to prevent its goals being achieved—at least insofar as its beliefs permit (Wooldridge, 1998; Wooldridge & Jennings, 1995).
17. **Inferential capability:** An agent can act on abstract task specification using prior knowledge of general goals and preferred methods to achieve flexibility; goes beyond the information given, and may have explicit models of self, user, situation and/or other agents (Bradshow, 1997).
18. **"Knowledge-level" communication ability:** The ability to communicate with persons and other agents with language more resembling humanlike "speech acts" than typical symbol-level program-to-program protocols (Bradshow, 1997).
19. **Prediction ability:** An agent is predictive if its model of how the world works is sufficiently accurate to allow it to correctly predict how it can achieve the task (Goodwin, 1993).
20. **Interpretation ability:** An agent is interpretive if it can correctly interpret its sensor readings (Goodwin, 1993).
21. **Sound:** An agent is sound if it is predictive, interpretive and rational (Goodwin, 1993).
22. **Proxy ability:** An agent can act on behalf of someone or something that is, acting in the interest of, as a representative of, or for the benefit of, some entity (Odell, 2000).
23. **Intelligence:** The agent's state is formalized by knowledge and interacts with other agents using symbolic language (Odell, 2000).
24. **Unpredictability:** An agent is able to act in ways that are not fully predictable, even if all the initial conditions are known (Odell, 2000). It is capable of nondeterministic behavior (Odell, 2000).
25. **Credibility:** An agent has a believable personality and emotional state (Odell, 2000).
26. **Transparency and accountability:** An agent must be transparent when required, but must provide a log of its activities upon demand (Odell, 2000).
27. **Competitiveness:** An agent is able to coordinate with other agents except that the success of one agent implies the failure of others (Odell, 2000).
28. **Ruggedization:** An agent is able to deal with errors and incomplete data robustly (Odell, 2000).

29. **Trustworthiness:** An agent adheres to laws of robotics and is truthful (Odell, 2000).

Agent Typology

Agents may be usefully classified according to the subset of these properties that they enjoy (Franklin & Graesser, 1996). There are, of course, other possible classifying schemes (Franklin & Graesser, 1996). For example, software agents might be classified according to the tasks they perform, for example, information gathering agents or email filtering agents (Franklin & Graesser, 1996). Or, they might be classified according to their control architecture (Franklin & Graesser, 1996). Agents may also be classified by the range and sensitivity of their senses, or by the range and effectiveness of their actions, or by how much internal state they possess (Franklin & Graesser, 1996).

There are several classification schemes or taxonomies proposed in the agent research community from which the following three are well acknowledged (Chira, 2003): (1) Gilbert's scope of intelligent agents (Bradshow, 1997), (2) Nwana's (1996) primary attributes dimension typology, and (3) Franklin's and Graesser's (1996) agent taxonomy.

A typology refers to the study of types of entities and there are several dimensions to classify existing software agents (Nwana, 1996). Agents may be classified according to (Bradshow, 1997): (1) mobility, as static or mobile, (2) presence of a symbolic reasoning model, as deliberative or reactive, (3) exhibition of ideal and primary attributes, such as autonomy, cooperation and learning, (4) roles, as information or Internet, (5) hybrid philosophies, which combine two or more approaches in a single agent, and (6) secondary attributes, such as versatility, benevolence, veracity, trustworthiness, temporal continuity, ability to fail gracefully and mentalistic and emotional qualities (Nwana, 1996).

Nwana (1996) identifies seven types of agents (Chira, 2003). Next, we enumerate and describe each agent type:

1. **Collaborative agents:** They are "able to act rationally and autonomously in open and time-constrained multi-agent environments" (Chira, 2003; Nwana, 1996). Key characteristics: autonomy, social ability, responsiveness, and pro-activeness (Chira, 2003; Nwana, 1996).
2. **Interface agents:** They support and assist the user when interacting with one or more computer applications by learning during the collaboration process with the user and with other software agents (Chira, 2003; Nwana, 1996). Key characteristics: autonomy, learning (mainly from the user but also from other agents), and cooperation with the user and/or other agents (Chira, 2003; Nwana, 1996).
3. **Mobile agents:** They are autonomous software programs capable of roaming wide area networks (such as WWW) and cooperation while performing duties (e.g., flight reservation, managing a telecommunications' network) on behalf of its user (Chira, 2003; Nwana, 1996). Key characteristics: mobility, autonomy, and cooperation (with other agents—e.g., to exchange data or information) (Chira, 2003; Nwana, 1996).
4. **Information/internet agents:** They are designed to manage, manipulate or collate the vast amount of information available from many distributed sources (information explosion) (Chira, 2003; Nwana, 1996). These agents "have varying characteristics: they may be static or mobile; they may be non-cooperative or social; and they may or may not learn" (Chira, 2003; Nwana, 1996).
5. **Reactive agents:** They act/respond to the current state of their environment based on a stimulus-response scheme (Chira, 2003; Nwana, 1996). These agents are relatively simple and interact with other agents in basic

ways but they have the potential to form more robust and fault tolerant agent-based systems (Chira, 2003; Nwana, 1996). Key characteristics: autonomy and reactivity (Chira, 2003; Nwana, 1996).

6. **Hybrid agents:** They combine two or more agent philosophies into a single agent in order to maximize the strengths and minimize the deficiencies of the most relevant techniques (for a particular purpose) (Chira, 2003; Nwana, 1996).
7. **Smart agents:** They are equally characterised by autonomy, cooperation, and learning (Chira, 2003; Nwana, 1996).

According to Nwana (1996), there are some applications that combine agents from two or more of the above types. Nwana (1996) refers to these as heterogeneous agent systems. This category of agent systems is generally referred to (by most researchers) as multi-agent systems (Chira, 2003).

Agent Architectures

Researchers working in the area of agents' architectures are concerned with the design and construction of agents that enjoy the properties of autonomy, reactivity, pro-activeness, and social ability (Wooldridge, 1998). Wooldridge (1999) states that agent architecture is essentially a map of the internals of an agent—its data structures, the operations that may be performed on these data structures, and the control flow between these data structures**.** Three classes of agent architectures can be identified (Wooldridge & Jennings, 1995): (1) deliberative or symbolic architectures are those designed along the lines proposed by traditional, symbolic AI, (2) reactive architectures are those that eschew central symbolic representations of the agent's environment, and do not rely on symbolic reasoning, and (3) hybrid architectures are those that try to marry the deliberative and reactive approaches (Wooldridge, 1998). Wooldridge and Jennings (1995) indicate that agent architectures can be viewed as software engineering models of agents and identify the above-mentioned classes of agent architectures.

Wooldridge (1999) considers four classes of agents. In our opinion most agents follow one of these four architectural classes. To continue, we enumerate and give a short description of each class:

1. **Logic based agents:** In which decision-making is realized through logical deduction (Wooldridge, 1999).
2. **Reactive agents:** In which decision-making is implemented in some form of direct mapping from situation to action (Wooldridge, 1999).
3. **Belief-desire-intention (BDI) agents:** In which decision-making depends upon the manipulation of data structures representing the beliefs, desires, and intentions of the agent (Wooldridge, 1999).
4. **Layered architectures:** In which decision making is realized via various software layers, each of which is more-or-less explicitly reasoning about the environment at different levels of abstraction (Wooldridge, 1999).

Agent Communication Approaches

One of the most important features of an agent is interaction. In other words, agents recurrently interact to share information and to perform tasks to achieve their goals (Kostakos & Taraschi, 2001). Without communication, different agents cannot know from each other who is doing what and how they can cooperate (Bussink, 2004). Therefore communication is a must if we want to set up a useful multi-agent system (Bussink, 2004).

There are several approaches to how this communication can take shape (Bussink, 2004). The two most important approaches are communication using communication protocols, and communication using an evolving language

(Bussink, 2004). Both techniques have their advantages and disadvantages (Bussink, 2004). In industrial applications communication protocols will be the best practice, but in systems where homogeneous agents can work together language evolution is a good option (Bussink, 2004). The basis for language evolution is in human communication (Bussink, 2004). The agent languages consist of grammars and vocabularies, just like any human language (Bussink, 2004). Some researchers even do research in the area of language evolution using agents in order to get more understanding of how human communication has evolved (Bussink, 2004). For a long time, the only way agents communicated was using communication protocols (Bussink, 2004). Therefore research often focussed on this area and a lot of specifications have been written (Bussink, 2004). Because of the formal nature of protocols, there are a quite a few widely known and used standards (Bussink, 2004).

Agent Communication Languages (ACLs)

The difficulty to precisely handle coordination and communication increases with the size of the agent-based software to be developed. A number of languages for coordination and communication have been proposed. Weiβ (2002) enumerates a list of such languages. Next, we enumerate and describe the most prominent examples of agent communication languages (ACLs) according to Weiβ (2002):

1. **Knowledge query and manipulation language (KQML):** It is perhaps the most widely used agent communication language (Weiβ, 2002).
2. **ARCOL ("ARTIMIS communication language"):** It is the communication language used in the ARTIMIS system (Weiβ, 2002). ARCOL has a smaller set of communication primitives than KQML, but these can be composed (Weiβ, 2002).
3. **FIPA agent communication language (FIPA-ACL):** It is an agent communication language that is largely inuenced by ARCOL (Weiβ, 2002). Together FIPA-ACL, ARCOL, and KQML establish a quasi standard for agent communication languages (Weiβ, 2002).
4. **Knowledge interchange format (KIF):** It is a logic-based language that has been designed to express any kind of knowledge and metaknowledge (Weiβ, 2002). KIF is a language for content communication, whereas languages like KQML, ARCOL, and FIPA-ACL are for intention communication (Weiβ, 2002).
5. **Domain independent COOrdination language (COOL):** It aims at explicitly representing and applying coordination knowledge for multi-agent systems and focuses on rule-based conversation management (Weiβ, 2002). Languages like COOL can be thought of as supporting a coordination/communication (or "protocol-sensitive") layer above intention communication (Weiβ, 2002).

Apart from these most prominent languages, several others showing unique properties have been proposed (Weiβ, 2002). Some of the above-mentioned languages follow:

1. Interagent communication language (ICL) (Weiβ, 2002)
2. AgentTalk (Weiβ, 2002)
3. Communication and coordination language (CoLa) (Weiβ, 2002)
4. Tuple centres spread over networks (TuCSoN) (Weiβ, 2002)
5. LuCe (Weiβ, 2002)
6. Simple thread language ++ (STL++) (Weiβ, 2002)
7. Strictly declarative modelling language (SDML) (Weiβ, 2002)

Agent Transportation Mechanisms

In agent environments, messages should be schedulable, as well as event driven (OMG Agent Working Group, 2000). They can be sent in synchronous or asynchronous modes (OMG Agent Working Group, 2000). The transportation mechanism should support unique addressing as well as role-based addresses (OMG Agent Working Group, 2000). Lastly, the transportation mechanism must support unicast, multicast, and broadcast modes and such services as broadcast behavior, nonrepudiation of messages, and logging (OMG Agent Working Group, 2000). Next, we enumerate and describe possible implementations of the agent transportation mechanism:

1. **Common object request broker architecture (COBRA):** It is the acronym for common object request broker architecture, OMG's open, vendor-independent architecture and infrastructure that computer applications use to work together over networks (The Object Management Group). Using the standard protocol IIOP, a CORBA-based program from any vendor, on almost any computer, operating system, programming language, and network, can interoperate with a CORBA-based program from the same or another vendor, on almost any other computer, operating system, programming language, and network (The Object Management Group).
2. **Object management group (OMG) messaging services:** OMG is an international trade association incorporated as a nonprofit in the United States (The Object Management Group). The OMG is currently specifying a new messaging service (The CORBA Object Group Service).
3. **JAVA messaging service:** It is the standard API for sending and receiving messages (Creative Science Systems).
4. **Remote method invocation (RMI):** It defines and supports a distributed object model for the Java language hiding the ORB from the programmer and providing an API for the development of distributed applications (Bracho, Matteo, & Metzner, 1999). Java remote method invocation (Java RMI) enables the programmer to create distributed Java technology-based to Java technology-based applications, in which the methods of remote Java objects can be invoked from other Java virtual machines, possibly on different hosts (Java.sun.com).
5. **Distributed component object model (DCOM):** Microsoft® Distributed COM (DCOM) extends the component object model (COM) to support communication among objects on different computers—on a LAN, a WAN, or even the Internet (DCOM Technical Overview). With DCOM, your application can be distributed at locations that make the most sense to your customer and to the application (DCOM technical overview).
6. **Enterprise Java Beans events:** The newest Java component model is Enterprise Java Beans (Tuukka Vartiainen, Java Beans, and Enterprise Java Beans). Besides its name, the Java language and the idea of component based software re-use; it has little or no similarities with the Java Beans standard (Tuukka Vartiainen, Java Beans, and Enterprise Java Beans). Enterprise Java Beans are located on the server and they support a distributed programming model that could be described as a flexible, two-way, object-oriented version of traditional client-server programming (Tuukka Vartiainen, Java Beans, and Enterprise Java Beans).

Ontology Languages and Editors

Besides an ACL, a common understanding of the concepts used among agents is necessary for

a meaningful agent communication. A common ontology is required for representing the knowledge from various domains of discourse (OMG Agent Working Group, 2000). The ACL remains just syntax without a shared common ontology containing the terms used in agent communication and the knowledge associated with them (Nwana & Wooldridge, 1996). Next, we enumerate and describe the most elaborated examples of such languages according to Weíβ (2002):

1. **Ontolingua and frame logic:** They are frame-based languages (Weíβ, 2002). Both of them extend first-order predicate logics (Weíβ, 2002). The key modeling primitive of these languages are frames as known from artificial intelligence (Weíβ, 2002).
2. **CLASSIC and LOOM:** They are description logics that allow an intentional definition of concepts (Weíβ, 2002).
3. **CycL:** It extends first-order predicate logic and was developed to enable the specification of large common-sense ontologies (Weíβ, 2002).

In addition, we enumerate and describe the most prominent ontology specification languages that are conform to syntactic and semantic Web standards according to Weíβ (2002):

1. **Simple HTML ontology extension (SHOE):** It is a language that slightly extends HTML and enables a hierarchical classification of HTML documents and the specification of relationships among them (Weíβ, 2002).
2. **Ontology exchange language (XOL):** It is an XML- and frame-based language for the exchange of ontologies (Weíβ, 2002).
3. **Ontology inference layer (OIL):** It aims at unifying formal semantics as offered by description logics, rich modelling primitives as offered by frame-based languages, and the XML and RDF Web standards (Weíβ, 2002). OIL can be seen as an extension of XOL offering both an XML-based and an RDF-based syntax (Weíβ, 2002).
4. **DAML-ONT and DAML-OIL:** They are the DAML (DARPA Agent Markup Language) languages (Weíβ, 2002). DAML-OIL, which replaces DAML-ONT and represents the state of the art in the field, has well-defined model-theoretic and axiomatic semantics (Weíβ, 2002).

Furthermore, we enumerate and describe three good examples of editors for ontology creation and maintenance according to Weíβ (2002):

1. **Protégé:** It supports single-user ontology acquisition (Weíβ, 2002).
2. **Webonto:** It supports multiple-user ontology acquisition over the Web (Weíβ, 2002).
3. **OntoEdit:** It supports multilingual development of ontologies and multiple inheritances (Weíβ, 2002).

Languages for Constructing Agent-Based Systems

Most agent systems are probably written in Java and C/C++ (Weíβ, 2002). Apart from these standard languages, several prototype languages for implementing agent-based systems have been proposed that all aim at enabling a programmer to better realize agent-specific conceptions (Weiß, 2002). Three paradigms for implementing agent systems have been proposed: agent-oriented programming, market-oriented programming and interaction-oriented programming (Weiß, 2002). Weíβ (2002) lists some of most prominent and best understood prototype languages following the agent-oriented paradigm (references to these languages are provided in Weiß, 2002). Next, we enumerate and describe the above mentioned prototype languages:

1. **AGENT-0, PLACA and AGENT-K:** AGENT-0 realizes the basic ideas of the agent-oriented programming paradigm as formulated by Shoham (Weíβ, 2002). A language that extends AGENT-0 toward planning is PLACA, and a language that aims at integrating AGENT-0 and KQML is AGENT-K (Weíβ, 2002).
2. **Concurrent MetateM:** It allows specifying the intended behavior of an agent based on temporal logics (Weíβ, 2002).
3. **AgentSpeak (L):** It is a rule-based language that has a formal operational semantics and that assumes agents to consist of intentions, beliefs, recorded events, and plan rules (Weíβ, 2002). AgentSpeak (L) is based on an abstraction of the PRS architecture (Weíβ, 2002).
4. **3APL:** It incorporates features from imperative and logic programming (Weíβ, 2002). 3APL has well defined operational semantics and supports monitoring and revising of agent goals (Weíβ, 2002).
5. **ConGolog:** It is a concurrent logic-based language initially designed for high-level robot programming (Weíβ, 2002).
6. **Agent process interaction language (APRIL), multiagent interaction and implementation language (MAIL/MAI2L), and VIVA:** Other examples of languages following the agent-oriented programming paradigm (Weíβ, 2002).

Nwana and Wooldridge (1996) classify constructing agent application languages according to a typology. Next, we present the above-mentioned classification (Nwana & Wooldridge, 1996):

1. **Collaborative agents:** The actor language actors and the agent-oriented programming languages Agent-0 and Placa.
2. **Interface, information and mobile agents:** The scripting languages TCL/Tk, Safe-TCL, Safe-Tk, Java, Telescript, Active Web tools, Python, Obliq, April and Scheme-48.
3. **Reactive agents:** The reactive language RTA/ABLE.

However traditional languages are still used to construct agent applications (Nwana & Wooldridge, 1996). It is possible to implement agent-based systems in languages like Pascal, C, Lisp, or Prolog (Nwana & Wooldridge, 1996). But as a rule, one would not choose to do so because such languages are not particularly well suited to the job (Nwana & Wooldridge, 1996). Typically, object-oriented languages such as Smalltalk, Java, or C++ lend themselves more easily for the construction of agent systems (Nwana & Wooldridge, 1996). This is because the concept of an "agent" is not too distant from that of an "object": Agents share some properties with objects such as encapsulation, and frequently, inheritance and message passing (Nwana & Wooldridge, 1996). However, agents differ distinctly from objects vis-à-vis polymorphism (Nwana & Wooldridge, 1996).

Tools and Platforms

A number of tools and platforms are available that support activities or phases of the process of agent-oriented software development (Weiβ, 2002). Most of them are built on top of and integrated with Java (Weiβ, 2002). While almost all available tools and platforms have their focus on implementation support, some of them do also support analysis, design, and test/debugging activities (Weiβ, 2002).

Weíβ (2002) makes a list of such tools and platforms separating them into often-sited academic and research prototypes and into commercial products for development support. References to the following tools and a brief description as well can be found in (Weiβ, 2002). Next, we present the above-mentioned classification:

1. **Academic and research activity:** ZEUS, Java Agent DEvelopment framework (JADE), Lightweight extensible agent platform (LEAP), agenTool, RETSINA, Java agent template, lite (JATLite), FIPA-OS, MADKIT, SIM_AGENT, Java-based agent framework for multi-agent systems (JAFMAS), agent building shell (ABS), open agent architecture (OAA), and Agentis
2. **Commercial activity:** AgentBuilder, JACK, intelligent agent factory and grasshopper

Serenko and Detlor (2002) state about the term agent toolkit that each vendor uses its own explanation of the term and for the needs of their report define an agent toolkit as any software package, application or development environment that provides agent builders with a sufficient level of abstraction to allow them to implement intelligent agents with desired attributes, features and rules. Some toolkits may offer only a platform for agent development, whereas others may provide features for visual programming (Serenko & Detlor, 2002). Serenko and Detlor (2002) categorize the available agent toolkits on the market into four major categories. Next, we present the four categories and the representative toolkits of each category:

1. **Mobile agent toolkits:** Concordia, Gossip, FarGo, and IBM Aglets
2. **Multi-agent toolkits:** MadKit, ZEUS, JADE, JATLite, and MAST
3. **General purpose toolkits:** FIPA-OS and Ascape
4. **Internet agent toolkits:** Microsoft Agent, Voyager, and NetStepper

Agent-Oriented Software Engineering (AOSE) Methodologies

Agent researchers have produced methodologies to assist engineers to create agent-based systems (Agent-Oriented Software Engineering). Some researchers have taken agent theory as their starting point and have produced methodologies that are rooted in that theory (Agent-Oriented Software Engineering). Other researchers have taken object techniques as their point of departure and have enriched them to be suitable for agents (Agent-Oriented Software Engineering). Others have taken knowledge engineering concepts and have extended them (Agent-Oriented Software Engineering). Researchers also have tried to assemble methodologies by combining features from different methodologies (Agent-Oriented Software Engineering). Yet other researchers have produced methodologies based on both agent and object technologies (Agent-Oriented Software Engineering).

Methodologies having as background the agent and multi-agent technology are characterized by a clear focus on capturing social-level abstractions such as agent, group, or organization, that is, on abstractions that are above the conventional object level (Weiβ, 2002). Methodologies having as background the object orientation are characterized by the attempt to appropriately extend existing object-oriented techniques such that they also capture the notion of agency (Weiβ, 2002). Methodologies having engineering background knowledge are characterized by an emphasis on the identification, acquisition and modeling of knowledge to be used by the agent components of a software system (Weiβ, 2002).

The most popular approaches based on agent and multi-agent technology are the following:

1. **Generic architecture for information availability (GAIA):** This is a method that distinguishes between analysis and design and associates different models with these two phases (Weiβ, 2002). Gaia focuses on organizational aspects in terms of concepts such as roles, interactions and acquaintances (Weiβ, 2002).
2. **Societies in open and distributed agent spaces (SODA):** This is another good

example of an analysis and design method that concentrates on the social (interagent) aspects of agent systems and that employs the concept of coordination models (Weiβ, 2002).

3. **Cassiopeia:** This is a design method that distinguishes three levels of behavior—elementary, relational, and organizational—and aims at capturing both structural and dynamic aspects of the target system (Weiβ, 2002).
4. **Aalaadin:** This is a general analysis and design framework that has its focus on the organizational level of multi-agent systems and is built on the three core concepts of agents, groups, and roles (Weiβ, 2002).

The most popular approaches based on object-oriented technology are the following:

1. **KGR:** This is a design and specification method for a particular class of agents, namely, BDI agents (Weiβ, 2002).
2. **Multiagent systems engineering (MaSE):** This method covers design and initial implementation through two languages called agent modeling language (AgML) and agent definition language (AgDL) and builds upon OMT and UML (Weiβ, 2002).
3. **Multiagent systems iterative view engineering (MASSIVE):** This method covers analysis, design and code generation, and combines standard software engineering techniques such as multi-view modeling, round-trip engineering, and iterative enhancement (Weiβ, 2002).
4. **Agent-oriented analysis and design (AOAD):** This analysis and design method proposes the use of extended class responsibility cards (CRCs) and the use of both the object modelling technique (OMT) and the responsibility driven design (RDD) method known from object-oriented development (Weiβ, 2002).
5. **Multi-agent scenario-based (MASB):** MASB is an analysis and design method that covers issues of both objects and agents via behavior diagrams, data models, transition diagrams, and object life cycles (Weiβ, 2002).

The most popular approaches based on knowledge engineering technology are the following:

1. **Conceptual modelling of multi-agent systems (CoMoMAS):** This is an elaborated extension of the CommonKADS methodology, supporting analysis, design, and automated code generation (Weiβ, 2002).
2. **Multi-agent system commonKADS (MAS-CommonKADS):** This is another extension of CommonKADS that supports analysis and design of agent-oriented systems (Weiβ, 2002).

Other agent-oriented software engineering methodologies (AOSE) are tropos, agent-oriented analysis and design, agent modelling technique for systems of BDI agents, agent oriented methodology for enterprise modelling, a process for agent societies specification and implementation (PASSI), prometheus, AOR, ROADMAP, OPM /MAS, ingenias, DESIRE, AAII methodology, cooperative information agents design, adept, AUML, ADELFE, MESSAGE /UML, the styx agent methology, SABPO, expectation-oriented analysis and design (EXPAND) and ODAC (Cernuzzi, Cossentino, & Zambonelli, 2004; Iglesias, Garijo, & Gonzalez, 1999; Agent-Oriented Software Engineering; Faculty Science Unitn; Weiβ, 2002; Wooldridge & Ciancarini, 2000).

AGENTS IN VIRTUAL ENTERPRISES (VES)

What is a Virtual Enterprise?

The term, and the concept, "virtual enterprise" (VE) emerged already in the beginning of the 1990s and could be seen as the further optimization and perfection of the basic ideas about dynamic networking (Putnik, 2004). Although the virtual enterprise research represents a growing and multidisciplinary area it still lacks a precise definition of the concepts and an agreement on the used terminology (Camarinha-Matos, 2002). So far, there is no unified definition for this paradigm and a number of terms are even competing in the literature while referring to different aspects and scopes of virtual enterprises (Camarinha-Matos, 2002). Akin concepts are supported by Gijsen, Szirbik, and Wagner (2002); Freitas Mundim, Rossi, and Stocchetti (2000); Putnik (2004) and Petersen et al. (2001).

The definitions range from the virtual enterprise as a simple subcontracting network to the virtual enterprise as a dynamic network, in which the partners share that share resources, risks and even markets, and which operates in a virtual environment or with virtual agents (Putnik, 2004). According to Do, Halatchev, and Neumann (2000) a virtual enterprise is a form of cooperation of independent market players (enterprises, freelancers authorities, etc.) which combine their core competencies in order to manufacture a product or to provide a service. Marík and McFarlane (2005) conclude that a virtual enterprise represents a cluster of organizations collaborating to achieve one or more goals. Katz and Schuh (1999) define that the virtual enterprise is based on the ability to create temporary co-operations and to realize the value of a short business opportunity that the partners cannot (or can, but only to lesser extent) capture on their own. Other attempts at defining virtual enterprises are listed in (Petersen et al., 2001).

In our opinion, an interesting definition that we adopt is the following:

A goal-oriented constellation of (semi)autonomous distributed entities. Each entity, which can be an organization and/or an individual, attempts to maximize its own profits as well as contribute to defining and achieving the overall goals of the virtual enterprise. Virtual enterprises are not rigid organizational structures within rigid frameworks, but rather (heterogeneous) ensembles, continuously evolving over time. (Petersen et al., 2001, p. 2)

Why to Use Agents in Virtual Enterprises?

Marík and McFarlane (2005) state that a virtual enterprise might address problems ranging from simple membership to distributed inventory management and synchronization of supply, production, and distribution schedules. They also support that these problems are inherently distributed, with each organization willing to share only limited information and having its own business goals in conjunction with the overall goal. All the above statements orientate to an agent technology solution.

According to Jennings et al. (1998), considering a virtual enterprise, the domain involves an inherent distribution of data, problem solving capabilities and responsibilities. In addition, the integrity of the existing organizational structure and the autonomy of its sub-parts need to be maintained (Jennings et al., 1998). Moreover, interactions are fairly sophisticated, including negotiation, information sharing, and coordination (Jennings et al., 1998). Besides, the problem solution cannot be entirely prescribed (Jennings et al., 1998). According to Jennings et al. (1998), all the above observations motivate the choice of agents as a technology solution as well.

According to Fox and Gruninger (1998), the entrepreneurial and virtual nature of the agile

enterprise coupled with the need for people and information to have a strategic impact entails a greater degree of communication, coordination and cooperation within and among enterprises. In other words, the agile organization must be integrated (meaning by the term integrated the structural, behavioural and information integration of the enterprise) (Fox & Gruninger, 1998). Petersen et al. (2001) support that cooperation is required both to perform work and to adapt the constellation to the varying needs of the environment. They state that goal-oriented and distributed nature of virtual enterprises implies that there is no central control; rather, the control is decentralized. According to their opinion, the distributed and goal-oriented nature of the virtual enterprise provides a strong motivation for the use of agents to model virtual enterprises.

The following parallelism demonstrates remarkable interest. According to Rahwan, Kowalczyk, and Yang (2001) the virtual enterprise creation could be viewed as a Cooperative System design problem. A Cooperative System is a system in which a set of autonomous agents (computational and human) interact with each other through sharing their information, decision making capabilities and other resources, and distributing the corresponding workload among themselves, in order to achieve common and complementary goals (Camarinha-Matos & Afsarmanesh, 1998). The above parallelism motivates as well the agents as a technology solution.

The nature of agents, by definition, enables decentralized control of the enterprise, which is desirable in a dynamic and flexible environment, and the behavior of the complete enterprise emerges as a result of the behaviors of the individual agents (Petersen et al., 2001).

Another strong point in favor of the adoption of agents is their versatility (Petersen et al., 2001). They can play two main roles (Petersen et al., 2001). First, they provide a flexible means of modeling the virtual enterprise in terms of cooperative work among the agents (Petersen et al., 2001). Second, they can be used to provide active support to the members of the virtual enterprise (Petersen et al., 2001). Thus, agents being computational entities, the resulting model provides an easy and efficient passage to the computational support that is required by virtual enterprises (Petersen et al., 2001).

According to Marík and McFarlane (2005), MASs and relevant technologies consider each company as an agent able to carry out specific (usually quite complex) functions. The agents are registered with a certain platform and communicate in a standard agent communication language (Marík & McFarlane, 2005). Virtual enterprise formation, as well as the joint planning and scheduling activities, is based on jointly known negotiation rules and scenarios (Marík & McFarlane, 2005). These are very similar (or identical) to protocols or auctions in the MAS domain (Marík & McFarlane, 2005). The highly specialized members of a virtual enterprise, such as brokers or professional network organizers, can easily find their counterparts in the MAS community—for example, various middle agents and brokers (Marík & McFarlane, 2005). The negotiation and brokering algorithms that have proven useful for the MAS domain can serve to formalize (and later automate) the corresponding virtual enterprise processes (Marík & McFarlane, 2005). Specialized agents called meta-agents could also serve as tools both to help detect the network's less efficient parts or bottlenecks and to provide advice supporting the virtual enterprise's self-evolution in the desired direction (Marík & McFarlane, 2005). Virtual enterprise creation is analogous to coalition formation in the MAS domain (Marík & McFarlane, 2005).

They also support that MAS concept of knowledge sharing, which classifies knowledge as public, private, and semiprivate, has high potential for virtual enterprises. Requirements for keeping agents' knowledge confidential and preventing knowledge disclosure, as well as specific security principles used with MASs,

can be reused for virtual enterprises (Marík & McFarlane, 2005).

Current Research Activity Focusing on Agents in Virtual Enterprises (VE)

Virtual enterprises have recently received increasing attention. Due to the advancement of distributed information technology and the changing needs of the business community, enterprises are expected to be more agile and responsive (Petersen et al., 2001). Many current developments in multi-agent systems (MAS) are more and more focused on the production of robust development environments (Camarinha-Matos, 2002). Considerable efforts are also being put on standardization of architectures and communication languages, which are important requirements for the industrial application of the paradigm (Camarinha-Matos, 2002). We have observed that there is a remarkable body of literature that studies the application of agent technology to virtual enterprises as researchers pay enough attention to this scientific area of activity. In continuance of the study, some prominent research efforts follow.

According to Yonghe and Biqing (1999), decision and control processes within the domain of virtual enterprises have not received deserved attention till now. Based on agent technology, they bought up architecture for control and decision-making during the dynamic creation and operation of a virtual enterprise. An approach for integrating different business units is presented (Yonghe & Biqing, 1999). Prototype software simulating the design of a new product in a virtual enterprise is developed (Yonghe & Biqing, 1999).

Petersen, Jinghai, and Matskin (2003) present the virtual enterprise formation process as an agent interaction protocol and an approach to its implementation. They have focused on the selection of partners within the formation process in order to understand these interactions and the contents of the messages that are exchanged between the agents. Based on this, they describe how the AGORA multi-agent architecture can be used to support the formation of a virtual enterprise.

Gou, Huang, Liu, and Li (2001) propose an agent-based virtual enterprise model and provide the agent collaboration mechanisms under the model, thereby achieving the agent based virtual enterprise modeling and operation control. Their agent-based approach achieves distributed control over the whole business process execution of the virtual enterprise.

According to Fankhauser and Tesch (1999), negotiations encourage agents to reason about the interests of their opponents. Thus, negotiations suffer from counter speculations (Fankhauser & Tesch, 1999). Auctions apply to asymmetric trading only; they either favor the auctioneer or the bidders (Fankhauser & Tesch, 1999). Both mechanisms do not promote agents to tell the truth (Fankhauser & Tesch, 1999). Therefore, they propose to use a trust-broker to mediate between the agents. They introduce three symmetric, negotiation free one-step protocols to carry out a sequence of decisions for agents with possibly conflicting interests. The protocols achieve substantially better overall benefit than random or hostile selection, and they avoid lies (Fankhauser & Tesch, 1999). They analyze the protocols with respect to informed vs. uninformed lies, and with respect to beneficial vs. malevolent lies, and show that agents are best off to know and announce their true interests.

Gong and Wang's (2000) research is a contribution to the model of multi-agent system (MAS) for supporting the dynamic enterprise model (DEM). It separates the business process from the organizational structure (organizational structure tier and business process tier), models each of them as MAS, and coordinates agents by the "yellow page" mechanism (Gong & Wang, 2000). This model not only can regulate itself in terms of DEM, but also is centered on the coordination strategies between agents composing it (Gong

& Wang, 2000). It is believed that the model of MAS is a practical way to build flexible enterprise information system (Gong & Wang, 2000).

Chrysanthis, Znati, Banerjee, and Shi-Kuo (1999) view the establishment of a virtual enterprise as a problem of dynamically expanding and integrating workflows in decentralized, autonomous and interacting workflow management systems. They focus on the idea of mobile agents called adlets and their use in establishing virtual enterprises that involves advertising, negotiating and exchanging control information and data as well as its management.

Szirbik, Aerts, Wortmann, Hammer, and Goossenaerts (2000) propose a systematisation of the monitoring and control aspects in a virtual enterprise. As an instrument, they use the mobile agent paradigm, defining the concept of a mobile agent web (MA-web). According to them, one of the roles of the agents in this environment is to mediate negotiations between the parties of the virtual enterprise. They make some assumptions about the new behavior and code of conduct in the MA-web, such as the willingness to share data and knowledge.

Based on the analysis of why agent-based mechanism is suitable and only suitable for cross-domain cooperation of virtual enterprise, Zhang et al. (2004) propose a framework to implement it. In their framework, there is a service information supply-demand center that is in charge of service information management, and agent is responsible for cooperative partner selecting before cooperation and interaction during cooperation. The relevant key strategies and basic interaction models are also described (Zhang et al., 2004).

Ouzounis and Tschammer (2001) discuss concepts and technologies that are considered to satisfy key requirements of dynamic virtual enterprises, and propose DIVE, a framework for the specification, execution and management of shared business processes in dynamic virtual enterprises.

Suh et al. (2005) describe an open and flexible infrastructure to support dynamic collaboration among companies through the entire lifecycle of the virtual enterprise. The proposed approach is an agent-enhanced architecture on which the conversation model is grafted (Suh et al., 2005). The collaboration among enterprises is modelled by a collaboration policy, which is a machine-readable specification of a pattern of message exchange among agents participating in the collaboration (Suh et al., 2005).

FUTURE TRENDS

Luck, McBurney, and Gonzalez-Palacios (2006) stated a thorough and outstanding approach about the future of multi-agent systems. As we consider their point of view extremely prominent, we appose at this point of the chapter some parts of their findings (for a more complete investigation consult (Luck et al., 2006)). Luck et al. (2006) extrapolated future trends in multi-agent systems by classifying them into four broad phases (current, short-term future, medium-term future and long-term future) of development of multi-agent system technology over the next decade.

At first phase, multi-agent systems are typically designed by one design team for one corporate environment, with participating agents sharing common high-level goals in a single domain (Luck et al., 2006). These systems may be characterized as closed (Luck et al., 2006). The communication languages and interaction protocols are typically in-house protocols, defined by the design team prior to any agent interactions (Luck et al., 2006). Design approaches, as well as development platforms, tend to be ad hoc, inspired by the agent paradigm (Luck et al., 2006). There is also an increased focus on taking methodologies out of the laboratory and into development environments, with commercial work being done on establishing industrial-strength development techniques and notations (Luck et al., 2006).

In the short-term future, multi-agent systems will increasingly be designed to cross corporate boundaries, so that the participating agents have fewer goals in common, although their interactions will still concern a common domain, and the agents will be designed by the same team, and will share common domain knowledge (Luck et al., 2006). Standard agent communication languages will be used, but interaction protocols will be mixed between standard and nonstandard ones (Luck et al., 2006). Development methodologies, languages and tools will have reached a degree of maturity, and systems will be designed on top of standard infrastructures such as Web services or Grid services, for example (Luck et al., 2006).

In the medium term future, multi-agent systems will permit participation by heterogeneous agents, designed by different designers or teams (Luck et al., 2006). Any agent will be able to participate in these systems, provided their (observable) behavior conforms to publicly stated requirements and standards (Luck et al., 2006). However, these open systems will typically be specific to particular application domains (Luck et al., 2006). The languages and protocols used in these systems will be agreed and standardized (Luck et al., 2006).

In the long-term future, we will see the development of open multi-agent systems spanning multiple application domains, and involving heterogeneous participants developed by diverse design teams (Luck et al., 2006). Agents seeking to participate in these systems will be able to learn the appropriate behavior for participation in the course of interacting, rather than having to prove adherence before entry (Luck et al., 2006). Selection of communications protocols and mechanisms, and of participant strategies, will be undertaken automatically, without human intervention (Luck et al., 2006).

The above-mentioned aspect about future is enhanced with the AOSE Technical Forum Group's (2004) perception of the future trends in the area of agent-oriented software engineering. According to AOSE Technical Forum Group (2004), the research in the area of agent-oriented software engineering is still in its early stages, and several challenges need to be faced before agent-oriented software engineering becoming a widely accepted and a practically usable paradigm for the development of complex software systems. One possible way to identify and frame the key research challenges in the area of agent-oriented software engineering is to recognize that such challenges may be very different depending on the "scale of observation" adopted to model and build a software system (AOSE Technical Forum Group, 2004).

At one extreme, the micro scale of observation is that where the system to be engineered has to rely on the controllable and predictable behavior of (a typically limited number) individual agents, as well as on their mutual interactions (AOSE Technical Forum Group, 2004). There, the key engineering challenges are related to extending traditional software engineering approaches toward agent-oriented abstractions (AOSE Technical Forum Group, 2004). Brand new modeling and notational tools, as well as possibly brand new software process models may be needed (AOSE Technical Forum Group, 2004).

At the other extreme, the macro scale of observation is the one where a multi-agent system is conceived as a multitude of interacting agents, for which the overall behavior of the system, rather than the mere behavior of individuals, is the key of interest (AOSE Technical Forum Group, 2004). In this case, a discipline of agent-oriented software engineering should focus on totally different problems, and should be able to develop novel "systemic" approaches to software engineering, possibly getting inspiration from areas such as complex systems sciences and systemic biology (AOSE Technical Forum Group, 2004).

In between, the meso scale of observation is where the need of predictability and control, typical of the micro scale, clashes with the emergence of phenomena typical of the macro scale (AOSE

Technical Forum Group, 2004). Therefore, any engineering approach at the meso scale requires accounting for problems that are typical of both the micro and the macro scale, and possibly for new problems specific to the meso scale (AOSE Technical Forum Group, 2004). These include: identifying the boundaries of a systems—which may be challenging in the case of open multi-agent systems; electing trust as a primary design issue; identifying suitable infrastructures for multi-agent systems support (AOSE Technical Forum Group, 2004).

As concerns the virtual enterprises' scientific domain, we believe that agent technology has much to offer with respect to the formation and the operation of a virtual enterprise. According to Camarinha-Matos (2002), several challenges remain open for MAS requiring further research, such as support for the full life cycle of the virtual enterprise, adoption of contract-based coordination models, necessary integration of MAS with several other paradigms, interoperation with legacy systems and enterprise applications, inclusion of specialized protocols and standards, and support of robust safety mechanisms.

There is a need to integrate ACL with mechanisms for safe communications (cryptography, digital signature, certification, etc.) that have been developed for virtual enterprises and e-commerce (Camarinha-Matos, 2002). The development of advanced simulation tools to support planning, optimization, and assessment of operation of virtual enterprises and distributed business processes is another open challenge that can benefit from a MAS approach (Camarinha-Matos, 2002). Finally it is important to stress that in order to be accepted by the industrial community, MAS applications need to be successfully demonstrated in complex real world pilot systems (Camarinha-Matos, 2002).

CONCLUSION

The area of software agents is vibrant and rapidly developing. A number of fundamental advances have been made in the design and the implementation of software agents as well as in the interaction between software agents. In this brief chapter, we have tried to convey some of the key concepts of the active field of software agents and make a reference point to a large body of literature outlining essential issues. We were limited to enumerate our findings of our survey regarding software agent technology, instead of judging them, aiming to provide a synoptic review of the basic aspects. It is up to the reader to judge how successful we have been in meeting our goal in this chapter. In addition, we have argued the issue of applying the agent technology to virtual enterprise. Our purpose was to offer a brief introduction of the application of agent technology to virtual enterprises and to provide some useful hints for further studying concerning the above-mentioned theme.

ABSTRACT

This chapter approaches paramount aspects related to test automation, introducing the importance of implementation in the software market and essential bases, such as adjustment to the organizational reality and establishment of an efficient strategy. Types of tools and directives for a successful implantation are presented. Test automation has been considered the main measure taken to enhance test efficiency — fundamental in the software-development process. Responsible for verifying and/or validating the quality of the executable product compared to performed documentation and client requirements. Therefore, with the chapter content here provided, we aim to provide the reader with an understanding of test automation and grant relevant orientations to assist implementing it.

INTRODUCTION

Given the growing complexity of applications and new technologies, such as the advent of the client/server environment (in particular Web applications), the effort necessary for application testing has increased.

To assure that software conforms to requirements, various test stages may be identified: unit, integration, system, and acceptance. Bugs' impact increases with the evolution of the test stage in

which they are found, in other words, the cost of detecting errors during unit test is less than integration and system tests.

Each use case has test objects that may need to be retested several times during the project, demanding resources. These retests normally are required when a new functionality is added or when a bug is corrected, because there is no guarantee that the changes made will impact negatively on other parts already constructed. Therefore, the assistance of a tool capable of repeating a test already executed in the past is quite interesting.

Besides, multiple execution paths and diversity of possible inputs and outputs of an application complicate the execution of manual tests, which may be simplified by automation. In addition, performance, load and volume tests are examples of tests that are difficult to be accomplished without the help of automated testing tools. There are also some types of tests that are almost impossible to be executed manually, for example, a test to verify a system's performance with thousands or millions of simultaneous accesses or having to use an enormous amount of data.

Automating software tests speeds development and reduces retesting effort spent in each stage, thus reducing time and cost. However, this reduction is normally noticed only after a while, because there are high investments in the implantation stage, such as organizational needs, training, and tools acquisition. Automation allows increase of amplitude and depth of developed tests.

Testing automation might or might not be helpful. It allows one to take advantage of idle machine time (i.e., the period in which the developer is not working) to execute tests. Therefore, test execution can be more effective and waste less resources.

BACKGROUND

Automated software testing is an activity that seems to have obvious benefits: tests may be executed swiftly, are more consistent, and may be repeated various times without increasing cost. However, it is not a trivial activity and requires effective planning and elaborate test-case definition, as well as other characteristics, which will be explained in more detail later in this chapter. Benefits and risks, possible tools, an implantation methodology and directives for script generation are also described.

An automated test between different phases of the development process has the purpose of verifying if what was constructed from that stage backwards is correct and is adequate as an input for the next stage. An example would be a programmer testing a software component before doing the integration of components.

The generated test process is automated and capable of ensuring that the system logically operates according to the code by executing the functions through a series of test cases.

With a tool, you can expect the test script to conduct the verification processes and return results that verify whether the product under test meets code logic.

A test engineer usually follows a procedure to decide whether a problem found is a defect. However, an automated test tool makes decisions based on methods invocation, during which it detects errors and defects. Thus, the tool makes an effort to remind the developers of the importance of adopting a good error-handling technique.

But, can a tool verify that all test tasks have been performed? The answer is based on the requirements of your organization and on the architecture of the software project (Li & Wu, 2004).

Tests to validate a product against specified client requirements are more subjective and cannot always be automated. An example is a test executed by a user in a beta-program.

MANUAL TESTING VS. AUTOMATED TESTING

Software testing is necessary to guarantee the quality of a software product, may be performed during the whole software development process, in a manual, automated or hybrid manner, using different types of tests and tools.

Automated software testing simulates system behavior using tools. The test actions performed on the application are specified in code (scripts and test classes). In a context where required tests are not possible or viable to be executed manually, automated software testing is very important. As examples in which automated tests are indicated, one has Automated tests are used in regression, load, performance, and endurance tests and tests involving a vast amount of data.

Regression tests require testing all constructed functionalities after one of them is changed or a new one is inserted. Automation helps in this process, providing repetition of tasks already executed. Thus, functionality tests already recorded may be executed again, decreasing retest efforts.

For load tests, a high amount of users simultaneously accessing the application is necessary (e.g., in the order of 100; 1,000; and 10,000). How can such a test be performed? Automation is a resource that can easily simulate this scenario.

When using test performance, an automation test tool is used to capture time measurements each time they are executed. Performance degradations can be detected by collecting these measurements and reviewing them as time series (Karner, 1993).

Endurance testing requires automation. In this type of test, a specific application behavior is observed with the execution of its functionalities for a certain amount of time — weeks or months. This way, it is possible to detect problems like memory leaks, stack corruption and wild pointers.

Some specific tests — such as installation, configuration, and usability tests and specific hardware operations tests — require a strong human intervention, as well as a specific human evaluation and validation. Manual tests are recommended for these kinds of tests, being executed by at least one person, following a test procedure with application input and output data.

Test automation has a high cost. Training and scripts maintenance are necessary and, in case the tools used are not free, licenses are needed according to the number of users. However, automation has become essential given to systems' high complexity, need of performance and stress testing, resulting in increase of testing time and cost, reduction of software quality and, after the recognition of importance of software tests, pressure over project development teams has increased.

Test execution may also be performed with hybrid methods, characterized by applying jointly manual and automated techniques in the same project. The choice will depend on a thorough analysis of time and resources available and test complexity. The degree of maintenance and human intervention must be taken into consideration given to application modifications.

Many tests are not executed many times during a project life cycle. In these cases it is more advantageous to execute the tests manually, because efforts employed in their automation do not provide large returns. Therefore, it is not recommended to automate 100% of the tests.

Manual and automated tests should not be compared only in terms of time, effort, and cost, because the value of a test is especially in the

information it provides. In the same way, manual and automated tests are not allowed to be compared in many cases, because they provide distinctive information, as seen before, for every type of test, one of them is normally indicated.

However, in certain situations it might be a reasonable goal to create the most extensive automated test suite, such as contractual or regulatory reasons, when it is necessary to prove that the final version passed a strong battery of tests; when tests will be delivered with the product so that customers can also run the tests themselves; when the product has stringent requirements for backwards compatibility, remaining for many versions, or when the only way to test some products is by writing programs to exercise them (Kaner, Bach, & Pettichord, 2002).

OVERVIEW OF AUTOMATED TESTING

Nowadays automated testing is considered the main resource to improve the efficiency of a test process (Rios & Moreira, 2003), using tools so that the computer is responsible for assistance, design achievement, execution or tests control. Information collection and their quick dissemination are assisted by automated tests to provide a faster feedback to the development team (Kaner, 2002).

Tools to execute automated tests normally simulate the use of an application by several users simultaneously, a high load of data processing, as well as repetition of tasks previously executed. Besides, automating regression tests is of great relevance for the maintenance phase, since tests executed during development may be repeated in new tests, when the system is already in production.

When the automation does not apply to the entire test process, it can be used to execute punctual tests. This occurs normally with some types of tests — such as load and performance tests — because they are truly difficult to be performed without the help of a tool, requiring big effort and many computational resources.

The preparation of automated tests takes more time than manual tests. This is mainly a consequence of high effort and cost necessary to generate and maintain automation code. Therefore, so that the investment may bring satisfactory return on investment, automation must help to achieve the specific tests mission (Kaner, 2002), providing a supply of functional and nonfunctional tests.

Automation must be introduced in a context where the test process is well performed, with well-defined activities and with a mature and experienced test team. Otherwise, automation will not assist the achievement of test objectives. For this reason, test processes must be fixed before automating them.

Specific management treatment is required, in other words, planning, execution, and control, because normally automation is characterized by its innovation and high investments, complexity, and risks. Without this management, the expected benefits may not be achieved, besides consuming resources and dispersing the team from their test objectives, consequently interfering on the quality of tested products. Moreover, previous strategies and planning definitions are necessary, so that risks are controlled, possibility of scripts reuse is increased and automation optimized.

Automated testing tools do not replace testers, nor will their work be simpler. Actually their effort will be redirected to essential activities of the test automation process. For this reason, it is of great relevance to prepare the group, because the success of automated testing depends predominantly on their skills.

TEST-STAGES AUTOMATION

Test automation may be applied to diverse stages: unit, integration, and systemic. Each one has peculiar characteristics and is implemented in a

different way. Next, these aspects will be shown for each test stage.

Automated Unit Testing

Unit tests consist of testing components individually. The tester verifies the input domain only for the unit in question, ignoring the rest of the system. These tests require code construction executed during depuration mode.

The developer has the responsibility to ascertain that units are correctly constructed, analyzing code, comparing it with the system's specification and checking if any functionality is missing or was not completely developed.

Tests and error corrections may be made at any stage of the development cycle. Nevertheless, some authors like Boehm (1981), have shown that the cost of searching and finding errors increases while the development advances. It is cheaper to fix defects during the codification stage.

Procedure to implement unit testing:

1. Prepare test environment.
2. Define input domain based on requirements and use cases.
3. Define, for every input, expected output based on requirements and use cases.
4. Implement components to be tested.
5. Group unit tests in collections of components.
6. Implement unit tests.
7. Execute unit testing.
8. Fix component tested, if there is an error.
9. Execute step 8 while any error remains.

Unit testing consists basically of:

1. Variables initiation, including database population.
2. Business rules or input functions are applied.
3. Destruction of variables, including the cleaning up of data input to data base.
4. Comparison between results of applied function with expected results, failing in case they differ.

Grouping unit tests forms a tree, where the leaves consist of the unit tests and in the other nodes are the groupings of unit tests. This technique allows automating and executing all tests, a subset of them, or each one individually.

Unit test automation enables dynamic problem detection, generating automated reports, and facilitates execution of regression tests, which are necessary for every meaningful code update.

Automated Integrated Testing

Integrated tests are performed to test various parts of the system (components, modules, applications, etc.) that were separately developed in a set. Integration tests are executed after each of the system's parts has been tested individually, using unit tests or systemic tests, in case of applications that communicate (with each other).

Analyzing the time line, you can notice that integrated tests are mainly performed after a unit test and before systemic tests, normally are executed by developers that create their own builds and test integrates units or by a specialized testing team.

Procedure to implement integrated tests:

1. Prepare test environment, using test data and test server, which are configured to simulate the production environment.
2. Identify test cases based on requirements and architecture.
3. Detail procedures for each test case.
4. Implement integrated tests.
5. Execute integrated tests.
6. Analyze results. If errors are found, they must be registered in the problem reports tool and associated to responsibles for the corresponding corrections. If none are found codification may stop.

7. Fix problems encountered.
8. Execute tests again. After ending it, return to step 6.

Automated System Testing

System testing is the most misunderstood and most difficult testing process. System testing is not a process of testing the functions of the complete system or program, because this would be redundant with the process of function testing (Myers, 2004). System testing compares the system or program with its original objectives (requirements).

In this stage a test environment, compatible with the one in which the system or program will be used, is necessary.

Various test types are performed during this stage: usability, functionality, performance, stress, and so on. Some of these may be automated to make execution more agile, especially in case of regression tests.

Systemic tests may be automated in several ways, but a list follows with their basic activities:

1. Prepare test environment, installing and configuring necessary hardware and software.
2. Design test cases.
3. Define automation strategy.
4. Select project scope for automation.
5. Implement systemic test scripts for each test case.
6. Execute systemic test.
7. Analyze results. If errors are found, they must be registered in the problems report tool and associated to responsibles for the corresponding corrections.
8. Fix problems found.
9. Generate reports with tests status.
10. Execute tests again, returning to step 6 after finishing them.

Automation Techniques

Automated functional test tools make use of some techniques that differentiate themselves basically because of the contents of the generated scripts: record & playback, scripts programming, data-driven and keyword-driven. These techniques will be explained as follows:

- **Record and playback:** Technique that consists of recording a test execution made on the application's interface and playing back this execution later. The generated scripts contain unalterable data, test procedures, and expected results. The advantage of this technique is the simplicity of generating scripts. However, there is a high sensibility to changes, which restricts a script's lifetime. For example, a simple change of an interface may lead to the necessity of recording again all the scripts, implying a high script maintenance cost.
- **Scripts programming:** Considering the components of the generated scripts, this technique is similar to the one above. However, this one allows updating generated scripts. With this resource, script programming has a higher rate of reuse, longer lifetime, and less difficulties to be maintained, compared to the technique of Record & Playback. Nevertheless, there is still a big volume of scripts and high-maintenance cost (Fantinato, Cunha, Dias, Mizuno, & Cunha, 2004).
- **Data-driven:** This is a technique that approaches test-data extraction through scripts, storing them in separate files. Therefore, scripts will only contain test procedures and actions for the application. This technique is useful for tests using different inputs and combinations of scripts with common test procedures (Kaner, 2002). This way, maintenance requires a reduced effort when it is

necessary to include, update, or delete any test data. However, this technique depends on the test-execution logic, in other words, if any step is added to the procedure (or removed) the script needs to be generated again.

Nevertheless, it allows automating in parallel: test data can be created while test procedures are being generated. The extraction of test data from scripts provides tests that are easy to understand and revise. Many test tools include direct support for the technique *data-driven* (Kaner, 2002).

- **Keyword-driven:** Based on retrieving test procedures from scripts, remaining only test data and specific test actions, which are identified by keywords. This resource's operation, being invoked by keywords and even receiving parameters, is similar to that of structured-program functions. An important enhancement of this technique is the reduction of script-maintenance effort if there is incorporation, removal, or modification of any step of a test-procedure execution (Fantinato et al., 2004).

  In spite of tools existent in the market recommending a specific testing technique, the organization needs to establish the most adequate technique according to their own test context after analyzing all possibilities.

Good Practices for Automation

A list of relevant practices to improve systemic test-script implementation and reuse follows, which may be used according to the adopted technique:

- When recording a script for a test case, some necessary initialization may be necessary — such as database connection, variables, and functions — which can be shared between test cases of the same use case or even between many use cases.
- Each script may be recorded independently from the others, having its own variables, initialization, and so on, although it would be better to share common objects for test scripts, in other words, use the concept of modularity. For example, if it is necessary to clean up a database for a specific use case before executing any test script, or if there are common script steps, a text file to store these steps may be used and later on can be included at scripts execution time. If these steps change, only one place will have to be modified.
- Another practice is to define functions executing a common activity for many scripts, and only call it from those scripts.
- A clean and robust code must be implemented. Comments should be made for important lines or code blocks. While implementing, possible maintenance may not be discarded.
- When a flow alteration or verification point in a script is recorded again, there must be some care to update only script sections where there really must be a change.
- To delete any garbage shown in a form, before inserting any data, a combination of keys should be used ("HOME", "SHIFT+END" and "DELETE") when recording an action of data input.
- If test scripts are recorded initially from a prototype (in case the application is still not available), it is necessary to certify that names of fields and IDs of clickable icons on screen will not be altered. If they are changed, the script will need an update later.
- Dynamic data for test scripts should be used (test data separate of scripts). The immediate benefit is that, if additional data is needed, more records can simply be added; there is

no need to modify the test script (Mosley & Posey, 2003).

BENEFITS AND RISKS

The benefits of automated tests are innumerable. Some of them will be described here, as well as risks that were considered most important.

A growing number of software versions to be tested exhausts the capacity of manual tests in terms of time, patience, input variation, attributes combination and, as consequence, cost. With advent of increasingly complex, integrated, and critical software, automated tests have become a necessity.

Benefits of test automation may be observed in any test stage, such as unit tests, integrated tests, and systemic tests.

Unit testing is a way of efficiently granting an applications quality. In this stage, a big quantity of errors can be detected and easier corrected. The manual execution of unit tests is a difficult process that consumes time and resources, being practically unviable since almost all system units must be tested, depending on the context, such as functions, subroutines, components, or classes.

Benefits of automated unit tests are easily noticed. During the project's life cycle unit tests, automation can decrease the costs of rewriting code, because more errors are found still in the codification stage. This test stage also grants more security when doing updates, since the entire set of tests are executed automatically. It is easier for programmers to write test routines that retain their value in time and assure the correct functioning of units. Besides, automated unit testing provides test results immediately after their execution.

In *integrated tests*, where the focus is on systems architecture and integration between different units developed, it is also indispensable to execute them automatically. The integration between system units may occur daily during the development process and it is important to always test the relationships between those components using automatic mechanisms, like continuous integration.

Automation of *systemic tests* requires attention and planning, because in this stage the functionalities' behavior is verified according to specified requirements. System testing is conducted at a higher level. During systemic tests, an examination is made of integration of parts that make up the entire system (Dustin, Rashka, & Paul, 1999).

For each test stage, automation must take into consideration possible software changes. However, systemic test scripts have their execution recorded in an application interface, therefore, there must be a special care avoiding costs of rework. Flexible scripts (dependencies with interface are minimized) can assist scripts maintenance.

In general, test automation in any stage allows:

- **Test effort reduction:** Introduction of automated test tools will not immediately reduce the test effort. Experience has shown that a learning curve is associated with attempts to apply automated testing to a new project and to achieve effective use of automated testing.
  While the testing effort will likely increase at first, a playback on test tool investment will appear after the first iteration of the tools' implementation, due to improved productivity of the test team.
  Manual tests must still be performed on the project, while a learning curve may exist due to effort with familiarization and efficiency in the use of the tool (Dustin et al., 1999).
- **Schedule reduction:** As the testing effort may actually increase, the testing schedule will not experience an initial decrease but may instead become extended. Therefore, permission to increase the schedule is required when initially introducing an automated test tool. Once an automatic testing

process is established and effectively implemented, the project can expect to experience gains in productivity and turnaround time, having a positive effect on schedule and cost (Dustin et al.,1999).

- **Improved regression testing:** An automated test tool provides simplified regression testing. Automated regression testing can verify in an expedient manner that no new bugs were introduced into a new build (Dustin et al., 1999).
- **Improved focus on advanced test issues:** Automated testing allows simple repeatable tests. A significant amount of tests are conducted on the basic user-interface operations of an application.

  Besides delaying other tests, the tedium of these tests exacts a very high toll on manual testers. Manual testing can become stalled due to the repetition of these tests, at the expense of progress on other required tests. Automated testing presents the opportunity to move on more quickly and to perform a more comprehensive test within the schedule allowed. That is, automatic creation of user interface operability tests gets these tests out of the way rapidly and releases test resources, allowing test teams to turn their creativity and effort to more complicated problems and concerns.
- **Increased test coverage:** Automated testing may increase breadth and depth of test coverage, yet there will still not be enough time or resources to perform a 100% exhaustive test. Even with automation, testing every combination of a system exhaustively is impossible. Therefore, there must be strategies (equivalence partitioning) to select relevant test data.
- **Productivity increase:** Having increased test coverage, automation also increases productivity. Testers may verify more test cases in less time than when using manual tests.
- **Improved performance testing:** Many load-testing tools are available that allow one to automatically test the performance of a system's functionalities, producing timing numbers and graphs and thresholds of the system. There is no longer the necessity to sit with a stopwatch in hand. The objective of performance testing is to demonstrate that a system functions in accordance with its performance requirement specifications regarding acceptable response time, while processing the required transaction volumes on a production-size database (Dustin et al., 1999).

From these benefits, we can observe that automation is essential, because, even with an extremely experienced tester, it is almost impossible to know all the relations and combinations between attributes of medium- and large-sized applications.

Even so, the implementation of a solution for automated tests, even with excellent test tools available, is not trivial and can fail mainly due to:

- **Nonqualified test team:** An automated tool requires new skills for test analysts, therefore additional training is required. An efficient automation is not that simple. Test scripts automatically generated by the tool during recording must be modified manually, which requires scripting knowledge, so as to make the scripts robust, reusable, and maintainable. To be able to modify the scripts, the test engineer must be trained on the tool and the tool's built-in scripting language (Dustin et al., 1999).
- **Inadequate tools:** The automation tool must be in accordance to the company's business needs with the test process introduced. There are many tools that automate tests and a correct choice cooperates to fully use features offered. There is not a tool clearly

superior to other tools for every situation. The choice of the most adequate tool depends on characteristics of applications, test stages to be automated, as well as the adopted organizational test policy.

Simply using tools, by themselves, will not promote a significant quality enhancement of developed products, if not accompanied by an adoption of a work methodology.

An incorrect choice may lead to automation failure, once the organizational testing needs will not be completely suppressed and resources and efforts addressed to manual tests deviated. Besides, given to the affected credibility, it may be difficult to obtain further investments of higher management to proceed with automation or even to reinforce manual tests.

- **Elevated cost with systemic test scripts maintenance:** This aspect may not compensate automation costs. Systemic test scripts have to be flexible enough to easily support various changes and insertion of new functionalities that appear during a project's life cycle.

  To create scripts easy maintainable, professionals with experience in software development are important. They are supposed to be capable of designing a modular script structure, in the same way as when doing a normal software design.
- **Automation of every test type:** As explained in this chapter, when tests require high human intervention it is not recommended to focus on automated tests.
- **Lack of planning and control of the automation process:** Test automation must be considered a separate project from the software development process. Cautions related to project management have to be taken, such as concerns with scope, time, cost, quality, integration, resources, and risks.

Execution of automated tests helps to provide reliable and stable applications. However, to reduce associated costs and risks, it is important to analyze factors mentioned earlier on. Thus automation benefits can be more evident in the organization and risks can be controlled by mitigation and/or contingency.

AUTOMATED TEST TOOLS

The tools for automated testing are instruments to make the testing process easier, replacing and/or assisting manual tests performed by testers. Various tools exist to be used in the various test stages.

Many organizations have successfully chosen and purchased a test tool, but around half of those organizations have not achieved any benefit from their investment because their tools have ended up not being used (*shelfware*) (Fewster & Graham, 1999). A way of easing this risk is by knowing better the available market categories and types of automated tools.

Categories and Types

While GUI-testing tools (also called "capture/playback" tools or functional-testing tools) are much hyped in the testing industry, it is important to be aware of the other types of tools available to support the testing life cycle. This item provides an overview of the available tools, listed in Table 1, supporting the various test activities.

The existent divisions of types of test tools are not uniform. Therefore, to be more didactic and easier to understand the purpose of each test tool, they may be divided into categories, and those categories have many types of tools associated with them, according to their objectives:

- **Test-development tools:** Assist test plan elaboration and generation of test cases and

Table 1. Tools by category and type

Tool Category	Type of Tool	Description	Example
Test Development	Test-procedure generator	Generates test procedures from requirements/design/object models	▪ TYX — Test Procedure Generation Wizards
	Test-data generator	Generates test data	▪ Tnsgen ▪ DTM Data Generator
	Test-data extraction	Extraction and verification of test data	▪ Kapow Web Collector
Test Execution	Unit testing	Unit API testing and assertions verification	▪ PyUnit ▪ JUnit ▪ HttpUnit
	Memory-leak detection	Verify that an application is properly managing its memory resources	▪ JProbe ▪ Pruify
	GUI-testing (capture/playback)	Automate GUI tests by recording user interactions with systems, so they may be replayed automatically	▪ Robot ▪ WinRunner ▪ QARun ▪ Functional Tester
	Load, performance, and stress testing	Load/performance and stress testing	▪ Robot ▪ LoadRunner ▪ JMeter ▪ JProbe
	Network testing	Monitoring, measuring, testing, and diagnosing performance across entire network	▪ CSSCheck ▪ Bobby
Test Support	Test management	Provide such test-management functions as test-procedure documentation, storage, and traceability	▪ TestManager ▪ TestDirector ▪ QADirector
	Code-coverage analyzers and code instrumentors	Identify untested code and support dynamic testing	▪ Clover ▪ NoUnit ▪ Jtest
	Metrics reporting	Read source code and display metrics information, such as complexity of data flow, data structure, and control flow. Can provide metrics about code size in terms of numbers of modules, operands, operators, and lines of code.	▪ McCabe Visual Quality
	Usability measurement	User profiling, task analysis, prototyping, and user walkthroughs	▪ SUMI
	Defect tracking (bug tracking)	Manage data base with found defects	▪ ClearQuest ▪ Bugzilla ▪ Jira

input data. Test development is responsible for designing tests and test data, being the most important set of activities in a testing process. Tests must enclose all requirements, otherwise, they will be invalid.

- **Test execution tools:** Assist test case execution and results evaluation; include also the capture/programming of test scripts.
- **Test support tools:** Assists test-specific activities, not being considered particular for tests. Include tools to support revisions, inspections, walkthroughs, project management, as well as tools for defect tracking and database managing.

Following are some key points regarding some of the types of test tools, according to their categories.

Test-Development Tools

- **Test-procedure generators:** A requirements-management tool may be coupled with a specification-based test-procedure (case) generator. The requirements-management tool is used to capture requirements information, which is then processed by the test-procedure generator. The generator creates test procedures by statistical, algorithmic, or heuristic means. In statistical test-procedure generation, the tool chooses input structures and values in a statistically random distribution, or a distribution that matches the usage profile of the software under test (Dustin, 2002).

  Most often, test-procedure generators employ action-, data-, logic-, event-, and state-driven strategies. Each of these strategies is employed to probe for a different kind of software defect. When generating test procedures by heuristic- or failure-directed means, the tool uses information provided by the test engineer. Failures discovered frequently in the past by the test engineer are entered into the tool. The tool then becomes knowledge-based, using the knowledge of historical failures to generate test procedures.
- **Test-data generators:** Test-data generators aid the testing process by automatically generating test data. Many tools on the market support the generation of test data and populating databases. Test-data generators can quickly populate a database based on a set of rules, whether data is needed for functional testing, data-driven load testing, or performance and stress testing.
- **Test-data extraction tools:** Using production data for testing purposes increases the integrity of testing by allowing testing teams to establish test scenarios using real test cases rather than relying on fabricated testing environments.

  A test-data extraction tool minimizes time to create test data and maximizes integrity and usability of data.

Test-Execution Tools

- **Unit-testing tools:** This type of tool is used to program and execute tests in units of the developed application. The units are normally classes, methods, or flows. Generally a unit-testing tool supports only one development language.
- **Memory-leak detection tools:** These tools are used for a specific purpose: to verify that an application is properly using its memory resources. These tools ascertain whether an application is failing to release memory allocated to it, and provide runtime error detection. Since memory issues are involved in many program defects, including performance problems, it is worthwhile to test an application's memory usage frequently.
- **GUI-testing tools (capture/playback tools):** Many automated GUI testing tools are on the market. These tools usually in-

clude a record-and-playback feature, which allows the test engineer to create (record), modify, and run (playback) automated tests across many environments. Tools that record the GUI components at the user-interface control are most useful. The record activity captures the keystrokes entered by the test engineer, automatically creating a script in a high-level language in the background. This recording is a computer program, referred to as a test script. Using only the capture and playback features of such a tool uses only about one-tenth of its capacity, however. To get the best value from a capture/playback tool, engineers should take advantage of the tool's built-in scripting language.

To create a reusable and maintainable test procedure, the test engineer must modify the recorded script. The outcome of the script becomes the baseline test. The script can then be played back on a new software build to compare its results to the baseline. The results can be compared pixel-by-pixel, character-by-character, or property-by-property, depending on the test-comparison type, and the tool automatically pinpoints the difference between the expected and actual result (Dustin, 2002).

- **Load, performance, and stress testing tools:** Performance-testing tools allow the tester to examine the response time and load capabilities of a system or application. The tools can be programmed to run on a number of client machines simultaneously to measure a client-server system's response times when accessed by many users at once. Stress testing involves running the client machines in high-stress scenarios to determine whether and when they break.
- **Network-testing tools:** The popularity of applications operating in client/server or Web environments introduces new complexity to the testing effort. The test engineer no longer exercises a single, closed application operating on a single system, as in the past. Client-server architecture involves three separate components: the server, the client, and the network. Interplatform connectivity increases potential for errors. As a result, the testing process must cover the performance of the server and the network, the overall system performance, and functionality across the three components (Dustin, 2002). Many network test tools allow the test engineer to monitor, measure, test, and diagnose performance across an entire network.

Test-Support Tools

- **Test-management tools:** Test-management tools support the planning, management, and analysis of all aspects of the testing life cycle. Some test-management tools, such as IBM's Rational TestStudio, are integrated with requirement- and configuration-management and defect-tracking tools, in order to simplify the entire testing life cycle.
- **Code-coverage analyzers and code-instrumentors tools:** Measuring structural coverage enables the development and test teams to gain insight into the effectiveness of tests and test suites. They are able to quantify the design complexities, help produce the integration tests, and measure the number of integration tests that have not been executed. Some of them measure multiple levels of test coverage, including segment, branch, and conditional coverage.
- **Metrics reporting tools:** Tools responsible for reporting metrics analyze code complexity and identify application passages that offer a higher fault risk, reporting quality metrics. With these tools it is possible to know parts of code that have or have not been tested.

  The usage of metrics-reporting tools assures higher product quality, because it is possible to have metrics showing the quality of what

is being developed.

- **Usability-measurement tools:** Usability engineering is a discipline that includes user-interface design, ergonomic concerns, human factors, graphics design, and industrial and cognitive psychology. Usability testing is largely a manual process of determining the ease of use and other characteristics of a system's interface (Dustin, 2002). However, some automated tools can assist with this process, although they should never replace human verification of the interface.
- **Defect tracking (bug tracking):** Most of the existing commercial tools present a conjunction of tool types or even categories. It may be a big advantage to obtain these integrated tools. However in some cases not all functionalities are needed and the tools cost may be an inhibitor. Therefore, it is very important to analyze test tools' costs and benefits thoroughly.

  Some test tools are intrusive, because it may be necessary to insert special code into the application program so that the automated tool may work correctly, interacting with the testing tool. Development engineers may be reluctant to incorporate this extra code. They may fear it will cause the system to operate improperly or require complicated adjustments to make it work properly. To avoid such conflicts, test engineers should involve the development staff in selecting an automated tool and if the tool requires code additions (not all tools do), developers need to know that well in advance.

  Intrusive tools pose the risk that defects introduced by testing hooks (code inserted specifically to facilitate testing) and instrumentation could interfere with normal functioning of the system.

  Besides, as with all technologies, test tools can be unpredictable. For example, repositories may become corrupt; baselines may not be restored, or may not always behave as expected. Often, much time must be spent tracking down a problem or restoring a back-up of a corrupted repository. Test tools are also complex applications in themselves, so they may have defects that interfere with the testing effort.

Programming Languages of Automated Test Tools

It has already been mentioned that there are a lot of test tools available on the market, and testing teams have used the tools and achieved great success. These test automation tools also include writing (i.e., coding) test scripts, which are software programs (Mosley & Posey, 2003). As such, they have their own programming languages and/or language extensions that are required to accommodate software-testing events, such as Java (JUnit and JProbe) or Visual Basic; in one of the standard scripting languages such as Perl, CGI, or VB Script; or in the operating system's command procedure language (Unix).

The scripting language is usually embedded in a capture/playback tool that has an accompanying source code editor. Some popular test tools write test scripts in Visual Basic 6.0 and execute the script in Visual Studio IDE. There is also literature that introduces how to write test scripts in Visual Basic 6.0 by hand. Some other tools are written in Java, such as JUnit, and JProbe and there are tools to write test scripts for software products run on Unix, Linux, and other platforms.

Test Tools Development

The usage of an automated tool will not always be adequate or provide necessary benefits. Diversified factors may lead to the necessity of building a tool:

- **Application incompatibility:** The application may contain an element that will cause compatibility problems with any capture/

playback tool on the market. If a work-around cannot be created, it may not be possible to use the capture/playback tool. Even if a work-around can be created, it may not be worth the effort, being more beneficial to create a customized tool.

- **Operating system incompatibility:** If there is a market absence of a tool, compatible with the various operation systems in use, there is no other choice than to consider building a customized tool that will work in the specific environment under test.
- **Specialized testing needs:** In case the test tool cannot reach a critical/complex component, an enhancement to the tool may be developed.

In case the organization chooses to develop a testing tool, resources, cost and time need to be determined, as well as management permission. The tools development must be treated as development effort of the project that demanded the use of the tool (Fewster & Graham, 1999). Many books provide detailed explanations of how to proceed to develop a test tool inside an organization, such as Li and Wu (2004) and Fewster and Graham (1999).

IMPLANTATION OF TEST AUTOMATION

Many companies, certain of the advantages of test automation, want to define a process of test automation to enhance the software-testing process, but do not know how to do it. Next, some phases are described which may be used for the test-automation implantation.

Introduce Automated Test Ideas

In this stage, the expectations management related to test automation and explanation of its benefits are performed, introducing automated test ideas to the organization.

Some imagine that a lot of time is spent with automation and that it has high costs. Therefore it is important to study its applicability (Donegan et al., 2005), verifying management, financial and structural benefits and risks involved, because the advantages and disadvantages of automation are to be made clear for everyone. At this moment, those involved with the implantation, including internal investors, are supposed to be conscious that normally the return on investment will be obtained in a medium or long term, since test automation does not reduce testing time as soon as it is introduced. This occurs given to time spent with tools initial learning, adaptation to the new testing process, among other factors mentioned before.

Generally, introducing tests automation requires a lot of investment. That does not happen only with the acquisition of a tool, but also with professional preparation of stakeholders and with maintenance of existent hardware to support the one being installed. Those variables must be considered in the projects' budget.

In this stage, an open communication with high management is fundamental, being constantly informed of organizational risks already detected, as well as direct benefits of automation, so that they may support the entire automation process even being aware of the existent challenges.

It is important to form a team with specialized professionals to begin the implantation of tests automation. The team must have at least one representative with knowledge of the organizational culture. These professionals will also be responsible for conducting the next stage.

After taking into account all the factors mentioned, the organization might take the decision of beginning test automation, or may abort the idea, being aware of risks and benefits involved. In case the decision is positive, some of the initial automated test ideas above have to be detailed in

a tests automation plan, defining tasks that will be executed.

Choose Test Tool

This stage guides the choice and evaluation of necessary tools for test automation.

Initially, the requirements of the tool are researched, according to organizational necessities: available resources, architecture of developed applications, platforms used, automation tool language, type and stage of desired test, and others. If possible, requirements should be prioritized conforming to the level of importance, making it possible to focus on key requirements in the evaluation process.

According to the requirements of highest importance, available tools in the market are selected. In case there is not any tool accessible to provide the organizational needs, the possibility of developing a homemade tool must be taken into account, which was seen earlier on in the chapter.

However, generally, a single test tool will not fulfill all the automated testing requirements for an organization, unless that organization works only with one type of operating system and one type of application. Expectations must be managed. It must be made clear that currently there is not a single tool on the market that is compatible with all operating systems and programming languages. This is only one reason why several tools are required to test the various technologies.

After preselecting the tools, there must be an assurance that the tools will fulfill the requirements and other points, like usability and performance. A way of doing this is using demo versions or doing hands-on. As a consequence, one or more tools are selected, according to company needs.

Refine Testing Process

This stage sketches the refinement of the organizational test process, including necessary activities for automated tests.

As an aftermath of the test tools choice, the process of implantation of automation begins. Now it is necessary to lay out objectives and strategies, by means of common architectures used in organizational projects. The strategy for automation in a company must contemplate directives that increase codification use and decrease their maintenance. See the "Good Practices" section.

After establishing these aspects, automation activities are defined. These activities are incorporated into the organizational testing process and stakeholders need to be properly trained. The mainly affected stakeholders are investigated, and a definition of the course goals (such as time and scope) is made.

A good way to consolidate the test process and chosen tools is to define a project to be automated and tested, called pilot project, applying the new test process and tools. It is necessary to monitor process planning, test-case elaboration, code creation, and tests execution and, especially, the results must be evaluated (Molinari, 2003).

All those involved in the test automation must participate, so that pertinent directives to the organizational context may be outlined and so that their commitment with the "Automation Product" is assured.

Develop Test Automation

Test Automation Planning

Conducting a common process of a Test Plan and designing test automation characterize the planning stage.

For the Test Plan, the scope of automation is defined and involved risks of the project in question are investigated, analyzed, and qualified. Besides, a test-automation strategy must be defined to orientate execution and monitoring, based on factors such as test scope, reuse of code, maintenance effort, and availability of time and resources.

Conventions of suites and code nomination may be established, as well as logical grouping relevant to worked scope. The most complex groups have to be identified and described in detail.

Test cases must have a well-defined design as they provide relevant information about the system to be tested without considering if tests are manual or automated. These test cases have to be analyzed, in order to identify the best automation possibilities. At this point, the test analyst must have a good understanding of how to raise valuable automation opportunities, in other words, opportunities that bring great aggregate value.

In case of automation of functional tests, another step consists of planning and designing useful test data, identifying the best way to communicate with code. See "Automation Techniques" section.

Test Automation Execution

Test execution approaches installation and configuration of tool and environment to initiate tests. This environment must also consider performance tests, which use various stations or virtual users. All necessary information concerning the environment must be contained in the test plan.

The preparation of a manual with instructions concerning chosen tools, test design information and adopted conventions is relevant.

The test team must develop test code based on the premises established during the planning stage and on the test projects already developed. The codes must be simple, robust, maintainable and, if possible, reusable.

After the test codes have been developed, unit, integrated and systemic tests can be performed. Generally, a different team of the one that executes systemic tests executes unit and integrated tests.

Each test team must report detected errors during test execution (integrated and systemic tests). A tool to report bugs facilitates this step.

Test Automation Management

Now that the tests are already planned and executed, they need to be managed. Control is essential for the test automation evolution analysis, with the perspective of analyzing if the new form of performing tests is acceptable and adaptable. Automation management is also fundamental to identify some points adopted during the planning stage that need to be adjusted, or even to reevaluate the tool with the purpose of certifying usability in the organization's context.

Tests codification must be constantly monitored, so that it can be a reflex of the application in such a way that modifications made in the product during its life cycle can also be contemplated in test code. This activity prevents reporting errors to the development team, caused by failure of test codification.

For systemic tests automation, when errors are found, it is necessary to do an analysis of them before sending the report to the development team, filtering duplicities and fake bugs, which are bugs caused by errors made during codification of tests.

Evaluate and Improve Test Automation

Automated test activities evaluation must be made during the whole test life cycle, so that improvements may be implanted. These enhancements can be observed along with execution of automated tests in organizational projects. Many of them are incorporated punctually into projects. The

company is, therefore, responsible for collecting, evaluating, and incorporating the improvements to the organizational process, when it is the case. Afterwards, stakeholders must be informed of changes made to the process and, if necessary, be trained.

Another important point is the test tool performance evaluation and determining what can be done to enhance it in the next project or test cycle.

RELATED WORKS

There are many works related to test automation: reports and case studies of organizations that have implemented automated software tests; research projects published in diverse events and magazines, creating models for test automation, elaborating efficient techniques for different types of automated tests, as well as others.

Organizations that develop software are constantly automating their tests to improve process and product quality, there are many examples to be found nowadays, here are two specific organizations using automated tests: Instituto Atlântico and BMC Software.

Instituto Atlântico implanted automation of functional system tests initially in a pilot project and, nowadays, automated tests are being used in other projects of the organization. Time spent to develop automated use case tests sometimes is superior to the time necessary to test it manually. However, Instituto Atlântico uses regression tests and this economizes time to execute tests, recovering the amount of time already used with codification after some increments. The tools used are those from Rational IBM: Robot, Test Manager and, more recently, Functional Tester. More details can be read in Donegan et. al (2005).

BMC Software developed a system to automate tests of a products suite called BMC's MetaSuite — family of applications client/server. They formulated orientations to choose people to automate tests and what should be automated.

BMC uses the tool QA Partner. One of the main gains using this tool is the easy maintenance of test scripts. Test cases are implemented before the interface is completely ready, because the test cases are independent of implementation details. In a week, BMC executed around three times each test case of three suite products. And those tests could be amply repeated in a more consistent manner. More information can be found in Pettichord (2001).

There are some interesting publications following, related to test automation, providing new approaches to automation. They may be adopted by organizations, if they are in conformity with objectives and purposes of the organization or specific project using automated tests.

Interface-Driven Model-Based Test Automation

The paper describes an interface-driven approach that combines requirement modeling to support automated test case and test driver generation. It focuses on how test engineers can develop more reusable models by clarifying textual requirements as models in terms of component or system interfaces. The focus of interface-driven modeling has been recognized as an improvement over the process of requirement-driven model-based test automation (Blackburn, Chandramouli, Busser, & Nauman, 2002).

Model-Based Approach to Security Test Automation

The paper summarizes the results of applying a model-based approach to automate security functional testing. The approach involves developing models of security function specifications (SFS) as the basis for automatic test-vector and test-driver generation (Blackburn, Busser, & Nauman, 2002).

FURTHER READING

A very good place to do some further reading is in the Web site http://www.stickyminds.com. You can find every kind of papers related to software tests, including some very interesting related to automated software testing

In terms of tools to automate tests, if you are interested in more examples of existent tools, we advise you to access Brian Marick's website http://www.testingfaqs.org (Marick, 2005). He presents an extensive list of tools for some types of automated tests. To learn more about the development of a tool to automate tests, it is interesting to read "Effective Software Test Automation — Developing an Automated Software Testing Tool" (Li, 2004), a book that teaches how to build a fully automated testing tool and provides expert guidance on deploying it in ways reaching high benefits.

In the section "Implantation of Test Automation" we showed a brief methodology to automate tests in an organization, however if you desire some further readings, it is interesting to read about the automate testing life-cycle methodology (ATLM) by Dustin, Rashka, and Paul (1999).

CONCLUSION

Good planning, clear definition of roles of those involved with automated tests, adequate tools and implantation with strong management to control risks and costs are essential so that the automated tests are successful in an organization.

Risks and benefits involved with automation need to be researched and afterwards informed to all stakeholders involved, especially to the high management, so that there is an effective compromise. Nevertheless, results obtained during test automation also have to be disclosed.

Automated tests are capable of increasing test coverage; because of time gain, cost subsided by future problems, and increase of the application's stability and investors trust.

A methodology for implantation of test automation was explained in this chapter, suggesting test automation to be implanted in stages, beginning with the decision of automation until process improvement, facilitating an efficient management and control of the automation process. An important stage for test automation is the choice of tools to be used. To make the right choice it is important to know the organization's real needs, testing-process maturity, test-team experience, automation techniques, and advantages and disadvantages of available commercial tools.

When initiating test automation it is important to customize the organizational test process according to required activities necessary for automated tests, training professionals, preparing environment, among other aspects given along the chapter. Thus it is possible to perceive that test automation must be treated as a project, requiring a plan, activities execution, and results monitoring. Therefore, it is more likely to obtain a positive return for the organization.

Chapter 1.16
Software Metrics and Measurements

Michalis Xenos
Hellenic Open University, Greece

INTRODUCTION

In the past few years, a large number of e-government and e-commerce systems have been developed, thus resulting to a constantly increasing number of software developers involved in software development for such systems. To ensure the production of high quality e-government and e-commerce systems, it is important for developers to collect and analyze measurable data that guide estimation, decision making, and assessment. It is common sense that one can control and manage better what he is able to measure.

Although there are major differences between e-commerce and e-government (e.g., access, structure and accountability; Jorgenson & Cable, 2002) there are no significant differences in terms of software metrics that can be applied to both. Metrics are used in e-government and e-commerce software development to measure various factors related to software quality and can be classified as product metrics, process metrics and recourse metrics. *Product metrics* are also called software metrics. These are metrics that are directly related to the product itself, such as code statements, delivered executables, manuals, and strive to measure product quality, or attributes of the product that can be related to product quality. *Process metrics* focus on the process of software development and measure process characteristics, aiming to detect problems or to push forward successful practices. *Resource metrics* are related to the resources required for software development and their performance.

This article focuses on product metrics and on how such metrics can aid in design, prediction and assessment of the final product quality, provide data used for decision making, cost and effort estimation, fault prevention, testing time reduction, and, consequently, aid in producing better software for e-government and e-commerce systems.

BACKGROUND

Measurement is the process by which numbers or symbols are assigned to attributes of entities in the real world so as to describe such entities according to clearly defined rules (Fenton & Pfleeger, 2004). In software development, measurements are conducted by using metrics. A *metric* is an empirical assignment of a value to an entity aiming to describe a specific characteristic of this entity. Measurements have been introduced into the e-government and e-commerce software development process in order to satisfy the need to control software development and produce higher quality results.

Since the mid 1970s when the first software metrics were proposed, a large number of metrics have been proposed in the following years. The proliferation of metrics was followed by more practical proposals on how to interpret results from metrics (see Shepperd & Ince, 1990) and methods combining metrics into measurement methodologies (see Xenos, 2003).

Public or private entities involved in software development for e-gsovernment and e-commerce applications can select from a variety of applied metrics those that are more suitable to be included in the development process (e.g., see Goodman, 2004; Kan, 2003). Therefore, taking into account the volume of literature that exists about software metrics, it is no more a question of finding metrics for an e-government or e-commerce project, rather than selecting the appropriate ones and extensively training engineering teams to utilize them (Hirsh, 2005). Given the large number of metrics (measuring almost everything), any attempt to select a metric without basing the selection on a detailed breakdown of the development needs and an extensive investigation of the proposed metric's applicability would result in minor benefits from its use or no benefits at all. To benefit from the use of metrics, apart from fully understanding the various existing metrics, one should also define well *why* he wants to measure, *what* to measure and *when* is the right time to measure it.

So the first question is: *Why use metrics?* The answer to this question is that metrics are needed to provide understanding of different elements of e-government and e-commerce software projects. Because it is not always clear what causes a project to fail, it is essential to measure and record characteristics of good projects as well as bad ones. Metrics provide indicators for the developed software. As Ragland (1995) stated, indicators are metrics or combinations of metrics that provide insights of the software development process, the software project, or the product itself. Measurements aim at the assessment of the status of the development process and the developed product. Therefore, metrics can be used for performance evaluation, cost estimation as Stamelos and Angelis (2001) have proposed, effort estimation, improving productivity, selecting best practices and—in general—for improving the quality of e-government and e-commerce systems.

This discussion leads to the next question: *What to measure?* As previously mentioned, process and product are what we need to measure. One may argue that, since the result of e-government and e-commerce projects is software, what we need to measure is only software. This is not true. According to Deming (1986), if the product you have developed is erroneous, do not just fix the errors, but also fix the process that allowed the errors into the product. This way you will not have to keep fixing the error in subsequent productions. Therefore, both process and product metrics and measurements are important in e-government and e-commerce software development.

It must be noted that, before selecting the appropriate metrics, it is very important to define the desired product quality characteristics. The selection of quality characteristics aids in defining what needs to be measured and what needs not, depending on the particular needs of the e-government and e-commerce application. In the early 1970s,

McCall, Richards, and Walters (1977) defined a framework for measuring such characteristics and proposed the Factors Criteria Metrics model—also known as FCM model—defining what is software quality in terms of subcharacteristics. Incorporating FCM and experience from similar proposals, years later, the ISO standard ISO/IEC 9126 (2001) standardized what product quality is in terms of subcharacteristics. Therefore the definition of product quality is important, as product metrics are used in the software development procedure to measure those product characteristics that are related to product quality.

Having defined the goals and reasons for measuring, the next question is: *When to measure?* Although measurements should be conducted throughout the entire e-government and e-commerce software development life cycle, their scope varies depending on the development phase. Different measurement goals are defined at different development phases, thus resulting into different kinds of metrics. In the early phases of e-government and e-commerce software development, metrics are used mainly for estimation purposes. It is useful to collect metrics relating to different projects as these can serve as historical data for future projects, aiding in better results.

In the intermediate phases of the e-government and e-commerce development process, metrics are used for project monitoring purposes and, in the meantime, code metrics are used to prevent errors. Furthermore, defect reports during testing are used for evaluating product quality and calibrating the measurement methods of the early phases. This purpose is also served by collecting external measurement data following project delivery, namely during the beta testing or maintenance phases of an e-government or e-commerce project. So the time to measure is determined by the requirements and the aims of the measurement program and can vary from a project to another.

Summarizing, using an oversimplifying statement, it could be said that metrics are an important instrument for the development of software to be integrated into e-government and e-commerce systems; metrics aid in making estimations in the early phases of a project, preventing problems in intermediate phases and evaluating quality in the late project phases.

USING METRICS IN SOFTWARE DEVELOPMENT FOR E-GOVERNMENT AND E-COMMERCE SYSTEMS

This section classifies product metrics in two categories—internal and external—provides a short definition and examples of each category, and discusses their advantages and disadvantages. The section concludes by presenting how these metrics can be combined and used in software development for e-government and e-commerce systems.

Product metrics can be categorized (Fenton & Pfleeger, 2004) as internal product metrics and external product metrics. *Internal product metrics* are those used to measure attributes of the product that can be measured directly by examining the product on its own irrespectively of its behavior. *External product metrics* are those used to measure attributes of the product that can be measured only with respect to how the product relates to its environment.

Internal Metrics

Internal metrics can be classified in three categories based on the product attributes they measure. These categories are size, complexity, and data metrics. As far as internal product metrics in general are concerned, it is important to mention that one of their major *advantages* is that they are easy to automate and therefore data collection can be made in an easy, automated, and cost-effective way. Furthermore, the measurement results can also be analyzed in an automated way using statis-

tical techniques and thus conclusions can be drawn rapidly. Tools such as QSUP (Xenos, Thanos, & Christodoulakis, 1996), Emerald (Hudepohl et al., 1996), GQM automation (Lavazza, 2000), and so forth have rendered internal measurements very easy to conduct. The screenshot from the metrics results of QSUP shown in Figure 1 is an example of the simple and automated way in which such measurements can be conducted. For further examples regarding metrics application, see Xenos (2003).

On the other hand, it should be mentioned that a major among the *disadvantages* of internal product measurements is the fact that they are often difficult to interpret. In other cases, the internal quantities measured are not clearly related to the external quality characteristics that one wants to assess. Such problems can only be solved in the framework of a well-defined measurement method that combines internal and external metrics, as will be discussed next.

External Metrics

Based on the ISO/IEC 9126 (2001) standard and on similar works such as Jung and Kim (2004), the *external factors* affecting software quality are Functionality, Usability, Efficiency and Reliability. For their definitions see "Key Terms," as defined by Kitchenham and Pfleeger (1996).

Figure 1. The results presentation window from QSUP Internal metrics

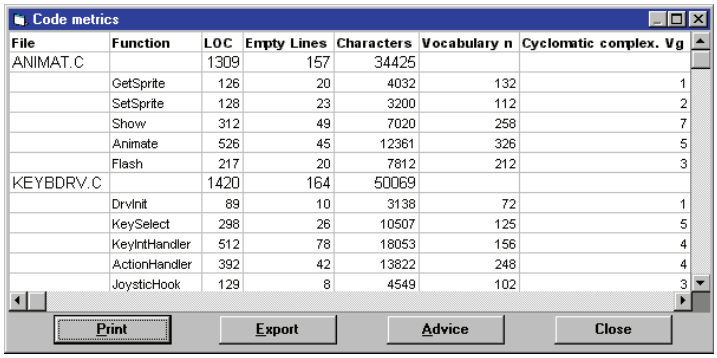

Table 1. High-level characteristics of e-commerce systems

Characteristics of e-commerce systems	Related quality factors
Easy access to the Web pages of the e-commerce system	Functionality, Usability, Efficiency
Easy navigation	Functionality, Usability
Adaptation to user profile	Functionality, Usability, Efficiency
Search engine service	Functionality, Usability, Reliability
Easy exit—undo functions	Functionality
Useful help service	Functionality, Usability, Efficiency
Electronic shopping cart	Functionality, Usability
Electronic shopping list	Functionality, Usability
Secure and reliable transactions	Functionality, Reliability
Security protocols SET, SSL	Reliability
Correct and accurate information about the products	Reliability
Direct delivery of the products	Usability, Efficiency
Indisputable financial transactions	Reliability
Recoverability of products and services	Usability, Functionality
Legitimate Web site	Reliability

External metrics are used to measure directly these four factors or the characteristics of which these factors are composed. For example, a set of high-level quality characteristics of e-commerce systems is presented in Table 1 (Stefani & Xenos 2001). This is important for the distinction between generic metrics and metrics defined especially for e-commerce systems.

Unlike internal metrics (measuring software internal characteristics and aiming at relating measurements of such characteristics to these factors), external metrics measure directly these factors or their characteristics. Such metrics can be based on subjective estimates. Among the means employed by external metrics are surveys on user opinion providing valuable measurements for software functionality or usability. Measures like defect reports or mean time between failures are used to determine product reliability, whereas measures like memory usage are used to determine efficiency.

As already mentioned, the application of external metrics implies that a certain extent of subjectivity is involved; even metrics that appear to be objective are often characterized by some degree of subjectivity. For example, defect reports seem to be a solid metric that can be used to objectively measure reliability. But the number of defect reports submitted by a user is influenced by issues such as the time and the extent of product usage, the user experience and even the user's motivation to edit and submit a defect report. Therefore, such metrics must be analyzed very carefully and under a framework that will take under consideration such issues.

One of the major *advantages* of external metrics is that they measure directly the desired external product quality characteristics, thus no further analysis or interpretation is needed. Additionally, external metrics contribute to a great extent to what is considered to be one of the main goals of e-government and e-commerce quality: user satisfaction. On the other hand, *disadvantages* and problems should be seriously taken under consideration when deciding to use external metrics, the most important of which being that such metrics are not objective and as a result additional effort is required to ensure their objectivity. Furthermore, they are not as cost effective as internal measurements and in many cases it is difficult to conduct measurements due to high error rates especially in cases that error detection techniques have not been used during measurements.

Combining Internal and External Metrics into a Measurement Method

As already mentioned, internal and external measurements must be conducted under a well-defined framework with precise goals. Before selecting the appropriate metrics for any project, a *quality manual* should be established collecting and documenting all metrics available for use in the software developing entity. This manual is a basic component of the metrics application process and includes the metrics, the measurement techniques as well as the guidelines for the application of metrics, the data analysis and the corrective actions required for improving the developing process of e-government and e-commerce systems. It should also be mentioned that the quality manual includes all metrics that are available regardless of how many times they have been used, or the availability of measurements data from past software development projects.

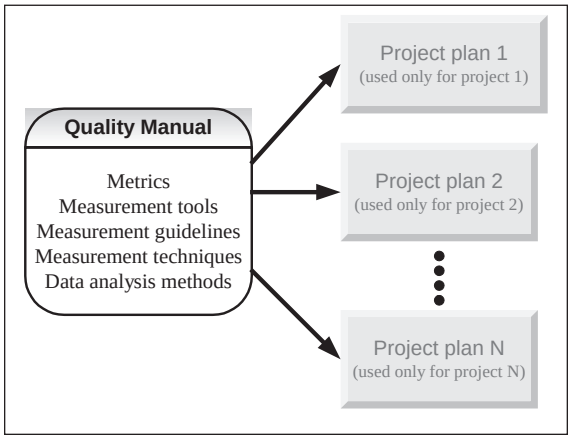
Then, for each e-government or e-commerce project, a set of metrics appropriate for this particular project is selected from the quality manual. The criteria on which the selection of metrics is based are the particular quality factors that the project places emphasis on. This set of metrics is documented—using the guidelines available in the quality manual—and consists the *quality plan* of the particular project. Thus, an e-government or e-commerce project quality plan should include all the metrics, measurement guidelines and goals applicable for the project. It is self-

evident that the project plan of a specific project may be entirely different from another project's plan and may use a completely different set of metrics. Figure 2 presents an illustration of the above procedure.

The quality plan of each e-government or e-commerce project should include internal metrics so as to provide an easy and inexpensive way to detect possible causes for low product quality, as this might be perceived by the end-users, and take early corrective action. It should also include external metrics—applied during alpha or beta testing and post shipment—so as to measure external quality factors, as well as the soundness of the internal metrics and measurements results or even calibrate internal metrics.

It should be noted that the successful selection of metrics and measurement techniques to be included in an entity's quality manual is heavily dependent on the entity's maturity. The adoption of sophisticated techniques and complex metrics by a company may prove to be ineffective, if it is not supported by years of experience with metrics and measurements and large volumes of data from past project measurements. Software developing companies should always keep this fact in mind and set feasible measurement goals not aiming too high at the early stages of metrics application.

Figure 2. Selection of metrics for each project



FUTURE TRENDS

For about 3 decades now, metrics have been used for the estimation of product related issues (such as product size, required effort, time required for testing, etc.) for early detection and prevention of problems during development and for product assessment after product release. Although in both cases metrics have proved to be successful in practice and have aided significantly towards developing higher quality e-government and e-commerce applications, the benefits from the use of metrics are not commonly recognized. This is partly due to the lack of awareness of metrics in small- and medium-size software developing companies. Although metrics are extensively used in large companies, in many cases, small- and medium-size enterprises are not even aware of the prospect and benefits of using metrics. However, this is constantly changing. More and more small- and medium-size e-government and e-commerce software-developing companies become aware of product metrics and measurements. Besides, the adoption of standards such as the ISO, or assessment in CMM higher levels, has contributed to this change since both standards are encouraging the use of metrics.

Another issue that is expected to change in the near future is the availability of more sophisticated tools. Although many measurement tools are available, using a number of metrics, there are not many tools available yet combining past projects' measurement data with current project data in order to aid in decision making. Combining metrics with decision support techniques, or methods for resolving uncertainty will lead to the development of valuable tools, which can aid towards higher quality software for e-government and e-commerce systems. A recent approach towards this direction (Fenton, Krause, & Neil,

2002) is using metrics and Bayesian networks for controlling software development, by automatically predicting defects in the released product.

CONCLUSION

This article introduced the reader to software metrics that are used to provide insight about different elements of e-government or e-commerce systems software. It presented internal metrics that can be applied prior to the release of the product to provide indications relating to quality characteristics, and external metrics applied after product delivery to give information about user perception of product quality.

Software metrics can be used to measure various factors related to software product development. These factors include estimation, early detection and prevention of problems, product assessment, etc. Their utilization within a measurements framework in combination to the use of automated tools can aid towards development process control and higher quality software for e-government and e-commerce systems.

Our focus was placed on the particular factors affecting the quality of e-government or e-commerce software. Such software can be measured effectively using a combination of generic internal software metrics and external metrics. The former are appropriate for most types of software, whereas the latter are designed especially for e-government or e-commerce systems.

KEY TERMS

External Metric: A metric used to measure attributes of the product that can be measured only with respect to how the product relates to its environment.

Functionality: The external quality factor that refers to a set of functions and specified properties that satisfy stated or implied needs.

Internal Metric: A metric used to measure attributes of the product that can be measured directly by examining the product on its own, irrespective of its behavior.

Measurement: A process by which numbers or symbols are assigned to attributes of entities in the real world in such a way as to describe them according to clearly defined rules.

Metric: An empirical assignment of a value in an entity aiming to describe a specific characteristic of this entity.

Quality Manual: A manual used by the software developing company that includes the metrics, the measurement techniques, the guidelines for the application of metrics data analysis, and the corrective actions required for improving the software developing process.

Quality Plan: A plan developed particularly for each software project that includes all the metrics, measurement guidelines and goals applicable for this project only.

Usability: The external quality factor that is defined as a set of attributes that bear on the effort needed for the use and on the individual assessment of such use by a stated or implied set of users.

Chapter 1.17
A Framework for Communicability of Software Documentation

Pankaj Kamthan
Concordia University, Canada

INTRODUCTION

The role of communication is central to any software development. The documentation forms the *message carrier* within the communication infrastructure of a software project.

As software development processes shift from predictive to adaptive environments and serve an ever more hardware diverse demographic, new communication challenges arise. For example, an engineer may want to be able to remotely author a document in a shell environment without the need of any special purpose software, port it to different computer architectures, and provide different views of it to users without making modifications to the original. However, the current state of affairs of software documentation is inadequate to respond to such expectations.

In this article, we take the position that the ability of documents to be able to communicate at all levels intrinsically depends upon their *representation*. The rest of the article proceeds as follows. We first outline the background necessary for later discussion. This is followed by a proposal for a quality-based framework for representing software documentation in descriptive markup and application to agile software documentation. Next, challenges and avenues for future research are outlined. Finally, concluding remarks are given.

BACKGROUND

Since the origins of software, and subsequently the recognition of software engineering as a discipline, documentation has had an important role to play. The use of documentation in software has a long and rich history (Furuta, Scofield, & Shaw, 1982; Goldfarb, 1981; Knuth, 1992).

There are various means that have been used for expressing software documentation. The documents could for example be expressed in structured natural language text (mimicking typewriting); Rich Text Format (RTF) and its implementations such as Microsoft Word; Hy-

pertext Markup Language (HTML), which supports multiple language characters and symbols that can reach a broad demographic worldwide, incorporates features of print publishing, and supports hyperlinking; the Portable Document Format (PDF); and TEX/LATEX and their variations that are oriented to mathematical typesetting. However, these traditional means suffer from one or more of the following limitations: they are proprietary and can only be authored or rendered by a proprietary software; the focus is not on software engineering but other disciplines such as generic office or scientific use; and the focus is mainly on the presentation or processing rather than on representation.

Descriptive markup (Goldfarb, 1981) is based on a rich model of text known as the ordered hierarchy of content objects (OHCO) (Coombs, Renear, & DeRose, 1987; DeRose, Durand, Mylonas, & Renear, 1997) that lends a hierarchical structure to documents. The Standard Generalized Markup Language (SGML) and its simplification the Extensible Markup Language (XML) are exemplary of descriptive markup. SGML/XML are both *meta-markup* mechanisms that lend a suitable basis for a concrete serialization syntax for expressing information in a software document. They define a document in terms of its OHCO structure with mnemonic names, usually inspired by the domain being addressed, for the content objects of the data. There is a large and increasing base of markup languages based on SGML/XML.

The focus in this article is primarily on XML. Indeed, the use of XML for software process documents has been proposed (Clements et al., 2002; Mundle, 2001). The DocBook/XML markup language has been deployed for software user documentation. These efforts, however, are oriented towards technology rather than descriptive markup or communicability (or quality in general); they do not provide comparisons with other means of representations, and they do not include details of challenges posed during document engineering.

DESCRIPTIVE MARKUP AND REPRESENTATION OF SOFTWARE DOCUMENTATION

We look at a software document from two viewpoints, namely that of a *producer* and that of a *consumer.* Based on that, the representation requirements that we consider pertinent for software documentation are the following:

- **Communicability Concerns for a Document Producer:** A provider, who is responsible for both internal and external documentation, could be interested in any of the following aspects: be able to express the domain under consideration well; have the flexibility of authoring and serving documents in different modalities; readily move documents between computing environments and over networks; easily manage the collection of documents, particularly as they scale (grow in number).
- **Communicability Concerns for a Document Consumer.** A consumer, whose main concern is external documentation, could be interested in any of the following aspects: access the documents on the device he/she is using that may be stand alone or connected to the Internet, and in the natural language/characters of choice; read or listen to the documents in the way he/she prefers that they should be presented; may want to simply look at the table of contents before reading further, or look up the definition of a term used in the main document. In some sense, a consumer would like a document to be "personalized."

These requirements motivated the proposal of a communicability framework, which we now discuss in detail.

A Framework for Communicability of Descriptive Markup-Based Software Documentation

The discussion of software documents and their representations that follows is based on the framework given in Table 1.

Semiotics (Nöth, 1990) is concerned with the use of symbols to convey knowledge. From a semiotics' perspective, a representation can be viewed on three interrelated levels: *syntactic*, *semantic*, and *pragmatic*. Our concern here is the pragmatic level, which is the practical knowledge needed to use a language for communicative purposes. Indeed, the goal of pragmatic quality is comprehension (Lindland, Sindre, & Sølvberg, 1994), and communicability is a prerequisite to that.

We acknowledge that there are time, effort, and budgetary constraints on producing a software document. We therefore include *feasibility*, a part of decision theory, as an all-encompassing factor to make the representation framework practical.

We now consider other aspects of the framework in more detail, starting with the principles underlying documents and their descriptive markup realizations.

Document Engineering Principles with a Descriptive Markup Perspective

The principles presented here are inspired by the established software engineering principles (Ghezzi, Jazayeri, & Mandrioli, 2003).

- **[DEP1] Separation of Concerns:** There are various concerns in document production and delivery, and to manage them effectively, each of these semantically different concerns need to be addressed separately. In particular, separation by parts, time, quality, and views are of special interest. SGML/XML provide means for separating structure, presentation, and logic in a document.
- **[DEP2] Abstraction:** This principle is based on the idea that it is often necessary in documents to highlight only the essentials while suppressing the details. The provision for table of contents and index of terms in a document are examples of abstraction. In descriptive markup, this could be realized by using mnemonic labels `<section>` and

Table 1. A high level view of the elements of a framework for communicability of software documentation

Software Document		
Pragmatic goal	Communicability	Feasibility
Quality attributes of concern	Evolvability, Heterogeneity, Interoperability, Processability, Renderability, Traceability, Universality	
Engineering principles	Abstraction, Anticipation of Change, Formality, Generality, Incrementality, Modularity, Separation of Concerns	
Representation model	Descriptive Markup	

<term> to encapsulate the name of a section and a special term, respectively and collating such appearances to obtain the desired result. Other examples in SGML/XML include the use of comments (<!-- ... -->) and in general metadata, the use of entities, or the use of a style sheet to hide content that one typically does not want rendered.

- **[DEP3] Modularity:** This principle is one way to realize separation by parts and therefore a special case of [DEP1] but is significant enough to be included separately here. [DEP2] is a prerequisite for modularity, which is essential for flexibility of future documents (Malloy, 2005). SGML and particularly XML provide various opportunities for modular documents, for example, by basing OHCO structure on a parent-child hierarchy, by including the concept of entities, or by "hiding" attributes inside the definition of an element in a document.
- **[DEP4] Anticipation of Change:** This principle is based on the premise that change in a (nontrivial) document is inevitable and to accommodate change we must be adequately prepared. By being text based (rather than binary) and being vendor and device independent, SGML/XML support this principle.
- **[DEP5] Incrementally:** This principle is related to [DEP1] and [DEP4] and is based on the notion that creating a representation of a document in increments should be encouraged. SGML/XML are in agreement with this. Indeed, it is a common markup practice to develop documents iteratively (in manageable steps) and check for conformance after each iteration.
- **[DEP6] Generality:** This principle is based on the assertion that the more general a document representation is, the broader the audience it can reach and the more reusable in different situations it is. SGML/XML are neutral to user context, vendor, domain, device, network, or programming language. They also support the largest character set currently available, namely the Universal Character Set (UCS)/Unicode.
- **[DEP7] Formality:** This principle, by requiring a formal (logical) syntax and semantics, aims to reduce the potential of ambiguity, contradictions, or misinterpretations and enables a more precise description of documents. XML has a well-defined syntax and semantics (Renear, Dubin, Sperberg-McQueen, & Huitfeldt, 2002). The Document Type Definition (DTD) provides a grammar for structural and data type constraints on the syntax and content of the elements and attributes in SGML/XML documents. In the case of XML, the capabilities of DTD have been strengthened in other grammar languages such as XML Schema and RELAX NG.

Attributes Impacting Communicability of a Software Document

In the following discussion we consider communicability as a "meta-concern" and discuss the low level list of attributes to address it. We also highlight relevant relationships between these attributes and with the abovementioned principles where needed.

- **[CA1] Evolvability:** This attribute especially depends on [DEP1-5]. Once a software document is created, it is highly likely that it will be maintained for corrective, adaptive, or perfective purposes. For example, a user manual may need to be transformed on computers with different capabilities for users with individual needs. The Resource Description Framework (RDF) and Dublin Core Metadata Element Set (DCMES) provide support for metadata (such as author information, date/time, history, or version-

ing) that can help track modifications.

- **[CA2] Heterogeneity:** This attribute especially depends on [DEP4-6] and is related to [CA3]. The elements of a document may need to be represented in a variety of different forms such as text, graphic, mathematical symbols, and so forth, and subsequently aggregated. Therefore, a representation must accommodate the possible compound or heterogeneous nature of a document. SGML/XML documents can be heterogeneous, where fragments of different markup (or even nonmarkup as long as the characters in it do not violate the document's character encoding) could be placed in a single document. XML Inclusions (XInclude) allows multiple possibilities of reuse: using a fragment of another document, a fragment of the current document, or an entire document (Figure 1).
- **[CA3] Interoperability:** This attribute is related to [CA2]. The heterogeneous forms in a document not only need to coexist in the same information container but also need to "talk" (interface) with each other and with the parent document. Namespaces in XML is a mechanism for uniquely identifying XML elements and attributes of a markup language, thus making it possible to create heterogeneous documents that unambiguously mix elements and attributes from multiple different XML documents (Figure 2).
- **[CA4] Processability:** This attribute depends on all [DEP1-7] and supports [CA5]. At times, we may need to manipulate (recast/transform, extract/filter, query, and so on) software documents to suit different circumstances. Support for querying XML documents is provided by XQuery and client- or server-side tree-based processing of XML documents is enabled by the Document Object Model (DOM) for which stable implementations are available. Extensible Stylesheet Language (XSL) is a style sheet language for associating presentation semantics with arbitrarily complex XML documents, while its companion XSL Transformations (XSLT) is a style sheet language for transforming XML documents into other documents, including nonXML, documents (Figure 2).
- **[CA5] Renderability:** This attribute especially depends on [DEP1-2]. A software

Figure 1. Opportunities of reuse for a software document in an XML environment

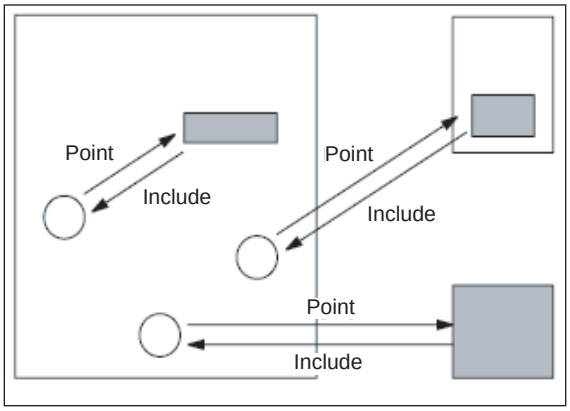

Figure 2. A heterogeneous software document in a descriptive markup transformation environment

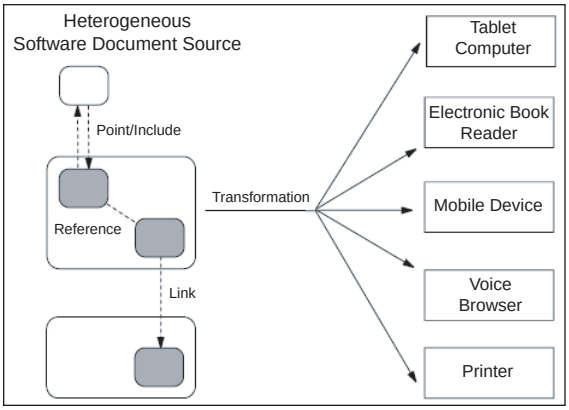

document must ultimately be rendered to a user's environment, and therefore presentation semantics (such as fonts, horizontal and vertical layout, pagination, and so on). The Document Style Semantics and Specification Language (DSSSL) is a style sheet language for SGML documents (that inspired XSL/XSLT). The Cascading Style Sheets (CSS) is a style sheet language for presenting simple XML documents on devices and agents with a variety of different configurations such as in Figure 2.

- **[CA6] Traceability:** This attribute depends on [DEP1,3]. A trace from `A` to `B` requires identification and location of, and means to reach, `B` from `A`. XML provides an `id` attribute for local identification of an element that can be used in conjunction with the Uniform Resource Identifier (URI) for global identification. HyTime, an ISO Standard, provides sophisticated linking functionalities for SGML documents including multi-directional links and linking to nonSGML data such as video clips. XML Linking Language (XLink) extends the unidirectional linking support in HTML and provides powerful bidirectional linking capabilities necessary for hypertext.
- **[CA7] Universality:** This attribute depends on [DEP6], and its underlying premise is that software documents should be created for all, irrespective of their individual context. XML is in agreement with the standards for accessibility and internationalization.

Application of the Framework: The Case of Agile Documentation

The bureaucracy inherent to traditional predictive software development processes and their perhaps over emphasis on documentation has in the last decade led to a shift to adaptive environments such as Extreme Programming (XP) and the Unified Process (UP). Although they are not document driven, documents continue to play an important role in stakeholder communication.

The term *agile document* was introduced in (Ambler, 2002) to imply customer-oriented, lightweight documents that could serve XP and UP. A collection of patterns for writing effective agile software documentation is given in (Rüping, 2003). Many of the patterns in it that deal with presentation and representation of documents can be concretely dealt with in our framework. For example, communicability aspects of structuring individual documents patterns are given by [CA1-7], layout and typography patterns are subsumed by [CA4, 5], whereas infrastructure and technical organization patterns are covered by [DEP1] and [CA1-4, 6].

Challenges to the Descriptive Markup Approach to Software Documentation

There are a few technical challenges to representations in descriptive markup. For example, descriptive markup in its source form, particularly when there are complex (usually nonlinear) structural relationships involved, can be error prone for direct authoring and is not considered very readable. There are openly available and mature SGML/XML authoring tools that ameliorate this to a certain extent. The processing based on DOM or transformations based on XSLT lead to in-memory tree, which is not always efficient for large documents for demanding situations (say, being transformed over a low bandwidth network in real time). One solution to this approach has been to use XSLT compilers instead of interpreters. Similarly, event-based processing such as Simple API for XML (SAX) could complement the DOM.

FUTURE TRENDS

As software documents become increasingly large in size and number and aim to serve diverse users, a systematic document engineering process is highly desirable. There are currently limited efforts in that direction (Glushko & McGrath, 2005).

XML, like any other technology, has its own set of issues if not used appropriately while authoring or processing (Harold, 2003) or if used beyond its scope (Megginson, 2005). In fact, addressing the issue of quality in all early software representations is crucial. To do that, an evaluation of XML using the Cognitive Dimensions of Notations (CDs) (Green, 1989), a generic framework for describing the utility of information artifacts by taking the system environment and the user characteristics into consideration, would be of interest.

A natural amplification of the previous discussion is a closer synergy with the current knowledge representation initiatives that are based on descriptive markup. The Semantic Web has recently emerged as an extension of the current Web that adds technological infrastructure for better knowledge representation, interpretation, and reasoning (Hendler, Lassila, & Berners-Lee, 2001) and could provide much more powerful representations of knowledge in a software document.

Finally, in spite of its broad use, documentation is not automatically useful by itself: Its value is realized only if it is well done (Weinberg, 1998), which could be viewed as one of or a combination of more than one dimensions of communicability. As documents become more like interactive applications, where they act as *user interfaces* to services provided by the software, the significance of assuring and evaluating their communicability will only increase.

CONCLUSION

Representation of documents so as to assure their communicability to the participants at all levels is critical. One way to foster that is by *partitioning* communicability into a manageable number of dimensions that could be dealt with directly and by choosing a suitable means of representation of software documents such as descriptive markup. The principles and attributes presented in our framework provide a basis for communicability dimensions and the SGML/XML *family* provides established technologies for descriptive markup.

The most important requirement for communicability from both the producer's and the consumer's standpoint is that they should have *options.* Indeed, if software documents are seen as carriers of commonsense knowledge (Minsky, 2000), then we should not seek one uniform way to present or represent them. This is echoed in the Redundant Recoding principle (Green, 1989), which is the ability to express information in a representation in more than one way, each of which simplifies different cognitive tasks. For that, documents need to be systematically created and strive for high quality. They also need to become *intelligent,* which in computational context usually implies that they carry *knowledge* amenable for automated processing. The Semantic Web provides a vehicle for representing knowledgeable software documents in descriptive markup.

KEY TERMS

Agile Document: A customer-oriented lightweight document that need not be perfect but just good enough.

Descriptive Markup: A model of text that focuses on the description of information using markup delimiters for consumption by both humans and machines.

Document Engineering: A discipline that is concerned with principles, tools, and processes that improve the ability to create, manage, and maintain documents.

Knowledge Representation: The study of how knowledge about the world can be represented and the kinds of reasoning that can be carried out with that knowledge.

Ontology: An explicit, formal specification of a conceptualization that consists of a set of terms in a domain and the relations among them.

Semiotics: The field of study of signs and their representations.

Single Source Approach: A technique that encourages a once-only creation of a resource, such as a document, in a manner so that it could be reused or repurposed for different contexts.

University of Alberta, Canada

Efe Igbide
University of Alberta, Canada

ABSTRACT

Amount of software engineering data gathered by software companies amplifies importance of tools and techniques dedicated to processing and analysis of data. More and more methods are being developed to extract knowledge from data and build data models. In such cases, selection of the most suitable data processing methods and quality of extracted knowledge is of great importance. Software maintenance is one of the most time and effort-consuming tasks among all phases of a software life cycle. Maintenance managers and personnel look for methods and tools supporting analysis of software maintenance data in order to gain knowledge needed to prepare better plans and schedules of software maintenance activities. Software engineering data models should provide quantitative as well as qualitative outputs. It is desirable to build these models based on a well-delineated logic structure. Such models would enhance maintainers' understanding of factors which influence maintenance efforts. This chapter focuses on defect-related activities that are the core of corrective maintenance. Two aspects of these activities are considered: a number of software components that have to be examined during a defect removing process, and time needed to remove a single defect. Analysis of the available datasets leads to development of data models, extraction of IF-THEN rules from these models, and construction of ensemble-based prediction systems that are built based on these data models. The data models are developed using well-known tools such as See5/C5.0 and 4cRuleBuilder, and a new multi-level evolutionary-based algorithm.

Single data models are put together into ensemble prediction systems that use elements of evidence theory for the purpose of inference about a degree of belief in the final prediction.

INTRODUCTION

Many organizations want to prepare reliable schedules of maintenance tasks. Such schedules would lead to on-time realization of these tasks and better management of resources. This is an important issue, especially in the case where maintenance tasks account for more than half of a typical software budget (Glass, 1989; Smith, 1999). Because of that, the software industry is exhibiting an increased interest in improving software maintenance processes. Software engineers use a number of different tools to support maintenance activities and make them more efficient. The most commonly used tools are tools for model-based software component analysis, metrics extraction, measurements presentation, and statistical analysis and evaluation. Besides that, software maintainers need tools that would help them to understand relationships between attributes of software components and maintenance tasks. Knowledge gained in this way would increase understanding of influence of software component attributes, such as size of code, complexity, functionality, and so forth, on efforts associated with realization of maintenance tasks.

There are four different categories of software maintenance: *corrective*—it involves changing software to remove defects; *adaptive*—it leads to changing software due to changes in software operating environment; *perfective*—it embraces activates that lead to improvement of maintainability, performance, or other software quality attributes; and *preventive*—it is defined as maintenance performed for the purpose of preventing problems before they happen. The corrective software maintenance is associated with activities related to elimination of software defects. This process is a key factor in ensuring timely releases of software and its updates, and high quality of software. Different tools and systems are used to support activities that are directly related to correction of defects. However, there is also a need to build systems that support decision-making tasks and lead to preparation of schedules and plans for defect removal processes. These systems should not only provide quantitative predictions but also give indications about plausibility of these predictions. Additionally, they should provide maintenance engineers with knowledge about defect removal efforts that explain obtained predictions. In summary, it is desirable to have a tool equipped with the ability to retrieve knowledge about relationships between attributes describing software and factors that directly or indirectly influence defect elimination activities.

Some of the important questions asked by managers and software maintenance engineers regarding removal of defects from software systems are:

- Does a defect removal process depend on functionality of software components?
- Does a defect removal process depend on the time when a defect entered the system?
- What are the factors that influence time needed to correct a single defect?
- What kind of relations between software component attributes and time needed to remove a defect can be found from software maintenance data?
- How confident can someone be about dependencies that have been found between a defect removal process and attributes of software components?

This chapter focuses on building software maintenance data models and their analysis. The aim is to build a prediction system that is able to provide software maintenance engineers with predictions regarding defect elimination efforts, knowledge about factors that influence these

efforts, and confidence measures for obtained predictions and gained knowledge.

Fulfillment of these objectives is achieved by the application of soft computing and machine learning methods for processing software engineering data. In a nutshell, the main idea of the proposed approach is to use multiple data processing techniques to build a number of data models, and then use elements of evidence theory to "merge" the outcomes of these data models. In this context, a prediction system is built of several rule-based models. The attractiveness of these models comes from the fact that they are built of IF-THEN rules that are easy to understand by people. In this chapter, three different tools for constructing IF-THEN rules are used. One of them constructs rules directly from the data, and the other two build decision trees first and extract rules from the trees. As the result, a large set of IF-THEN rules is created. Each rule is evaluated based on its capability to perform predictions. This evaluation is quantified by degrees of belief that represent goodness of the rules. The degrees of belief assigned to the rules that are fired, for a given input data point, are used to infer an overall outcome of the prediction system. The inference engine used in the system is built based on elements of evidence theory.

This chapter can be divided into three distinctive parts. The first part embraces background information related to data models. It starts with a description of work related to the area of software engineering data models (the *Software Data Models* section). An overview of rule-based systems and ensemble prediction systems is in the *Rule-Based Models and Ensemble Systems* section. The *Evidence Theory and Ensemble-Based System* section contains a description of the proposed ensemble-based prediction system. This section also contains an overview of the concept of the proposed system, its basic components, and the inference engine. The second part of the chapter is dedicated to the description of the datasets used here and the results of their analysis. In the *Software Engineering Maintenace Data* section, a software dataset is presented. Predictions of efforts needed to remove defects are presented in the *Base-Level Data Models, Extracted Knowledge and Confidence in Results* section. This section also includes a set of IF-THEN rules which represent knowledge extracted from the software maintenance models. Descriptions of ensemble-based prediction systems and analysis of their predictions are in the *Ensemble-Based Prediction System* section. And, finally, there is the *Conclusions* section.

The third part of the chapter contains three appendices: Appendix I is a short introduction to Evolutionary Computing; Appendix II is a brief introduction to the topic of decision trees and an evolutionary-based technique used for construction of decision trees; and Appendix III describes elements of evidence theory and the transferable belief model.

SOFTWARE DATA MODELS

Software engineering data collected during development and maintenance activities are seen as a valuable source of information about relationships that exist among software attributes and different aspects of software activities. A very important aspect that becomes very often associated with software systems is software quality. Software quality can be defined two-fold: (1) as the degree to which a system, component, or process meets specified requirements; and (2) as the degree to which a system, component, or process meets customer or user needs or expectations (IEEE 610.12). In light of that definition, the most essential expectation is the absence of defects in software systems. This aspect alone touches almost every phase of a software life cycle. The coding, testing, and integration, as well as the maintenance phase are directly related to the issue of constructing high quality software. However, building and maintaining a defect-free system

is not a trivial task. Many activities, embraced under the umbrella of software quality assurance, are performed in order to detect defects, localize them in a code, remove them, and finally verify that the removal process has been successful. In order to plan these activities effectively, there is a need to understand what makes a code defective, and how much time and effort is needed to isolate and eliminate defects. Development of software prediction models attempts to address those issues.

Prediction models aim at predicting outcomes on the basis of a given set of variables: they estimate what should be the outcome of a given situation with a certain condition defined by the values of the given set of variables. The steps that have to be performed during development of such models are:

- selection of the outcome attribute;
- selection of predictor (input) variables;
- data collection;
- assembly of the model;
- validation of the model; and
- updates and modifications of the model.

In the case of software engineering, prediction models that can be used to predict a number of quantities related to software quality and maintenance activities, are used for many years. These models proved to provide reasonable accuracy (Schneidewind, 1995, 1997). Many different software metrics are utilized as predictor (input) variables. The most common ones are complexity and size metrics, testing metrics, and process quality data.

The most popular software prediction models are models predicting quality-related aspects of software modules. A number of these models have been reported in the literature:

- **Tree-Based Models:** Both classification and regression trees are used to categorize software modules and functions; different regression tree algorithms—CART[1]-LS (least squares), S-PLUS, and CART-LAD (least absolute deviation)—are used to build trees to predict the number of faults in modules in Khoshgoftaar and Seliya (2002); in another case, regression trees are constructed using a concept of fault density (Gokhale & Lyu, 1997); a study on the use of a classification tree algorithm to identify fault prone software modules based on product and process metrics is presented in Khoshgoftaar and Allen (1999); tree-based models are used to uncover relationships between defects and software metrics, and to identify high-defect modules together with their associated measurement characteristics (Takahashi, Muroaka, & Nakamura, 1997; Troster & Tian, 1995);
- **Artificial Neural Network-Based Models:** Neural networks are recognized for their ability to provide good results when dealing with data that have complex relationships between inputs and outputs; neural networks are used to classify program modules as either high or low risk based on two criteria—a number of changes to enhance modules and a number of changes to remove defects from modules (Khoshgoftaar & Allen, 1998; Khoshgoftaar & Lanning, 1995);
- **Case-Based Reasoning Models:** Case-based reasoning (CBR) relies on previous experiences and uses analogy to solve problems; CBR is applied to predict software quality of the system by discovering fault-prone modules using product and process metrics as independent variables (Berkovich, 2000);
- **Fuzzy-Based Models:** Concepts of fuzzy sets and logic are used to build data models using linguistic labels; the work related to building fuzzy-based systems for prediction purposes is presented in Reformat, Pedrycz, and Pizzi (2004), where fuzzy neural networks are constructed for defect

predictions; a fuzzy clustering is used in Yuan, Khoshgoftaar, Allen, and Ganesan (2000), where a modeling technique that integrates fuzzy subtractive clustering with module-order modeling for software quality prediction is presented, a case study of a large legacy telecommunication system to predict whether each module should be considered fault-prone is conducted;

- **Bayesian Belief Network-Based Models:** Bayesian belief networks (BBN) address a complex web of interconnections between multiple factors; belief networks are used for modeling the complexities of software taking uncertainty into consideration (Neil & Fenton, 1996; Neil, Krause, & Fenton, 2003). BBN are also applied to construct prediction models that focus on the structure of the software development process explicitly representing complex relationships between metrics (Amasaki, Takagi, Mizuno, & Kikuno, 2003).

Thorough comparisons of different approaches used for building software quality prediction models can be found in Fenton and Neil (1999, 2005) and Khoshgoftaar and Seliya (2003).

Besides classification of software modules, a close attention is also given to the issues related to prediction of efforts associated with detection and correction of defects. One of the first papers dedicated to the topic of prediction of maintenance efforts is Jorgensen (1995). This paper reports on the development and use of several software maintenance effort prediction models. These models are developed applying regression analysis, neural networks, and the optimized set reduction method. The models are used to predict maintenance task efforts based on the datasets collected from a large Norwegian company. The variables included in the effort prediction models are: a cause of task, a degree of change on a code, a type of operation on a code, and confidence of maintainer. An explanation of efforts associated with software changes made to correct faults while software is undergoing development is investigated in Evanco (1999, 2001). In this case, the ordinal response models are developed to predict efforts needed to isolate and fix a defect. The predictor variables include extent of change, a type of change, an internal complexity of the software components undergoing the change, as well as fault locality and characteristics of the software components being changed. The models are developed and validated on three Ada projects. A model for estimating adaptive software maintenance efforts in person hours is described in Hayes, Patel, and Zhao (2004). A number of metrics, such as the lines of code changed and the number of operators changed, are found to be strongly correlated to maintenance efforts.

RULE-BASED MODELS AND ENSEMBLE SYSTEMS

Data models can be categorized into two major groups: black-box models and white-box models. The black-box models provide a user with the output values without indicating a way in which those outputs are calculated. This means that knowledge about relationships existing between the inputs and the output is not discovered. Conversely, the white-box data models, also called transparent models, allow their users to gain knowledge about the data being modeled. A careful inspection of a model's structure and its analysis provides an insight into relationships existing among values of data attributes. Rule-based models are well-known examples of white-box models. A rule-based model consists of a number of IF-THEN rules. A number of different techniques for development of IF-THEN rules exist. Some of these techniques construct rules directly from the data, while others build decision tress first and then extract rules from the trees.

Rule-Based Models

Rule-based modeling is a most common form of computational model. Rules are generally well suited to study behavior of many different phenomena. These models receive information describing a situation, process that information using a set of rules, and produce a specific response as their output (Luger, 2002; Winston, 1992). Their overall structure is presented in Figure 1.

In its simplest form, a rule-based model is just a set of IF-THEN statements called rules, which encode knowledge about phenomenon being modeled. Each rule consists of an IF part called the premise or antecedent (a conjunction of conditions), and a THEN part called the consequent or conclusion (predicted category). When the IF part is true, the rule is said to fire, and the THEN part is asserted—it is considered to be a fact.

A set of IF-THEN rules is processed using Boolean logic. The expert system literature distinguishes between "forward chaining" and "backward chaining" as a method of logical reasoning. Forward chaining starts with a set of characteristics about a situation—a feature vector of independent variables—and applies these as needed until a conclusion is reached. Backward chaining, in contrast, starts with a possible conclusion—a hypothesis—and then seeks information that might validate the conclusion. Forward chaining systems are primarily data-driven, while backward chaining systems are goal-driven. A forward chaining method of reasoning is used in prediction systems.

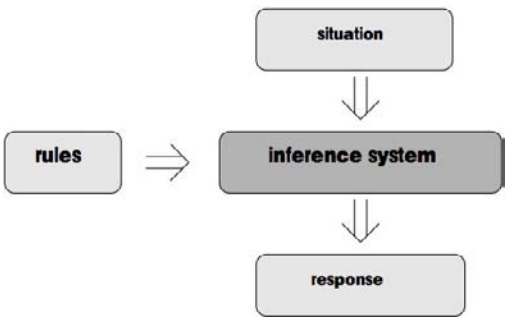
The IF-THEN based model with forward chaining works in the following way: the system examines all the rule conditions (IF) and determines a subset, the conflict set, of the rules whose conditions are satisfied. Of this conflict set, one of those rules is triggered (fired). When the rule is fired, any actions specified in its THEN clause are carried out. Which rule is chosen to fire is a function of the conflict resolution strategy. Which strategy is chosen can be determined by the problem and is seen as one of the important aspects of the development of rule-based systems.

In any case, it is vital as it controls which of the applicable rules are fired and thus how the entire system behaves. There are several different strategies, but here are a few of the most common ones:

- **First Applicable:** Is based on the fact that the rules are put in a specified order. The first applicable rule is fired.
- **Random:** It is based on a random selection of a single rule from the conflict set. This randomly selected rule is fired.
- **Most Specific:** This category is based on the number of conditions attached to each rule. From the conflict set, the rule with the most conditions is chosen.
- **Least Recently Used:** Is based on the fact that each rule is accompanied by a time stamp indicating the last time it was used. A rule with the oldest time stamp is fired.
- **"Best" Rule:** This is based on the fact that each rule is given a "weight" which specifies how much it should be considered over other rules. The rule with the highest weight is fired.

Another important aspect of the development of rule-based models, besides the reason-

Figure 1. Structure of a rule-based model



ing scheme, is the generation of rules. As it has been mentioned earlier, there are many different methods and techniques of doing that. IF-THEN rules can be generated on the basis of expert knowledge where they are created by a person during interaction with a domain expert, or automatically derived from available data using a variety of different approaches and tools (see Appendix II; RuleQuest; 4cData).

Ensemble Systems

A ensemble system is composed of several independently built models called base-level models. Each base-level model is developed differently by applying different construction techniques/methods using a single set of training data points, or using single technique that is applied to different data point subsets. The prediction outcome of such a system is based on processing outputs coming from all base-level models being part of the system. The process of construction of a ensemble system embraces two important phases (Todorovski & Dzeroski, 2000):

- the generation of a diverse set of base-level models; and
- the combination of outcomes generated by these models.

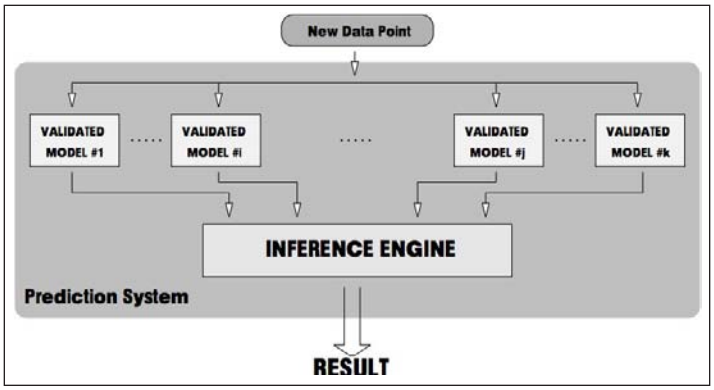
There are two groups of approaches for generation of base-level models. The first group can be represented by probably the most popular and simplest approach where a single learning algorithm is applied to different subsets of training data. Two best known methods are: random sampling with replacement called bagging (Breiman 1996; Todorovski et al., 2000), and re-weighting misclassified training data points called boosting (Freund & Schapire, 1996; Todorovski et al., 2000). The other group of methods is based on applying some modifications to model construction algorithms while using an identical set of training data points. A number of works is dedicated to comparison of such methods (Ali, 1995; Ali & Pazzani, 1996; Kononenko & Kovacic, 1992; Kwok & Carter, 1990).

The second important task of constructing ensemble systems is the fusion of outputs generated by base-level models. The most popular techniques applied here are distribution summation, voting, and naïve Bayesian combination (Kononenko et al., 1992). Another technique of combining models' outputs is based on the application of meta-decision trees. The role of meta-decision trees is to specify which model should be used to obtain a final classification. An extensive experimental evaluation of a new algorithm for learning meta-decision trees based on C4.5 algorithm was performed in Todorovski et al. (2000). In total, five learning algorithms of generating multi-model systems have been compared: two algorithms for learning decision trees, a rule learning algorithm, a nearest neighbor algorithm, and a naïve Bayes algorithm (Winer, Brown, & Michels, 1991). A building system based on multiple models can improve the accuracy and stability of the system significantly.

EVIDENCE THEORY AND ENSEMBLE-BASED SYSTEM

Application of different methods for generation of IF-THEN rules may lead to the discovery of different relationships among data attributes. The same situation occurs when a single rule-generation method is used on different subsets of the same data. The aim is to take advantage of that and build a system that combines many rule-based models and generates a single output based on the outputs of the base-level models. The fact that the rules, which constitute the models, are not equally good creates a need for taking that into consideration. This means that a process of combining the outputs of rules has to use information about prediction capabilities of the rules, that is, information about a number of proper and

Figure 2. The structure of an ensemble-based prediction system



false predictions made by each rule. The proposed system addresses these issues. It is based on the utilization of the following ideas:

- **Application of a number of rule-based models constructed using different methods on the same/or different subsets of data:** This provides means for thorough exploitation of different extraction techniques and increases possibilities of discovering significant facets of knowledge embedded in the data.
- **Application of the concept of basic belief masses from evidence theory (Shafer, 1976; Smets, 1988) that are used to represent goodness of the rules:** This provides assessment of quality of the rules from the point of view of their prediction capabilities.
- **Utilization of the transferable belief model (Smets, 1994):** Built on the evidence theory to reason, based on basic belief masses, about a given data point belonging to a specific category and to provide a confidence measure for the result.

Concept

The pivotal point of the proposed system is the application of elements of evidence theory. The basic concept of the theory—basic belief mass (see Appendix III for details)—is also a fundamental concept used to build the proposed prediction system. In a nutshell, the approach can be described in just a few sentences: all IF-THEN rules are treated as propositions equipped with basic belief masses (*bbm* in short); the *bbm* of all rules which are fired at a given time are used by an inference engine to derive probabilities of occurrence of different outcomes (the universe of possible outcomes is defined a priori and is related to the phenomenon under investigation).

The *bbm* represents the degree of belief that something is true. Once *bbm* is assigned to a rule it means that if the rule is satisfied by a given data point then there is the belief equal to *bbm* that this data point belongs to a category indicated by the rule. At the same time, the belief of value *1-bbm* is assign to a statement that it is not known to which category the data point belongs. In other words, every rule, which is satisfied by a given data point "generates" two numbers:

- one that indicates a belief that a given data point belongs to a category indicated by the rule (its value is equal to *bbm*); and
- one that indicates that a given data point can belong to any category (its value is *1-bbm*).

Of course, the higher the *bbm* value of the rule, the higher the belief that a given data point belongs to a category indicated by the rule, and the smaller the belief that a data point can belong to any category.

Figure 2 presents the structure of the system and the data flow during a prediction process. The system is composed of a set of validated models and an inference engine. For prediction purposes, a new data point is fed into each model. The *bbm* values of all rules fired by the data point together with categories identified by these rules constitute the input to the inference engine. Details of this engine are presented in the sub-section, *Inference Engine.*

Development and Validation of IF-THEN Models

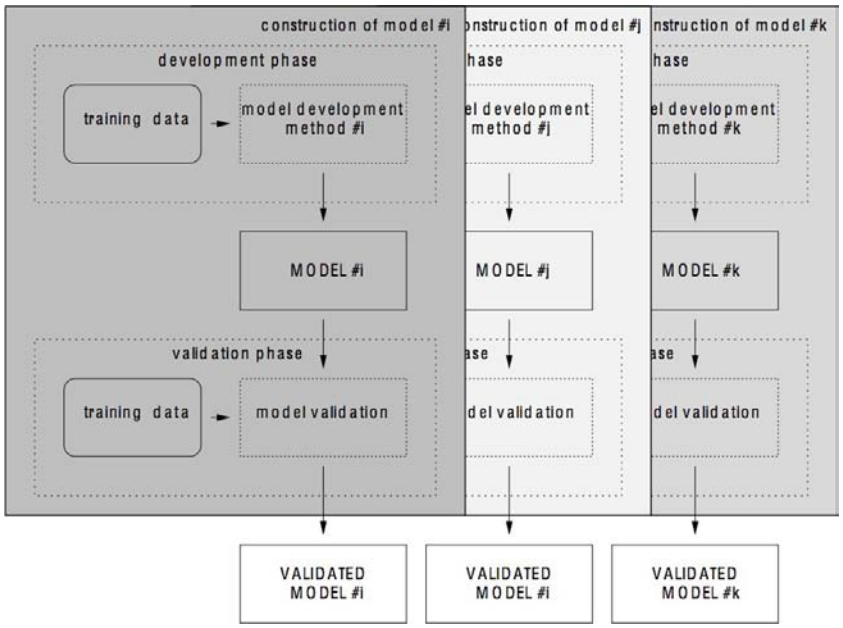
The construction stages of the proposed ensemble-based prediction system are shown in Figure 3. The first step in this process is the development of IF-THEN based models using different techniques. These models are built based on a subset of available data, which is called a training dataset.[2] This process can be performed multiple times using different training sets. This means better exploration and exploitation of the available data.

The value of *bbm* is assigned to each rule based on its coverage and prediction rate. Each rule of each model is "checked" against all training data points. This process results in generation of bbm_T (*T* stands for training) values. They are indicators of goodness of the rules. The formula (called the Laplace ratio) used for calculations of bbm_T is:

$$bbm_T = \frac{No\_Classified_T + 1}{No\_Classified_T + No\_Misclassified_T + 2} \quad (1)$$

where $No\_Classified_T$ represents a number of training data points properly classified for a given category, and $No\_Misclassified_T$ represents a total number of training data points that has been misclassified by the rule.

Figure 3. Construction of an ensemble-based prediction system: Development and validation stages



The first step in the evaluation of goodness of rules is performed based on their prediction capabilities tested against the data used for their development. To make this evaluation more reliable, the second step of the evaluation of rules' goodness is performed. This process is based on the performance of the rules when they are "tested" against data that has not been used during the development purposes. This subset of the data is called a validation dataset. Bbm_V (where V stands for validation) values are calculated:

$$bbm_V = \frac{No\_Classified_V + 1}{No\_Classified_V + No\_Misclassified_V + 2} \quad (2)$$

This time, $No\_Classified_V$ represents a number of validation data points properly classified for a given category, and $No\_MisClassified_V$ represents a total number of validation data points misclassified by the rule.

Following that, both bbm_T and bbm_V values are combined. It means that bbm_T values are *updated*. For this purpose, the Dempster's combination rule is used (Appendix III, Equation 8). The formula is:

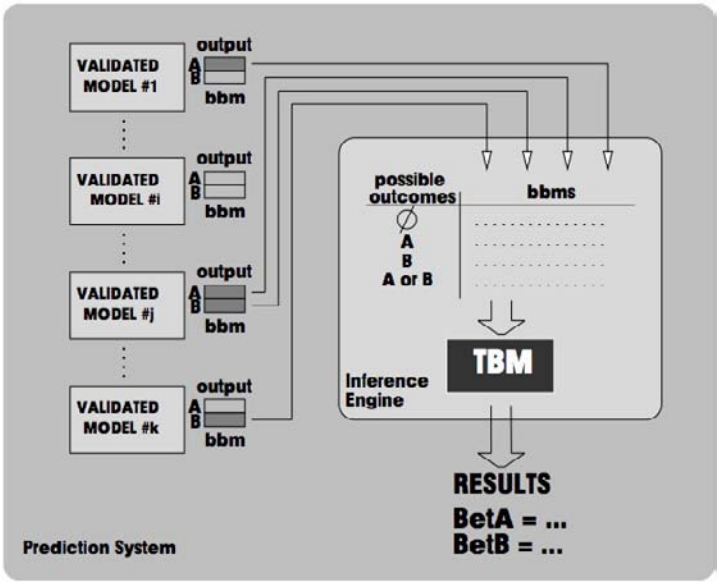
$$bbm_{UPDATE} = (1.0 - (1.0 - bbm_T) * (1.0 - bbm_V)) \quad (3)$$

These two stages, as shown in Figure 3, constitute the construction process of the ensemble-based prediction system. For each split of data into training and validation sets, a number of different models can be constructed. Overall, the process results in a number of different base-level models, which are building blocks of the proposed prediction system.

Inference Engine

The base-level models developed using different methods and data subsets together with the inference engine constitute the ensemble-based prediction system (Figure 2). The inference engine is an implementation of the following concept. A new data point is sent to all models. It activates a number of rules that leads to generation of

Figure 4. The inference engine, its inputs and outputs (a case with two possible outcomes)



outputs and *bbm* (bbm_{UPDATE} to be precise) values. The *bbm* values indicate the belief that this data point belongs either to the same or to a number of different categories. In the case where a single category is identified by all outputs, the inference engine is not engaged—it is predicted that the data point belongs to the identified category. In the case where a number of different categories are identified, the transferable belief model (TBM) (Smets & Kennes, 1994) is used to derive possibilities that the data point belongs to each of the identified categories. This process is represented in Figure 4. All models that have their rules fired provide results and *bbm* values to the inference engine. A table filled with *bbm* values is constructed. Each row of this table represents a possible combination of existing categories in the domain of interest (*Ø, A, B, A or B* in Figure 4). The TBM processes this table. The results are presented as pignistic probabilities of the data point belonging to different categories. This process is illustrated by a simple example.

Table 1. Bbm values of model outputs

Model	Output	IF-THEN rule	bbm
first	I	M1-c1-R1	0.60
		M1-c1-R2	**0.85**
		M1-c1-R3	**0.75**
	II	M1-c2-R1	0.67
		M1-c2-R2	0.94
		M1-c2-R3	0.80
second	I	M2-c1-R1	0.80
		M2-c1-R2	0.90
		M2-c1-R3	0.67
	II	**M2-c2-R1**	**0.90**
		M2-c2-R2	0.94
		M2-c2-R3	**0.85**

Example

Two IF-THEN based models have been built to represent relationships between an n-dimensional input and a single-dimensional output. There are two categories distinguished in the output space: *I* and *II*. Each of the models contains three IF-THEN rules for each category. Rules and their *bbm* values are shown in the Table 1.

Let's assume that a new data point has been obtained and the system is used to predict which category this point belongs to. When checked against all rules listed previously, the input data point satisfies the following set of rules: from the first model—M1-c1-R2, M1-c1-R3, and from the second—M2-c2-R1 and M2-c2-R3. *Bbm* values associated with satisfied rules are: 0.85 and 0.75 from the first model, and 0.90 and 0.85 from the second model. Table 2 is prepared based on these values. In the case of the first model, two rules are fired. The values 0.85 and 0.75 represent beliefs that the data point belongs to the category *I*, the values 0.15 and 0.25 indicate that there is still belief that this point can belong to any category—in this case, category *I* or category *II*. The same process is repeated for the rules from the second model. The values in Table 2 are the input to TBM.

Inside TBM, the *bbm* values are combined using the conjunctive combination rule (Appendix III, Equation 11). The results of this operation are presented in Table 3.

The next step is to calculate pignistic probabilities *BetP*. One of these probabilities represents the belief that the data point belongs to the category *I*, another that it belongs to the category

Table 2. Bbms assigned to each possible category by satisfied rules

Possible outcome	M1-c1-R2	M1-c1-R3	M2-c2-R1	M2-c2-R3
0	0	0	0	0
Category I	0.85	0.75	0	0
Category II	0	0	0.90	0.85
Category I or II	0.15	0.25	0.10	0.15

Table 3. Basic belief masses assigned to each possible output

x	m(x)
0	0.9481
Category I	0.0144
Category II	0.0369
Category I or II	0.0006

Table 4. Pignistic probability (BetP) values

BetP(Category I)	0.2834
BetP(Category II)	0.7166

II. These pignistic probabilities *BetP* are computed based on the *bbm* values according to the TBM using Equation 8 from Appendix III as shown in Box 1.

As the result of these calculations, Table 4 was created. Based on the values from this table, it can be said that in this particular case, a prediction is as follows: the new data point belongs to *Category I* with the belief of 0.2834, and to the *Category II* with the belief of 0.7166.

SOFTWARE ENGINEERING MAINTENANCE DATA

The process of development of base-level prediction models, extraction of knowledge, and construction of the ensemble-based prediction system is illustrated using the dataset from the Naval Research Laboratories (The Data and Analysis Centre for Software). The details regarding the origin of the data and their attributes are presented next. For the experimental purposes, the dataset has been divided into three sets: a training set containing data points that are used to develop base-level data models, a validation set containing data that are used to validate confidence in rules extracted from the models, and a testing set that contains data points used to evaluate prediction capabilities of the models.[3]

The data were collected at the Naval Research Laboratories (NRL) to evaluate development methodologies used on the project called The Architecture Research Facility (ARF). This project was to aid the rapid simulation of different computer architectures for research and evaluation purposes.

The original dataset consists of 117 defect reports dealing with 143 defects, which were isolated and corrected during ARF development. The dataset also includes 253 records describing each component in the project. For the purposes of the chapter, the original dataset is pre-processed. The main emphasis is put on defect elimination activates. In particular, two aspects are of interest: a number of components that have to be examined during elimination of a defect; and the effort needed to correct a defect.

Box 1. Equation 8 from Appendix III

$$BetP(CatI) = \frac{m(CatI) + \frac{m(CatIorII)}{2}}{1 - m(0)} = \frac{0.0144 + \frac{0.0006}{2}}{1 - 0.9481} = 0.2834$$

$$BetP(CatII) = \frac{m(CatII) + \frac{m(CatIorII)}{2}}{1 - m(0)} = \frac{0.0369 + \frac{0.0006}{2}}{1 - 0.9481} = 0.7166$$

The modified dataset contains only data related to components with defects. There are 129 data points. Table 5 contains a few examples of these data points. The data points have been divided into three sets: a training set of 86 data points, a validation set containing 20 data points, and a testing set which has 23 data points.

The number of components that have to be examined during elimination of a defect is the first aspect of maintenance activities investigated in the chapter. The attributes of data points used in this case are represented in Table 6. There are two groups of attributes in the INPUT set. The first one represents types of defects of interest and development phases during which these defects have been introduced into a system. The second set contains attributes describing software components such as line of codes, number of comments, number of preprocessor statements, as well as subjective complexity and functionality. The OUTPUT is *Number of Components Examined*.

The second point of interest is related directly to a process of elimination of defects. In this case, the attention is put on the time needed to remove a single defect. The attributes of data points used in this case are shown in Table 7. As it can be seen, the attributes chosen here are almost identical to the ones from the previous investigation. The only difference is that the attribute *Number of Examined Components* has been added to the first group of INPUT attributes. This time, the OUTPUT attribute is *Effort needed to Eliminate a Defect*.

Table 5. Examples of data points

Type of defect	Phase of Entering	Lines of Code	No. of Comm.	Preproc. Statements	Subjective Complexity	Funct.	No. of Exam. Comp.	Elimination Time
clerical	code test	88	29	6	easy	error handling	single	<1 hour, 1day>
language	code test	83	42	2	easy	control	single	<1 hour, 1day>

BASE-LEVEL DATA MODELS, EXTRACTED KNOWLEDGE AND CONFIDENCE IN RESULTS

The first step in data analysis and modeling is dedicated to the development of base-level data models that can be used for prediction purposes. The base-level models used here are rule-based models (see the *Rule-Based Models and Ensemble System* section). Three methods of building these models are selected in order to illustrate the idea of utilization of very different model development techniques. The first rule-based model is generated using See5/C5.0 (RuleQuest). The See5/C5 tool is an updated version of the well-known C4.5 algorithm (Quinlan, 1993). It has the capability of generating classifiers that are expressed as decision trees or sets of IF-THEN rules. The commercially-available tool called 4cRuleBuilder (4cData) is used to build the second data model. This tool uses supervised learning techniques to generate a data model from discrete numerical or nominal data, and has built-in discretization schemes for continuous attributes. Overall, 4cRuleBuilder generates compact rules that use a small number of selectors. The third model is a set of rules extracted from a decision tree constructed using the evolutionary-based technique GAGP described in Appendix II. In general, different model development techniques can be used to build rule-based data models which become elements of the proposed prediction system.

The following step in the analysis of data focuses on the evaluation of IF-THEN rules that represent relationships between attributes of software components and different defect measures: a number of components examined to remove a defect and the time needed to eliminate a defect. At that point, the goodness of rules is estimated via monitoring and validation of prediction capabilities of the rules (see the *Development and Validation of the IF-THEN Models* sub-section).

Number of Components Examined During Elimination of Defect

First, the issue of a number of components that has to be examined in order to eliminate a defect is investigated. Three base-level prediction models have provided the prediction rates that are presented in Table 8. A visual inspection of decision trees (for See5/C5.0 and GAGP) and rules (for 4cRuleBuilder) has indicated existence of terminal nodes of trees and rules for both categories, *single*

Table 8. NRL data prediction models: Prediction rates for number of examined components

Model	Prediction Rate
See5/C5.0	65.22%
4cRuleBuilder	60.87%
GAGP	56.52%

component examined and *multiple components examined*. The model generated by See5/C5.0 tool provides the highest prediction rate.[4]

Validation Process

Eleven IF-THEN rules are extracted from the decision tree generated by See5C5.0—four rules for the category *single component examined* and seven for *multiple components examined*. The application of 4cRuleBuilder tool results in six rules for *single component examined*, and five rules for *multiple components examined*. GAGP method leads to the generation of 21 rules: 14 for *single component examined* and seven for *multiple components examined*. In total, 43 rules are generated. Right now, the task is to select a relatively small set of rules that are the most significant and valuable for maintainers. Following the idea of goodness of rules (see the *Development and Validation of the IF-THEN Models* sub-section), the bbm_{UPDATE} values are used to "rank" all the rules and select the best ones.

Table 9. Original and updated bbm values

rule	bbm_T	bbm_{UPDATE}
See5/C5.0		
NC_See5_c1_1	**0.791**	**0.833**
NC_See5_c1_2	**0.770**	**0.750**
NC_See5_c2_1	**0.833**	**0.883**
NC_See5_c2_2	**0.800**	**0.889**
4cRuleBuilder		
NC_4cRB_c1_1	**0.950**	0.950
NC_4cRB_c1_2	0.929	**0.985**
NC_4cRB_c1_5	**0.941**	**0.988**
NC_4cRB_c2_1	0.818	**0.900**
NC_4cRB_c2_2	**0.898**	0.898
NC_4cRB_c2_3	**0.857**	**0.923**
GAGP		
NC_GAGP_c1_2	**0.909**	**0.952**
NC_GAGP_c1_9	**0.889**	**0.941**
NC_GAGP_c2_1	**0.800**	**0.889**
NC_GAGP_c2_3	**0.857**	0.857
NC_GAGP_c2_7	0.765	**0.907**

The *bbm* values assigned to the rules are presented in Table 9. The table contains only the rules that are best after the development stage (with the highest values of bbm_T) and the ones that are the best after the validation stage (with the highest value of bbm_{UPDATE}).

The rules generated by See5/C5.0 that are the best after the development process are also the best after the validation process (see bold entries in Table 9). For the rules NC_See5_c1_1[5] and NC_See5_c_2, their *bbm* values have increased after the validation phase. As it can be seen on the basis of other rules, none of the updated *bbm* values is smaller that the original one (there are some cases where *bbm* values do not change—this means that a rule has not been satisfied by any validation data point).

The same validation process has been performed on rules generated by 4cRuleBuilder. In the case of two rules NC_4cRB_c1_1 and NC_4cRB_c2_3, their *bbm* values have increased and the rules stay among the best ones. For the other two rules—NC_4cRB_c1_1 and NC_4cRB_c2_2—their *bbm* values have not changed. However, the *bbm* values of the other two rules NC_4cRB_c1_2 and NC_4cRB_c2_1 have increased and have become higher than the *bbm* values of NC_4cRB_c1_1 and NC_4cRB_c2_2. As the result, a set of best rules has been modified.

The validation process performed on rules generated by GAGP method has brought a single change in the category—*multiple components examined* (see Table 9). The rule NC_GAGP_c2_3 has been replaced by NC_GAGP_c2_7, which has the higher value of *bbm*. The *bbm* values of the rules from the category *single component examined* have improved.

Analysis of Best Rules

For the category *single component examined*, the range of bbm_{UPDATE} values is from 0.750 to 0.988. The rules with highest bbm_{UPDATE} values are generated by 4cRuleBuilder: NC_4cRB_c1_2 with bbm_{UPDATE} of 0.985, and NC_4cRB_c1_5 with bbm_{UPDATE} of 0.988. The rules NC_See5_c1_1 and NC_See5_c1_2, generated by See5/C5.0, have the lowest bbm_{UPDATE} values among three sets.

An interesting observation can be made when all the rules from the category *single component examined* are compared. Rules NC_GAGP_c1_9 and NC_4cRB_c1_5 are similar (see the following rules). It looks like both of them use the attributes *defect type* and *functionality* to predict a single component examination. The set of values of the attribute *defect type* from both rules are overlapping. In the case of the attribute *functionality*, the values used by the GAGP generated rule are a subset of the values used by the rule generated by 4cRuleBuilder. Such similarity and high bbm_{UPDATE} values of these rules indicate that both of them can be used to support prediction for a single component examination. The conclusion which can be derived here is: if *defect type* is *Clerical_Error* or *Requirements_Incorrect* and *functionality* of components with these defects is *Control* or *Error_Handling* then there is a need to examine just one component to be able to understand an impact of these defects and remove them.

Rule: NC_4cRB_c1_5:

if DEFECT_TYPE is *Multiple_Design_Error* or *Clerical_Error* or *Functional_Spec_Incorrect* **&**
FUNCTIONALITY is *Error_Handling* or *Control* or *Data_Accessing*
then SINGLE COMPONENT is examined

Rule: NC_4cRB_c1_9:

if DEFECT_TYPE is *Clerical_Error* or *Requirements_Incorrect* **&**
FUNCTIONALITY is *Error_Handling* or *Control*
then SINGLE COMPONENT is examined

Another pair of rules that draws attention is the pair containing the rules NC_4cRB_c1_2 and NC_GAGP_c1_2 (see the following rules). The rule generated by GAGP method uses a subset of values of the attribute *defect type* that are used by the rule NC_4cRB_c1_2. Also in the case of the attribute *lines of code*, there is some substantial overlapping. Overall, the rule generated by 4cRuleBuilder seems more specific. Once again, high values of bbm_{UPDATE} make these rules good candidates for prediction activities.

Rule NC_4cRB_c1_2:

if DEFECT_TYPE is *Single_Design_Error* or *Multiple_Design_Error* or *Clerical_Error* or *Language_Use_Error* or *Functional_Spec._Incorrect* or *Multiple_Error* **&**
PHASE WHEN ERROR ENTERD SYSTEM is *Requirements_Definition* or *Functional_Specification* or *Code_Testing* **&**
LINES OF CODE is less than 85 or in the range <108, 167> or more than 207 **&**
NUMBER OF COMMENTS is less than 29 or in the range <45, 103> or more than 128 **&**
NUMBER OF PREPROCESSOR STATEMENTS is less than 9
then SINGLE COMPONENT is examined

Rule NC_GAGP_c1_2:

if DEFECT_TYPE is *Single_Design_Error* or *Multiple_Design_Error* or *Multiple_Error* **&**
LINES OF CODE is less than 141 **&**
COMPLEXITY is *Easy*
then SINGLE COMPONENT is examined

From rules generated by See5/C5.0, only one rule—NC_See5_c1_1—is attractive. It is a very simple rule with relatively high value of $bbm_{UPDATE,}$ and a high coverage—more than 30 data points satisfied both the antecedent and the consequential parts of this rule. It is also a very intuitive rule. Definitely it is worth considering during a prediction process.

Rule NC_See5_c1_1:

if COMPLEXITY is *Easy*
then SINGLE COMPONENT is examined

In the case of the category *multiple components examined*, the rules have bbm_{UPDATE} values in the range: from 0.833 up to 0.923. Smaller maximum indicates that it is difficult to find a dominating rule describing a relationship among attributes of software components and a need for multiple components examination. The inspection of the rules points only to a single pair of rules NC_See5_c2_2 and NC_GAGP_c2_2 (see the following rules). There is a perfect much in the case of the attributes *defect type* and *complexity*. There is also some overlap existing for the attribute *lines of codes*. Based on that and high values of bbm_{UPDATE}, this pair can be treated as plausible rules describing a relationship among software attributes and a number of components which should be examined to fully understand an impact the defect *Functional_Spec._Incorrect* makes.

Rule NC_See5_c2_2:

if DEFECT_TYPE is *Functional_Spec._Incorrect* &
LINES OF CODE is more than 134 &
COMPLEXITY is *Easy*
then **MULTIPLE COMPONENTS are examined**

Rule NC_ GAGP_c2_2:

if DEFECT_TYPE is *Functional_Spec._Incorrect* &
LINES OF CODE is in the range <141, 481> &
COMPLEXITY is *Easy* &
FUNCTIONALITY is *Computational*
then **MULTIPLE COMPONENTS are examined**

Time Needed to Eliminate a Defect

The prediction rates for the models representing effort needed to eliminate a defect are presented in Table 10. In this case, the highest prediction rate is obtained using the model generated by GAGP method.

Table 10. NRL data prediction models: Prediction rates for defect removal time

Model	Prediction Rate
See5/C5.0	56.52%
4cRuleBuilder	56.52%
GAGP	65.22%

Validation Process

Prediction models developed for the second NRL dataset leads to the extraction of 49 rules. Validation of rules generated by See5/C5.0 has brought only one change (see Table 11). The rule ET_See5_c2_2 has been replaced by the rule ET_See5_c2_4.

The bbm_{UPDATE} value of the rule ET_See5_c2_4 increased and suppressed the bbm_{UPDATE} value of the rule ET_See5_c2_2. A similar situation has occurred in the case of rules generated by 4cRuleBuilder. Only one rule has been replaced by a new rule. In this case, however, it has happened in the category *effort for elimination of a defect less than one hour*. The rule ET_4cRB_c1_1 has been replaced by ET_4cRB_c1_6. Validation of the original set of rules generated by GAGP method has also brought a single change. In the

Table 11. Original and updated bbm values

rule	bbm_T	bbm_{UPDATE}
See5/C5.0		
ET_See5_c1_1	**0.938**	**0.974**
ET_See5_c1_2	**0.667**	**0.800**
ET_See5_c2_1	**0.875**	**0.875**
ET_See5_c2_2	**0.833**	0.833
ET_See5_c2_4	0.727	**0.842**
ET_See5_c3_1	**0.556**	**0.714**
4cRuleBuilder		
ET_4cRB_c1_1	**0.900**	0.844
ET_4cRB_c1_2	**0.944**	**0.966**
ET_4cRB_c1_6	0.857	**0.968**
ET_4cRB_c2_1	**0.882**	**0.938**
ET_4cRB_c2_9	**0.900**	**0.947**
ET_4cRB_c3_1	**0.500**	**0.500**
GAGP		
ET_GAGP_c1_3	**0.889**	**0.970**
ET_GAGP_c1_7	**0.889**	**0.889**
ET_GAGP_c2_1	**0.667**	**0.833**
ET_GAGP_c2_4	**0.833**	**0.714**
ET_GAGP_c2_6	**0.875**	**0.875**

case of the category *effort for elimination of a defect more than one hour but less than one day,* the bbm_{UPDATE} value of the rule ET_GAGP_c2_4 has decreased. At the same time, the bbm_{UPDATE} value of the rule ET_GABP_c2_1 has increased from 0.666 to 0.833, and this rule has become one of the best rules.

Analysis of Best Rules

As in the case of the previous experiment, let's examine the best IF-THEN rules (marked by bold fonts in Table 11). For the category *effort for elimination of a defect less than one hour* the range of bbm_{UPDATE} values is from 0.800 to 0.974. The examination of the rules from this category points to three rules ET_See5_c1_1, ET_GAGP_c1_3, and ET_GAGP_c1_7 (see the following rules). High values of bbm_{UPDATE} and similarity of the rules mean that they can be summed up with a very simple statement: if *defect type* is *Clerical_Error* then *time need to correct this defect is less than one hour.*

Rule ET_See5_c1_1:

if DEFECT TYPE is *Clerical_Error*
then DEFECT ELIMINATION TIME is less than 1 hour

Rule ET_GAGP_c1_3:

if DEFECT TYPE is *Clerical_Error* &
FUNCTIONALITY is *Computational* or *Data_Accessing*
then DEFECT ELIMINATION TIME is less than 1 hour

Rule ET_GAGP_c1_7:

if DEFECT TYPE is *Clerical_Error* &
FUNCTIONALITY is *Control*
then DEFECT ELIMINATION TIME is less than 1 hour

In the category *effort for elimination of a defect more than one hour but less than one day* the rules generated by 4cRuleBuilder have the highest values of bbm_{UPDATE}. A rule ET_4cRB_c2_1 (see the following rules) seems to be a very important one. Two other rules—ET_See5_c2_4 generated by See5/C5.0 and ET_GAGP_c2_6 generated by GAGP method—are very similar. The rule ET_See5_c2_4 overlaps with ET_4cRB_c2_1 in the case of the attributes—*defect type* and *complexity.* The rule ET_GAGP_c2_6 overlaps in the case of the attributes—*defect type* and *functionality.* All this and the high bbm_{UPDATE} values indicate that these three rules can be useful in prediction of time needed to eliminate defects.

Rule ET_4cRB_c2_1:

if DEFECT TYPE is *Multiple_Design_Error* or *Language_Use_Error* or *Functional_Spec._Incorrect* or *Other_Error* **&**
NUMBER OF COMMENTS in less than 130 or more than 181 **&**
NUMBER OF PREPROCESSOR STATEMENTS is less than 5 or more than 10 **&**
COMPLEXITY is Easy or Moderate **&**
FUNCTIONALITY is Computational or Data_Accessing or Error_Handling
then DEFECT ELIMINATION TIME is more than 1 hour but less than 1 day

Rule ET_See5_c2_4:

if DEFECT TYPE is *Language_Use_Error* **&**
COMPLEXITY is *Easy*
then DEFECT ELIMINATION TIME is more than 1 hour but less than 1 day

Rule ET_GAGP_c2_6:

if DEFECT_TYPE is *Single_Design_Error* or *Other_Error* **&**
FUNCTIONALITY is *Computational* or *Data_Accessing*
then DEFECT ELIMINATION TIME is more than 1 hour but less than 1 day

The category *effort for elimination of a defect more than one day* is very poorly represented in the generated sets of rules. A possible reason for that is a very non-uniform distribution of data points among three categories. The category *effort for elimination of a defect more than one day* is represented by only three per cent of data points. The rule generated by See5/C5.0 is the best. Its bbm_{UPDATE} value is 0.714.

Rule ET_See5_c3_1:
if NUMBER_OF_COMPONENTS_EXAMINED is *Multiple* **&**
COMPLEXITY is *Hard*
then DEFECT ELIMINATION TIME is more than 1 day

ENSEMBLE-BASED PREDICTION SYSTEM

The IF-THEN rules have been extracted from the base-level data models (see the *Base-Level Data Models, Extracted Knowledge and Confidence in Results* section). An important aspect of this extraction is related to the concept of rules' goodness. As the result, all rules have been evaluated and confidence measures (*bbm* values) have been assigned to them. The next step is to use this and build a system that combines different rules and takes these confidence measures into account. The results of this task are presented in the following text.

Number of Components Examined

The ensemble-based prediction system for predicting the number of components to be examined during defect removal is constructed. It is tested on all data points from the testing set. Two aspects of the results are important—a prediction rate and confidence measures for the obtained predictions.

The testing set contains 23 data points. Using only a single set of rules generated by See5/C5.0, 4cRuleBuilder, and GAGP, the prediction rates are 65.22%, 60.87%, and 56.52%, respectively (see Table 8). In the case of the ensemble-based prediction systems, the prediction rate has increased. The system that uses voting as the fusion method provides the prediction rate of 69.57%, and the system proposed here, that uses the elements of evidence theory, has the prediction rate of **73.91**% (this translates to 17 proper predictions). Among all testing data points, seven data points satisfy rules that indicate contradicting predictions. The rest of the data points are uniquely identified as belonging to a single category (most data points satisfy at least a single rule from each model, however some points satisfy only rules coming from two models). In all these cases, the pignistic probability BetP that a given data point belongs to a single category is very high at 0.99. More interesting is the case of seven data points that have led to non-unanimous prediction results. The rules that are satisfied by these seven points are presented in Table 12.

It can be easily observed that each of these points is not univocally classified to a single category. Rules generated by See5/C5.0 have problems with data points no. 1 (two rules of different categories fired), 4 (wrong rule fired), and 7 (two rules of different categories fired). Rules generated by 4cRuleBuilder are misled for points no. 2 (two rules of different categories fired), 3

Table 12. Rules satisfied by the seven "confusing" data points

	See5/C5.0	4cRuleBuilder	GAGP	Original Category	Predicted Category
1	c1_4 c2_4	c1_3	c1_10	I	I
2	c1_4	c1_5 c2_2	c1_4	I	I
3	c1_4		c2_3	I	II
4	c1_4	c2_1	c1_13	II	II
5	c1_1	c2_1	c1_12	I	I
6	c2_7	c1_2 c2_1 c1_6	c2_7	II	II
7	c1_4 c2_5	c2_3	c2_3	II	II

Table 13. BetP values for the seven "confusing" data points

Data points	1	2	3	4	5	6	7
BetP (cat. I: single comp. examined)	0.892	0.993	0.207	0.391	0.843	0.014	0.005
BetP (cat. II: multiple comp. examined)	0.108	0.007	0.793	0.609	0.157	0.986	0.995

(no rules fired), 5 (wrong rule fired), and 6 (two rules of different categories fired). In the case of rules generated by GAGP points no. 3 (wrong rule fired) and 4 (wrong rule fired) are wrongly predicted. The BetP values obtained for these seven points are shown in Table 13.

Special attention should be paid to the data point no. 4. Rules generated by See5/C5.0 (NC_See5_c1_4 with bbm_{UPDATE} of 0.545) and GAGP (NC_GAGP_c1_13 with bbm_{UPDATE} of 0.667) indicate that the point should be classified as category I. However, the rule NC_4cRB_c2_1, which is one of the best 4cRuleBuilder rules and has bbm_{UPDATE} value of 0.900, has a strong influence on the overall result.

Time Needed to Eliminate a Defect

The ensemble-based prediction system is also built for predicting time needed to remove a single defect. Prediction rates and the confidence measures for obtained predictions are recorded. The testing set contains 23 data points. Using only a single set of rules generated by See5/C5.0, 4cRuleBuilder, and GAGP, the prediction rates are 56.52%, 56.52%, and 65.22%, respectively (see Table 10). The prediction rate increases to **78.26**% (this translates to 18 proper predictions) for the proposed ensemble-based prediction system that uses basic belief masses. The ensemble-based system with voting has the prediction rate of

Table 14. Rules satisfied by the 12 "confusing" data points

	See5/C5.0	4cRuleBuilder	GAGP	Original Category	Predicted Category
1	c1_3 c2_6		c1_6	I	I
2	c1_3 c2_6	c2_3	c2_2	III	II
3	c2_6	c1_6	c2_2	III	II
4	c1_3 c2_1		c2_9	I	I
5	c2_4	c2_2 c3_1 c2_5 c2_6	c2_2	II	II
6	c3_1	c1_4 c2_2 c3_1	c2_3	III	III
7	c1_3 c2_6	c1_1 c2_4	c2_1	I	II
8	c2_8	c2_2 c3_1		II	II
9	c1_3 c2_2	c2_3 c2_7		II	II
10	c1_1 c1_3	c1_2 c2_5 c1_3	c1_3	I	I
11	c1_3 c2_4	c1_1		II	I
12	c1_1	c1_2 c2_5	c1_3	I	I

69.57%. The analysis of the proposed prediction process indicates that 12 data points satisfy rules that indicate contradicting predictions. The remaining 11 data points are unanimously predicted by the rules of the system. Confidence measures for these predictions are around 0.99. The rules fired for the 12 "confusing" points are presented in Table 14.

It can be easily observed that each of these points is not univocally classified to a single category. Rules generated by See5/C5.0 have problems with data points no. 1 (two rules of different categories fired), 2 (two rules of different categories fired), 3 (wrong rule fired), 4 (two rules of different categories fired), 7 (two rules of different categories fired), 9 (two rules of different categories fired), and 11 (two rules of different categories fired). Rules generated by 4cRuleBuilder are misled for points no. 1 (no rules fired), 2 (wrong rule fired), 4 (no rules fired), 5 (two rules of different categories fired), 6 (three rules of different categories fired), 7 (two rules of different categories fired), 8 (two rules of different categories fired), 10 (two rules of different categories fired), 11 (wrong rule fired), and 12 (two rules of different categories fired). In the case of the rules generated by GAGP, the points no. 2, 3, 6, 7, and 11 are wrongly predicted due to firing of the wrong rule. The values of the pignistic probabilities BetP calculated by TBM are included in Tables 15 and 16.

The most interesting are data points no. 3, 6, and 7. In the case of the point number 3, the rules generated by See5/C5.0 and GAGP indicate that this point should belong to the category I, however a higher bbm_{UPDATE} value of the 4cRuleBuilder rule (comparing to bbm_{UPDATE} of See5/C5.0 and GAGP rules) has changed the verdict of the prediction system. It can be seen that the probability that the point belongs to the category II is relatively high—0.878. The point number 6, on the other hand, satisfies one rule of the category I, two rules of the category II, and two rules of the category III. The prediction system classifies this data point to a proper category. However, in the case of BetP probabilities, it can be seen that BetP(category III) is only slightly larger than BetP(category II). In the case of the point no. 7, a high bbm_{UPDATE} value of GAGP rule ET_GAGP_c2_1 (supported by bbm_{UPDATE} values of ET_See5_c2_6 and ET_4cRB_c2_4) has caused false prediction; the rules ET_See5_c1_3 and ET_4cRB_c1_1 have bbm_{UPDATE} values too small to increase the value of the probability BetP for Category I.

Table 15. BetP values for the 12 "confusing" data points: Points 1 to 6

Data points	**1**	**2**	**3**	**4**	**5**	**6**
BetP (cat. I: time less than 1 hour)	0.638	0.031	0.599	0.055	0.001	0.108
BetP (cat. II: time between 1 hour and 1 day)	0.308	0.962	0.381	0.932	0.996	0.434
BetP (cat. III: time more than 1 day)	0.054	0.007	0.020	0.013	0.003	0.458

Table 16. BetP values for the 12 "confusing" data points: Points 7 to 12

Data points	**7**	**8**	**9**	**10**	**11**	**12**
BetP (cat. I: time less than 1 hour)	0.119	0.014	0.002	0.999	0.673	0.999
BetP (cat. II: time between 1 hour and 1 day)	0.878	0.913	0.998	0.001	0.309	0.001
BetP (cat. III: time more than 1 day)	0.003	0.055	0.000	0.000	0.018	0.000

CONCLUSION

In this chapter, an intelligent method of analysis of software engineering data is illustrated. It applies evolutionary computation methods for development of models, and elements of evidence theory to combine base-level models in order to create an ensemble-based prediction system that has capabilities to determine confidence measures for the generated predictions. Application of a number of rule-based models developed with different techniques enhances prediction capabilities and allows for more comprehensive extraction of knowledge from the data. Confidence measures associated with predictions and extracted knowledge help to better understand the relationships between attributes of data and the mechanisms leading to generation of predictions.

Proposed method is applied to analysis of software corrective maintenance data. The purpose of this analysis is to find and understand relationships between attributes of software, types of defects, and efforts needed to conduct defect elimination tasks. Special attention is put on two aspects of defect elimination process: a number of software components that have to be examined to remove a single defect and a total time needed to remove a defect. The prediction systems, extracted knowledge, and results of prediction processes are described and investigated.

ENDNOTES

1 CART stands for Classification And Regression Trees (Breiman, Friedman, Olshen, & Stone, 1984).

2 The proposed approach assumes the following split of data: 20% of data points are randomly selected to constitute a testing dataset, this set does not change for the time of the whole experiment, the data points from this set are used for evaluation of constructed ensemble-based prediction systems; the remaining 80% of data is randomly split into a training set (60%) and a validation set (20%).

3 The dataset is divided into training, validation, and testing sets to comply with the construction process of the ensemble-based prediction system (see the *Evidence Theory and Ensemble-Based System* section).

4 All results presented in the chapter are for testing data.

5 The following schema has been applied to identify generated rules: <two letters identifying dataset name>-<construction method>-<class number>-<rule number>.

APPENDIX I: EVOLUTIONARY COMPUTING

A variety of evolutionary algorithms (EAs), such as genetic algorithms (Goldberg, 1989) and genetic programming (Koza, 1992), have been successfully applied to numerous problems (Back, Fogel, & Michalewicz, 2000) both at the level of structural and parametric optimization. EAs are search methods utilizing the principles of natural selection and genetics (Holland, 1972). Concisely, EAs operate on a set of candidate solutions, called a population, to a given problem. The candidate solutions are evaluated based on their ability to solve the problem. The results of the evaluation are used in a process of forming a new set of solutions. The choice of individuals that are passed to the next population is performed in a process called selection. This process is based on "goodness" of candidate solutions. Additionally, genetic operators, that is, crossover and mutation, are employed to modify selected candidates. Such sequence of actions is repeated until some final criterion is fulfilled. The sequence of activities of EAs is presented in Figure 5.

Genetic Algorithms

Genetic algorithms (GAs) (Goldberg, 1989) are one of the most popular EAs. In the case of GAs, candidate solutions to a given problem are encoded into chromosome-like data structures named genotypes. The problem to be solved is encoded into a special function called a fitness function. This function embraces all requirements imposed on the solution to the problem. The genotypes, after being decoded into phenotypes which are solutions in the problem domain, constitute inputs to the fitness function. They are evaluated based on their ability to solve the problem. The results of the evaluation are used in a selection process based on favoring individuals with higher fitness values. The selection can be performed in numerous ways. One of them is called stochastic sampling with replacement. In this method, the entire population is mapped onto a roulette wheel where each individual is represented by the area corresponding to its fitness. Individuals of the next population are chosen by repetitive spinning of the roulette wheel.

Finally, the operations of crossover and mutation are performed on the individuals. Crossover allows exchange of information among individual genotypes in the population and provides innovative capability to the GAs. Its role is to explore the search space in a process of exchanging chromosome parts. Two randomly selected chromosomes are "cut" and "merge" to "produce" a new one. Two parent chromosomes are randomly selected, and two children are created by swapping sequences of genes. In its simplest form, a single crossover point is used. The percentage of individuals that go through crossover is "controlled" by the crossover probability pc.

The role of mutation is to introduce diversity into the population and promote a probabilistic-like traversing of the search space. Mutation builds a new chromosome by making an alteration to a single gene. All genes in all chromosomes are altered with the mutation probability pm.

The evolution of candidate solutions is halted when perfect fitness is achieved or some specified maximum number of generations is passed. The candidate solution that has the best fitness, after termination, is deemed as the discovered solution. Originally, only chromosomes with binary genes have been used. However, right now there are versions of GAs that use integer or floating-point numbers as genes.

Genetic Programming

Genetic programming (GP) (Koza, 1992) can be seen as an extension of the genetic paradigm into the area of programs. It means, that objects, which constitute population, are not fixed-length strings that encode candidate solutions to the given problem, but they are programs. In general, these programs are expressed as parse trees, rather than as lines of code.

In the case of GP, each candidate solution is built using two sets:

- the function set, $F = \{f_{1(b\_1)}; f_{2(b\_2)}; \ldots; f_{n(b\_n)}\}$, of functions with arity > 0; each function from F takes a specified number of arguments, defined as $b_1; b_2; \ldots b_n$;
- the terminal set $T = \{ t_1; t_2; \ldots; t_n \}$ of 0-arity functions or constants.

Sets F and T are defined a priori. The process of constructing candidate solutions starts by selecting a function, f_i, randomly from the set F. For each of the b_i arguments, this process is repeated where a random function or terminal may be selected to fill each argument position. If a terminal is selected, the generation process is completed for this branch of the function. If a function is selected, the generation process is recursively applied to each argument of this function. A user specifies a maximum depth of parse trees in order to limit the size of the candidates. For example, using the function set F = {AND; OR; NOT} and the terminal set T = {a; b; c; d}, two sample programs that could be created are shown in Figure 6.

Depending on the type of elements of the function and terminal sets, different structures can be built and different problems can be targeted. All stages of evolutionary algorithms—selection, crossover and mutation—are applied to all structures. Modifications of these structures are performed via manipulations on the lists (Koza, 1992).

Detailed descriptions of GP, GAs, or other evolutionary-based algorithms can be found in Back et al. (2000), Goldberg (1989), Holland (1972), and Koza (1992).

APPENDIX II: DECISION TRESS AS DATA MODELS AND THEIR EVOLUTIONARY-BASED CONSTRUCTION

Decision Trees

Decision trees are very attractive representations of underlying data relationships (Mitchell, 1997). They are very intuitive and relatively easy to understand by users. Their graphical representation provides a simple way of finding connections among data points and translating them into IF-THEN rules. The trees are very well suited to perform classification/prediction tasks.

Decision trees consist of a series of nodes with a top node called the root node. Each tree is built by means of a top down growth procedure. The building process is based on training data that contain data points (vectors) with a number of attributes. One of these attributes determines the category to which the data point belongs. At each node, called the attribute node, the training data is partitioned to the children nodes using a splitting rule (see Figure 7). A splitting rule can be of the form: if $V < c$ then s belongs to L, otherwise to R, where V is a selected attribute, c is a constant, s is the data sample and L and R are the left and right branches of the node. In this case, splitting is done using one attribute and a node has two branches (two children). In general, a node can have more branches and the splitting can be done based on several attributes. The best splitting for each node is searched based on a "purity" function calculated from the data. The data is considered pure when they contain data points from only one category. Most frequently used purity functions are entropy, gini-index, and twoing-rule. The data portion that falls into each children node is partitioned again in an effort to maximize the purity function. The tree is constructed until the purity of the data points in each leaf node is at a pre-defined level. Each leaf node is then labeled with a category determined based on majority rule: node is labeled to the category to which majority of the training data points at that node belong. Such nodes are called terminal nodes.

Evolutionary-Based Construction of Decision Trees

Concept

The approach used for construction of decision trees is based on combination of genetic algorithms (GAs) and genetic programming (GP). This approach allows for targeting two problems simultaneously—searching for the best splitting in attribute domains (discretization problem) and finding the most suitable attributes for splitting rules. The approach combines GAs' strength to search through numeric spaces together with GP's strength to search symbolic spaces. Moreover, a process of construction of decision trees—defining splitting and selecting node attributes—can be "controlled" by different functions which represent different objectives essential for a given classification/prediction process. In a nutshell, the approach is to construct a decision tree via performing two-level optimization: parametric using GAs and structural using GP.

A graphical illustration of the approach is shown in Figure 8. The GA is used at the higher level and its goal is to search for the best splitting of attributes' domains. The GA operates on a population of strings, where each string—GA chromosome—is a set of possible splittings for all attributes. Each GA chromosome is evaluated via a fitness function. Evaluation of each chromosome is performed by running

a GP optimization. This means that the GP searches for the best decision tree that can be constructed for the splitting represented by the GA chromosome. Consequently, the GP operates on a population of lists that are blueprints of decision trees. In other words, each individual of the GP population—a list—represents a single decision tree. The population of decision trees evolves according to the rules of selection and genetic operations of crossover and mutation. Each GP individual is evaluated by means of a certain fitness function. The GP returns the best value of the fitness function together with the best decision tree to the GA. The fitness value returned by the GP becomes the fitness value of the evaluated GA chromosome. Such approach ensures evaluation of each GA chromosome based on the best possible decision tree that can be constructed for the splitting represented by this chromosome.

To find the best solution, the GA creates and continuously modifies chromosomes—splittings and then, for each splitting, it invokes GP to generate the best decision tree. The following algorithm summarizes the steps that are used with the multi-level approach:

STEP 1: randomly generate an initial population of GA chromosomes (each chromosome contains information about a number of splittings and about splitting points for each attribute);
STEP 2: WHILE termination criterion not reached DO:
  STEP 2_1: evaluate each GA chromosome (splitting) by invoking GP
    STEP 2_1_1: randomly generate an initial population of trees for a given splitting;
    STEP 2_1_2: WHILE termination criterion not reached DO:
      STEP 2_1_2_1: calculate a performance measure (fitness value) representing how well each candidate solution performs the designated task, in the case when candidate solutions are decision trees it means classification/prediction of data points from a training dataset;
      STEP 2_1_2_2: select the decision trees for reproduction;
      STEP 2_1_2_3: modify decision trees using crossover and mutation;
    STEP 2_1_3: identify the fittest solution to the problem -- the best decision tree and return it to GA
  STEP 2_2: select candidate solutions—splittings—for reproduction to the next generation;
  STEP 2_3: apply genetic operators (crossover and mutation) to combine and modify splittings;
STEP 3: identify the fittest solution—the best splitting and associated with it the best decision tree.

Optimization Objective

One of the most important aspects of the approach is its flexibility to construct decision trees based on objectives that can reflect different requirements regarding the classification/prediction process and the different character of data. These objectives are represented by fitness functions. The role of the fitness function is to assess how well the decision tree classifies the training data. The simplest fitness function represents a single objective ensuring the highest classification/prediction rate without taking into consideration the classification/prediction rate for each data category. In such case, the fitness function is as follows:

$$Fit\_Fun_A = \frac{K}{N} \tag{4}$$

where N represents the number of data points in a training set, and K represents the number of correctly classified/predicted data points. Such fitness function gives good results when the numbers of data points in each category are comparable. In many cases, the character of processed data is such that not

all categories are represented equally. In this case, a fitness function should be such that it ensures the highest possible classification/classification rate for each category. An example of such fitness functions is presented in the following:

$$Fit\_Fun_B = \prod_{i=1}^{c} \frac{k_i + 1}{n_i} \tag{5}$$

where c represents a number of different categories, n_i represents a number of data samples that belong to a category i, and k_i is a number of correctly classified data points of a category i.

APPENDIX III: BASICS OF EVIDENCE THEORY

Let's start with a set of worlds Ω called the *frame of discernment.* One of the worlds, denoted ω_0, corresponds to the actual world. The agent (it may be a piece of software, system) does not know which world in Ω corresponds to the actual world ω_0. Nevertheless, the agent has some idea, some opinion about which world might be the actual one. So for every subset I of Ω, called the *focal element*, the agent can express the strength of its opinion that the actual world ω_0 belongs to *A.* This strength is denoted *bel(A)* and called a belief function (see the following text for the formal definition). Extreme values for *bel* denote full belief (1) or no belief at all (0). The larger *bel(A),* the stronger the agent believes that ω_0 belongs to *A.*

Basic Belief Assignments

One of the concepts of the theory is a basic belief assignment (*bba*). Related to belief function *bel*, one can define its so-called Moebius transform, denoted *m* and called a basic belief assignment. Let

$$m : 2^{\Omega} \rightarrow [0,1]$$

where *m(A)* is called the basic belief mass (*bbm*) given to $A \subseteq \Omega$. The value of *m(A)* represents belief that supports *A*—that is, the fact that the actual world ω_0 belongs to *A* without supporting any more specific subset. In the case, when ω_0 belongs to *A*, and nothing more is known about the value of ω_0, then some part of belief will be given to *A*, but no subset of *A* will get any positive support. In that case, *m(A) > 0* and *m(B)=0* for all $B \subseteq A$ and $B \neq A$.

Belief Functions

The *bbm m(A)* does not quantify belief, denoted *bel(A),* that the actual world ω_0 belongs to *A.* Indeed, the *bbm m(B)* given to any subset *B* of *A* also supports that ω_0 belongs to *A.* Hence, the belief *bel(A)* is obtained by summing all the *bbm m(B)* for $B \subseteq A$. At the end:

$$bel(B) = \sum_{\varnothing \neq B \subseteq A} m(B) \qquad \forall A \subseteq \Omega, A \neq \varnothing \qquad bel(\varnothing) = 0 \tag{6}$$

The belief function *bel* satisfies the following inequality:

$\forall n > 1, \forall A_1, A_2, ..., A_n \subseteq \Omega$:

$$bel(A_1 \cup A_2 \cup ... \cup A_n) \geq \sum_i bel(A_i) - \sum_{i>j} bel(A_i \cap A_j) ... - (1)^n bel(A_1 \cap A_2 \cap ... \cap A_n) \tag{7}$$

As such, the meaning of these inequalities is not obvious except when *n=2*. These inequalities generalize the idea that agent's belief that the actual world belongs to $A \subseteq \Omega$ can be larger than the sum of the beliefs the agent gives to the elements of a partition of *A*.

Combination of Two Belief Functions

Suppose there are two "distinct" pieces of evidence Ev1 and Ev2 produced by two sources of information. Let bel_1 and bel_2 be the belief functions induced by each piece of evidence. These two belief functions, with the focal elements A_i and B_j respectively, may be combined into a new belief function using Dempster's (1968) rule of combination. The rule specifies the combined belief mass, *m*, assigned to each focal element C_k, where *C* is the set of all subsets produced by *A* and *B*. The rule is:

$$m(C_k) = \frac{\sum_{A_i \cap B_j = C_k; C_k \neq \varnothing} m(A_i)m(B_j)}{1 - \sum_{A_i \cap B_j = \varnothing} m(A_i)m(B_j)} \tag{8}$$

where the focal elements of $bel_1=A=\{A_1, A_2, \ldots, A_i\}$ and $bel_2=B=\{B_1, B_2, \ldots, B_j\}$. The combination of two belief functions is also know as taking the orthogonal sum, $\oplus$, and is written as:

$$bel_3 = bel_1 \oplus bel_2 = (m(C_1),...,m(C_k)) \tag{9}$$

The meaning of distinct for two pieces of evidence has been left undefined. It lacks rigorous definition. Intuitively, it means the absence of any relation. In this case, the belief function bel_2 induced by the second source is not influenced by the knowledge of the belief function bel_1 induced by the first source and vice versa (Smets, 1992).

Transferable Belief Model

Dempster-Shafer theory has been used to develop the transferable belief model (TBM) (Smets, 1994). The model represents quantified beliefs and is based on belief functions *bel*. The TBM departs from the classical Bayesian approach in that the additivity encountered in probability theory is not assumed. For instance, there is no assumption that *bel(A)=0* implies that $bel(\neg A) = 1$. In fact $bel(A) = bel(\neg A) = 0$ is even possible. The additivity property is replaced by inequalities like:

$$bel(A \cup B) \geq bel(A) + bel(B) - bel(A \cap B) \tag{10}$$

In the TBM, one assumes that bel is a capacity monotone of order infinite. Given a belief function bel, a probability function is generated that is used to make decision by maximizing expected utilities. It requires the construction of the betting frame, that is, a list of alternatives on which the bet must be made. Let BetFrame denotes the betting frame. The granularity of BetFrame is such that if by necessity two alternatives are not distinguishable from a consequence-utility point of view, than they are pooled into the same granule.

Once the betting frame is determined, the *bbms* are transformed by the so-called pignistic transformation into the pignistic probabilities $BetP : 2^{\Omega} \rightarrow [0,1]$ with:

$$BetP(A) = \sum_{X \subseteq Bet_{Frame}, X \neq \varnothing} \frac{m(X)}{1 - m(\varnothing)} \frac{\#(A \cap X)}{\#(X)} \tag{11}$$

for all

$$A \subseteq Bet_{Frame}, A \neq \varnothing$$

#(X) is the number of granules of the betting frame BetFrame in *X*, and *m()* is called the basic belief mass. By construction, the pignistic probability function *BetP* is a probability function, but it is qualified as pignistic to avoid the error that would consist in considering this probability function as someone's beliefs. Someone's beliefs are represented by *bel*, and *BetP* is just the additive measure needed to compute expected utilities when decision must be made (Savage, 1954).

Chapter 1.19
An Overview of Software Quality Concepts and Management Issues

Alain April
École de technologie supérieure, Québec, Canada

Claude Y. Laporte
École de technologie supérieure, Québec, Canada

ABSTRACT

This chapter introduces the generally accepted knowledge on software quality that has been included in the (SWEBOK) Software Engineering Body of Knowledge (ISOTR 19759, 2005). One chapter of the SWEBOK is dedicated to software quality (April et al., 2005). It argues that ethics play an important role in applying the quality models and the notions of cost of quality for software engineers. It also describes the minimal content required in a software quality assurance plan. Finally an overview of what to expect in the upcoming international standards on software quality requirements, which transcend the life cycle activities of all IT processes, is presented.

INTRODUCTION

The business value of a software product results from its quality as perceived by both acquirers and end users. Therefore, quality is increasingly seen as a critical attribute of software, since its absence results in financial loss as well as dissatisfied users, and may even endanger lives. For example, Therac-25, a computer-driven radiation system, seriously injured and killed patients by massive overdosing (Levenson & Turner, 1993). Improving recognition of the importance of setting software quality requirements and of assessing quality causes a shift in the "center of gravity" of software engineering from creating technology-centered solutions to satisfying stakeholders.

Software acquisition, development, maintenance, and operations organizations confronted with such a shift are, in general, not adequately equipped to deal with it. Until recently, they did not have at their disposal the quality models or measurement instruments to allow (or facilitate) the engineering of quality throughout the entire software product life cycle. The objective of software product quality engineering is to achieve the required quality of the product through the definition of quality requirements and their implementation, measurement of appropriate quality attributes, and evaluation of the resulting quality. The objective is, in fact, software product quality.

This chapter is structured in accordance with the SWEBOK classification of the software quality body of knowledge (www.swebok.org) shown in Figure 1.

SOFTWARE QUALITY FUNDAMENTALS

Agreement on quality requirements, as well as clear communication on what constitutes quality, require that the many aspects of quality be formally defined and discussed. Over the years, authors and organizations have defined the term "quality" differently. IBM used the phrase "market-driven quality", which is based on achieving total customer satisfaction. This definition was influenced by the total quality management approach of Phil Crosby (1979), who defined quality as "conformance to user requirements". Watts Humphrey (Humphrey, 1990), looking at quality in the software industry, defined it as "achieving excellent levels of fitness for use". More recently, quality has been defined in ISO 9001 (2000) as "the degree to which a set of inherent *characteristics* fulfills the *requirements*." The next section looks at how organizational culture and individual ethics play a role in quality in the organization.

Culture and Ethics

Edward B. Tylor (1871) defined human culture as "that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities and habits acquired by man as a member of society." Culture guides the behaviors, activities,

Figure 1. Adapted breakdown of software quality topics (ISOTR 19759, 2005)

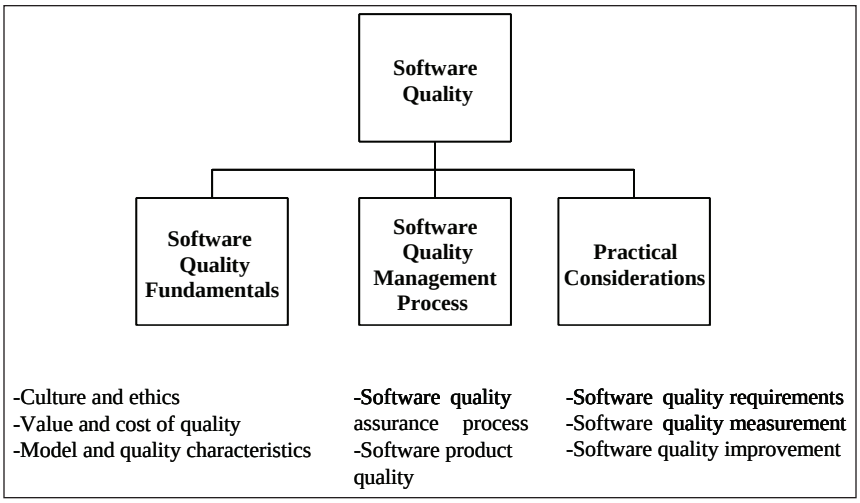

Figure 2. A software engineering culture (Wiegers, 1996)

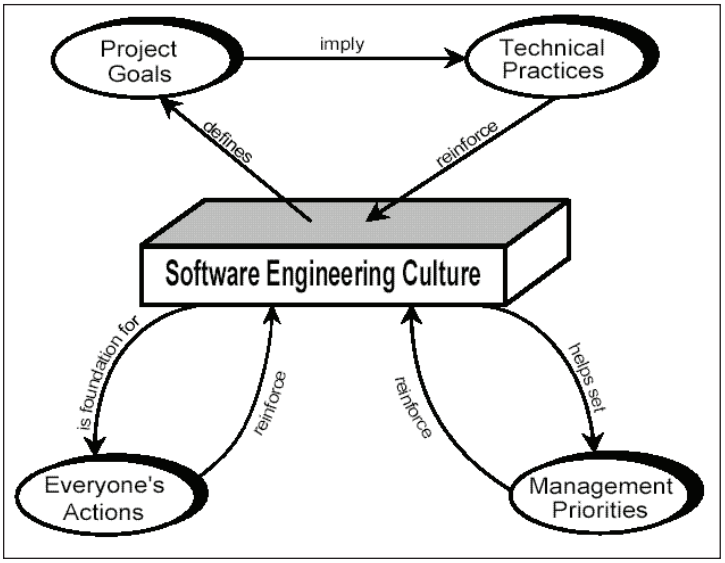


priorities, and decisions of an individual, as well as those of an organization. Karl Wiegers (1996), in his book *Creating a Software Engineering Culture*, illustrates (see Figure 2) the interaction between the software engineering culture of an organization, its software engineers and its projects. Why should we, as technical people, care about such a "soft" issue? First, a quality culture cannot be bought. It needs to be developed, mostly at the beginning, by the founders of the organization. Then, as employees are selected and hired, the initial leader's culture will start to slowly adjust to the pressures of the environment, as shown in Figure 2. Quality culture cannot be "bolted on" to an organization; it has to be designed-in and nurtured. The ultimate aim of upper management is to instill a culture that will allow the development of high-quality products and offer them at competitive prices, in order to generate revenues and dividends in an organization where employees are committed and satisfied.

The second reason why we should be interested in the cultural aspects of quality is that any change an organization wants to make, for example, moving up on the Capability Maturity Model integration^{SM} (CMMi^{SM}) (SEI, 2002) maturity scale, cannot simply be ordered; the organization has to cope with the current culture when making a change in maturity, especially when such a change implies a profound change in that culture. An organization cannot just "buy and deploy" off-the-shelf processes that contain quality. It has been demonstrated that one of the major inhibitors of change is the culture of the organization. The management of change is imperative (Laporte & Trudel, 1998) in order to achieve the desired result.

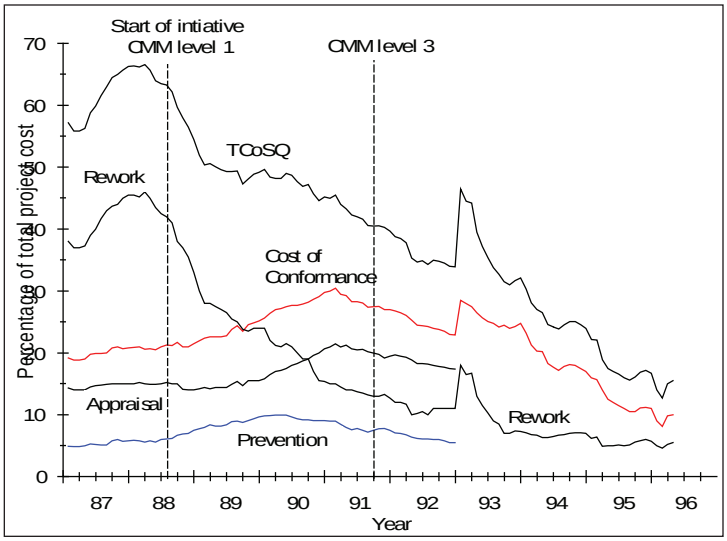
The issue of quality is also central to the Code of Ethics, developed by and for software engineers, which was released in 1999 (Gotterbarn, 1999; Gotterbarn et al., 1999; IEEE-CS, 1999). The Code describes eight top-level technical and professional obligations against which peers, the public, and legal bodies can measure a software engineer's ethical behavior. Each top-level obligation, called a principle, is described in one sentence and supported by a number of clauses which gives examples and details to help in inter-

pretation and implementation of that obligation. Software engineers adopting the Code commit to eight principles of quality and morality. The following are examples: Principle 3 (Product) states that software engineers shall ensure that their products and related modifications meet the highest professional standards possible. This principle is supported by 15 clauses, and clause 3.10 reads that software engineers shall ensure adequate testing, debugging, and review of software and related documents on which they work. The Code has been translated into eight languages: Chinese, Croatian, English, French, Hebrew, Italian, Japanese, and Spanish, and all versions are available at http://seeri.etsu.edu/Codes/default.shtm. It has been publicly adopted by many organizations, as well as by a few universities as part of their curriculum in software engineering.

Value and Costs of Quality

To promote a quality approach to software, a number of arguments must be developed to support its value and benefits. Quality, as a whole, is not always perceived positively and is a hard sell for software project managers. One famous book (Crosby, 1979) addressing the cost of quality has been published on this topic. Since its publication, many organizations, mainly manufacturers, have successfully promoted the use of the cost of quality concepts and framework in their project management processes. A few papers have been published on the adoption of these concepts in the software industry (Campanella, 1990; Diaz, 2002; Dobbins, 1999; Galin, 2004a; Mandeville, 1990; Slaughter et al., 1998), but very few case studies have been published by the software industry itself (Dion, 1993; Haley, 1996; Houston, 1999; Knox, 1993). A paper by Haley of Raytheon (Haley, 1996) illustrates very well the links between the cost of rework and the investment needed to reduce waste. Haley also illustrates that a long-term perspective is needed, as well as a commitment from senior management, in order to capture the benefits. Another fact illustrated by Haley is the link between the investment/benefits and the Capability Maturity Model for Software (CMM)® (Paulk et al., 1993) maturity level of an organization (see Figure 3). At the initial CMM maturity level, most, if not all, organizations have

Figure 3. Improvement data (Dion, 1993; Haley, 1996)



no reliable data or measurement system. When an organization has reached levels 2 and 3, it has the foundation to measure and select beneficial process improvement areas. Many organizations have published the results obtained in climbing the maturity ladder. They show the relationships between maturity level, quality, productivity, and project cost.

Galin (2004b), in a recent software quality assurance book, illustrates the cost and benefits of quality practices. As shown in Table 1, the addition of effective quality practices, such as inspection and review, even reduce the cost of a project by eliminating rework. The left-hand column lists typical quality assurance activities, such as reviews and inspections, of an on-going project. The middle column shows the effectiveness of typical defect removal activities included in a software quality plan. It shows that such a process would deliver a product where 93.1% of the total defects have been detected, leaving 6.9% of them, for a QA cost of 1014.3 units. On the right-hand side, two activities have been added to the quality plan: a design inspection and a code inspection. Even though these activities are not free (18.5 and 158.6 units, respectively), the net result is that 97.4% of the total defects have been detected, leaving only 2.6% of the defects in operation. Note also that the total QA cost is 760.4 units, compared to 1014.3 units previously.

The following quote from Norman Augustine (1997) summarizes this section: "It costs a lot to build bad products."

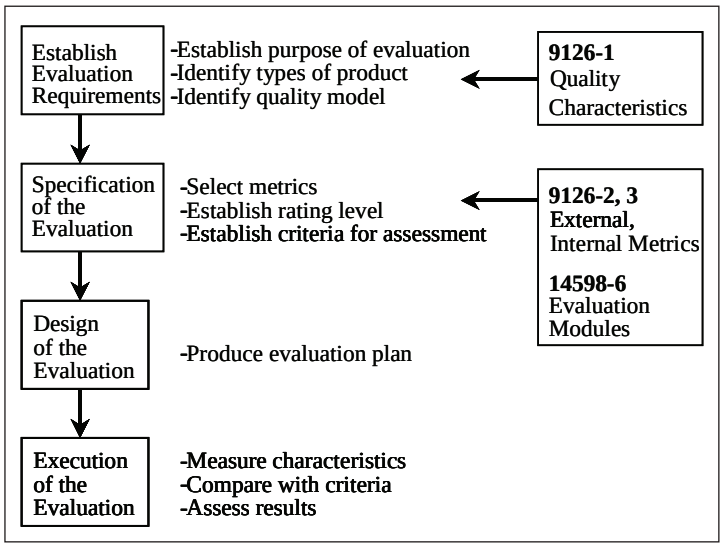
Model and Quality Characteristics

Quality models for software have been developed to assess both software processes and software products. Software process engineering has made many advances in the last decade and has introduced numerous quality models and standards concerned with the definition, implementation, measurement, management, change, and improvement of the software engineering process itself. Assessing the quality of software products requires that the quality characteristics of software be defined and measured. The quality of a software product is determined by its properties. Some of these are inherent to the software product, while others are assigned, by priority, to the software product during its requirements definition process. Process quality is concerned with the technical and managerial activities within the software engineering process that are performed during software acquisition, development, maintenance, and operation.

Table 1. Illustration of the cost and benefits of quality practices (Galin, 2004a)

Quality assurance activity	Standard plan		Comprehensive plan	
	Percentage of defects removed	Cost of removing defects (cost units)	Percentage of defects removed	Cost of removing defects (cost units)
1. Requirements specification review	7.5%	7.5	9%	9
2. Design inspection	--	--	28.7%	71.8
3. Design review	21.3%	53.2	7.4%	18.5
4. Code inspection	--	--	24.4%	158.6
5. Unit test – code	25.6	166.4	4.2%	27.3
6. Integration test	17.8%	284.8	9.8%	156.8
7. Documentation review	13.9%	222.4	9.9%	158.4
8. System test	7.0%	280	4%	160.
Total for internal QA activities	**93.1%**	**1014.3**	**97.4**	**760.4**
Defects detected during operation	6.9%	759	2.6%	286
Total	**100.0%**	**1773.3**	**100%**	**1046.4**

Figure 4. ISO/IEC 14598 – Evaluation process (Sur03)



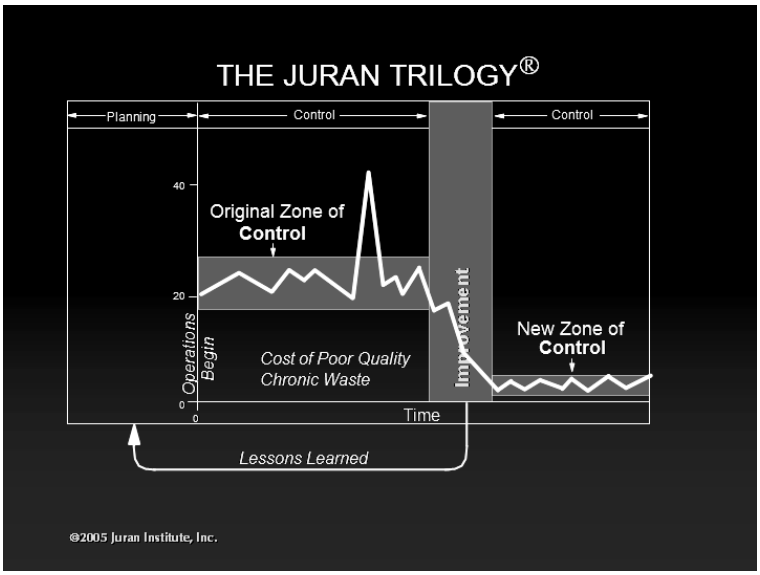
In contrast, software product quality models describe the many quality attributes of software. These have been presented by many authors (Boehm et al., 1978; McCall et al., 1977) and have more history. Although this is an older topic, it has not quite reached the popularity of software process quality models. During the early years, the terminology for software product quality differed from one model of software quality to another. Each model had a different number of hierarchical levels and number of characteristics, and the different naming conventions were especially confusing. Based on these efforts, the International Organization for Standardization (ISO) normalized three software product quality models (i.e., internal quality, external quality, and quality in use) (ISO 9126, 2001) and accompanied them with a set of guides like ISO/IEC14598 which explains how to evaluate a software product (see Figure 4).

SOFTWARE QUALITY MANAGEMENT PROCESS

Software quality management (SQM) defines processes, process owners, requirements for those processes, measurements of the process, their outputs, and, finally, feedback channels (Arthur, 1992). SQM processes are useful for evaluating the process outcome as well as the final product.

The Juran Trilogy Diagram, illustrated in Figure 5, depicts quality management as comprising three basic processes: quality planning, quality control, and quality improvement. The diagram shows how waste caused by mismanaging quality, or not managing it, can be reduced by introducing quality improvement and feeding back the lessons learned from this into the quality planning process. Many, if not most, software engineering managers are not aware of the magnitude of the waste, i.e., between 30 and 40%, in their processes.

Figure 5. Juran trilogy diagram



Software quality management processes consist of many activities. Some may find defects directly, while others indicate where further examination may be valuable. Planning for software quality involves:

1. defining the required product in terms of its quality characteristics;
2. planning the processes to achieve the required product quality.

Some of the specific SQM processes are defined in standard IEEE 12207 (1996):

- Quality assurance process
- Verification process
- Validation process
- Review process
- Audit process

These processes encourage quality and also find possible problems, but they differ somewhat in their emphasis. SQM processes help ensure better software quality in a given project. They also, as a by-product, provide management with general information, including an indication of the quality of the entire software engineering process.

SQM processes consist of tasks and techniques to indicate how software plans (e.g., management, development, and configuration management) are being implemented and how well the intermediate and final products are meeting their specified requirements. Results from these tasks are assembled into reports for management before corrective action is taken. The management of an SQM process is tasked with ensuring that the results of these reports are accurate.

As described in this Knowledge Area (KA), SQM processes are closely related; they can overlap and are sometimes even combined. They seem largely reactive in nature because they address the processes as practiced and the products as produced, but they have a major role at the planning stage in being proactive in terms

of the processes and procedures needed to attain the quality characteristics and degree of quality needed by the stakeholders in the software.

Risk management can also play an important role in delivering quality software. Incorporating disciplined risk analysis and management techniques into the software life cycle processes can increase the potential for producing a quality product (Charette, 1989). Refer to the Software Engineering Management KA of the SWEBOK for material related to risk management.

Software Quality Assurance Process

Software quality assurance processes have been found to have a direct effect on the quality of a software product. During a software development project, it is difficult to completely distinguish the quality of the process used to develop the software from the quality of the product itself. Process quality assurance influences process quality, which in turn influences the quality characteristics of the software product.

Process quality is addressed by two important process models, ISO9001 and CMMi^{SM} (SEI, 2002). First, ISO9001:2000 (ISO 9001, 2000) is an international standard, while CMMi is a process model. Compliance with the key quality concepts of the ISO9001:2000 standard requires an interpretation for each industry. Software, a service industry, has initially had more difficulty interpreting and implementing the ISO9001 standards (Bouman et al., 1999; May, 2002; Niessink, 2000). Service organizations also experience greater difficulty dissociating the final product from the processes used in its production (May, 2002). To help with this problem, additional guidance has been developed by the ISO for the implementation of ISO9001:2000 in the software industry (Hailey, 1998; May, 2002). This guide, numbered ISO90003 (2004), helps link all the software-related standards to the quality system required by ISO9001:2000.

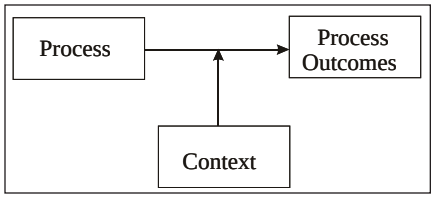
In contrast, CMMi (SEI, 2002) is a process model which proposes proven practices at different maturity levels. It is divided into process areas, and the following are key to quality management: (a) process and product quality assurance; (b) process verification; and (c) process validation.

There was initially some debate over whether ISO9001:2000 or CMMi should be used by software engineers to ensure quality. It has been observed that many organizations use their ISO9001 certification assets as a stepping stone toward meeting the CMMi requirements. It is believed that level 3 of CMMi is reachable for an organization that already has ISO9001:2000 certification. In competitive situations, it is not unusual to find that the two are used concurrently to meet shared quality objectives.

In general, process quality models are concerned with process outcomes. However, in order to achieve the process outcomes desired (e.g., better quality, better maintainability, greater customer satisfaction), we have to implement and measure the process in action.

Current quality models are not complete at this time, as there are many other factors to consider which have an impact on outcomes. Other factors, such as the context, industry domain, capability of the staff, and the tools used also play an important role (see Figure 6). "Furthermore, the extent to which the process is institutionalized or implemented (i.e., process fidelity) is important, as it may explain why 'good' processes do not give the desired outcomes" (ISOTR19759, 2005).

Figure 6. Relationships between process and outcomes (ISOTR19759, 2005)



A word of caution is needed with regard to the term *software quality assurance* (SQA). It is actually a misnomer, because SQA cannot *assure* quality, but only *provide adequate assurance*. ISO 12207 (ISO/IEC12207.0-96) defines an SQA process as a process for providing adequate assurance that the software products and processes in the project life cycle conform to their specified requirements and adhere to their established plans.

The persons or groups providing SQA services need to be independent of the developers in order to provide an unbiased opinion on the conformance of products and processes to the standards imposed by a customer, an organization, or a country. SQA services can be provided by an entity that may be internal or external to the developing organization.

An SQA plan, often mandated by an SQA standard, derives its requirements from the contract, the project plan, and the organization's quality system. It defines the means that will be used to ensure that software developed for a specific product satisfies the user's requirements and is of the highest quality possible within project constraints. The content and format of an SQA plan are available in government documents, such as ESA and NASA, or publicly, in standards such as IEEE standard 730 (IEEE730, 2002).

ISO/IEC 12207 (1996) proposes a minimal content for the SQA plan:

- Quality standards, methodologies, procedures, and tools for performing quality assurance activities (or their references in the organization's official documentation);
- Procedures for contract review and their coordination;
- Procedures for identification, collection, filing, maintenance, and disposition of quality records; resources, schedule, and responsibilities for conducting the quality assurance activities;
- Selected activities and tasks from processes, such as verification, validation, joint review, audit, and problem resolution.

To illustrate the importance of SQA practices, Table 2 (Cusumano et al., 2003) lists a few practices included in a sample of Japanese and American organizational processes. The data show the percentage of sampled projects using a particular practice.

Table 2. Organizational quality practices (Cusumano et al., 2003)

Practices Used	Japan	US
Architectural specifications 7	0.4% 5	4.8%
Functional specifications 9	2.6% 7	4.2%
Detailed designs 8	5.2%	32.3%
Design reviews 1	00%	77.4%
Code reviews	74.1%	71%
Regression testing	96.3%	71%

Table 3. Performance comparison (Cusumano et al., 2003)

Performance Crieria	Japan	US
Median output (see note 1) 4	69 2	70
Median defect rate (see note 2)	.020 .	400
Note 1: Output per programmer-month of effort in new Lines of Code (LOC).		
Note 2: Number of defects reported per 1000 LOC (in the 12 months after delivery to customers).		

Table 4. Productivity and quality improvements over a decade (Cusumano et al., 2003)

	Japan – 1990	Japan - 2003	US – 1990	US -2003
Productivity	389	469	245	270
Quality	.20	.020 .	83 .	400

Table 3 from the same paper shows the performance data resulting from implementation of the practices. As can be observed, the increased performance of the practices in Japan resulted in increased productivity and quality performance in that country.

Table 4 illustrates the important improvements, especially in quality, measured in Japan and the US over the 10-year period.

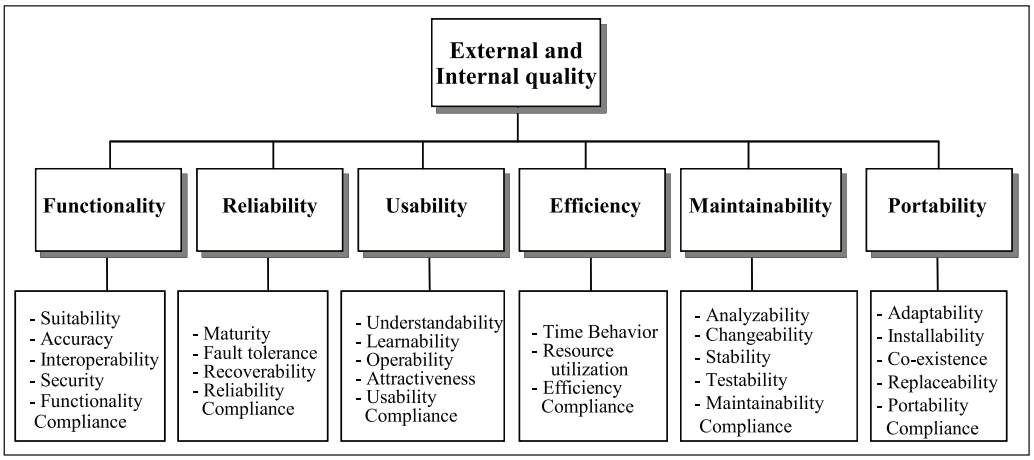
Software Product Quality

The quality of software is not only influenced by the quality of the process used to develop it, but by the quality of the product as well. Software product quality has also been the subject of much research and of many international standards and publications. Software engineers determine, with the stakeholders, the real purpose of future software. In this regard, it is of prime importance to keep in mind that the customer's requirements come first and that they should include non-functional requirements like quality, not just functionality. Thus, the software engineer has a responsibility to elicit quality requirements from future software which may not be made explicit at the outset. It is key that the software engineer assess their relative importance, as well as the level of difficulty in achieving each of them. The section on value and cost of quality presented the additional processes associated with defining and assessing software quality that need to be added to software projects, and each carries additional costs.

Software product quality standards define the related quality characteristics and subcharacteristics, as well as measures which are useful for assessing software product quality (Suryn et al., 2003). In the standards, the meaning of the term *product* is extended to include any artifact which is a software process outcome used to build the final software product. Examples of a product include, but are not limited to, an entire system requirements specification, a software requirements specification for a software component of a system, a design module, code, test documentation or reports produced as a result of quality analysis tasks.

The software product quality model provided in ISO/IEC 9126-1 (ISO9126, 2001) defines six quality characteristics: functionality, reliability, usability, maintainability, portability and efficiency, as well as quality in use, which is defined as

Figure 7. External/internal quality of ISO/IEC 9126 (ISO9126-2001)



effectiveness, productivity, safety, and satisfaction (see Figure 7). The six quality characteristics have defined subcharacteristics, and the standard also allows for user-defined components. The intention is that the defined quality characteristics cover all quality aspects of interest for most software products and, as such, can be used as a checklist for ensuring complete coverage of quality early in the specifications phase.

The quality model suggests three views: internal quality, external quality, and quality in use.

Internal quality provides a 'white box' view of the software and addresses properties of the software product that typically are available during development. External quality provides a 'black box' view of the software and addresses properties related to its execution. "The quality-in-use view is related to application of the software in its operational environment, for carrying out specified tasks by specified users. Internal quality has an impact on external quality, which again has an impact on quality in use. (Suryn et al., 2003)

External and internal quality models presented by ISO/IEC9126 are less trivial and have to be explained further. Let us take the maintainability of software as a quality attribute, and see both the external and internal perspectives in action.

From an external point of view, maintainability attempts to measure the effort required to diagnose, analyze, and apply a change to a software product. Thus, an external measure of maintainability would constitute the effort to make a specific change.

From an internal product point of view, the quality model proposes measurement of the attributes of the software that influence the effort required to modify it. A good example is source code complexity. Structural complexity measures are generally extracted from the source code using observations on the program/classes/module/functions and graph representation of software source code. The more complex the source code, the more difficult it is to grasp its meaning and to understand and document it. These studies are based on work carried out in the 1970s by Curtis, Halstead, and McCabe (Curtis, 1979; Halstead, 1978; McCabe, 1976). These are all internal measures, which in turn affect the external point of view of maintainability.

While most product quality publications have described product quality in terms of the final software and system performance, sound software engineering practice requires that key artifacts impacting quality be evaluated throughout the software development and maintenance processes.

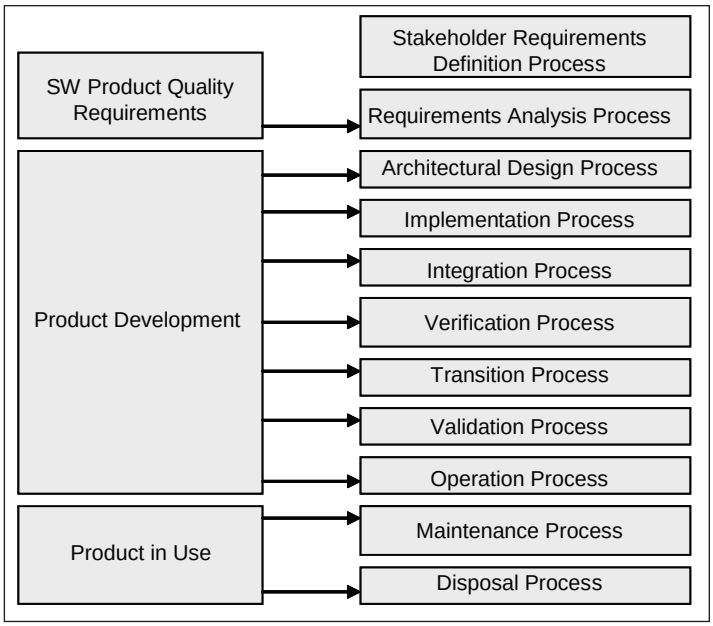
PRACTICAL CONSIDERATIONS

Software Quality Requirements

In order to implement software process and product quality, the software engineer must choose and document quality characteristics at the outset of the projects during the requirements definition process. A generic life cycle model like ISO/IEC 15288—*System life cycle processes* demonstrates generic stages of a typical development process (Figure 8) and the mapping to show *how* standards can be used across all stages of the life cycle of a software product.

We have already stated that both functional and non-functional requirements are captured using the requirements definition process (Pfleeger, 2001). Functional requirements specify what a product should do. Non-functional requirements, also called quality requirements, place constraints on the functional requirements. The quality requirements need to refer to a quality model, like the one described in ISO/IEC 9126-1, to be well understood. Quality requirements address important issues of quality for software products. Software product quality requirements are needed for:

Figure 8. Product life cycle mapping to the technical process life cycle (Suryn et al., 2003)



- Specification (including contractual agreement and call for tender)
- Planning (e.g., feasibility analysis and translation of external quality requirements into internal quality requirements)
- Development (early identification of quality problems during development)
- Evaluation (objective assessment and certification of software product quality)

The requirements definition process typically takes all stakeholders' needs, requirements, and expectations into consideration and ranks them by priority. All relevant stakeholders must be identified before the exercise begins. A first analysis activity during the requirements definition process is aimed at identifying user requirements, sometimes also called business requirements. This view of software requirements should be documented in wording that is easily understood by both users and customers.

Business requirements describe the functionality that the software executes as needed by the stakeholders. Good functional requirements are expressed clearly and are consistent. All requirements need to be correct, non-redundant, and not be in conflict with other requirements. Each requirement has to be uniquely identified and traceable to identified stakeholders. They should also be documented in the business requirements specification (BRS). If a stakeholder requirement is not taken into consideration, the software engineer needs to state the reason why in the documentation.

The second analysis activity is aimed at transforming stakeholder functional requirements into system requirements that can be used by designers to build software. This more technical view of requirements is called a software requirements specification (SRS). During this second analysis activity, the quality requirements are added to the functional requirements. They need to be stated

clearly and unambiguously. It is the software engineer's responsibility to go through each quality characteristic and assess the need to include it in the project. System requirements should also be verifiable and state both the business requirements and the non-functional requirements that the software must possess in order to satisfy all stakeholder requirements. If they do not, they may be viewed, interpreted, implemented, and evaluated differently by different stakeholders. If the software engineer does not become involved in promoting the non-functional requirements, they may be ignored altogether. This may result in software which is inconsistent with user expectations and therefore of poor quality.

We have often talked about stakeholders, but who are they? Stakeholders include all individuals and organizations with a legitimate interest in the software. Different stakeholders will express different needs and expectations that represent their own perspective. For example, operators, testers, and quality engineers are stakeholders. These needs and expectations may change throughout the system's life cycle and need to be controlled when changed. The stakeholders rarely express non-functional requirements, as they may have an unclear understanding of what quality really means in a software process. In reality, they typically perceive it initially as more of an overhead than anything else. Quality requirements will often appear as part of a contractual agreement between acquirer and developer. They may also be required for a specific product quality evaluation when some level of software criticality is reached and human lives are at risk.

We have already stated that a software quality requirement should refer to a specific quality model. To clearly specify quality requirements, ISO/IEC working group six (WG6) of the software engineering subcommittee (SC7) is developing a standard as part of the new ISO/IEC 25000 — *SQuaRE* (*S*oftware Product *Qua*lity *R*equirements and *E*valuation) initiative. The Quality Requirements standard will include a new section for the specification of quality requirements.

A number of obligations are likely to be imposed on software engineers that demand conformance to this new section of ISO/IEC 25000. First, each quality requirement will need to be categorized and prioritized according to an explicit quality model, like:

- Quality-in-use requirement;
- External quality requirement;
- Internal quality requirement.

A software quality requirement will also need to be specified with reference to a set of functional properties. It is also possible that critical functional properties will create an obligation to impose some quality characteristics on a quality requirement.

Since each quality requirement needs to be assessed throughout all the life cycle stages, it needs to be specified in terms of a measurement function and be assigned target values. This new standard will provide examples of measures which may be adapted to specific organizational needs for specifying quality requirements. This new standard is also likely to recommend that software engineers develop and maintain a list of quality measures that are used consistently across their organization. Applying the same set of measures makes it possible to create a homogeneous repository of historical data, which in turn helps in the creation of predictive models such as productivity and estimation models.

The new standard could also focus on the notion of the degree of uncertainty associated with a quality requirement. Measures tending to yield large deviations need to be explained because of their erratic behavior. Explanations include the measurement process of that measure and the errors associated with each of its components.

Many quality standards already identify the review and approval stages, so that the set of

quality requirements is identified and reviewed, and who approved them is clearly stated. The last item likely to appear in such a standard refers to the need for quality requirements, just like functional requirements, to be managed according to a configuration and change management system throughout the entire project.

Software Quality Measurement

The main reason why product quality measurement is only slowly gaining acceptance is the inherent difficulty of measuring in a practical way its quality-impacting processes and artifacts throughout the software engineering process. Some product quality perspectives (e.g., size and source code structure) have been easier to measure than others (e.g., suitability, replaceability, and attractiveness). "Furthermore, some of the dimensions of quality (e.g., usability, maintainability and value to the client) are likely to require measurement in qualitative rather than quantitative form" (ISOTR19759, 2005).

For practical purposes, the software engineer will need to define the quality requirements and the means to assess them early on in the life cycle of the project. During the requirements definition stage, statements about the quality of each quality characteristic are defined as expressing the capability of the software to perform at, and maintain, a specified level of service. The measurement approach requires that individuals who carry out software engineering activities capture the measures and make a judgment about the degree to which the many software properties fulfill their specified requirements as agreed by the stakeholders. Both qualitative and quantitative measures can be collected during all stages of the software life cycle.

The ISO9126 quality model offers definitions of software properties which can be distinguished as quantitative or qualitative. Before quality attributes can be captured and validated, someone has to design them. Then, the most practical means possible must be implemented to measure them.

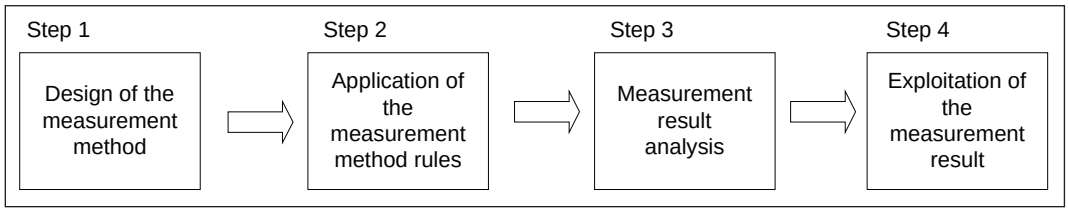
We measure by applying measurement method rules (see Step 2 in Figure 9). A measurement method is a logical sequence of operations that can be used by software engineering personnel to quantify an attribute on a specified scale. The result of applying a measurement method is called a base measure. The ISO9126 quality characteristics that were defined and agreed on can now be measured.

A list of "Quality Measures" is available in ISO/IEC 9126 and ISO/IEC 14598, and the standards present examples of mathematical definitions and guidance for practical measurement of internal quality, external quality, and quality in use.

The proposed ISO/IEC 25000–*SQuaRE* will help by providing guidance, as follows:

- **Measurement reference model and guide** — to present introductory explanations, the

Figure 9. Software measurement method (Abran & Jacquet, 1997)



reference model and the definitions that are common to measurement primitives, internal measures, external measures, and quality-in-use measures. The document will also provide guidance to users for selecting (or developing) and applying appropriate measures;

Example: the construction phase creates intermediate, non-executable software products that can only be evaluated from a static point of view. In this case, users will be directed to the internal quality measures standard, where they can choose the measures that best serve their information needs;

- **Measurement primitives** — to define a set of base and derived measures, or the measurement constructs for the internal quality, external quality, and quality-in-use measurements;
- **Measures for internal quality** — to define a set of internal measures for quantitatively measuring internal software quality in terms of quality characteristics and subcharacteristics;
- **Measures for external quality** — to define a set of external measures for quantitatively measuring external software quality in terms of quality characteristics and subcharacteristics;
- **Measures for quality in use** — to define a set of measures for measuring quality in use. The document will provide guidance on the use of the quality-in-use measures.

Software Quality Improvement

As defined by the ISO/IEC 12207 (1996) standard, an Improvement Process is a process for establishing, assessing, measuring, controlling, and improving a software life cycle process. This definition assumes that an organization already has a written development process in place. A first step in any improvement strategy is to assess the current situation (i.e., a baseline), and then to identify improvement goals and implement the actions required to achieve the goals. Similarly, quality improvement should follow the same steps. Important assumptions are that the organization has stable processes such that data collected are reliable and that they are quality data. If no data are available, some baseline activities have to be performed. The measurement and analysis process area of the CMMi (SEI, 2002) describes the basic components of such a process.

The organization then has to establish quality goals. One approach is to use the well-known Goal Quality Metric (GQM) method (Basili & Rombach, 1988). The organization determines its business goals, and then the technical personnel establish quality goals in order to meet the organization's goals. The quality goals could be established using the Cost of Quality approach or a standard business case approach, that is, by evaluating the cost of prevention and evaluation and the cost of internal and external failure.

Quality could be improved, first, by removing defects as early as possible in the development life cycle using techniques such as reviews, walkthroughs, and inspections (IEEE-1028, 1997), and second, by putting in place defect prevention activities. Software inspection (Gilb & Graham, 1993; IEEE-1028, 1997; Radice, 2002) is an example of a widely recognized quality improvement practice. A Web site displays this technique and provides a wealth of supporting information (www.goldpractices.com/practices/fi/index.php). The inspection process is typically composed of six stages: plan, kick-off meeting, document checking, logging meeting, editing (i.e., rework), and follow-up (Figure 10).

As shown in Table 5, the defect detection effectiveness of inspections can reach 84%. Radice (2002) has collected data from organizations of different CMMi maturity levels which show an effectiveness varying from as low as 50% to as much as 100% (Table 6).

Figure 10. Inspection process (Adapted from Holland, 1998)

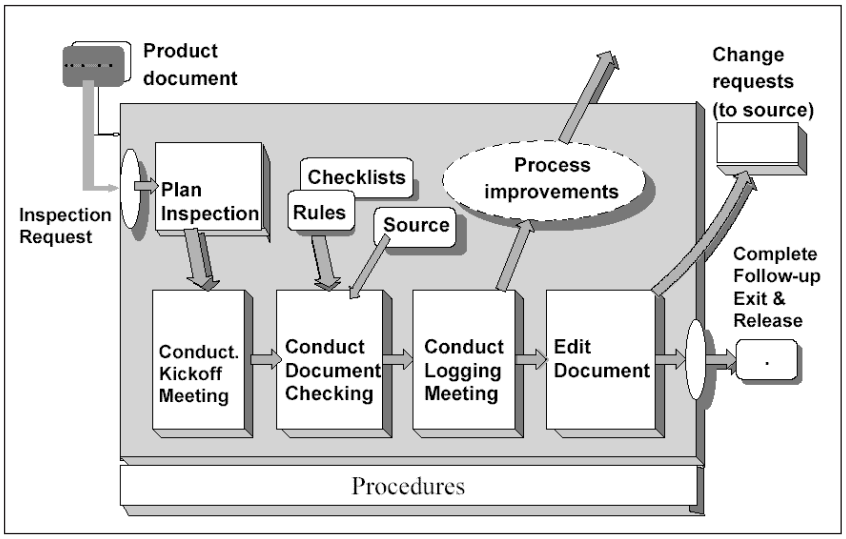


Table 5. Distribution of defect detection effectiveness of inspections (Briand et al., 1998)

Defect Detection Technique	Minimum Value	Most Likely Value	Maximum Value
Design Inspections	25%	57%	84%
Code Inspections	19%	57%	70%

Table 6. Defect detection effectiveness (Radice, 2002)

CMM Maturity Level	Defect Removal Effectiveness
Level 5	90% - 100%
Level 4	75% - 90%
Level 3	65% - 75%
Level 2	50% - 65%
Level 1	Less than 50%

Table 7. Distribution of average effort to detect defects (Briand et al., 1998)

Defect Detection Technique	Minimum Value	Most Likely Value	Maximum Value
Design Inspections	0.58	1.58	2.9
Code Inspections	0.67	1.46	2.7
Testing	4.5	6	17

It is interesting to note that using inspection to detect defects is more effective than testing. Table 7 (Briand et al., 1998) shows the average effort required to detect defects in hours per defect. Unfortunately, even though it has been around for close to 30 years (Fagan, 1976), most organizations ignore this practice. Many organizations, if not most, rely only on tests performed toward the end of the development process to identify defects, even though tests are much less effective than inspections at defect removal. One of the reasons is that inspections find defects where they occur, while testing finds only the symptoms, and then only very late in the development cycle.

FUTURE TRENDS AND CONCLUSION

To illustrate the current state of the quality of many shrink wrap software vendors, here is a typical warranty statement as printed on a software product: *By opening this sealed software media package, you accept and agree to the terms and conditions printed below. If you do not agree, **do not open the package**. Simply return the sealed package. The software media is distributed on an 'AS IS' basis, without warranty. Neither the authors, the software developers nor Acme Inc make any representation, or warranty, either express or implied, with respect to the software programs, their quality, accuracy, or fitness for a specific purpose. Therefore, neither the authors, the software developers nor Acme Inc shall have any liability to you or any other person or entity with respect to any liability, loss, or damage caused or alleged to have been caused directly or indirectly by the programs contained on the media. This includes, but is not limited to, interruption of service, loss of data, loss of consulting or anticipatory profits, or consequential damages from the use of these programs. If the media is defective, you may return it for a replacement.*

As more customers demand quality from their vendors, the competitive marketplace will eventually respond to these demands, and software products will be warranted in the same way as any other products. Vendors will be held responsible for making the appropriate corrections at their expense like other industrial sectors. Already a few organizations have demonstrated that quality, productivity, cycle time, and cost could all be improved provided that senior management commit adequate resources and time to improvement. Diaz (1997, 2002) has published results of major improvement programs at Motorola and General Dynamics. For example, at General Dynamics, rework dropped from 23.2% to 6.8%, phase containment effectiveness increased from 25.5% to 87.3%, defects reported by customers dropped from 3.2 per thousand source lines of code (KSLOC) to 0.19, and productivity increased by a factor of 2.9. Such organizations have the data to manage the quality of their processes and their products. As stated by Boehm and Sullivan (2000), since design is an investment activity, knowing the economics of software engineering, these organizations can offer their customers an optimized value proposition by using the proper processes, tools, and metrics.

There is no instant gain, however, as illustrated in Figure 3. It takes time to define and stabilize a process, measure its performances, and make improvements. Those organizations that have succeeded know that improvements require not only resources, but also a major culture change. By definition, a cultural change takes time and can rarely be imposed, and it has to be managed from the top, with senior executives no longer requesting unrealistic schedules with unrealistic budgets to deliver quality products. Moreover, if software developers in the West do not shape up rapidly, what has happened and is still happening to the automobile industry may happen to them, that is, a take-over by foreign, high-quality, lower-cost manufacturers.

With the arrival of India (Moitra, 2001) and China (Ju, 2001) into the software market with their focus on quality and process maturity, the software industry will be pushed to move faster; otherwise, Darwin will favor those who survive this fight.

Chapter 1.20
Handling of Software Quality Defects in Agile Software Development

Jörg Rech
Fraunhofer Institute for Experiemental Software Engineering (IESE), Germany

ABSTRACT

Software quality assurance is concerned with the efficient and effective development of large, reliable, and high-quality software systems. In agile software development and maintenance, refactoring is an important phase for the continuous improvement of a software system by removing quality defects like code smells. As time is a crucial factor in agile development, not all quality defects can be removed in one refactoring phase (especially in one iteration). Documentation of quality defects that are found during automated or manual discovery activities (e.g., pair programming) is necessary to avoid wasting time by rediscovering them in later phases. Unfortunately, the documentation and handling of existing quality defects and refactoring activities is a common problem in software maintenance. To recall the rationales why changes were carried out, information has to be extracted from either proprietary documentations or software versioning systems. In this chapter, we describe a process for the recurring and sustainable discovery, handling, and treatment of quality defects in software systems. An annotation language is presented that is used to store information about quality defects found in source code and that represents the defect and treatment history of a part of a software system. The process and annotation language can not only be used to support quality defect discovery processes, but is also applicable in testing and inspection processes.

INTRODUCTION

The success of software organizations—especially those that apply agile methods—depends on their ability to facilitate continuous improvement of their products in order to reduce cost, effort, and time-to-market, but also to restrain the ever increasing complexity and size of software systems. Nowadays, industrial software development

is a highly dynamic and complex activity, which is not only determined by the choice of the right technologies and methodologies, but also by the knowledge and skills of the people involved. This increases the need for software organizations to develop or rework existing systems with high quality within short periods of time using automated techniques to support developers, testers, and maintainers during their work.

Agile software development methods were invented to minimize the risk of developing low-quality software systems with rigid process-based methods. They impose as little overhead as possible in order to develop software as fast as possible and with continuous feedback from the customers. These methods (and especially extreme programming (XP)) are based upon several core practices, such as *simple design*, meaning that systems should be built as simply as possible and complexity should be removed, if at all possible.

In agile software development, organizations use quality assurance activities like refactoring to tackle defects that reduce software quality. *Refactoring* is necessary to remove *quality defects* (i.e., bad smells in code, architecture smells, anti-patterns, design flaws, negative design characteristics, software anomalies, etc.), which are introduced by quick and often unsystematic development. As time is a crucial factor in agile development, not all quality defects can be removed in one refactoring phase (especially in one iteration). But the effort for the manual discovery, handling, and treatment of these quality defects results in either incomplete or costly refactoring phases.

A common problem in software maintenance is the lack of documentation to store this knowledge required for carrying out the maintenance tasks. While software systems evolve over time, their transformation is either recorded explicitly in a documentation or implicitly through a versioning system. Typically, problems encountered or decisions made during the development phases get lost and have to be rediscovered in later maintenance phases. Both expected and unexpected CAPP (corrective, adaptive, preventive, or perfective) activities use and produce important information, which is not systematically recorded during the evolution of a system. As a result, maintenance becomes unnecessarily hard and the only countermeasures are, for example, to document every problem, incident, or decision in a documentation system like bugzilla (Serrano & Ciordia, 2005). The direct documentation of quality defects that are found during automated or manual discovery activities (e.g., code analyses, pair programming, or inspections) is necessary to avoid wasting time by rediscovering them in later phases.

In order to support software maintainers in their work, we need a central and persistent point (i.e., across the product's life cycle) where necessary information is stored. To address this issue, we introduce our annotation language, which can be used to record information about quality characteristics and defects found in source code, and which represents the defect and treatment history of a part of a software system. The annotation language can not only be used to support quality defect discovery processes, but is also applicable for testing and inspection processes. Furthermore, the annotation language can be exploited for tool support, with the tool keeping track and guiding the developer through the maintenance procedure.

Our research is concerned with the development of techniques for the discovery of quality defects as well as a quality-driven and experience-based method for the refactoring of large-scale software systems. The instruments developed consist of a technology and methodology to support decisions of both managers and engineers. This support includes information about where, when, and in what configuration quality defects should be engaged to reach a specific configuration of quality goals (e.g., improve maintainability or reusability). Information from the diagnosis of quality defects supports maintainers in select-

ing countermeasures and acts as a source for initiating preventive measures (e.g., software inspections).

This chapter targets the handling of quality defects in object-oriented software systems and services. It is concerned with the theory, methodology, and technology for the handling of defects that deteriorate software qualities as defined in ISO 9126 (e.g., maintainability, reusability, or performance). We describe the relevant background and related work concerning quality defects and quality defect handling in agile software projects, as well as existing handling techniques and annotation languages. The subsequent section encompasses the morphology of quality defects as well as their discovery techniques. As the core of this chapter, we present the techniques for handling quality defects after their discovery in an agile and time-critical environment and define an annotation language to record information about quality defects and their history in source code. Thereafter, a section is used to describe the annotation language that is used to record the treatment history and decisions in the code itself. Finally, we summarize several lessons learned and requirements one should keep in mind when building and using quality defect handling methods and notations in an agile environment. At the end of this chapter, we summarize the described approach and give an outlook to future work and trends.

BACKGROUND

This section is concerned with the background and related work in agile software engineering, refactoring, and quality defects. It gives an overview of quality defect discovery, the documentation of defects, as well as source code annotation languages.

Agile Software Development

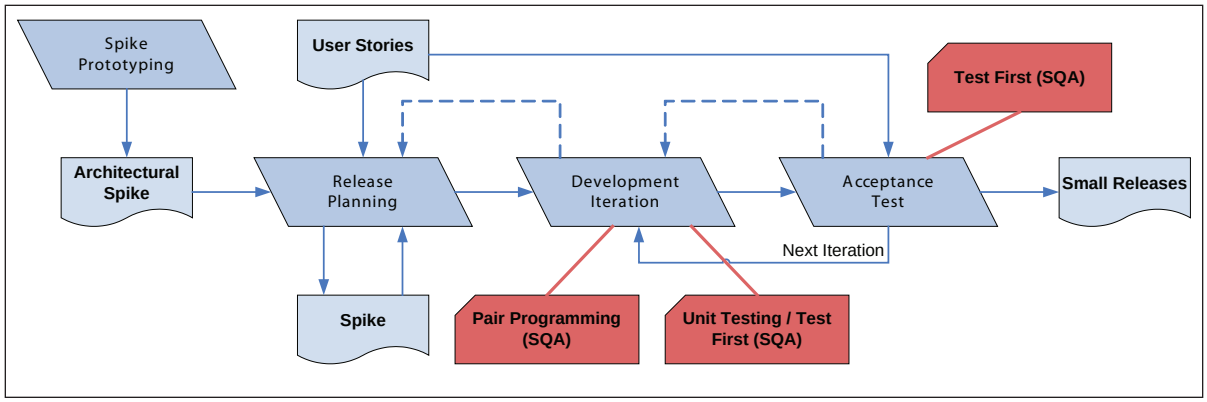
Agile software development methods impose as little overhead as possible in order to develop software as fast as possible and with continuous feedback from the customers. Agile methods have in common that small releases of the software system are developed in short iterations in order to create a running system with a subset of the functionality needed for the customer. Therefore, the development phase is split into several activities, which are followed by small maintenance phases. In contrast to traditional, process-oriented SE, where all requirements and use cases are elicited, agile methods focus on few essential requirements and incrementally develop a functional system in several short development iterations.

Today, extreme programming (XP) (Beck, 1999) is the best-known agile software development approach. 0 shows the general process model of XP, which is closely connected to refactoring, basically being its cradle (Beck & Fowler, 1999).

These agile methods (and especially extreme programming (XP)) are based upon 12 principles (Beck, 1999). We mention four of these principles, as they are relevant to our work.

1. **Planning Game** is the collective planning of releases and iterations in the agile development process and is necessary for quickly determining the scope of the next release. If the requirements for the next iteration are coherent and concise, more focus can be given to one topic or subsystem without making changes across the whole system.
2. **Small releases** are used to develop a large system by first putting a simple system into production and then releasing new versions in short cycles. The smaller the change to the system, the smaller the risk of introducing complexity or defects that are overlooked in the refactoring (or SQA) phases.

Figure 1. Agile software development (here the XP process)



3. **Simple design** means that systems are built as simply as possible, and complexity in the software system is removed, if at all possible. The more understandable, analyzable, and changeable a system is, the less functionality has to be refactored or reimplemented in subsequent iterations or maintenance projects.
4. **Refactoring** is necessary for removing qualitative defects that are introduced by quick and often unsystematic development. Decision support during refactoring helps the software engineer to improve the system.

In the highly dynamic processes used in agile methods, teams and organizations need automated tools and techniques that support their work without consuming much time. Especially in the refactoring phase, where the software is revised, automation can be used to detect *quality defects* such as code smells (Fowler, 1999), antipatterns (Brown, Malveau, McCormick, & Mowbray, 1998), design flaws (Riel, 1996), design characteristics (Whitmire, 1997), or bug patterns (Allen, 2002). Techniques from KDD support the refactoring of software systems (Rech, 2004), and techniques from knowledge management can foster experience-based refactoring (Rech & Ras, 2004).

Quality Defect Discovery

A central research problem in software maintenance is still the inability to change software easily and quickly (Mens & Tourwe, 2004). To improve the quality of their products, organizations often use quality assurance techniques to tackle defects that reduce software quality. The techniques for the discovery of quality defects are based upon several research fields.

- **Software Inspections** (Aurum, Petersson, & Wohlin, 2002; Ciolkowski, Laitenberger, Rombach, Shull, & Perry, 2002), and especially code inspections are concerned with the process of manually inspecting software products in order to find potential ambiguities as well as functional and non-functional problems (Brykczynski, 1999). While the specific evaluation of code fragments is probably more precise than automated techniques, the effort for the inspection is higher, the completeness of an inspection

regarding the whole system is smaller, and the number of quality defects searched for is smaller.

- **Software testing** (Liggesmeyer, 2003) and debugging is concerned with the discovery of defects regarding the functionality and reliability as defined in a specification or unit test case in static and dynamic environments.
- **Software product metrics** (Fenton & Neil, 1999) are used in software analysis to measure the complexity, cohesion, coupling, or other characteristics of the software product, which are further analyzed and interpreted to estimate the effort for development or to evaluate the quality of the software product. Tools for software analysis in existence today are used to monitor dynamic or static aspects of software systems in order to manually identify potential problems in the architecture or find sources for negative effects on the quality.

Furthermore, several specific techniques for quality defect discovery already exist (Marinescu, 2004; Rapu, Ducasse, Girba, & Marinescu, 2004). Most of the tools such as Checkstyle, FindBugs, Hammurapi, or PMD analyze the source code of software systems to find violations of project-specific programming guidelines, missing or overcomplicated expressions, as well as potential language-specific functional defects or bug patterns. Nowadays, the Sotograph can identify "architectural smells" that are based on metrics regarding size or coupling (Roock & Lippert, 2005).

But the information from these techniques and the resulting CAPP or *refactoring* activities are typically lost after some time if they are not documented in external documents or *defect management* systems (e.g., bugzilla). And even these external data sources are prone to get lost over several years of maintenance and infrastructure changes. The only information that will not get lost is typically the source code itself.

Refactoring

Beside the development of software systems, the effort for software evolution and maintenance is estimated to amount to 50% to 80% of the overall development cost (Verhoef, 2000). One step in the evolution and development of software systems is the process of reworking parts of the software in order to improve its structure and quality (e.g., maintainability, reliability, usability, etc.), but not its functionality. This process of improving the internal quality of object-oriented software systems in agile software development is called *refactoring* (Fowler, 1999). While refactoring originates in from the agile world, it can, nevertheless, be used in plan-driven (resp. heavyweight) software engineering. In general, refactoring (Fowler, 1999; Mens et al., 2004) is necessary to remove quality defects that are introduced by quick and often unsystematic development.

The primary goal of agile methods is the rapid development of software systems that are continuously adapted to customer requirements without large process overhead. During the last few years, refactoring has become an important part in agile processes for improving the structure of software systems between development cycles. Refactoring is able to reduce the cost, effort, and time-to-market of software systems. Development, maintenance, and reengineering effort are reduced by restructuring existing software systems (on the basis of best practices, design heuristics, and software engineering principles), especially in the process of understanding (the impact of new changes in) a system. A reduction of effort also reduces the length of projects and therefore, cost and time-to-market. Furthermore, refactoring improves product quality and therefore is able to reduce the complexity and size of software systems. Especially in agile software

development, methods as well as tools to support refactoring are becoming more and more important (Mens, Demeyer, Du Bois, Stenten, & Van Gorp, 2003).

However, performing manual discovery of quality defects that should be refactored result in either very short or costly refactoring phases. While several automations for refactoring have already been developed (e.g., "extract method" refactoring), the location, analysis, and removal is still an unsystematic, intuitive, and manual process. Today, several techniques and methods exist to support software quality assurance (SQA) on higher levels of abstraction (e.g., requirement inspections) or between development iterations (e.g., testing). Organizations use techniques like refactoring to tackle *quality defects* (i.e., bad smells in code (Beck & Fowler, 1999), architecture smells (Roock et al., 2005), anti-patterns (Brown et al., 1998), design flaws (Riel, 1996; Whitmire, 1997), and software anomalies (IEEE-1044, 1995), etc.) that reduce software quality.

Refactoring does not stop after discovery; even if we had solved the problem of discovering every quality defect possible, the information about the defect, the rationales of whether it is removed (or not), and the refactorings used have to be documented in order to support maintainers and reengineers in later phases. If one knows how to remove a specific quality defect or a group of quality defects, one still needs support, as it is not clear where and under which conditions refactoring activities should be used. Furthermore, product managers need support to organize chains of refactorings and to analyze the impact of changes due to refactorings on the software system. Analogously, quality managers and engineers need information to assess the software quality, identify potential problems, select feasible countermeasures, and plan the refactoring process as well as preventive measures (e.g., code inspections).

Defect Documentation

Today, various repositories exist for documenting of information about defects, incidents, or other issues regarding software changes. This information can be stored in configuration management systems (e.g., CVS, SourceSafe), code reuse repositories (e.g., ReDiscovery, InQuisiX), or *defect management systems.*

The last category is also known as bug tracking (Serrano et al., 2005), issue tracking (Johnson & Dubois, 2003), defect tracking (Fukui, 2002), or source code review systems (Remillard, 2005). They enable a software engineer to record information about the location, causes, effects, or reproducibility of a defect. Typical representatives of defect management systems are open-source variants such as Bugzilla (Serrano et al., 2005), Scarab (Tigris, 2005), Mantis (Mantis, 2005), or TRAC (TRAC, 2005). Commercial versions include Tuppas (Tuppas, 2005), Census from Metaquest (MetaQuest, 2005), JIRA from Atlassian (Atlassian, 2005), or SSM from Force10 (Force10, 2005). These tools are predominantly used in defect handling to describe defects on the lower abstractions of software systems (i.e., source code) (Koru & Tian, 2004) separated from the code.

Defect classification schemes (Freimut, 2001; Pepper, Moreau, & Hennion, 2005) like ODC (Orthogonal Defect Classification) (Chillarege, 1996) are used, for example, in conjunction with these tools to describe the defects and the activity and status a defect is involved in. The ODC process consists of an opening and closing process for defect detection that uses information about the target for further removal activities. Typically, removal activities are executed, but changes, decisions, and experiences are not documented at all—except for small informal comments when the software system is checked into a software repository like CVS.

From our point of view, the direct storage of information about defects, decisions about them, or refactorings applied in the code (as a central point of information) via *annotation languages* such as JavaDoc (Kramer, 1999), doxygen (van Heesch, 2005), or ePyDoc (Loper, 2004) seems to be a more promising solution. The next section describes the relevant background and related work for annotation languages, which are used to record historical information about the evolution of a code fragment (e.g., a method, class, subsystem, etc.).

Source Code Annotation Languages

Annotation languages such as JavaDoc (Kramer, 1999), ePyDoc (ePyDoc, 2005), ProgDOC (Simonis & Weiss, 2003), or Doxygen (van Heesch, 2005) are typically used to describe the characteristics and functionality of code fragments (i.e., classes, methods, packages, etc.) in the source code itself or in additional files. Today several extensions, especially to JavaDoc, are known that enable us to annotate which patterns (Hallum, 2002; Torchiano, 2002), aspects (Sametinger & Riebisch, 2002), or refactorings (Roock & Havenstein, 2002) were or will be used on the source code, and which help us to describe characteristics such as invariants, pre-/ post-conditions, or reviewer names (JSR-260, 2005; Tullmann, 2002). These extensions to the annotation language are called taglets. They are used by doclets in the extraction using, for example, the JavaDoc program. These tools collect the distributed information blocks and generate a (online) documentation rendered in HTML or another file format (e.g., PDF) for better viewing. Typically, these documentations describe the application program interface (API) as a reference for software engineers. Similarly, tools and notations like Xdoclet offer additional tags that are used to generate many artifacts such as XML descriptors or source code. These files are generated from templates using the information provided in the source code and its JavaDoc tags.

Typical content of code annotations is, for example, used to describe the:

- Purpose of a class, field, or method.
- Existence of (functional) defects or workarounds.
- Examples of using the code fragment.

In the following sections and tables, we describe the tags currently available for annotating source code using JavaDoc. JavaDoc is a name for an annotation language as well as the name of a tool from Sun Microsystems to generate API documentation and is currently the industry standard for documenting software systems in Java. The tool uses the tags from the JavaDoc language to generate the API documentation in HTML format. It provides an API for creating doclets and taglets, which allows extending the system with one's own tags (via taglets) and the documentation with additional information (via doclets).

As listed in 0, JavaDoc currently consists of 19 tags that might be used to describe distinguished information (e.g., such as return values of a method) or to format text passages (e.g., to emphasize exemplary source code). The standard tags appear as "`@tag`" and might include inline tags, which appear within curly brackets "`{@tag}`." Inline tags only appear within, respectively behind, standard tags or in the description field (e.g., "`@pat.name … {@pat.role …}`").

Developers can use the JavaDoc tags when documenting source code in a special comment block by starting it with "`/**`" and ending it with "`*/`." A tag is indicated by using an "@" ("at") sign right before the tag name. An example of a JavaDoc comment used for a method is in Box 1.

As an extension to JavaDoc, four refactoring tags were developed in Roock et al. (2002) as described in 0.

Box 1.

/**	Start of JavaDoc comment
* Sorts an array using quicksort	Description of the method
* @author John Doe	Indicate the author
* @param productArray	Describe a parameter
* @return Array The sorted array	Describe the return value
*/	End of JavaDoc comment

Table 1. General tags of the JavaDoc annotation language

Tag	Description	Origin	Type
@author	May appear several times and indicates who has created or modified the code.	JavaDoc 1.0	Context
@param	Describes one parameter of a method (or template class).	JavaDoc 1.0	Function
@return	Describes the returned object of a method.	JavaDoc 1.0	Function
@throws	Describes the (exception-) objects that are thrown by this method.	JavaDoc 1.2	Function
@exception	Synonym for @throws.	JavaDoc 1.0	Function
@version	States the version of this code structure.	JavaDoc 1.0	Context
@since	States the version since when this code was implemented and available to others.	JavaDoc 1.1	Context
@deprecated	Indicates that this code structure should not be used anymore.	JavaDoc 1.0	Status
@see	Adds a comment or link to the “See also” section of the documentation. May link to another part of the documentation (i.e., code).	JavaDoc 1.0	Reference
@serialData	Comments the types and order of data in a serialized form.	JavaDoc 1.2	Context
@serialField	Comments a ObjectStreamField.	JavaDoc 1.2	Context
@serial	Comments default serializable fields.	JavaDoc 1.2	Context
<@code>	Formats text in code font (similar to <code>).	JavaDoc 1.5	Format
<@docRoot>	Represents the relative path to the root of the documentation.	JavaDoc 1.3	Reference
<@inherit-Doc>	Copies the documentation from the nearest inherited code structure.	JavaDoc 1.4	Reference
<@link>	Links to another part of the documentation (i.e., code structure) as the @see tag but stays inline with the text and is formated as “code.”	JavaDoc 1.2	Reference
<@linkPlain>	Identical to <@link> but is displayed in normal text format (i.e., not code format).	JavaDoc 1.4	Reference
<@literal>	Displays text without interpreting it as HTML or nested JavaDoc.	JavaDoc 1.5	Format
<@value>	The value of a local static field or of the specified constant in another code.	JavaDoc 1.4	Reference

Table 2. Refactoring tags by Roock et al. (2002)

Tag	Description
@past	Describes the previous version of the signature.
@future	Describes the future signature of the element.
@paramDef	States the default value expected for a parameter. The syntax is @paramDef <parameter> = <value>.
@default	Defines the default implementation of an abstract method.

Table 3. Pattern tags by Torchiano (2002)

Tag	Description
@pat.name	States the standard name of the pattern as defined in (Gamma, Richard, Johnson, & Vlissides, 1994) (and other).
<@pat.role>	Inline-tag of pat.name that describes the part of the pattern that is represented by this element (e.g., “Leaf” in a composite pattern).
@pat.task	Describes the task performed by the pattern or its role.
@pat.use	Describes the use of the pattern or a role, typically by a method.

Table 4. Other tags

Tag	Description
@contract	Defines bounds of a parameter (or other value). Syntax is “@contract <requires> <min> <= <parameter> <= <max>.”
@inv, @invariant	States an invariant. Syntax is “@inv <boolean expression>.”
@pre	States the precondition for a method.
@post	States the postcondition for a method. This includes information about side effects (e.g., changes to global variables, fields in an object, changes to a parameter, and return values (except if stated in @return).
@issue	Indicates a new requirement or feature that could be implemented. Syntax is @issue [description ...].
@reviewedBy	Indicates a code review for the associated class/interface was completed by a reviewer. Syntax is @reviewedby <name> <date> [notes ...].
@license	Indicates the copyright license used for this code fragment. Syntax is @license [description ...].
@category	Annotates the element with a free attribute / category. @category <category>.
@example	@example <description>.
@tutorial	Link to a tutorial.
@index	Defines the text that should appear in the index created by JavaDoc.
@exclude	States that this element should not be included in the API by the JavaDoc command.
@todo	Indicates that further work has to be done on this element.
@internal	Comments to this element that are internal to the developer or company.
@obsolete	Used if deprecated elements are actually removed from the API.
@threadSafe	Indicates whether this element is threadsafe.
@pattern	Formally describes a pattern existence with the syntax @pattern <pattern name>.<instance name> <role name> <text>.
@aspect	Describes an aspect existence with the syntax @aspect <name> <text>.
@trace	Describes a pattern existence with the syntax @trace <name> <text>.

Table 5. Annotation languages in comparison

Language	Extension	# of Tags	Test Info	Inspection Info	Pattern Info	Refactoring Info
JavaDoc 1.5	Standard	19	No	No	No	No
	Roock et al.	5	Semi-Formal (1)	No	No	Informal (4)
	Torchiano	10	No	No	Semi-Formal (3)	No
	Sametinger et al.	3	No	No	Informal (3)	No
	Tullmann	4	No	Informal (1)	No	No
	Kramer	3	Informal (3)	No	No	No
	JSR-260	9	No	No	No	No

To note the existence of patterns in a software system as well as the task and role as described in the pattern definitions, several tags were developed by Torchiano (2002) and are listed in 0.

Furthermore, several other groups of annotations exist for various purposes. The following tags are from Roock et al. (2002) (@contract), Kramer (1998) (@inv, @pre, @post), Tullmann (2002) (@issue, @todo, @reviewedBy, @license), Sametinger et al. (2002) (@pattern, @aspect, @trace), and JSR-260 (2005) (@category, @example, @tutorial, @index, @exclude, @todo, @internal, @obsolete, @threadSafe).

The characteristics of source code annotation languages can be differentiated by the number of tags and the formality of their expressiveness. We differentiate between three categories of formality:

1. **Formal:** An explicit and unambiguous specification of the content. A formal tag might include an informal section like a description or note to the formal part (e.g., the tag "param" in JavaDoc has an informal part to describe the meaning of the parameter). In particular, the formal part of a tag must be processable by a computer.
2. **Semi-formal:** A structured or formal representation that is ambiguous or not directly processable by a computer.
3. **Informal:** An unstructured and possibly ambiguous specification of content.

In summary, the tags used in JavaDoc and its extensions can be used to describe characteristics of the source code on a relatively granular or semi-formal level. The processing of these annotations can be used to generate API documentations with additional information about patterns, aspects, or signature changes. The recording of quality defects discovered and refactorings applied as well as rationales or experiences about their application can only be accomplished using free text in the API description.

Furthermore, these annotation languages and their extensions have different target areas in the field of software quality assurance in order to store information about tests, inspections, patterns, and refactorings. 0 shows a comparison of several annotation languages in relevant areas.

Quality Defects and Quality Defect Discovery

The main concern of software quality assurance (SQA) is the efficient and effective development of large, reliable, and high-quality software systems. In agile software development, organizations use techniques like refactoring to tackle "bad smells in code" (Beck et al., 1999), which reduce software

qualities such as maintainability, changeability, or reusability. Other groups of defects that do not attack functional, but rather non-functional aspects of a software system are architecture smells (Roock & Lippert, 2004), anti-patterns (Brown et al., 1998), design flaws (Riel, 1996; Whitmire, 1997), and software anomalies in general (IEEE-1044, 1995).

In this chapter, we use the umbrella term *quality defects* (QD) for any defect in software systems that has an effect on software quality (e.g., as defined in ISO 9126), but does not directly affect functionality. Whether the quality defect is automatically discoverable (Dromey, 1996, 2003) or not (Lauesen & Younessi, 1998), an annotation language and method that can be used to support the handling of quality defects should record information about quality characteristics and quality defects in order to represent their status and treatment history. This section will elaborate on this concept and describe several quality defects, their interrelation, symptoms, and effects.

Today, various forms of quality defects exist with different types of granularity. Some target problems in methods and classes, while others describe problems on the architecture or even process levels. In this chapter, we only focus on quality defects on the code level. The representatives on this level are:

- **Code Smells:** The term code smell is an abbreviation of "bad smells in code," which were described in Beck et al. (1999). Today, we have many code smells that are semi-formally described and can be used for manual inspection and discovery. There are at least 38 known code smells with 22 in Fowler (1999), 9 new ones in Wake (2003), 5 new ones in Kerievsky (2005), and 2 in Tourwe and Mens (2003). Code smells are indicators for refactoring and typically include a set of alternative refactoring activities in their description, which might be used to remove them.
- **Architectural Smells:** Very similar to code smells are architectural smells that describe problems on the design level. Yet, the 31 architectural smells described in Roock et al. (2005) do not only apply on the design level but also on the code level. They typically describe problems regarding classes in object-oriented software and interrelations between them.
- **Anti-Patterns:** Design patterns (Gamma et al., 1994) and anti-patterns (Brown et al., 1998) represent typical and reoccurring patterns of good and bad software architectures and were the start of the description of many patterns in diverse software phases and products. While patterns typically state and emphasize a single solution to multiple problems, anti-patterns typically state and emphasize a single problem to multiple solutions. An anti-pattern is a general, proven, and non-beneficial problem (i.e., bad solution) in a software product or process. It strongly classifies the problem that exhibits negative consequences and provides a solution. Built upon similar experiences, these anti-patterns represent "worst-practices" about how to structure or build a software architecture. An example is the "lava flow" anti-pattern, which warns about developing a software system without stopping sometimes and reengineering the system. The larger and older such a software system gets, the more dead code and solidified (bad) decisions it carries along.
- **Bug Patterns:** These patterns are concerned with functional aspects that are typically found in debugging and testing activities. In Allen (2002), 15 bug patterns are described, which describe underlying bugs in a software system.
- **Design Flaws and (Negative) Design Characteristics:** Whitmire (1997) describes nine distinct and measurable characteristics of an object-oriented design. These characteristics

such as "similarity" describe the degree to which two or more classes or domain-level abstractions are similar in terms of their structure, function, behavior, or purpose.

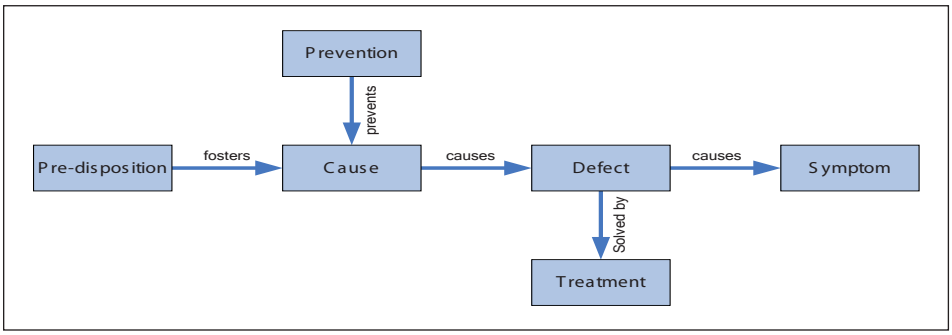
- **Design Heuristics:** Design heuristics provide support on how to construct software systems and, in a way, define quality defects by their absence. They range from the "information hiding" principle to guidelines such as "Eliminate irrelevant classes from your design." There are 61 design heuristics described in Riel (1996) and 14 principles described in Roock et al. (2005).

As listed, there are many quality defects of various granularities and they are described in different forms. To give a more concrete idea of quality, we describe two of them in the following:

1. **Long Method:** In object-oriented programming, one should pay attention to the fact that methods are not too long. The longer a method, the more difficult it is to be understood by a developer. Comprehensibility and readability are negatively affected by the length of a method and thus negatively affect maintainability and testability. Moreover, a short understandable method typically needs less comments than a long one. Another advantage of short methods is the fact that a developer does not constantly scroll and break his reading flow. The most obvious method for discovering long methods is the metric number of lines (LOC) per method. But the question of which method is too long and constitutes a problem is not easily answered. This must either be specified or found by detecting anomalies from the standard distribution. Nevertheless, a method exceeding this threshold value must not necessarily be shortened if other, more important, quality constraints would be negatively affected.
2. **Shotgun Surgery:** This denotes the problem that several classes are always changed in the same group, for example, if the system is adapted to a new database scheme and the same two classes are changed each time. The expandability of the system is thus constrained, and if one class is forgotten during a change, it is more likely to fail. The discovery of shotgun surgery is very difficulty and requires either change metrics or specified rules.

While these problems might not represent problems that have a directly tangible effect on quality, they might become problematic in future evolution or refactoring activities and should be

Figure 2. Conceptual model of the quality defect ontology (software product level)



removed as fast as possible—if the time is available. These are only two of many described quality defects. Nevertheless, they show that quality defects describe problems on different levels of complexity and might occur in parallel in one situation (i.e., in one code fragment).

0 depicts the general model for the concepts that are used to describe quality defects and that are linked to them. A software system might have *predispositions* that foster or enable the creation of quality defects. These defects themselves have *causes* that are responsible for the defects being integrated into the system. The quality *defects* might have a negative as well as a positive effect on specific qualities and are perceivable via specific *symptoms*. Finally, the defects are solved or removed via specific treatments after they are discovered, or the causes might be prevented by special preventive measures.

In software engineering (SE) and especially in the case of quality defects for a software product, the context of a defect can be described as listed in 0.

In the example on the right side, the predisposition "bad architecture" causes a "cluttered functionality," which results in a "shotgun surgery" defect. This quality defect can be discovered by the symptom of "recurring changes to the same set of software units" and might be removed by the "inline class" refactoring. A prevention of this problem would be a "good" systematic architecture with clear separation of functionality (e.g., in the form of a pattern-based architecture).

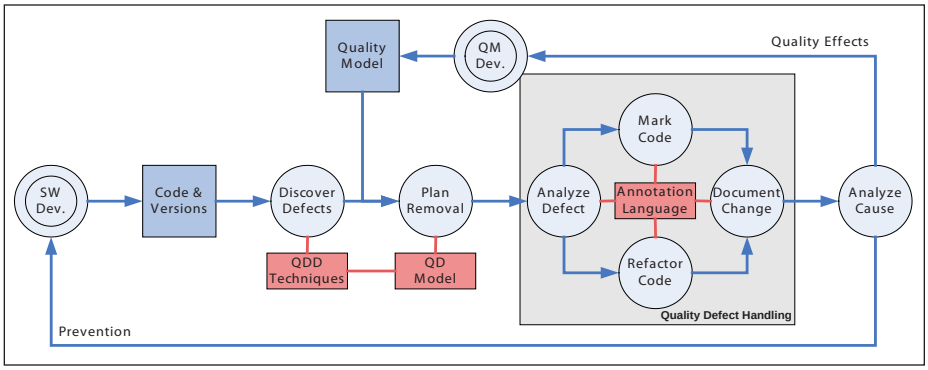
Handling of Quality Defects

Typically, during agile development with short iterations, several quality defects are introduced

Table 6. Examples for software engineering techniques

	Example 1	Example 2
Predisposition	Data processing system	Lack of good architecture/design
Cause	Large data processing algorithms	Distributed functionality
Defect	"Long method"	"Shotgun surgery"
Side-effects of defect	Increase analyzability effort	Increased maintenance effort
Symptom	Many lines of code	Recurrent changes to the same units
Treatment	Extract method	Inline class(es)
Side-effects of treatment	Increased subroutine calls (worsens performance)	Divergent change
Prevention	Optimize algorithm (phase)	Pattern-based architecture

Figure 3. The quality defect discovery and handling process model



into the software system and are discovered especially in the refactoring phase. To facilitate the annotation of source code and the processing of quality defect removal, a mechanism to store the information from the QDD process is required.

The Handling Process

In the following, the general process of quality defect discovery and refactoring is depicted. 0 shows the process model that is either initiated during software development or during a special maintenance (resp. refactoring) activity.

In the execution of the process, the following sub-processes are performed:

- **Discover Defects:** Manual or automatic quality defect discovery techniques are used to analyze the source code and versions thereof from the software repository. Potential quality defects are identified and the affected code (of the most current version) is annotated.
- **Plan Removal:** Based on the discovered quality defects (annotated with a special tag) and a previously defined quality model, a sequential plan for the refactoring of the software system (or part thereof) is constructed.
- **Analyze Defects:** The software engineer processes the list of potential quality defects based on their priority, analyzes the affected software system (or part thereof), and decides if the quality defect is truly present and if the software system can be modified without creating too many new quality defects.
- **Refactor Code:** If the quality defect is to be removed from the software system, the engineer is briefed about the existing quality defects and their rationales as well as about available refactorings, their impact on software quality, and previously made experiences with the kind of quality defect and refactoring at hand.
- **Mark Code:** If a potential quality defect is unavoidable or its removal would have a negative impact on an important quality (e.g., performance), this decision is recorded in the affected part of the software system to prevent future analysis of this part.
- **Document Change:** After the refactoring or marking, the software system is annotated with specific tags about the change or decision, and the experience about the activity is recorded within an experience database (i.e., a database in an experience factory (Basili, Caldiera, & Rombach, 1994b) for storing, formalizing, and generalizing experiences about software development and refactoring activities (e.g., to construct defect patterns from multiple similar defect descriptions)).
- **Analyze Cause:** Statistics, information, and experiences about the existence of quality defects in the software systems are fed back into the early phases of the software development process to prevent or at least reduce their reoccurrence. Preventive measures include, for example, software requirement inspections or goal-oriented training of employees. Furthermore, information about dependencies between qualities, quality defects, and refactorings are fed back into the quality model development process in order to continuously improve the techniques for quality model development.

Decision Support in Handling

In order to support decisions about what to refactor in a software system, we developed several methods and techniques. The following questions act as the guiding theme for the development and enactment of decision-making (i.e., the “plan removal” or “refactor code” phase) as well as

understanding (i.e., the "analyze defect" or "document change" phase) in refactoring phases:

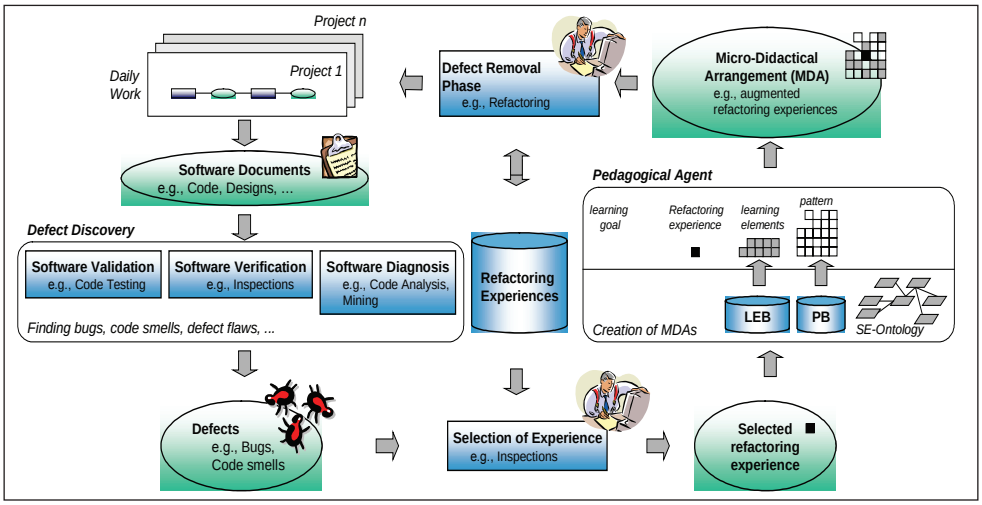
- **Decision problem 1:** Which quality defects should be refactored and which might stay in the system?
- **Decision problem 2:** In which sequence should one refactor multiple quality defects in order to minimize effort?
- **Comprehension problem 1:** How does one understand and detect the quality defect in the concrete situation?
- **Comprehension problem 2:** How does one understand the refactoring in the concrete situation and its effect on the software system?
- **Decision problem 3:** Which refactoring should one use if multiple ones are available?
- **Comprehension problem 3:** Which information should one record after refactoring or marking for later evolution, maintenance, or reengineering activities?
- **Decision problem 4:** Did the understanding of the problem or the refactoring result in valuable experience that should be recorded to support later activities (possibly by others)?
- **Comprehension problem 5:** How should one record the experience?

Decision Support in Software Refactoring

Our approach encompasses several methods for supporting the decision of where, when, and in what sequence to refactor a software system as depicted in 0. Beginning from the left upper corner and going counterclockwise, knowledge about quality defects from defect discovery processes is used to retrieve experiences associated with similar defects from previous refactorings. These experiences are used to handle quality defects in the defect removal phase. Additionally, suitable experiences are augmented by so-called micro-didactical arrangements (MDA) (Ras, Avram, Waterson, & Weibelzahl, 2005), which initiate learning processes and aim at improving the understandability, applicability, and adaptability of the experience in the specific context.

As shown in 0, we define six phases, based on the quality improvement paradigm (QIP) (Basili,

Figure 4. Experience-based semi-automatic reuse of refactoring experiences



Caldiera, & Rombach, 1994a), for the continuous handling of quality defects. In contrast to the quality defect handling process as depicted in 0, these phases are not concerned with quality defects in a specific product, but with the learning process about the quality defects themselves and their effect on the software qualities. 0 represents the realizations of phase 2 ("discover defect"), phase 3 ("plan removal"), and phase 4 (the "quality defect handling" block).

In 0, we first start with the definition of the quality model consisting of qualities that should be monitored and improved. For example, this may result in different goals (i.e., quality aspects), as reusability demands more flexibility or "openness," while maintainability requires more simplicity. Phase 2 is concerned with the measurement and preprocessing of the source code to build a basis for quality defect discovery (i.e., "discover defects"). Results from the discovery process (i.e., quality defects) are represented and prioritized to plan the refactoring in phase 3 (i.e., "plan removal"). Here, the responsible person has to decide which refactorings have to be executed (i.e., "analyze defect") in what configuration and sequence, in order to minimize work (e.g., change conflicts) and maximize the effect on a specific quality. In phase 4, the refactoring itself is (or is not) applied to the software system (i.e., "Refactor Code" or "Mark Code") by the developer, which results in an improved product. Phase 5 compares the improved product with the original product to detect changes and their impact on the remaining system (i.e., "analyze cause"). Finally, in phase 6, we document the experiences and data about the refactoring activity, changes to the software system, and other effects in order to learn from our work and continuously improve the model of relationships between quality, refactorings, and quality defects.

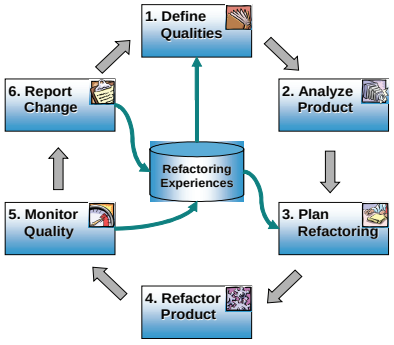
As indicated previously, the KDD sub-processes are grouped in phase 2. We select source code from a specific build, preprocess the code, and store the results in the code warehouse, analyze the data to discover quality defects, discover deviations from average behavior, cluster code blocks with severe or multiple quality defects, and represent discovered and prioritized quality defects to the user.

An Example of DS for QDD

For example, we may detect a method in an object-oriented software system that has a length of 300 LOC. As described in Fowler (1999), this is a code smell called long method. A long method is a problem especially in maintenance phases, as the responsible maintainer will have a hard time understanding the function of this method.

One suitable refactoring for the mentioned code smell might be the refactoring simply called extract method: the source code of the long method is reviewed to detect blocks that can be encapsulated into new (sub-)methods. Experiences with the extract method refactoring are used to support the decision on where, when, how, and if the refactoring has to been implemented. For example, the developer might remark that every block of code that has a common meaning, and could be commented respectively, could also be extracted into several smaller methods. Furthermore, the developer might note that the extraction of (sub-) methods, from methods implementing

Figure 5. Quality-driven refactoring



complex algorithms, can affect the performance requirements of the software system and therefore might not be applicable.

Additionally, the generation of new methods might create another smell called "large class" (i.e., the presence of too many methods in a class), which might complicate the case even further. Finally, the new experiences are annotated by the developer and stored in the refactoring experience base.

While this example only touches a simple quality defect and refactoring, more complex refactorings influence inheritance relations or introduce design patterns (Fowler, 1999).

An Annotation Language to Support Quality Defect Handling

This section describes, defines, and explains a language that will be used to annotate code fragments that are either contaminated by quality defects or checked by a software engineer and cleared of quality defects. As described in the background section, several annotation languages for the annotation of source code already exist that are not adequate. This new language is used to keep decisions about quality defects persistent and over time builds a "medical history" of the source code fragment (e.g., a class).

Goals and Characteristics of Annotation Languages

All annotation languages represent a basis for describing additional information about the software system directly at the code level. *Target groups* (or users) for the documentation/annotation language are:

- **Developers,** who want to use the source code and acquire information via the API descriptions (e.g., for software libraries).
- **Testers,** who want to develop test cases and need information about the pre- and post-conditions as well as the functionality to be tested.
- **Maintainers,** who want to evolve the system and need information about existing quality defects, rationales for their persistence (e.g., refactoring would cause loss of performance), or past refactorings (e.g., to update the software documentation such as design documents).

In our case, an annotation language that is targeted at supporting the handling of quality defects should encompass several key aspects. The requirements for such an annotation language should cover uses such as:

- **Annotate change** for later understanding by the same and other readers (e.g., maintainers).
- **Mark fragment** that a quality defect is detected but can or must stay in the system.
- **Note membership** in a larger quality defect or refactoring activity that encompassed multiple code fragments for later impact analyses.
- **Annotate quality aspects** for later reuse, etc.
- **Tag additional information** in the code fragment freely or based on a classification (e.g., "problematic class," "quicksort algorithm," "part of subsystem X") to support later reuse or maintenance/reengineering activities (similar to social software or Web 2.0 approaches).

We identified the following information blocks of an annotation language that should be recorded with an annotation language and that are based on the six knowledge types from knowledge management (Mason, 2005):

- **Know-what:** Record the currently present *quality defects* that were found manually or automatically.

- **Know-how:** Record the *transformation history* (similar to the medical history of a human patient).
- **Know-why:** Record the *rationales* why a refactoring was applied or why a quality defect is still present in order to prevent recurrent defect analysis or refactoring attempts.
- **Know-where:** Record the *location* in the annotated code as well as associated code fragments that where changed as well.
- **Know-who:** Record the tool or *person* (i.e., developer or maintainer) who applied the refactoring.
- **Know-when:** Record the time or *version* when the quality defect was found or the refactoring was applied. This could also be used to define a trigger when a refactoring has to be applied (e.g., if several other (larger) refactorings or design decision have to be made).
- **Context:** Record the frame of reference or context in which the quality defect was discovered. This includes especially the quality model used to decide which quality defect has a higher priority over other quality defects.

The following requirements for tags and other constructs in such an annotation language to support refactoring and maintenance activities are:

- **Unambiguous:** The names of tags, quality defects, refactorings, or other reoccurring terms should be unique and used consistently throughout the system.
- **Machine-readable:** The syntax of tags should be formal, exact, and consistent to avoid confusion and enable the interpretation and usage by supporting systems (e.g., defect discovery tools).
- **Local completeness:** The power of the syntax should be large enough to cover all existing cases. Full comprehensiveness is probably not possible except by allowing informal free text attributes.
- **Flexibility:** The syntax should not limit the extension by new tags or tag attributes.
- **Independence:** Tags should describe information that is mutually exclusive, and the occurrence of two or more tags should be independent from one another.

Beside the additional documentation of the software system, the annotation language will increase the semantic coupling between code fragments and reduce the presence of quality defects such as “shotgun surgery.”

RAL: The Refactoring Annotation Language

The refactoring annotation language (RAL) is used to record the currently existing quality characteristics, symptoms, defects, and refactoring of a code fragment regarding a specific quality model. Furthermore, it is used to store the rationales and treatment history (e.g., sequence of refactorings).

In the following tables, the core set of tags from RAL are described based on the JavaDoc syntax and using existing JavaDoc and supportive tags, that are used in the description and will be described after the core tags. Information blocks starting with a double cross “#” indicate an ID or standardized term from an external, controlled vocabulary or taxonomy.

A symptom tag as defined in 0 describes a metric or characteristic of the code fragment and is used as an indicator for the statistical or rule-based identification of quality defects. The tag acts as an annotation of a specific symptom from a controlled vocabulary in order to have a unique identifier and a reference for further information about the symptom. The since tag from JavaDoc is used to identify the version based on which the quality symptom was first calculated.

The quality defect as defined in 0 represents a code smell, antipattern, etc. present in this code

Table 7. The @symptom tag

Tag Syntax	@symptom <#Symptom-ID> <@value value> <@since #version>
Example	@symptom “LOC” @value “732” @since 1.2

Table 8. The @defect tag

Tag Syntax	@defect <#QD-ID> <@since #version> <@status #Status> <@rationale text>
Example	@defect “Long Method” @since 1.2 @status “untreated”

Table 9. The @refactoring tag

Tag Syntax	@refactoring <#Refactoring-ID> <@rationale text> <@status #Status> <@link fragment> <@ author name>
Example	@refactoring “Extract Method” “Applied as quality model rates maintainability higher than performance” @status “treated” @link “ExtractedMethod” @author “John Doe”

Table 10. The @quality-model tag

Tag Syntax:	@quality-model Name <@see file>
Example	@quality-model “QM-Dep1-Project2” @see <A href=http://www.sw-quality.de/QM-Dep1-Project2.pdf>

Table 11. Support tags

Tag	Description
@status	“@status #status” indicates the current status of the superior tag or source code using the vocabulary “discovered,” “inWork,” “treated,” or (deliberately) “untreated.”
@rationale	“@rationale text” declares a rationale about the existence or status of the superior tag or source code.

fragment. It is used to annotate a specific quality defect from a controlled vocabulary in order to have a unique identifier and reference for more information about a specific quality defect type and potential treatments. The since tag from JavaDoc is used to identify the version where the quality defect was first noticed.

A refactoring tag as defined in 0 is a description of a single refactoring that was applied for removing one or more quality defects. Optionally, a project-internal URI to other code fragments directly affected by the refactoring (e.g., if two classes interchange a method during the same refactoring) can be stated.

The quality model tag as defined in 0 is used as a reference to the quality model that defines which quality characteristics are important, what priority or decision model lies beneath, and which quality defects are relevant to a specific part of the software system. Optionally, it refers to a URI of a file containing the specific (machine-readable) quality model.

The supportive tags used in the previous tag descriptions are given in 0.

Depending on the processor that would render a quality documentation from these tags, some tags might be used only once and inherited by lower levels. For example, the quality model tag needs only be stated once (e.g., for the whole project) or twice (e.g., for the client and server part) in a software system.

RAL is primarily used to annotate source code. Therefore, in order to annotate documents of higher abstraction, like UML-based design

documents (e.g., platform-independent models in MDA) using the XMI Format or formal requirement documents, similar languages (probably based on other languages such as JavaDoc) need to be defined.

Handling Quality Defects Using RAL

Software annotation languages like JavaDoc or Doxygen and extensions like RAL can now be used to document the functionality, structure, quality, and treatment history of the software system at the code level. The formal basis of the language enables tools to read and write this information automatically to generate special documents or trigger specific actions.

The core tags `@symptom`, `@defect`, and `@refactoring` build on top of each other and might be recorded by several different tools. This enables the intertwined cooperation of different tools, each with a specific focus, such as to calculate metrics or to discover quality defects. For example, one tool might measure the source code and its versions to extract numerical and historical information and write it into `@symptom` tags (e.g., lines of code). Another tool might analyze this information to infer quality defects (e.g., "long method") that are recorded in `@defect` tags. Finally, a tool might offer refactorings to a developer or a maintainer during his work and note applied refactorings or rationales in explicit `@refactoring` tags.

Developers and maintainers of a software system are supported in the handling of quality defects in the following activities:

- Repetitive refactoring of a specific kind of quality defect (e.g., "large method"), as they do not have to switch between different defects or refactoring concepts.
- Reuse of knowledge about the refactoring of specific quality defects to judge new quality defects.
- Recapitulation of the change history of the code fragment to update software documentation such as design documents.
- Retrieval of information about persons who developed or refactored this part of the system and should know about its purpose and functionality.
- Product or quality managers of the software system might use the information to:
- Evaluate the quality based on information extracted via the tags about the amount or distribution of quality defects.
- Analyze specific dates or groups of persons that might have introduced specific kinds of quality defects and might need further training.

SUMMARY AND OUTLOOK

Agile software development methods were invented to minimize the risk of developing low-quality software systems with rigid process-based methods. They impose as little overhead as possible in order to develop software as fast as possible and with continuous feedback from the customers. To assure quality, agile software development organizations use activities such as refactoring between development iterations. *Refactoring*, or the restructuring of a software system without changing its behavior, is necessary to remove *quality defects* (i.e., bad smells in code, architecture smells, anti-patterns, design flaws, software anomalies, etc.) that are introduced by quick and often unsystematic development. However, the effort for the manual discovery of these quality defects results in either incomplete or costly refactoring phases. Furthermore, software quality assurance methods seem to ignore their recurring application.

In this chapter, we described a process for the recurring and sustainable discovery, handling, and treatment of quality defects in software systems.

We described the complexity of the discovery and handling of quality defects in object-oriented source code to support the software refactoring process. Based on the formal definition of quality defects, we gave examples of how to support the recurring and sustainable handling of quality defects. The annotation language presented is used to store information about quality defects found in source code and represents the defect and treatment history of a part of a software system. The process and annotation language can not only be used to support quality defect discovery processes, but also has the potential to be applied in testing and inspection processes.

Recapitulating, we specified an annotation language that can be used in agile software maintenance and refactoring to record information about quality defects, refactorings, and rationales about them. Similar annotation languages such as JavaDoc or doxygen as well as third party extensions are not able to encode this information in a machine-readable and unambiguous format.

The proposed framework including the handling process promises systematic and semi-automatic support of refactoring activities for developers, maintainers, and quality managers. The approach for recording quality defects and code transformations in order to monitor refactoring activities will make maintenance activities simpler and increase overall software quality. Likewise, the user monitors daily builds of the software to detect code smells, identical quality defects, or groups thereof, and initiates repetitive refactoring activities, minimizing effort caused by task switches.

REQUIREMENTS FOR QUALITY DEFECT HANDLING IN AGILE SE

When building systems and languages for quality defect handling in agile software development, several requirements should be kept in mind.

The annotation language in the form of a code annotation language like JavaDoc or in the form of an external documentation such as a Defect Tracking system or a Wiki should be integrated into the programming language used and into the development environment. If it is not integrated, the information might easily be lost due to the high workload and time constraints in agile development. Especially in an agile environment, the developers, testers, and maintainers should be burdened with as little additional effort as possible.

Therefore, the more formal the descriptions of an annotation language are and the more information can be extracted from the code and development environment (e.g., from the refactoring techniques), the less information is required from the developers.

OUTLOOK

The trend in research is to increase automation of the mentioned processes in order to support the developers with automated refactoring or defect discovery systems.

We expect to further assist software engineers and managers in their work and in decision making. One current research task is the development of taglets and doclets to generate specific evolution documents. Furthermore, we are working on the analysis and synthesis of discovery techniques with statistical and analytical methods based on textual, structural, numerical, and historical information.

Although we can record and use this information in several applications, we currently do not know if the amount of information might overwhelm or annoy the developer and maintainer. If dozens of quality defects are found and additional refactorings are recorded, this might be confusing and should be hidden (e.g., in an editor of the IDE) from the developer. Very old

information (e.g., from previous releases of the software) might even be removed and stored in an external document or database.

Chapter 1.21
Different Views of Software Quality

Bernard Wong
University of Technology Sydney, Australia

ABSTRACT

This chapter examines the different definitions of quality and compares the different models and frameworks for software quality evaluation. It will look at both historical and current literature. The chapter will give special attention to recent research on the Software Evaluation Framework, a framework for software evaluation, which gives the rationale for the choice of characteristics used in software quality evaluation, supplies the underpinning explanation for the multiple views of quality, and describes the areas of motivation behind software quality evaluation. The framework has its theoretical foundations on value-chain models, found in the disciplines of cognitive psychology and consumer research, and introduces the use of cognitive structures as a means of describing the many definitions of quality. The author hopes that this chapter will give researchers and practitioners a better understanding of the different views of software quality, why there are differences, and how to represent these differences.

INTRODUCTION

Adopting an appropriate Quality Assurance philosophy has been often viewed as the means of improving productivity and software quality (Hatton, 1993; Myers, 1993). However unless quality is defined, it is very difficult for an organization to know whether it has achieved quality clearly. To date, this has usually involved conformance to a standard such as AS3563 or ISO9001 or following the Capability Maturity Model of the SEI. The challenge often faced is that one finds as many definitions of quality as writers on the subject. Perhaps, the latter have been remarkably few in number considering the obvious importance of the concept and the frequent appearance of the term quality in everyday language.

Though the topic of software quality has been around for decades, software product quality research is still relatively immature, and today it is still difficult for a user to compare software quality across products. Researchers are still not clear as to what is a good measure of software

quality because of the variety of interpretations of the meaning of quality, of the meanings of terms to describe its aspects, of criteria for including or excluding aspects in a model of software, and of the degree to which software development procedures should be included in the definition. A particularly important distinction is between what represents quality for the user and what represents quality for the developer of a software product.

Perceptions of software quality are generally formed on the basis of an array of cues. Most notably, these cues include product characteristics (Boehm et al., 1976; Carpenter & Murine, 1984; Cavano & McCall, 1978; McCall et al., 1977; Kitchenham & Pfleeger, 1996; Kitchenham & Walker, 1986; Sunazuka et al., 1985). The cues are often categorized as either extrinsic or intrinsic to the perceived quality. Simply, intrinsic cues refer to product characteristics that cannot be changed or manipulated without also changing the physical characteristics of the product itself; extrinsic cues are characteristics that are not part of the product (Olson & Jacoby, 1972). Price and brand are thus considered to be extrinsic with respect to product quality.

This chapter examines the different definitions of quality and compares the different models and frameworks for software quality evaluation. This chapter will address both the topics of interest for the information systems community and the software engineering community. It will look at both historical and current literature. The chapter will give special attention to recent research on the Software Evaluation Framework, a framework for software evaluation, which gives the rationale for the choice of characteristics used in software quality evaluation, supplies the underpinning explanation for the multiple views of quality, and describes the areas of motivation behind software quality evaluation. The framework has its theoretical foundations on value-chain models, found in the disciplines of cognitive psychology and consumer research, and introduces the use of cognitive structures as a means of describing the many definitions of quality.

BACKGROUND

Software users today are demanding higher quality than ever before, and many of them are willing to pay a higher price for better quality software products. The issue of software quality has come to the forefront in Europe, the United Kingdom, the United States, and more recently Australia. The quality movement in software is not new. A search of the information systems literature has shown that attempts to achieve quality software have been on-going for many years. Software quality models include the product-based view (Boehm et al., 1976; Carpenter & Murine, 1984; Cavano & McCall, 1978; McCall et al., 1977; Kitchenham & Pfleeger, 1996; Kitchenham & Walker, 1986; Sunazuka et al., 1985), process focused models following a manufacturing-based view (Coallier, 1994; Dowson, 1993; Humphrey, 1988; Ould, 1992; Paulk, 1991), and more recently, techniques and tools to cater for the user-based view (Delen & Rijsenbrij, 1992; Erikkson & McFadden, 1993; Juliff, 1994; Kitchenham, 1987; Kitchenham & Pickard, 1987; Thompsett, 1993; Vidgen et al., 1994). However, the many models and approaches seem to contradict each other at times. Garvin (1984) tries to explain these contradictions by introducing different views of quality. He describes the models as transcendental-based view, product-based view, manufacturing-based view, economic-based view, and user-based view, which we will define later.

As the software market matures, users want to be assured of quality. They no longer accept the claims of the IT department at face value, but expect demonstrations of quality. There is a firm belief that an effective quality system leads to increased productivity and permanently reduced costs, because it enables management

to reduce defect correction costs by emphasizing prevention. A better-designed development process will accrue fewer lifetime costs, and higher productivity will therefore be possible. As such, many attempts at improving quality have been to focus on the development processes. However, productivity measurements are worthless unless they are substantiated by quality measurements. To develop software quickly, on time, and within budget is no good if the product developed is full of defects. It is the view of many that the costs of correcting defects in software late in development can be orders of magnitude greater than the cost of correcting them early (Kitchenham & Pfleeger, 1996; Pfleeger, 2001). Preventing defects in the first place can save even more. Productivity measurements require quality measurements.

The market for software is increasingly a global one, and organizations will find it increasingly difficult to succeed and compete in that market unless they produce and are seen to produce quality products and services. From simple issues concerning efforts required to develop software systems, there have been a myriad of developments and directions that have occurred since the beginning of the last decade concerning the process of software development. From all of these new directions, the consideration of the quality of the software produced is one of the major thrusts that have occurred. Software used to be a technical business, in which functionality was the key determinant of success. Today, one can no longer just adopt this view.

THE MEANING OF QUALITY

The Oxford English Dictionary (OED, 1990) states that quality is the "degree of excellence." While this definition of quality is found in an internationally accepted dictionary, it must be pointed out that there are many variations to this definition, which are not given here.

A formal definition of quality is provided by the International Standards Organization (ISO, 1986): *The totality of features and characteristics of a product or service that bear on its ability to satisfy specified or implied needs.*

This standard definition associates quality with the products' or services' ability to fulfill its function. It recognizes that this is achieved through the features and characteristics of the product. Quality is associated both with having the required range of attributes and with achieving satisfactory performance in each attribute.

The best-known and most widely adopted definition of quality is simply "fitness for use" or some variant thereof. For example, Wimmer (1975) and Genth (1981) adopted the definition "fitness for use." Box (1984) defined quality as "the degree to which a product fulfils its functions, given the needs of the consumer," and Kotler (1984) speaks of "the rated ability of the brand to perform its functions as perceived by consumers." Kawlath (1969) defined perceived quality as "the fitness for certain goals."

Maynes (1976) proposed the following definition: "The quality of a specimen (a product/brand/seller/combination) consists of the extent to which the specimen provides the service characteristics that the individual consumer desires." A similar definition is suggested by Monroe and Krishnan (1985): "Perceived product quality is the perceived ability of a product to provide satisfaction relative to the available alternatives." Kuehn and Day (1962) stated that the quality of a product depends on how well it fits in with patterns of consumer preferences.

Kupsch and Hufschmied (1978) regarded quality as a bundle of need-satisfying attributes. A similar position was taken by Oxenfeldt (1950). Bockenhoff and Hamm (1983) defined quality as the composite of all product attributes irrespective of whether these attributes are in reality existent in the product and objectively measurable, and whether consumers are correct in their evaluations.

Thurstone (1985) suggested: "Quality is the index that reflects the extent to which the customer feels that his need, the product, and his expectations for that product overlap." He concluded that the relevant measure of quality does not reside in the product but in the customer. A similar position is taken by Wolff (1986) who argued that quality should be measured from the customer's perspective: "If the customer says it's good, it's good; if he says it's bad, it's bad."

Trenkle (1983) distinguished three manifestations of quality:

- neutral concept (i.e., "much quality" - "not much quality"), defined as the nature of a product, given by the whole of all the attributes which discriminates the product from the other products in the same category;
- evaluative concept ("good quality" - "bad quality"), defined as the fitness for use of a product, given by the whole of all the attributes that are relevant to the evaluation of the product;
- positive judgment ("quality products"), defined as superior or excellent with respect to all attributes.

Some researchers have followed Wittgenstein's (1953) linguistic approach that "the meaning of a word is its use in the language" and explored the word quality in terms of everyday use of the term. For instance, quality often means reliability, general approval, or general excellence in the eyes of the consumers (Holbrook & Corfman, 1983). The ordinary language approach, however, does not get one very far conceptually with respect to the meaning of perceived quality.

The Different Perspectives of Quality

There are numerous definitions and meanings given to quality. The previous section lists some of the popular definitions; however, they do not necessarily describe the perceptions of quality held by all individuals. David Garvin (1984) concluded in his paper "that quality is a complex and multifaceted concept." He described quality as being made up of five different perspectives — the transcendental-based view, the product-based view, the manufacturing-based view, the economics-based view, and the user-based view.

Transcendental-Based View

According to the transcendental-based view, quality is synonymous with "innate excellence." It is both absolute and universally recognizable, a mark of uncompromising standards and high achievement. Nevertheless, proponents of this view claim that quality cannot be defined precisely; rather, it is a simple, not analyzable property that we learn to recognize only through experience. This definition borrows heavily from Plato's discussion of beauty, where he argues that beauty is one of the "platonic forms," and, therefore, a term that cannot be defined. Like other such terms that philosophers consider to be "logically primitive," beauty (and perhaps quality as well) can be understood only after one is exposed to a succession of objects that display its characteristics.

Product-Based View

Product-based definitions are quite different; they view quality as a precise and measurable variable. According to this view, differences in quality reflect differences in the quantity of some ingredient or attribute possessed by a product. For example, high quality ice cream has high butterfat content, just as fine rugs have a large number of knots per square inch. This approach lends a vertical or hierarchical dimension to quality, for goods can be ranked according to the amount of the desired attribute they possess. However, an unambiguous ranking is possible only if virtually all buyers consider the attributes in question preferable.

Product-based definitions of quality first appeared in the economics literature, where they were quickly incorporated into theoretical models. In fact, the early economic research on quality focused almost exclusively on durability, simply because it was so easily translated in the above framework. Since durable goods provide a stream of services over time, increased durability implies a longer stream of services — in effect, more of the good. With regard to software, durability can be understood as the length of time a piece of software is used in a live environment. Of course, one recognizes that the software may need upgrades from time to time, as products can require repairs or modifications. Quality differences could, therefore, be treated as differences in quantity, considerably simplifying the mathematics.

There are two obvious corollaries to this approach. First, higher quality can only be obtained at higher cost. Because quality reflects the quantity of attributes that a product produces, and because attributes are considered to be costly to produce, higher quality goods will be more expensive. Second, quality is viewed as an inherent characteristic of goods, rather than as something ascribed to them. Because quality reflects the presence or absence of measurable product attributes, it can be assessed objectively and is based on more than preferences alone.

User-Based View

Garvin (1984) states that the user-based definitions start from the opposite premise that quality "lies in the eyes of the beholder." Individual consumers are assumed to have different wants or needs, and those goods that best satisfy their preferences are those that they regard as having the highest quality. This is an idiosyncratic and personal view of quality and one that is highly subjective. In the marketing literature, it has led to the notion of "ideal points:" precise combinations of product attributes that provide the greatest satisfaction to a specified consumer; in the economics literature, to the view that quality differences are captured by shifts in a product's demand curve and in the operations management literature, to the concepts of "fitness for use." There are two problems in each of these concepts. The first is practical — how to aggregate widely varying individual preferences so that it leads to meaningful definitions of quality at the market level. The second is more fundamental — how to distinguish those product attributes that connote quality from those that simply maximize consumer satisfaction.

A more basic problem with the user-based view is its equation of quality with maximum satisfaction. While the two are related, they are by no means identical. A product that maximizes satisfaction is certainly preferable to one that meets fewer needs, but is it necessarily better as well? The implied equivalence often breaks down in practice. A consumer may enjoy a particular brand because of its unusual features, yet may still regard some other brand as being of higher quality. In the latter assessment, the product's objective characteristics are also considered.

Even perfectly objective characteristics, however, are open to varying interpretations. Today, durability is regarded as an important element of quality. Long-lived products are generally preferred to those that wear out more quickly. This was not always true until the late nineteenth century; durable goods were primarily possessions of the poor, for only wealthy individuals could afford delicate products that required frequent replacement or repair. The result was a long-standing association between durability and inferior quality, a view that changed only with the mass production of luxury items made possible by the Industrial Revolution.

Manufacturing-Based View

Manufacturing-based definitions focus on the supply side of the equation and are primarily concerned with engineering and manufactur-

ing practice. Virtually, all manufacturing-based definitions identify quality as "conformance to requirements." Once a design or a specification has been established, any deviation implies that the specification may not be complete. Excellence is equated with meeting specifications and with "making it right the first time."

While this approach recognizes the consumer's interest in quality, its primary focus is internal. Quality is defined in a manner that simplifies engineering and production control. On the design side, this has led to an emphasis on reliability engineering (Boehm, 1963; Garvin, 1984); on the manufacturing side, to an emphasis on statistical quality control (Garvin, 1984; Juran & Gryna, 1980). Both techniques are designed to weed out deviations early: the former, by analyzing a product's basic components, identifying possible failure modes, and then proposing alternative designs to enhance reliability; and the latter, by employing statistical techniques to discover when a production process is performing outside acceptable limits.

Each of these techniques is focused on the same end: cost reduction. According to the manufacturing-based approach, improvements in quality (which are equivalent to reductions in the number of deviations) lead to lower costs, for preventing defects is viewed as less expensive than repairing or reworking them (Crosby, 1978; Erikkson & McFadden, 1993; Garvin, 1984). Organizations are, therefore, assumed to be performing suboptimally: were they only to increase their expenditures on prevention and inspection — testing prototypes more carefully or weeding out a larger number of defective components before they become part of fully assembled units — they would find their rework, scrap, and warranty expenses falling by an even greater amount.

Economic-Based View

Economic-based definitions define quality in terms of costs and prices. According to this view, a quality product is one that provides performance at an acceptable price or conformance at an acceptable cost. Under this approach, a $500 running shoe, no matter how well constructed, could not be a quality product, for it would find few buyers.

Garvin shows how each of these views can be used to define product quality. Engineers who believe a product has set characteristics often adopt the product-based view. These characteristics are used as the measure of quality. The manufacturing-based view is adopted when one believes the quality development process determines a quality product. And more recently, many organizations have been certified with the Capability Maturity Model, CMM, or SPICE (Paulk, 1991; Paulk et al., 1993). Certification assesses the manufacturing process and is awarded on successfully having a quality management system in place. Economists who believe that price has a correlation with quality adopt the economics-based view. And lastly, the user-based view is the one which emphasizes that each individual will have his or her own perception of quality. Garvin (1984) states that most existing definitions of quality fall into one of these categories, be they conformance to specification, meeting user requirements, or best development practice.

In a more recent paper, Braa and Ogrim (1994) also tried to expand the definition of quality. Rather than just focusing on technical properties, they considered the functional and organizational aspects of quality. Five aspects of quality are introduced.

Technical Quality

Technical quality refers to a system's structure and performance. The technical quality of a computer system is the basis of its functionality — the computer must perform expected operations. However, there is no need for a technically excellent computer system; it is more important that it suits the work tasks it is supposed to support.

Use Quality

By use quality we mean quality as experienced by the users when working with the computer-based system. Use quality is difficult to specify in advance. It is often necessary to experiment with design models, such as prototypes, to express needs and claims (Greenbaum & Kyng, 1991). Throughout the specification and design activities, users and developers will then learn about the limitations and the possibilities of the computer system in use. Consequently, learning is an important factor in the specification process, as well as in design.

Aesthetic Quality

In many other disciplines, such as the car industry, or building industry, aesthetic quality is used to evaluate the quality of artifacts. The idea of aesthetics is usually related to physical objects. However, aesthetics can also be applied to immaterial objects, for example, the notion of elegant proofs in mathematics. However, the aesthetic perspective is almost always neglected in software development (Dahlborn & Mathiassen, 1993; Stolterman, 1991). One possible exception is the design of user interfaces. An aspect of aesthetic quality is "elegance," introduced as a criterion by which to assess quality (Checkland & Scholes, 1990). An attempt to increase aesthetic quality and make it more visible is to raise questions such as: Is the transformation well designed? Is it aesthetically pleasant? Is it overcomplicated? Is it over- or under-engineered? These assessments allow the users' subjective experiences as well as the professionals' experience of similar systems to be included in the judgment of quality.

Symbolic Quality

Computer systems are not only artifacts, they are also used as symbols in the organization. This view is supported by Feldman and March's (1981) study of the use of information in organizations. They found that information is often used symbolically, e.g., signaling a well-driven organization, independent of whether the information is used or not. Symbolic, as well as aesthetic, aspects of computer systems are important factors in tailoring a system to the business philosophy and organization culture. For example, an organization wishing to have an innovative and modern image should have computer systems with graphical user interfaces and colors. Symbolic quality may be contradictory to the use quality. This can be illustrated by a hotel owner who wanted to install a computerized reception system. It turned out that the main purpose of the system was to create the impression of a modern, successfully run hotel and to recruit educated personnel. Not much attention was paid to the functionality of the system. If the motivation is of a symbolic character, as in this example, the use quality will probably be ignored.

Organizational Quality

When a computer system is well adapted to the organization, it can be said to be of high organizational quality. When assessing the quality of information systems, questions of economy, power and interests will arise sooner or later: Are the computer systems developed for the interests of individual users, for groups of users, or for the organization as a whole? Different user groups may have diverging, perhaps contradictory, ideas of what signifies good quality. A personnel control and wage system might represent good use quality for management and the personnel department, but not for the workers who are being controlled. A medical journal system in a hospital may be of good quality for the doctors, but at the same time decrease the influence of the nurses and use of their competence. This may, in turn, decrease the quality if their work. The different groups of users make different demands on functionality, in order to support their work. If these different

interests are not met, an intersection of several interests is developed and the result could be a computer system, which is not suited for anyone. This, in turn, may decrease the organizational quality of the system.

Hyatt and Rosenberg (1996) add another quality perspective, the project manager's view. The project manager views the software quality as "software that works well enough to serve its intended function and is available when needed". Project managers are usually concerned in producing software that is reliable, maintainable, and keeps customers satisfied. They usually face budget and/or time constraints, which will impede either one of their quality goals. The constraints will potentially sacrifice the testing (level, extent, and depth), walkthrough inspections, and documentation, which are some of the factors contributing to software quality. While Hyatt and Rosenberg focus only on the view of the project manager, it must be pointed out that many definitions of quality share this same view (Box, 1984; Genth, 1981; Wimmer, 1975).

The Software Perspective of Quality

Researchers in the software engineering area have tried different ways to define quality. In fact, they have moved progressively from the product-based view, to the manufacturing-based view, and more recently to the user-based view. They have also focused heavily on technical quality with a growing consideration for use quality and aesthetic quality. However, no models in software engineering seem to exist following the transcendental, economic, aesthetic, symbolic, or organizational based views of quality.

Table 1 presents some of the software quality models introduced in this chapter. There are other quality models; however, these are the most discussed models in the literature. These are only the most notable among many in research. At first glance, the list of software quality models gleaned from a review of literature is daunting. One might conclude that they are many and varied; however, many of these models are developments of earlier ones, and some are combinations of others with

Table 1. Various software quality models and their relationship to Garvin's and Braa's quality perspectives

Software quality models	Garvin's quality perspective	Braa's quality perspective
McCall	Product view	Technical Quality
Boehm	Product view	Technical Quality
Gilb	Product view	Technical Quality
Murine	Product view	Technical Quality
Schmitz	Product view	Technical Quality
Schweiggert	Product view	Technical Quality
Willmer	Product view	Technical Quality
Hausen	Product view	Technical Quality
ISO9000-3	User view	Technical Quality
ISO9126	User view, product view	Use Quality
Dromey	Product view	Technical Quality
COQUAMO	User, manufacturer, product view	Technical Quality, Use Quality
Squid	User, manufacturer, product view	Technical Quality, Use Quality
CMM	Manufacturer view	Technical Quality
Bootstrap	Manufacturer view	Technical Quality
Trillium	Manufacturer view	Technical Quality
MMM	Manufacturer view	Technical Quality
Scope	Manufacturer view	Technical Quality
Processus	Manufacturer view	Technical Quality
SPICE	Manufacturer view	Technical Quality
QFD	User, manufacturer, product view	Technical Quality, Use Quality

and without uniqueness. For example, ISO quality factors are very similar to those in the earlier McCall and Boehm models. Bootstrap, Trillium, and MMM are all evolutions of CMM. SPICE is an evolution of Bootstrap, CMM, trillium, and ISO9001. SCOPE and PROCESSUS are efforts at combining process and product through connecting ISO9001 and ISO9126. And SQUID uses elements of ISO9126 and McCall. In most cases, the reworking can be considered one researcher's improvements on another's. This leaves few originals. Shari Pfleeger (1997) states that since models illustrate the relationship between apparently separate events, the lack of real variety in models in software engineering is symptomatic of a lack of system focus.

The research on software quality indicates that it is divided into two main schools of thought. There is the Product school, where practitioners advocate that to clearly define, measure, and improve quality, one must measure characteristics of the software product which best influence quality. Then there is the Process school, where practitioners advocate that one may be unable to properly define quality, but states that a product's quality is improved when the software engineering process used to make the product is improved. A process model's quality factors refer to the product development life cycle as a way of expressing the product's quality.

According to this product-process division, Boehm's model, the COQUAMO model, McCall's model, Murine's SQM model, ISO9126, SQUID, and Dromey's model are all examples of product models: they focus on the final product. The process model includes ISO9001-3, CMM, SPICE, BOOTSTRAP, Trillium, and MMM. SCOPE and PROCESSUS are a composite of both product and process models.

The Product Quality models are basically those models that view quality as inherent in the product itself. These models decompose the product quality into a number of quality factors (some models describe it as quality features, criteria, or characteristics). They are decomposed further into lower levels. The lowest are the metrics to measure or indicate the criteria. The metrics are used to assess the quality of the software. The result of the assessment is compared against a set of acceptance criteria. This determines whether the software can be released. Many of the software quality models in this group do not suggest what metric values are acceptable and hence leave it to the software practitioner to decide.

The Process Quality models are those models that emphasize process improvement and development standards, with the aim that the process improvements will lead to improving the quality of the product. In the past, much software development was performed without proper process and management control. The software developers were more guided by intuitive approach or habit, rather than by using any particular standards. Rae et al. (1995) emphasizes the importance of standardizing the development process and states that it will reduce software development to a rational and well-defined series of tasks, which can be managed and controlled (Rae et al., 1995). Watts Humphrey (1988), in introducing the CMM, stated that the premise of the CMM lies in the relationship between the quality of the process and the quality of the product. The belief is that effective process management will be the key factor in producing high quality software. However, Gillies (1992), Paulk et al. (1993), and Rae et al. (1995) indicated that the adoption of a good quality process will not automatically guarantee a good quality product.

Schneidewind (1996) and Fenton (1996) debated whether the existence of a standard process is good enough to improve the quality of software. Schneidewind's view is that there is a need for a standard first, even though it is not perfect. Fenton argued that a good standard process is required to improve the quality of a product and a bad standard will not help at all. In my opinion, a standard is necessary as a guideline. However, as resources to set up the standards are scarce,

they have to be initially established as well as possible. The standards have to be constantly reviewed and updated, because the technology and software engineering methodology change. Fenton suggested that organizations should contribute to the resources.

Voas (1997) criticizes the software process movement in general and claims that the focus of software process movement and methods on improving quality give the impression that "clean pipes can produce only clean water." He states that we must not forget the part to be played by product oriented methods, with their focus on software metrics and system level testing that allow the developing product to be sampled for its internal quality. He claims that the preoccupation with process quality in the software industry is partly a result of the difficulty of reliable testing. And software metrics, he adds, as do others such as Gulezian (1995), brings its own set of problems related to what exactly measures should be, as well as how and when they are best measured. For example, although software reliability assessment has been accepted as a measure of software quality, most reliability models predict failure by looking at error history (Voas, 1997). Unfortunately, this data can be computed differently by different models, so the reliability results may not even be reliable. Gulezian states that structural metrics cannot capture the dynamics of software behavior where an input is transformed into an output by a set of instructions. Thus we see from this direction that much of the future of software quality lies linked to research in metrics, and providing some acknowledgment of the roles of both product and process measurement in the quality of a piece of software. While much more can be said of the process models, focus in the rest of the chapter will be given to product quality.

Criticism of Models

The product models, particularly McCall's and Boehm's models (and the later ISO9126), have had similar criticisms aimed at them from multiple directions (Rozman et al., 1977). These criticisms have all stated that there is a lack of clear criteria for selection of not only the higher-level quality attributes but also of the subcharacteristics. There is a lack of consensus between researchers on what level a quality characteristic should be placed and for the apparent arbitrary placement of these characteristics, for the lack of agreement on terminology, and for the paucity of discussion of the measurement aspect of each of the models. An additional complication and criticism of McCall's and Boehm's models is that each of the quality subcharacteristics is not related to a single quality factor. This complicates measurement and interpretation of results. For example, McCall's model shows the quality factor *flexibility* influenced by quality characteristics of *self-descriptiveness, expandability, generality, modularity.* To further confound interpretation of any measurements that might have been gathered, these same quality subcharacteristics also influence the quality factors *portability, reusability, interoperability* as well as *testability* and *maintainability.* In ISO9126 each subcharacteristic influences only one high level quality factor — the model is completely hierarchical.

Gillies (1992) and Kitchenham and Pfleeger (1996) stated that there are a number of issues with the hierarchical models:

1. The selection of quality factors and criteria seem to be made arbitrarily. It implies that there is no rationale for determining:
    - which factors should be included in the quality model and
    - which criteria relate to a particular quality factor.
2. The hierarchical models cannot be tested or validated, because they do not define the quality factors in a measurable way.
3. The measurement methods of both models

have a large degree of subjectivity, hence the software quality cannot be measured objectively.

4. In 1987, Perry Gillies (1992) pointed out that some quality factors or criteria conflict with each other due to inverse relationships. For example, there is an inverse relationship between usability and efficiency. The improvements in human-computer interface will increase the usability of the software; however, it will lead to reduction in efficiency as more coding will be required.

Despite the criticism, both models (especially McCall's) form the basis for most of the research in software quality today.

Kitchenham and Walker (1986) made a number of observations. They stated that there seemed to be little supporting rationale for including or excluding any particular quality factor or criteria. In fact, definitions of quality factors and criteria were not always consistent when comparing one model to the next. Different terminologies between the models exist, with little explanation for the meanings behind them. There was no rationale for deciding which criteria relate to a particular factor. Thus the selection of quality characteristics and subcharacteristics can seem arbitrary. The lack of rationale makes it impossible to determine whether the model is a complete or consistent definition of quality.

Though quality has been widely used and accepted, the differences between them highlights how one's view can dictate the perception of quality. The degree of subjectivity varies substantially from one question to another, even though all responses are treated equally. This variation makes combining metrics difficult, if not impossible. Moreover, when appropriate, the detail and complexity of the response should be reflected in a richer measurement scale. For example, while it is reasonable to expect a yes or no response to the question "Does this module have a single exit or entry point?", questions about documentation clarity probably require a multiple-point ordinal scale to reflect the variety of possible answers.

The models recommend direct measures, but most of them do not describe clearly how to conduct the measure. There appears to be no description of how the lowest level metrics are composed into an overall assessment of higher leveled characteristics. In particular, then, there is no means for verifying that the chosen metrics affect the observed behavior of a factor. That is, there is no attempt to measure factors at the top of the hierarchy, so the models are not testable.

More Recent Developments of Product Models

Dromey's Model

A more recent and promising model of product quality is found in Dromey (1995), who strongly pushes for a more comprehensive software quality model. He holds that software does not manifest quality attributes; rather it exhibits product characteristics that imply or contribute to quality attributes. He states that most models fail to deal with the product characteristics. Dromey's model expresses the same internal view as the classic Boehm and McCall models, because he specifically aims at quality of software code (although he claims this can be applied equally well to other artifacts of the development cycle such as requirements specification or user interfaces). He states that the requirements of any product model are that it provides an adaptable methodical system for building quality into software, and it classifies software characteristics and quality defects. He proposes a bottom up/top down approach. In bottom up one begins with a set of structural forms whose quality carrying properties are identified and must be satisfied. These properties impact certain higher leveled quality attributes. This allows a bottom up movement by ensuring particular product properties are satisfied, for example, for programmers. In his top down appraisal, designers

begin with the quality attribute and move to the quality carrying property. In this way, for example, designers may identify properties that need to be satisfied for each structural form.

Dromey's model is broad enough to be applied across languages and projects — as long as it evolves as new languages evolve. Dromey provides a substantial contribution to the software quality field in that he has provided a complex analysis, which established direct lines between tangible product characteristics and quality attributes. However, his complete disregard for characteristics that can be evaluated externally could be argued to result in an excellent product that does not do what the customer has requested. The model also needs to be broadened to include the same principles applied to other aspects of the design process such as requirements specification.

The Dromey model has been developed to address many of the problems of the earlier models. Dromey (1995) criticized the earlier quality models for failing to deal adequately with the product characteristic problems and to link the quality factors/attributes to product characteristics. He points out that hierarchical models that use top-down decomposition are usually rather vague in their definitions of lower levels. They thus offer little help to software developers who need to build quality products. To overcome this, he proposed specific quality-carrying properties and systematic classification of quality defects. The quality-carrying properties are:

1. Correctness properties (minimal generic requirements for correctness)
2. Structural properties (low level, intramodule design issues)
3. Modularity properties (high level, intermodule design issues)
4. Descriptive properties (various forms of specification/documentation)

Correctness properties fall broadly into three categories that deal with computability, completeness, and consistency. Structural properties have focused upon the way individual statements and statement components are implemented and the way statements and statement blocks are composed, related to one another, and utilized. The modularity properties address the high-level design issues associated with modules and how they interface with the rest of the system. And the descriptive properties reflect how well the software is described. Explicit comments are added to a program to document how the implementation realizes its desired functionality by manipulating variables with prescribed properties.

Dromey believes that it is impossible to build high-level quality attributes such as reliability or maintainability into products. Rather, software engineers must build components that exhibit a consistent, harmonious and complete set of product properties that result in the manifestations of quality attributes.

Dromey's approach is important because it allows us to verify models. It establishes a criterion for including a particular software property in a model and a means of establishing when the model is incomplete. For example, each quality-carrying property has quality impact, for example, reliability and quality defects. By identifying the defects, the software developer will take measures to prevent the defect from occurring.

Kitchenham and Pfleeger (1996) noted that Dromey's quality model provides a constructive approach to engineering software quality which can be refined and improved further. Dromey even developed tools to assist in the production of quality software, a static analyzer to detect quality defects, and a programming language aimed at preventing developers from building defects into their programs.

The criticism of Dromey's model is that he does not use the metric approach in measuring

the software quality. This is because he uses the concept of defect classification. However, as Kitchenham and Pfleeger (1996) pointed out, the model is proof that there are other means to measure quality.

Constructive Quality Model (COQUAMO)

Kitchenham shares Dromey's concern for the need for precision in measurement out of the quality models. She has developed various models in her search to define and measure software quality. COQUAMO (Gulezian, 1995) was developed to further this research. It was the REQUEST (Reliability and Quality for European Software Technology) project which adapted Boehm's COCOMO model to use the more precise measurement of Rome Laboratory Software Quality Framework. (RLSQF provided a framework for using certain metrics for measuring 29 software oriented attributes and relating them to 13 user-oriented quality factors). The beauty of COQUAMO was that Kitchenham saw the need for measurement tools to vary from one environment to another. This was a substantial improvement on all research to date, which had been trying to increase the objective measurements for specific characteristics, without producing any results.

Kitchenham introduced the concept of a "quality profile" and made a distinction between subjective and objective quality measures. It is an attempt to integrate the user, manufacturer, and product views in one software quality model (Kitchenham & Pfleeger, 1996). The COQUAMO model was developed based on Gilb's model and Garvin's views of quality (Gillies, 1992).

The COQUAMO model consists of the following components:

1. **Transcendent Properties:** these are qualitative measures that are hard to measure. People have different views and definitions. An example is usability.
2. **Quality Factors:** these are system characteristics, which are made up of measurable factors of quality metrics and quality attributes. The quality factors themselves could be subjective or objective characteristics such as reliability and flexibility.
3. **Merit Indices:** these define the system subjectively. They are measured subjectively by quality ratings.

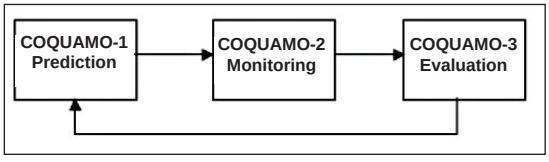
The objectives of COQUAMO and the relevant tools to assist the software developers are in the following table:

- to predict product quality
- to monitor progress toward quality
- to evaluate the results as feedback to improve prediction of the next project

The initial input to COQUAMO-l are estimates of the following quality drivers:

- product attributes such as quality requirements
- process attributes such as process maturity
- personnel attributes such as the developer's experience and motivation
- project attributes such the quality norm expected
- organizational attributes such as quality management

Figure 1. COQUAMO toolset diagram (Gillies, 1992)



The toolset of COQUAMO-2 consists of guidelines to monitor the progress toward quality product, while toolset COQUAMO-3 provides guidelines to assess the quality of the product and compare it against the prediction. The result of this will be input to COQUAMO-1 for the next project.

The distinctive characteristic of this model that differentiates it from previous models is that the evaluation and feedback processes are introduced here to improve the quality of software in the next project. There is a similarity with some aspects of Total Quality Management (TQM) in software quality modeling, that is, improvement of quality. This is featured by the COQUAMO-3 toolset.

The SQUID Product Model

The SQUID model, an ESPRIT 3 SQUID project (Kitchenham et al., 1997), was the result of a reassessment by Kitchenham of what constituted a quality model. It was developed after COQUAMO and after the results of the ESPRIT project concluded that there were no software product metrics that were likely to be good predictors of final product qualities. Kitchenham built SQUID based on these results and held firmly to the importance of monitoring and controlling internal measures.

Based on the McCall and ISO9126 models, SQUID aimed to use measurable properties to link internal properties and external characteristics to quality characteristics. A key principle to the SQUID model is that it must be customized for each project/product. Kitchenham states that the underlying principle of SQUID is that software quality requirements cannot be considered independently from a particular software product. Kitchenham acknowledges her alignment with Gilb (1996) on this point when he states that quality requirements arise from the operational properties required of the software, or of its support/maintenance environment. SQUID provides a concrete link between a concrete feature/component and the quality factor. The SQUID approach is to use measurement as the link between the product quality requirements and the quality characteristics (it uses ISO9126 characteristics as accepted results of research). In the application of the model to a product, concrete internal measures, with targets, are developed for the desired software properties, which reference quality characteristics. For example, the internal measures for the software property correctness were the number of faults detected, and the grouping into which the faults fell.

The SQUID model comes far closer than any in being able to balance the need for internal and external views and being able to consider the change in characteristics and metrics that are involved with each type of software in each context. The model's necessary broadness to suit this recognized need means that it takes a different form from the other models. There is no naming of quality factors and quality characteristics. The true strength of this model, as already stated, is its ability to be used in any project.

Other Approaches to Quality Evaluation

Quality Function Deployment (QFD) is a rigorous and high-structured process used in manufacturing. It provides a means of translating customer requirements into the appropriate technical requirements for each stage of product development and production. The process has been adopted in software engineering (Delen & Rijsenbrij, 1992; Erikkson & McFadden, 1993; Juliff, 1994; Thompsett, 1993). It required that before each software development project began, the appropriate characteristics along with the degree of importance of these characteristics had to be first identified by the stakeholders. The project quality would then be measured against these functions. Though QFD is very much a product definition process which helps businesses identify and integrate user needs and requirements to a product, Thompsett (1993) states that QFD is a tool which can help

define software quality. Erikkson and McFadden (1993) claim that this approach gives a good structure within which users' needs are taken into account and progressively refined to give appropriate product metrics. QFD has been described as a customer-driven system that attempts to get early coupling between the requirements of the customer and system designers. It has not only proven itself in manufacturing and service environments, but has been shown to be equally beneficial in software development (Erikkson & McFadden, 1993; Juliff, 1994; Thompsett, 1993). Erikkson & McFadden (1993) describe several benefits of QFD from their case study:

- QFD encourages focus on customer needs and helps to prioritize the requirements.
- QFD encourages developers to think in terms of defect prevention.
- QFD is a powerful communication vehicle that allows modeling of the discussions between customers, software designers, and other participants.
- QFD allows easy tracking of important customer requirements to the related software characteristics, product features, and product metrics.
- QFD provides an opportunity to follow the consequences in the process.
- As can be seen from this list, QFD is a powerful manufacturing process to ensure customer requirements are met. QFD differs from traditional models, in that its approach is to develop software products from the customers' perspective, not from the suppliers' perspective. While QFD supports the many views of quality, described by Garvin (1984), it does not try to understand the differences, nor does it try to identify similarities between customers.

Vidgen et al. (1994) proposed a framework to define quality based on the multiview development method (Wood, 1992; Wood-Harper & Avison, 1992). They believed that multiple perspectives of software quality are required if one is to assess product quality properly. The framework was based on customer satisfaction, relating the product with its use and the services provided to support it. The three views of IS quality provide the basis for the multiple perspective. It was not merely an exercise in looking at the same object from different angles, but it entailed different assumptions about what quality is. Though this framework was introduced, no further research followed.

Criticism of These Recent Models

Kitchenham acknowledges some problems with the SQUID model (Kitchenham et al., 1997). Using the ISO9126 model as a framework led her to make recommendations for on-going improvements to the ISO9126 standard. Among her recommendations is a request for a further broadening of the ISO9126 standard. Her reasons are good ones and may lead critics of the broadness of ISO9126 to rethink their reasons for seeking further specificity. She says that insofar as software products do not have a standard set of functional requirements, then it seems that rather than give a fixed set of quality requirements, the standards should specify how the quality characteristics should be defined by those involved in the project. From this generic outline, the development team would have guidance to develop their product model. Kitchenham also states that the lower level properties should be clearly classified as external or internal characteristics. She finally recommends that research should focus on ways to validate quality models. She acknowledges the contribution Dromey's (1995) research has made in providing a criterion for including a software property in a model. Dromey supports this need for a broad model to be developed by those involved in the project and states that it would involve the project team specifying the subcharacteristics of each quality characteristic of each component, establishing the

metrics that correlate to the characteristics of the software product and to the environment in which it is functioning, and to provide a rating level that expresses a degree of user satisfaction. Since each set of users and developers needs is different, each rating level will change. This is a complex task that would require much guidance.

Vollman (1993) provides additional comment on this issue of model broadness: not only is the subdivision of quality characteristics influenced by the evaluator's point of view and the product's context, but when this occurs, the algorithms applied when evaluating will need to differ. In 1993, the ISO9000 standards included a publication that was the precursor to this need for the measure to be applied by multiple evaluators in multiple situations, and stated that an organization should use whatever metrics it deems appropriate to its applications as long as the ISO9000 metrics methodology is followed. Schneidewind (1993) states that this broadness allows metrics to be used by developers, managers, quality assurance organizations, maintainers, and users. Clearly the newest metric for software quality measurement will receive much heated discussion as a result of the move to balance internal measures with measures of external product attributes.

From this section, it can be concluded that there have been vast improvements in defining software quality. Yet overall, software product quality research is still relatively immature, and today it is still difficult for a user to compare software quality across products. Researchers are still not clear as to what is a good measure of software quality because of the variety of interpretations of the meaning of quality, of the meanings of terms to describe its aspects, of criteria for including or excluding aspects in a model of software, and of the degree to which software development procedures should be included in the definition (Comerford, 1993). Although many of the criticisms of product models are valid, Voas (1997) proposes that because product-oriented methods are more focused on achieving quality than assessing it, they play a critical role in software quality research. He contends firmly that software behavior, irrespective of the software's development history, is what defines software quality. He sees organizations and research caught in a bind with software testing measuring the right thing but with insufficient precision and process measurement more accurately measuring the wrong thing.

MEASURING QUALITY WITH THE SOFTWARE EVALUATION FRAMEWORK

There have been many studies on the topic of software quality, yet little empirical studies on what influences the perception of quality for different people. Earlier research of Wong (Wong, 1998; Wong & Jeffery, 1995, 1996) concluded that different groups of people view quality in different ways and that it was possible to group people with similar definitions of quality and similar choices of characteristics in their quality assessment process.

During the past 30 years there have been many studies on the topic of software quality; however, there have been none on a framework for software quality, which considers the motivation behind the evaluation process, other than the earlier version of this framework introduced by Wong and Jeffery (2001). This framework is based on the notion that software evaluators are influenced by their job roles. This is supported by earlier studies (Wong, 1998; Wong & Jeffery, 1995, 1996) where stakeholders with different job roles were found to focus on different sets of software characteristics when evaluating software quality. What motivates these differences is found within the broader context of value, where studies have shown that values are a powerful force in influencing the behavior of individuals (Rokeach, 1968; Yankelovich, 1981).

The theoretical basis for developing such a framework was based on the theory found in cognitive psychology and adopted by Gutman's Means-End Chain Model (Bagozzi, 1997; Bagozzi & Dabholkar, 2000; Gutman, 1982, 1997; Valette-Florence, 1998), which posits that linkages between product characteristics, consequences produced through usage, and personal values of users underlie the decision-making process or, in this case, the software quality evaluation process. It is the aim of the framework to not only show the relationships between the characteristics and software quality, but also show that there are relationships between the characteristics and the desired consequences, and between the characteristics and the sought-after values.

Personal values are beliefs people have about important aspects of themselves and the goals toward which they are striving. Personal values are the penultimate consequences of behavior for people: their feelings of self-esteem, belonging, security, or other value orientations. As such, personal values are part of the central core of a person. That is, personal values determine which consequences are desired and which are undesired.

Values have been shown to be a powerful force in influencing the behaviors of individuals in all aspects of their lives (Rokeach, 1968; Yankelovich, 1981). It is proposed in this research, that their use in software quality evaluation shows the behavior of software evaluators and the relationship between the software characteristics, the desired consequences, and the values sought. Several attempts in consumer research have been made to provide a theoretical and conceptual structure connecting consumers' values to their behavior (Gutman, 1982; Howard, 1977; Vinson et al., 1977; Young & Feigin, 1975). The basis by which the study is performed is via adopting Gutman's means-end chain model (Bagozzi, 1997; Bagozzi & Dabholkar, 2000; Gutman, 1982, 1997; Valette-Florence 1998), which posits that linkages between product characteristics, consequences produced through usage, and personal values of users underlie the decision-making process or, in our case, the software quality evaluation process. The term *means* refers to the software product and services, and *ends* refers to the personal values important to the user.

Gutman's model is able to give a complete representation of the means-end chain, representing linkages from the characteristics to the values, along with the capability of explicating the chain. Earlier models (Howard, 1977; Vinson et al., 1977; Young & Feigin, 1975) failed to consider the means-end chain. They focused only on the consequences and values without considering how they relate to the characteristics or attributes. The means-end chain model seeks to explain how a person's choice of a product or service enables him or her to achieve his or her desired result. Such a framework consists of elements that represent the major usage processes that link personal values to behavior. Two assumptions underlie this model:

- all user actions have consequences; and
- all users learn to associate particular consequences from the usage of the product or service.

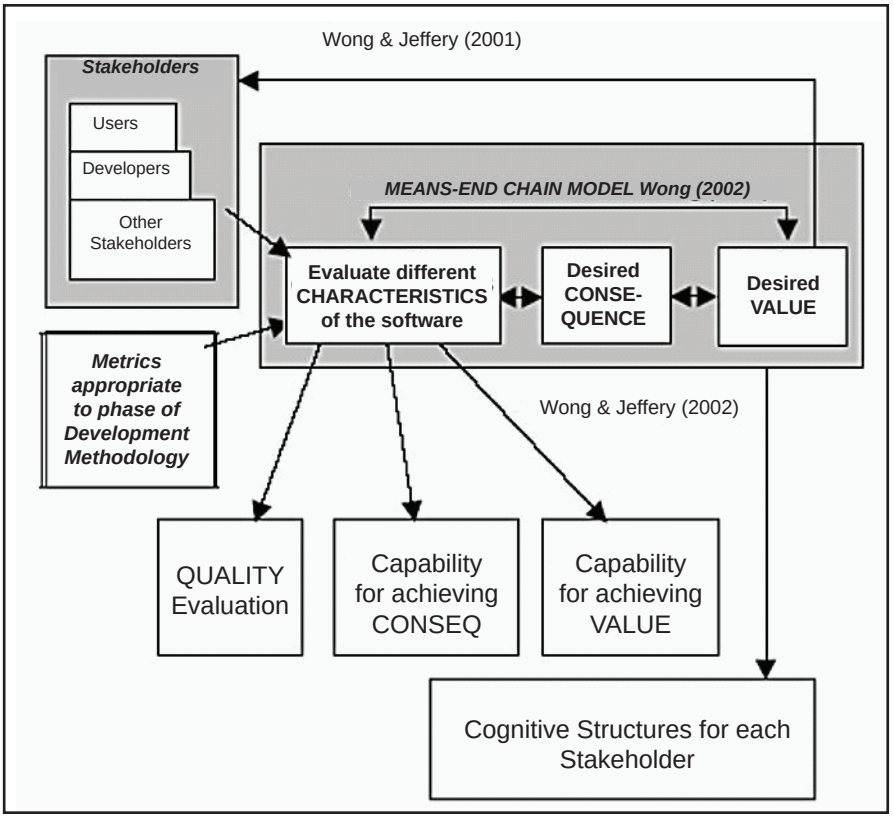
Consequences may be desirable or undesirable; they may stem directly from usage or the act of usage, or occur indirectly at a later point in time or from others' reaction to one's consumption behavior. The central aspect of the model is that users choose actions that produce desired consequences and minimize undesired consequences. Of course, because it is the characteristics that produce consequences, consideration for the characteristics that the software product possesses must be made. Therefore, it is important to make aware the characteristic-consequence relations. Overall, the characteristic-consequence-value interrelations are the focus of the model. Values provide the overall direction, consequences determine the selection of specific behavior in specific situations, and the characteristics are what is in

the actual software product that produces the consequences. It is knowledge of this structure that permits us to examine the underlying meaning of quality.

As highlighted in the literature, the benefit of utilizing Gutman's model in the framework is that it shows how the desired values influence the behaviors of individuals in all aspects of their lives (Gutman, 1982; Rokeach, 1968; Yankelovich, 1981). Gutman's model suggests that the desired consequences and the values sought are the motivators behind the choice of characteristic for software evaluation. In addition to this, the framework also highlights the significance of this relationship through the relationships between characteristics and consequences and also between the characteristics and value. It is through these relationships that the possibility of using the characteristics to evaluate each consequence and value becomes apparent.

The framework shown in Figure 2 is based on Gutman's Means-End Chain Model. As can be seen in this diagram, the framework consists of a number of boxes describing the three elements of Gutman's model, the stakeholders who evaluate the software quality, the outcome for the quality evaluation, and the arrows linking these elements, while also describing the direction of the influence. The Means-End Chain Model has been placed in the main box, as it is proposed, in this framework, to be the central influence for the choice of characteristics used in software evaluation, and the influence for the differences found between stakeholders. The framework not

Figure 2. SEF: Software evaluation framework



only shows the related elements, which influence software quality evaluation, but also introduces a way of describing the relationships between the characteristics, the consequences, and the values. These diagrams are called cognitive structures. Cognitive structures can be drawn for each stakeholder, allowing stakeholder differences to be described through a diagram (Wong, 2002, 2003a; Wong & Jeffery, 2001).

The recent studies of Wong and Jeffery (Wong, 2002, 2002a; Wong & Jeffery, 2001, 2002) provide the premise to this framework. An exploratory study by Wong and Jeffery (2001), utilized a qualitative approach to explore the influence of value on the choice of characteristics, and to determine whether cognitive structures could be used as a tool to represent the links between the characteristics, consequences, and values. The results of the study not only gave strong support for the influence of value on the choice of characteristic in software evaluation, but also supported earlier pilot studies on stakeholder differences (Wong, 1998; Wong & Jeffery, 1995, 1996), identifying different cognitive structures for users and developers.

A more recent paper by Wong (2002a) reported on a large quantitative study, which tested the appropriateness of utilizing Gutman's Means-End Chain Model (Bagozzi, 1997; Bagozzi & Dabholkar, 2000; Gutman, 1982, 1997; Valette-Florence, 1998) in software evaluation. Unlike previous studies of Gutman's Model, this study showed strong support for the Means-End Chain Model in a software evaluation setting. The results showed strong correlations between the characteristics, the consequences and the values, and supported the results of the qualitative study (Wong & Jeffery, 2001) described earlier.

The Software Evaluation Framework has also been applied to the requirements phase of the software development project (Wong, 2003a, 2003b, 2004). The results showed support for the use of the framework. The results showed that the measurements between the different phases are not the same, though the motivation behind the choice of these measurements is the same for a stakeholder group. The study also finds that the two groups of stakeholders are very similar in the measurements they choose for evaluating requirements documents; however, the motivation behind their choice of these measurements differs between the stakeholder groups. These results are a contrast to that of the implementation phase. More recently, studies have also been conducted on the metrics, which could be used to measure the characteristics of the software product (Wong, 2003a, 2003c, 2004, 2004a).

CONCLUSION

An exhaustive and critical review of the research concerned specifically with software product quality is reviewed in this chapter. It is clear that some models have provided more progress toward refining the definition of software quality while others have contributed to a better understanding of the process for measuring software quality. While the attempts of many of the models have been admirable, the development of the Software Evaluation Framework has succeeded in introducing a framework which fills the gaps found in many of the models.

Several broad conclusions can be drawn from the literature.

First, it is understood that there are different views of quality and that an understanding of these views is required; however, it is difficult to adopt all views at the same time when evaluating software. Though a number of assertions have been made in the literature regarding the multiple views of quality, there have not been many studies to support this, nor are there any frameworks or models which give the rationale for the different views.

Second, we know little about what rationale is used for selecting a characteristic for software evaluation. There is a need to consider what

motivates the characteristics used in software evaluation for EACH different view.

Third, the Software Evaluation Framework, introduced in this chapter, showed support for applying Gutman's Means-End Chain Model in software quality evaluation. The results endorse the links between characteristics, consequences and values, which have been regarded as rich constructs for understanding software evaluator behavior (Izard, 1972; Rokeach, 1973; Tolman, 1951). The results of the study provided further evidence of a connection between patterns of characteristics, consequences, and values and gives valuable support for the use of cognitive structures as a means of describing this relationship. Knowing this relationship is valuable for marketing and promoting the software, which is important for software acceptance. Software developers have often been challenged with conducting appropriate software demonstrations. For many developers, there is a lack of understanding of what is important to the user. The Software Evaluation Framework introduces the motivation for user acceptance of the software and allows the developer to have a better understanding of the desired consequences and how they are related to the software. The framework is valuable for understanding the differences in views of quality among the many stakeholders in a software development project. The cognitive structures introduced a way of describing these differences, showing clearly the characteristics of the software product, which are significant in their evaluation of software quality, along with the desired consequences and sought-after values associated with these characteristics.

Fourth, the use of the cognitive structures, introduced in the Software Evaluation Framework, can better the understanding of the characteristics selected for quality evaluation and how they are related to what the evaluators seek as desired consequences from the use of the software. The cognitive structures not only showed that users and developers differ in their choice of characteristics, but show differences in the consequences sought and the values desired. Software Quality has been described as a combination of characteristics, with ISO9126 being adopted as the current international standard. However, though support for ISO9126 appeared in some of the results, evidence suggests that non-ISO9126 characteristics are also important when evaluating software quality. This is supported by the cognitive structures and the results of earlier studies of Wong and Jeffery (Wong, 1998; Wong & Jeffery, 1995, 1996). The results found that ISO9126 characteristics, usability, and functionality strongly affect software quality for both developers and users, while technical characteristics, like portability and maintainability, were only significant for the developers. However, the results surprisingly found operational characteristics, like efficiency and reliability, to minimally affect software quality. This result was not expected since many of the measurements for software quality, like defects and failures, focus on reliability. As to the non-ISO9126 characteristics, support was found to be important for both users and developers, while the economic and institutional characteristics were only relevant for users. It is evident that further work is required to identify whether the non-ISO9126 characteristics should be part of the ISO9126 set of characteristics. The use of the cognitive structures can also help to identify the problems that may be occurring in current evaluation practices. Software Quality is seldom confined to just one characteristic, though very often, reliability seems to be the only focus. Defects and failures have often been the only metrics collected. While reliability, an operational characteristic, is important, the results of the research show that other metrics need to be collected if a more generally applicable set of measure for Software Quality is desired for different stakeholders.

Chapter 1.22
Software Configuration Management in Agile Development

Lars Bendix
Lund Institute of Technology, Sweden

Torbjörn Ekman
Lund Institute of Technology, Sweden

ABSTRACT

Software configuration management (SCM) is an essential part of any software project and its importance is even greater on agile projects because of the frequency of changes. In this chapter, we argue that SCM needs to be done differently and cover more aspects on agile projects. We also explain how SCM processes and tools contribute both directly and indirectly to quality assurance. We give a brief introduction to central SCM principles and define a number of typical agile activities related to SCM. Subsequently, we show that there are general SCM guidelines for how to support and strengthen these typical agile activities. Furthermore, we establish a set of requirements that an agile method must satisfy to benefit the most from SCM. Following our general guidelines, an agile project can adapt the SCM processes and tools to its specific agile method and its particular context.

INTRODUCTION

In traditional software development organisations, software configuration management (SCM) is often pushed onto the projects by the quality assurance (QA) organisation. This is done because SCM in part can implement some QA measures and in part can support the developers in their work and therefore helps them to produce better quality. The same holds true for agile methods—SCM can directly and in-directly contribute to better QA on agile projects.

Software configuration management (SCM) is a set of processes for managing changes and modifications to software systems during their

entire life cycle. Agile methods embrace change and focus on how to respond rapidly to changes in the requirements and the environment (Beck, 1999a). So it seems obvious that SCM should be an even more important part of agile methods than it is of traditional development methods. However, SCM is often associated with heavily process-oriented software development and the way it is commonly carried out might not transfer directly to an agile setting. We believe there is a need for SCM in agile development but that ist should be carried out in a different way. There is a need for the general values and principles of SCM, which we consider universal for all development methods, and there is a need for the general techniques and processes, which we are certain will be of even greater help to agile developers than they are to traditional developers.

There are some major differences in agile projects compared to traditional projects that heavily influence the way SCM can—and should—be carried out. Agile methods shift the focus from the relation between a project's management and the customer to the relation between developers and the customer. While traditional SCM focuses on the projects and company layers in Figure 1, there is a need to support developers as well when using SCM in agile projects. Shorter iterations, more frequent releases, and closer collaboration within a development team contribute to a much greater stress on SCM processes and tools.

Agile methods are people-oriented rather than process-oriented and put the developer and the customer in focus. As a consequence, SCM has to shift its primary focus from control activities to that of service and support activities. The main focus on audits and control needs to be replaced by a main focus on supporting the highly iterative way of working of both the team and the developers, as seen in Figure 2. From a QA point of view, the control measures are moved down to the developers themselves with the purpose of shortening the feedback loop in agile methods. So SCM does not directly contribute to the QA on an agile project, this is the task of the processes that the agile method in question prescribes. However, by supporting said processes and making them easier and safer to practice SCM indirectly is a big factor in QA on agile projects.

The traditional process-oriented view of SCM has also lead to several misconceptions of agile methods from an SCM point of view. The lack of explicit use of SCM and its terminology has lead quite a few people to conclude that agile methods are not safe due to an apparent lack of rigorous change management. However, a lot of

Figure 1. The different layers of SCM

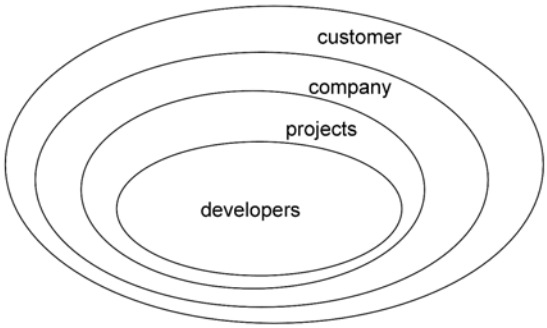

Figure 2. The main development loops in agile

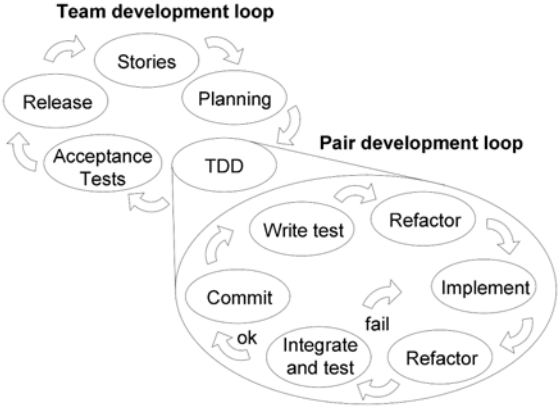


SCM activities are actually carried out in agile methods although they are not mentioned explicitly. Bendix and Hedin (2002) identify a need for better support from SCM, in particular for refactoring in order for this practice to be viable. Koskela (2003) reviews agile methods in general from an SCM point of view and concludes that only a few of the existing agile methods take SCM explicitly into account. He also notices that most methods highly value SCM tool support but that SCM planning has been completely forgotten. There is thus a need to provide guidance for using SCM or for implementing SCM in agile. The SCM literature mostly takes the control-oriented view of SCM (Berlack, 1992; Buckley, 1993; Hass, 2003; Leon, 2005) and there is very little written about team- and developer-oriented support activities (Babich, 1986; Mikkelsen & Pherigo, 1997; Bendix & Vinter, 2001; Berczuk & Appleton, 2003). These activities are the ones that can benefit agile methods the most and should therefore be emphasized more when used in an agile setting. However, it is important to stress that agile methods need the whole range of SCM support from developer through to customer.

In the next section, we provide background information about SCM for those who are not so familiar with SCM, and describe and define a number of SCM-related agile activities to establish a terminology. In Section 3, we give general guidelines for how these agile activities can be supported by SCM and how agile methods could benefit from adopting more SCM principles. We also provide pointers to literature where more details can be found. Future trends for SCM in the agile context are described in Section 4, and in Section 5 we draw our conclusions.

BACKGROUND

This section gives an introduction to the concepts and terminology in SCM that serve as a background for the analysis in following sections. We also define and describe activities in agile methods that are related to SCM or affected by SCM in one way or the other.

SCM Activities

SCM is a method for controlling the development and modifications of software systems and products during their entire life cycle (Crnkovic, Asklund, & Persson Dahlqvist, 2003). From this viewpoint, SCM is traditionally divided into the following activities: configuration identification, configuration control, configuration status accounting, and configuration audit (Leon, 2005). These activities reflect mostly the part of a development project with relations to the customer. However, since agile methods are often more developer centric, there is also a need for a more developer-oriented view of SCM than the traditional control-oriented view above. Typical developer-oriented aspects of SCM include: version control, build management, workspace management, concurrency control, change management, and release management (Bendix & Vinter, 2001). We present each activity from a general perspective and explain both its purpose and what is included in the activity. After this introduction, the reader should be familiar with these basic SCM concepts and their purpose, so we can use them for our analysis in the next section.

Configuration Identification

Configuration identification is the activity where a system is divided into uniquely identifiable components, called configuration items, for the purpose of software configuration management. The physical and functional characteristics of each configuration item are documented including its interfaces and change history. Each configuration item is given a unique identifier and version to distinguish it from other items and other versions of the same item. This allows us to reason about

a system in a consistent way both regarding its structure and history. Each item can be either a single unit or a collection (configuration) of lower level items allowing hierarchical composition. During configuration identification a project baseline and its contents are also defined, which helps to control change as all changes apply to this uniquely defined baseline.

Configuration Control

Software is very different from hardware as it can be changed quickly and easily, but doing so in an uncontrolled manner often leads to chaos. Configuration control is about enabling this flexibility in a controlled way through formal change control procedures including the following steps: evaluation, coordination, approval or disapproval, and implementation of changes. A proposed change request typically originates from requests for new features, enhancement of existing features, bug reports, etc. A request is first evaluated by a Change Control Board (CCB) that approves or disapproves the request. An impact analysis is performed by the CCB to determine how the change would affect the system if implemented. If a request is approved, the proposed change is assigned to a developer for implementation. This implementation then needs to be verified through testing to ensure that the change has been implemented as agreed upon before the CCB can finally close the change request.

Configuration Status Accounting

Developers are able to track the current status of changes by formalizing the recording and reporting of established configuration items, status of proposed changes, and implementation of approved changes. Configuration status accounting is the task to provide all kinds of information related to configuration items and the activities that affect them. This also includes change logs, progress reports, and transaction logs. Configuration status accounting enables tracking of the complete history of a software product at any time during its life cycle and also allows changes to be tracked compared to a particular baseline.

Configuration Audits

The process of determining whether a configuration item, for instance a release, conforms to its configuration documents is called configuration audit. There are several kinds of audits each with its own purpose but with the common goal to ensure that development plans and processes are followed. A functional configuration audit is a formal evaluation that a configuration item has achieved the performance characteristics and functions defined in its configuration document. This process often involves testing of various kinds. A physical configuration audit determines the conformity between the actual produced configuration item and the configuration according to the configuration documents. A typical example is to ensure that all items identified during configuration identification are included in a product baseline prior to shipping. An in-process audit ensures that the defined SCM activities are being properly applied and controlled and is typically carried out by a QA team.

Version Control

A version control system is an invaluable tool in providing history tracking for configuration items. Items are stored, versions are created, and their historical development is registered and conveniently accessible. A fundamental invariant is that versions are immutable. This means that as soon as a configuration item is given a version number, we are assured that it is unique and its contents cannot be changed unless we create a new version. We can therefore recreate any version at any point in time. Version control systems typically support configuration status accounting by providing automatic support for history track-

ing of configuration items. Furthermore, changes between individual versions of a configuration item can be compared automatically and various logs are typically attached to versions of a configuration item.

Build Management

Build management handles the problem of putting together modules in order to build a running system. The description of dependencies and information about how to compile items are given in a system model, which is used to derive object code and to link it together. Multiple variants of the same system can be described in a single system model and the build management tool will derive different configurations, effectively building a tailored system for each platform or product variant. The build process is most often automated, ranging from simple build scripts to compilation in heterogeneous environments with support for parallel compilation. Incremental builds, that only compile and link what has changed, can be used during development for fast turn around times, while a full build, rebuilding the entire system from scratch, is normally used during system integration and release.

Workspace Management

The different versions of configuration items in a project are usually kept in a repository by the version control tool. Because these versions must be immutable, developers cannot be allowed to work directly within this repository. Instead, they have to take out a copy, modify it, and add the modified copy to the repository. This also allows developers to work in a controlled environment where they are protected from other people's changes and where they can test their own changes prior to releasing them to the repository. Workspace management must provide functionality to create a workspace from a selected set of files in the repository. At the termination of that workspace, all changes performed in the workspace need to be added to the repository. While working in the workspace, a developer needs to update his workspace, in a controlled fashion, with changes that other people may have added to the repository.

Concurrency Control

When multiple developers work on the same system at the same time, they need a way to synchronize their work; otherwise it may happen that more than one developer make changes to the same set of files or modules. If this situation is not detected or avoided, the last developer to add his or her changes to the repository will effectively erase the changes made by others. The standard way to avoid this situation is to provide a locking mechanism, such that only the developer who has the lock can change the file. A more flexible solution is to allow people to work in parallel and then to provide a merge facility that can combine changes made to the same file. Compatible changes can be merged automatically while incompatible changes will result in a merge conflict that has to be resolved manually. It is worth noticing that conflicts are resolved in the workspace of the developer that triggered the conflict, who is the proper person to resolve it.

Change Management

There are multiple and complex reasons for changes and change management needs to cover all types of changes to a system. Change management includes tools and processes that support the organization and tracking of changes from the origin of the change to the approval of the implemented source code. Various tools are used to collect data during the process of handling a change request. It is important to keep traceability between a change request and its actual implementation, but also to allow each piece of code to be associated to an explicit change request. Change management is also used to provide valuable metrics about the progress of project execution.

Release Management

Release management deals with both the formal aspects of the company releasing to the customer and the more informal aspects of the developers releasing to the project. For a customer release, we need to carry out both a physical and a functional configuration audit before the actual release. In order to be able to later re-create a release, we can use a bill-of-material that records what went into the release and how it was built. Releasing changes to the project is a matter of how to integrate changes from the developers. We need to decide on when and how that is done, and in particular on the "quality" of the changes before they may be released.

Agile Activities

This section identifies a set of agile activities that either implement SCM activities or are directly affected by SCM activities. The presentation builds on our view of agile methods as being incremental, cooperative, and adaptive. Incremental in that they stress continuous delivery with short release cycles. Cooperative in that they rely on teams of motivated individuals working towards a common goal. Adaptive in that they welcome changing requirements and reflect on how to become more effective. While all activities presented in this section may not be available in every agile method, we consider them representative for the agile way of developing software.

Parallel Work

Most projects contain some kind of parallel work, either by partitioning a project into sub-projects that are developed in parallel, or by implementing multiple features in parallel.

Traditional projects often try to split projects into disjoint sub-projects that are later combined into a whole. The incremental and adaptive nature of agile methods requires integration to be done continuously since new features are added as their need is discovered. Agile methods will therefore inevitably lead to cooperative work on the same, shared code base, which needs to be coordinated. To become effective, the developers need support to work on new features in isolation and then merge their features into the shared code base.

Continuous Integration

Continuous integration means that members of a team integrate their changes frequently. This allows all developers to benefit from a change as soon as possible, and enables early testing of changes in their real context. Continuous integration also implies that each member should integrate changes from the rest of the team for early detection of incompatible changes. The frequent integration decreases the overall integration cost since incompatible changes are detected and resolved early, in turn reducing the complex integration problems that are common in traditional projects that integrate less often.

Regular Builds

Agile projects value frequent releases of software to the customer and rapid feedback. This implies more frequent builds than in traditional projects. Releases, providing added value to the customer, need to be built regularly, perhaps on a weekly or monthly basis. Internal builds, used by the team only, have to be extremely quick to enable rapid feedback during continuous integration and test-driven development. This requires builds to be automated to a large extent to be feasible in practice.

Refactoring

The incremental nature of agile methods requires continuous Refactoring of code to maintain high quality. Refactorings need to be carried out as

a series of steps that are reversible, so one can always back out if a refactoring does not work. This practice relies heavily on automated testing to ensure that a change does not break the system. In practice, this also means that it requires quick builds when verifying behavioural preservation of each step.

Test-Driven Development

Test-driven development is the practice that test drives the design and implementation of new features. Implementation of tests and production code is interleaved to provide rapid feedback on implementation and design decisions. Automated testing builds a foundation for many of the presented practices and requires extremely quick builds to enable a short feedback loop.

Planning Game

The planning game handles scheduling of an XP project. While not all agile methods have an explicit planning game, they surely have some kind of lightweight iterative planning. We emphasize planning activities such as what features to implement, how to manage changes, and how to assign team resources. This kind of planning shares many characteristics with the handling of change requests in traditional projects.

SCM IN AN AGILE CONTEXT

In the previous section, we defined some agile activities that are related to SCM and we also outlined and described the activities that make up the field of SCM. In this section, we will show how SCM can provide support for such agile activities so they succeed and also how agile methods can gain even more value from SCM. It was demonstrated in Asklund, Bendix, and Ekman (2004) that agile methods, in this case exemplified by XP, do not go against the fundamental principles of SCM. However, it also showed that, in general, agile methods do not provide explicit nor complete guidance for using or implementing SCM. Furthermore, the focus of SCM also needs to shift from control to service and support (Angstadt, 2000) when used in agile. SCM does not require compliance from agile, but has a lot of good advice that you can adapt to your project if you feel the need for it—and thus value people and interactions before tools and processes (Agile Manifesto, 2001).

In this section, we first look at how SCM can support and service the agile activities we defined in the previous section. Next, we look at how agile methods could add new activities and processes from SCM and in this way obtain the full benefit of support from SCM.

How Can SCM Techniques Support Agile?

SCM is not just about control and stopping changes. It actually provides a whole range of techniques and processes that can service and support also agile development teams. Agile methods may tell you what you should do in order to be agile or lean, but in most cases, they are also very lean in actually giving advice on how to carry out these agile processes. In this sub-section, we show how SCM techniques can be used to support and strengthen the following SCM-related agile activities: parallel work, continuous integration, regular builds, refactoring, test-driven development, and planning game.

Parallel Work

Agile teams will be working in parallel on the same system. Not only on different parts of the system leading to shared data, but also on the same parts of the system, leading to simultaneous update and double maintenance. Babich (1986) explains all the possible problems there are when coordinating a team working in parallel—and

also the solutions.

The most common way of letting people work in parallel is not to have collective code ownership, but private code ownership and locking of files that need to be changed. This leads to a "split and combine" strategy where only one person owns some specific code and is allowed to change it. Industry believes that this solves the problem, but the "shared data" problem (Babich, 1986) shows that even this apparently safe practice has its problems (e.g., combining the splits). These problems are obviously present if you practise parallel work as well. In addition, we have to solve the "simultaneous update" problem and the "double maintenance" problem, when people actually work on the same file(s) in parallel.

The "shared data" problem is fairly simple to solve—if the problem is sharing, then isolate yourself. Create a physical or virtual workspace that contains all of the code and use that to work in splendid isolation from other people's changes. Obviously you cannot ignore that other people make changes, but having your own workspace, you are in command of when to "take in" those changes and will be perfectly aware of what is happening.

The "simultaneous update" problem only occurs for collective code ownership where more people make changes to the same code at the same time. Again, the solution is fairly simple, you must be able to detect that the latest version, commonly found in the central repository, is not the version that you used for making your changes. If that is not the case, it means that someone has worked in parallel and has put a new version into the repository. If you add your version to the repository, it will "shadow" the previous version and effectively undo the changes done in that version. If you do not have versioning, the new version will simply overwrite and permanently erase the other person's changes. Instead you must "integrate" the parallel changes and put the resulting combined change into the repository or file system. There are tools that can help you in performing this merge.

The "double maintenance" problem is a consequence of the "protection" from the "shared data" problem. In the multiple workspaces, we will have multiple copies of every file and according to Babich (1986) they will soon cease to be identical. When we make a change to a file in one workspace, we will have to make the same change to the same file in all the other workspaces to keep the file identical in all copies. It sounds complicated but is really simple, even though it requires some discipline. Once you have made a change, you put it in the repository and—sooner or later—the other people will take it in from the repository and integrate it if they have made changes in parallel (see the "simultaneous update" problem).

A special case of parallel work is distributed development where the developers are physically separated. This situation is well known in the SCM community and the described solutions (Bellagio & Milligan 2005) are equally applicable to distributed development as to parallel work. There are solutions that make tools scale to this setting as well. Distributed development is thus not different from parallel work from an SCM perspective, as long as the development process that SCM supports scales to distributed development.

In summary, we need a repository where we can store all the shared files and a workspace where we can change the files. The most important aspect of the repository is that it can detect parallel work and that it can help us in sorting out such parallel work. Also it should be easy and simple to create whole workspaces. Most version control tools are able to do that and there is no need to use locking, which prevents real parallel work, since optimistic sharing works well. We must thus choose a tool that can implement the copy-merge work model (Feiler, 1991).

Continuous Integration

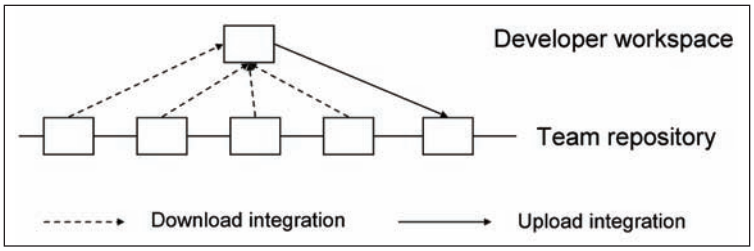
In traditional projects, the integration of the contributions of many people is always a painful process that can take days or even weeks. Therefore, continuous integration seems like a mission impossible, but this is actually not the case. The reason why integration is painful can be found in the "double maintenance" problem (Babich, 1986)—the longer we carry on the double maintenance without integrating changes, the greater the task of integration will be. So there are good reasons for integrating as often as possible, for instance after each added feature.

Integrating your change into the team's shared repository is often a two-step process. The reason is that tools usually cannot solve merge conflicts and re-run automated tests to check the quality in one step. First, you have to carry out a "download" (or subscription) integration where you take all the changes that have been added to the repository since you last integrated and integrate them into your workspace, as shown in Figure 3, where a box represents a new version of the configuration. If nothing new has happened, you are safe and can do the "upload" (or publication) integration, which simply adds your changes as the latest versions in the repository. If something has changed in the repository, it can be either new versions of files that you have not changed—these can simply be copied into your workspace—or files that you have changed where there may be conflicting changes. In the latter case you have to merge the repository changes into your own changes. At this point, all other people's changes have been integrated with your changes and your workspace is up-to-date, so you could just add the result to the repository. However, you should check that the integration actually produced a viable result and check the quality of it. This can be done by running a set of quality tests (e.g., unit tests, acceptance tests), and if everything works well, then you can add the result to the repository—if your workspace is still up-to-date. Otherwise, you have to continue to do "download" integrations and quality checks until you finally succeed and can do the "upload" integration, as shown in Figure 3.

This way of working (except for the upload quality control) is implemented in the strict long transactions work model (Feiler, 1991). You will notice that in this process, the upload integration is a simple copy of a consistent and quality assured workspace. All the work is performed in the download integration. Following the advice of Babich (1986), this burden can be lessened if it is carried out often as the changes you have to integrate are smaller. So for your own sake you should download integrate as often as possible. Moreover, for the sake of the team you should upload (publish) immediately when you have finished a task or story so other people get the possibility to synchronize their work with yours.

What we have described here is the commonality between the slightly different models and approaches presented in Aiello (2003), Appleton,

Figure 3. Download and upload integration



Berczuk, and Konieczka (2003a, 2003b, 2004a), Appleton, Berczuk, and Cowham (2005), Farah (2004), Fowler and Foemmel (2006), Moreira (2004) and Sayko (2004). If you are interested in the details about how you can vary your approach to continuous integration depending on your context, you can consult the references.

Continuous integration leads to an increased velocity of change compared to traditional development. This puts additional strains on the integration process but is not a performance problem on the actual integration per se. However, there may be performance issues when the integration is combined with a quality gate mechanism used to determine whether changes are of sufficient quality to be integrated in the common repository or not. Even if this quality gate process is fully automated, it will be much slower than the actual merge and upload operation and may become a bottleneck in the integration process. It may therefore not always be possible to be true to the ideal that developers should carefully test their code before uploading their changes in which case you could use a more complex model for continuous integration (Fowler & Foemmel, 2006) that we will describe next under regular builds.

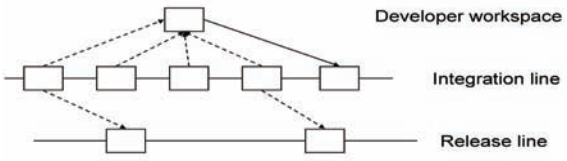
Regular Builds

When releases become frequent it also becomes important to be able to build and release in a lean way. If not, much time will be "wasted" in producing these releases that are needed to get customer feedback. Making it lean can be done in three ways: having always releasable code in the repository, performing a less formal release process, and automation of the build and release processes.

Before you can even think about releasing your code, you have to assure that the code you have is of good quality. In traditional development methods this is often done by a separate team that integrates the code and does QA. In agile, this is done by the developers as they go. The ideal situation is that the code in the repository is always of the highest quality and releasable at any time. This is not always possible and you can then use a mix between the traditional way and the agile ideal by having multiple development lines. The developers use an integration line to check in high quality code and to stay in sync with the rest of the developers. The QA-team uses a separate line to pull in changes from the integration line and does a proper and formal QA before they "promote" the approved change to the release line, as seen in Figure 4.

In agile methods, there is a general tendency to move the focus of QA from coming late in the development process, just before release, to being a centre of attention as early as possible in the development process. This means that agile can do with a less formal release process than traditional projects because much of the work has already been done. However, there is still a need to do physical and functional audits and to work with bill-of-materials such that earlier releases can be re-created again if needed. In agile methods, functional audits can be carried out by running the

Figure 4. Working with integration and release lines



acceptance tests. They are the specification of the requirements that should be implemented. To be really sure that we have implemented everything we claim, we should check the list of acceptance tests against the list of requirements we claim have been implemented in this release. We also need to check whether all the files that should be in the release (e.g., configuration files, manual, documentation, etc.) are actually there.

When releasing becomes a frequent action, there is a much greater need to automate it. The actual creation of the release can be automated by using build tools; acceptance tests and the verification that all files are there can be automated by writing simple scripts.

More information about regular builds can be found in Appleton and Cowham (2004b).

Refactoring

Refactoring is an important part of agile methods but also to some extent in traditional methods. The purpose of a Refactoring is not to implement new functionality, but rather to simplify the code and design.

In general, there are two different situations where you do refactorings: as part of a story to simplify the code before and/or after the implementation of the story's functionality; and architectural refactorings that are needed to implement a whole new set of features. In both cases, the two main problems are that a refactoring may touch large parts of the code and that the refactoring should be traceable and possible to undo. The latter means that there is the need for version control tool to keep track of the steps of each refactoring and make it possible to back out of a refactoring if it turns out that is does not work.

The fact that refactorings tend to be "global" possibly affecting large parts of the code, puts even greater strains on the continuous integration since there are more possibilities of merge conflicts. The recommendation for successful application of continuous integration is to integrate very often to reduce the risk of merge conflicts. The same goes for refactorings that should be split up into many small steps that are integrated immediately when they are done.

If you need to refactor code to facilitate the ease of implementing a story, then this refactoring should be seen as a separate step and integrated separately—the same goes if you need to refactor after the implementation of the story. For the architectural refactorings, we need to split the refactoring up into smaller tasks such that there will be as little time as possible between integrations to lower the risk of merge conflicts. Larger refactorings should also be planned and analysed for impact such that it is possible to coordinate the work to keep down the parallel work, or at least to make people aware of the fact that it is going on.

For a more specific treatment of the problems architectural refactorings can cause to SCM tools and the continuous integration process and how these problems can be dealt with, we refer the reader to Ekman and Asklund (2004) and Dig, Nguyen, and Johnson (2006).

Test-Driven Development

The short version of test-driven development is design a little—where you design and write tests, code a little, and finally run the tests to get feedback. Here the crucial part is to get feedback on what you have just changed or added. If that cannot happen very quickly, test-driven development breaks down with respect to doing it in small increments. If you want to run your tests after writing a little code, you must be able to re-build the application you want to test very quickly—if you have to wait too long you are tempted to not follow the process as it is intended.

So what is needed is extremely quick re-builds, a matter of a few minutes or less, and the good news is that SCM can provide that. There are techniques for doing minimal, incremental builds that will give you a fast turn-around time, so you

can run your tests often without having to wait too long. Make (Feldman, 1979) is the ancestor of all minimal, incremental build tools, but there exists a lot of research on how to trade "consistency" of a build for time (Adams, Weinert, & Tichy, 1989; Schwanke & Kaiser, 1988). For the small pair development loop in Figure 2, we might be satisfied with less than 100% consistency of the build as long as it is blisteringly fast. For the big team development loop in Figure 2 (i.e., integrating with others), speed might not be that important while consistency of the build is crucial. A properly set up SCM system will allow developers to have flexible build strategies that are tailored to specific parts of their development cycle.

Another aspect of test-driven development is that if we get an unexpected result of a test-run, then we have to go bug hunting. What is it that has caused the malfunction? If you run tests often, it means that you introduced the bug in the code that you wrote most recently—or as Babich puts it "an ounce of derivation is worth a pound of analysis" (Babich, 1986)—meaning that if we can tell the difference in the code between now and before, we are well under way with finding the bug. Version control tools provide functionality for showing the difference between two versions of the same file and some tools can even show the structural differences between two versions of a configuration.

Planning Game

Agile methods use stories, or similar lightweight specification techniques, as the way that customers specify the requirements of the system, and acceptance tests to specify the detailed functionality. These stories specify changes to the system and correspond to change requests when analyzed from an SCM perspective. The stories, or change requests, have to be estimated for implementation cost by the developers and then prioritised and scheduled by the customer during the planning game. For someone coming from SCM this sounds very much like the traditional way of handling change requests: an impact analysis has to be carried out to provide sufficient information for the Change Control Board to be able to make its decision whether to implement the change request, defer it, or reject it. So we can see that the parallel to estimation in agile is impact analysis (Bohner & Arnold, 1996) in traditional SCM. Likewise, the parallel to the customer prioritising is the chair of the Change Control Board taking decisions (Daniels, 1985). For the planning game to work properly, it is important that everyone is aware of what his or her role is—and that they seek information that will allow them to fill that role well. It is also important to be aware of the fact that the traditional formal change request handling process can indeed—and should—be scaled to fit the agility and informality that is needed in an agile method.

How Can SCM Add More Value to Agile?

In agile methods, there is very much focus on the developers and the production process. In the previous sub-section, we have seen how many of these processes can be well supported by techniques and principles from SCM. However, agile methods often overlook the aspects of SCM that deal with the relation to the customer and where traditional SCM has special emphasis. In the following, we look at the traditional SCM as represented by the four activities of configuration identification, configuration control, configuration status accounting, and configuration audit (Leon, 2005). For each activity, we describe what new activities and processes could be added to agile methods to help provide a more covering support for the development team.

Configuration Identification

The most relevant part of configuration identification for agile methods is the identification

and organisation of configuration items. Some artefacts are so important for a project that they become configuration items and go into the shared repository. Other artefacts (e.g., sketches, experiments, notes, etc.) have a more private nature and they should not be shared in order not to confuse other people. However, it may still be convenient to save and version some of the private artefacts to benefit from versioning even though they are not configuration items. They can be put into the repository but it is very important that the artefacts, configuration items and not, are structured in such a way that it is absolutely clear what a configuration item is and what a private artefact is. Structuring of the repository is an activity that is also important when it contains only configuration items.

Configuration identification is an SCM activity that traditionally is done up-front, which goes against the agile philosophy. However, there can be some reason in actually trying to follow the experience that SCM provides. Rules for identifying configuration items should be agreed upon, such that they can be put into the repository and information about them shared as early as possible. More importantly, though, is that the structuring of configuration items should not be allowed to just grow as the project proceeds, because most SCM tools do not support name space versioning (Milligan, 2003) (i.e., handling structural changes to the repository while retaining the change history).

Configuration Control

The part of configuration control that deals with the handling of change requests is taken care of by a planning game or similar activity. However, two important aspects of configuration control are neglected by most agile methods: tracking and traceability.

In traditional SCM, change requests are tracked through their entire lifetime from conception to completion. At any given point in time, it is important to know the current state of the change request and who has been assigned responsibility for it. This can benefit agile methods too as they also need to manage changes and coordinate the work of different people. In some agile methods there is an explicit tracker role (chromatic, 2003) that is responsible for this activity.

Traceability is an important property of traditional SCM and is sometimes claimed to be the main reason for having SCM. It should be possible to trace changes made to a file back to the specific change request they implement. Likewise, it should be possible to trace the files that were changed when implementing a certain change request. The files that are related to a change request are not just source code files, but all files that are affected by that change (e.g., test cases, documentation, etc). Another aspect of traceability is to be able to know exactly what went into a specific build or release—and what configurations contain a specific version of a specific file. The main advantage of having good traceability is to allow for a better impact analysis so we can be informed of the consequences of changes and improve the coordination between people on the team.

Configuration Status Accounting

This activity should be seen as a service to everyone involved in a project including developers and the customer, even though it traditionally has been used primarily by management and in particular project managers. Configuration status accounting can be looked at as simple data mining where you collect and present data of interest. Many agile methods are very code centred and the repository is the place where we keep the configuration items that are important for the project, so it is natural to place the meta-data to mine in the same repository. Configuration status accounting does not need to be an upfront activity like configuration identification, but can be added as you discover the need. However, you should be aware that the

later you start collecting data to mine, the less data and history you get to mine. Usually this is seen as an activity that benefits only managers, but there can be much support for the developers too—all you have to do it to say what kind of meta-data you want collected and how you want it to be presented. If you do not document changes in writing, then it is important that you can get hold of the person that did a change; when you have shared code, then it is important to see who is currently working on what.

Configuration Audit

Configuration audit can be looked at as a verification activity. The actual work, considered as a QA activity, has been done elsewhere as part of other processes, but during the configuration audits, it gets verified that it has actually been carried out. The functional configuration audits verify that we have taken care of and properly closed all change requests scheduled for a specific build or release. The physical configuration audit is a "sanity check" that covers the physical aspects (e.g., that all components/files are there—CD, box, manual) and that it can actually be installed. Even though configuration audit is not directly a QA activity, it contributes to the quality of the product by verifying that certain SCM and QA activities have actually been carried out as agreed upon. Configuration audits are needed not because we mistrust people, but because from time to time people can be careless and forget something. The basis for automating the functional configuration audit in agile is there through the use of unit and acceptance tests.

SCM Plans and Roles

You definitely need to plan and design your SCM activities and processes very carefully on an agile project. Moreover, they have to be carried out differently from how they are done on traditional projects and the developers will need to know more about SCM because they are doing more of it on an agile project.

This does not imply that you should write big detailed SCM plans the same way as it is being done for traditional projects. The agile manifesto (Agile Manifesto, 2001) values working software over comprehensive documentation. The same goes for SCM where you should value working SCM processes over comprehensive SCM plans. In general, what needs to be documented are processes and activities that are either complex or carried out rarely. The documentation needs to be kept alive and used—otherwise it will not be up-to-date and should be discarded. We can rely on face-to-face conversation to convey information within a team when working in small groups and maybe even in pairs. However, if the team grows or we have a high turnover of personnel, that might call for more documentation. If possible, processes should be automated, in which case they are also documented.

In general, agile projects do not have the same specialization in roles as on traditional projects. Everyone participates in all aspects of the project and should be able to carry out everything—at least in theory. This means that all developers should have sufficient knowledge about SCM to be able to carry out SCM-related activities by themselves. There will, for instance, not be a dedicated SCM-person to do daily or weekly builds or releases on an agile project. However, to do the design of the SCM-related work processes, even an agile team will need the help of an SCM expert who should work in close collaboration with the team such that individuals and interaction are valued over processes and tools (Agile Manifesto, 2001).

SCM Tools

In general, SCM is very process centric and could, in theory, be carried out by following these

processes manually. However, agile methods try to automate the most frequently used processes and have tools take care of them (e.g., repository tools, build tools, automated merge tools, etc). Fortunately, the requirements that agile methods have to SCM tooling are not very demanding and can, more or less, easily be satisfied by most tools. For this reason, we do not want to give any tool recommendations or discuss specific tools, but rather focus on the general requirements and a couple of things to look out for. Furthermore, most often, you just use the tool that is given or the selection is based on political issues.

Using parallel work, we would need a tool that works without locking and thus has powerful merge capabilities to get as painless an integration as possible. Using test-driven development, we need to build very often so a fast build tool is very helpful—and preferably it will be flexible such that we can sometimes choose to trade speed for consistency. Working always against baselines, it would be nice if the repository tool would automatically handle bound configurations (Asklund, Bendix, Christensen, & Magnusson, 1999) so we should not do that manually.

However, a couple of things should be taken into account about SCM tooling. Because of refactoring and the fact that the architecture is grown organically, there will be changes to the structure of the files in the repository. This means that if the tool does not support name space versioning (Milligan, 2003), we will have a harder time because we lose history information and have no support for merging differing structures. However, this can be handled manually and by not carrying out structural changes in parallel with other work. It is much more problematic to actually change your repository tool in the middle of a project. Often you can migrate the code and the versions but you lose the meta-data that is equally as valuable for your work as the actual code. Therefore, if possible, you should try to anticipate the possible success and growth of the project and make sure that the tool will scale to match future requirements.

FUTURE TRENDS

While resisting the temptation to predict the future, we can safely assume that the increased use and awareness of SCM in agile development will result in a body of best practices and increased interaction between agile and SCM activities. Furthermore, we expect to see progress in tool support, including better merge support and increased traceability to name a few.

Continuous integration is an activity that has already received much attention and is quite mature and well understood. Many other SCM-related activities require continuous integration and we expect to see them mature accordingly when that foundation is now set. This will result in new best practices and perhaps specific SCM-related sub-practices to make these best practices explicit. A first attempt to specify SCM sub-practices for an agile setting is presented in Asklund, Bendix, and Ekman. (2004) and we expect them to mature and more sub-practices to follow.

SCM tools provide invaluable support and we envision two future trends. There is a trend to integrate various SCM-related tools into suites that support the entire line of SCM activities. These tools can be configured to adhere to pretty much any desired development process. They may, however, be somewhat heavyweight for an agile setting and as a contrast, we see the use of more lightweight tools. Most SCM activities described in this chapter can be supported by simple merge tools with concurrency detection.

Parallel work with collective code ownership can benefit from improved merge support. Current merge tools often operate on plain text at the file level and could be improved by using more fine-grained merge control, perhaps even with syntactic and partially semantics aware merge. An alternative approach is to use very fine-grained merge combined with support for increased awareness to lower the risk of merge conflicts. The increased use of SCM will also require merge support for

other artefacts than source files.

The use of SCM in agile development will enable better support for traceability and tracking of changes. A little extra effort can provide bi-directional traceability between requirements, defects, and implementation. However, more experience is needed to determine actual benefits in an agile context before one can motivate and justify this extra "overhead."

SCM is being used more and more in agile methods, despite not being mentioned explicitly. However, it is often carried out in the same way as in traditional projects, but can benefit from being adapted to this new setting. The practices presented in this chapter adapt SCM for agile methods but more widespread use will lead to even more tailored SCM. In particular, SCM practices will be further refined to fit an agile environment and probably lead to more agile SCM. Some of these ideas may indeed transfer to traditional projects, providing more lightweight SCM in that setting as well.

CONCLUSION

SCM provides valuable activities that enhance the QA for agile development. The main quality enhancement does not stem directly from SCM but indirectly by supporting other quality enhancing activities. Traceability is, for instance, crucial to evaluate any kind of quality work, and configuration audits verify that SCM and QA activities have been carried out.

We have shown how typical agile activities can be supported directly by SCM techniques while retaining their agile properties. For instance, continuous integration demands support from SCM tools and processes to succeed while build and release management can help to streamline the release process to enable frequent releases. SCM can thus be used to support and strengthen such developer-oriented activities.

SCM is traditionally very strong in aspects that deal with the relation to the customer. Agile methods can benefit from these activities as well. Configuration control allows precise tracking of progress and traceability for each change request. Lightweight SCM plans simplify coordination within a team and help in effective use of other SCM-related activities. These are areas that are often not mentioned explicitly in agile literature.

There is, in general, no conflict between agile methods and SCM—quite the contrary. Agile methods and SCM blend well together and enhance each other's strengths. Safe SCM with rigorous change management can indeed be carried out in an agile project and be tailored to agile requirements.

SCM tools provide help in automating many agile activities, but we must stress that what is important are the SCM processes and not so much a particular set of tools. There are also many agile activities that could be supported even better by enhanced tool support. For instance, current merge tools are often fairly poor at handling structural merges such as refactorings; often this results in loss of version history and traceability, and incomprehensible merge conflicts.

Many agile teams already benefit from SCM, but we believe that a more complete set of SCM activities can be offered to the agile community. Tailored processes and tools will add even more value and may indeed result in SCM activities that are themselves agile, which may even have an impact on more traditional software development methods.

ABSTRACT

Governance is the exercise of control and direction over a subject such as a society, an organization, processes, or artifacts, by using laws and policies that are defined, deployed, and executed. In this chapter we develop this definition into a formal conceptual model that can be applied to a variety of governance domains. At the heart of this model lies the concept of the governance solution and its lifecycle. The governance solution embodies the set of mechanisms—decision rights, policies, controls, and measurements—applied to a governance scope in order to achieve some governance goals. As part of the lifecycle, the effectiveness of the governance solution is measured, and corrections and alignments are made as necessary. We demonstrate how this model can be applied to multiple governance domains by providing examples from IT governance as well as software-development governance. We conclude by providing a detailed scenario in the

software-development governance space, which looks at large software organizations undergoing transition to agile development methodology. We further demonstrate how the governance model is instantiated and evolved in the context of this scenario.

INTRODUCTION

The field of information technology (IT) governance has garnered an increased amount of attention in recent years. However, it is still struggling to provide a universally agreed-upon definition and a complete model for IT governance, along with the required tools and techniques.

The definitions of IT governance that can be found in the literature from Broadbent (1998), Chulani, Clay, Yaeli, Wegman, and Cantor (2006), Van Grembergen and De Haes (2004), Weill and Ross (2004), and Williams (2005) and they all share common ideas, such as the need to increase the value of IT to the organization while reducing risk. For example, *Weill and Ross (2004) focus on decision rights and define IT governance as* "specifying the decision rights and accountability framework to encourage desirable behavior in the use of IT" (p. 8). Van Grembergen and De Haes (2004) address the alignment of the IT organization with the business needs, and define IT governance as "the leadership and organizational structures, processes, and relational mechanisms that ensure that the organization's IT sustains and extends the organization's strategy and objectives" (p. 1).

Chulani et al. (2006) include both decision rights and the alignment with business needs: "Within IBM, a widely accepted definition for IT governance is:

- Governance that pertains to an organization's information technology activities and the way those activities support the goals of the business
- Decision making rights associated with IT as well as the mechanisms and policies used to measure and control the way IT decisions are made and carried out within the organization" (p. 10).

In recent years, several IT governance and control frameworks, such as CobiT[1], ITIL[2], ISO-17799[3] have been developed. These frameworks help business management, IT management, quality practitioners, and auditors understand what needs to be done; yet they are far from being complete. Dahlberg and Kivijärvi (2006) outline the limitations of CobiT as a process-centric framework and suggest a new framework that takes an integrated process and structural approach, and links into corporate governance.

Another limitation stems from the fact that CobiT is a high-level framework targeted at IT organizations that support a business unit or a business organization. CobiT considers software development activities only within the context of providing a supporting service in a value chain for another business unit, rather than as a central business activity in itself. Software development activities are briefly described in CobiT as part of the high-level control objective AI2, "Acquire and Maintain Application Software." CobiT thus lacks a description of governance mechanisms that are appropriate for organizations with a large focus on software development. To that end, organizations need to refer to other standards and frameworks that focus more on software development and control of software development activities.

This chapter is aimed at bridging the gap between high-level IT governance and software development governance. We first present a model for governance in general, and then use the model to describe IT and software development domain-specific governance. The model is built based on a review of the literature and a set of scenarios, as explained in the next section. We use the process of transition to agile software development (Beck & Andres, 2004; Dubinsky, Hazzan, Talby, &

Keren, 2006; Highsmith, 2002) to demonstrate the domain-specific governance schemes.

The agile approach to software development has emerged over the last decade, becoming mainstream as more and more organizations adopt agile practices (Barnett, 2006). The approach is based on a manifesto[4] that emphasizes the individuals involved in the software development, collaboration with the customer, and the need to provide testable working software. Several principles and methods (Highsmith, 2002) are used by software teams in different capacities (Ambler, 2007). As agile software development becomes more common, software organizations are becoming more interested in governing the transition to an agile approach.

We present data from the first author's involvement in two software-development projects that were carried out at two different organizations that underwent the transition to agile. The first project was developed by the IT department of a financial organization. The second project was developed by the software group of an international product provider. The action research method (Lewin, 1948) is used in this field of transition to agile processes, where the researchers plan an action, execute it while collecting data, analyze the data and reflect on it, and then define the next action by refining their role. The data emerged from their participation in planning sessions, guiding retrospective processes, involvement in refining the process and product measures, and consulting to higher management on the adoption of agile methodologies into the work procedures.

GOVERNANCE MODEL

This section presents a model for governance. The purpose of the model is to uniformly represent the main concepts involved in a governing process and their interrelationships. The development of this model started with a literature review, and built upon existing work using a set of scenarios that relate to project management, software engineering, and development processes. The literature review included CobiT; Val IT[5]; ISO 17799; OCEG Foundation[6]; CMMI[7]; SWEBOK[8]; Weill and Ross (2004); and Abrams, von Känel, Mueller, Pfitzmann, and Ruschka-Taylor (2006). The set of scenarios is based on our field experience as well as experiences of other practitioners and researchers with whom we collaborate. The model attempts to abstract the elements of governance found in the various references and domains. We therefore start with the dictionary definitions of the word governance rather than with one of the many domain governance definitions that exist in previous works.

We begin by examining the general meaning of governance and incrementally introduce elements of the model that stem from that basic definition. The model reflects our view of how governance and governance processes should be organized and may require modifications to describe some existing situations.

The word govern is defined[9] as "to exercise continuous sovereign authority over; especially to control and direct the making and administration of policy in" and also "to control, direct, or strongly influence the actions and conduct of." The first part of the definition implies that

- Governance is an ongoing process;
- There must exist an entity with legitimate rights to exercise authority over the things that are subject to governance;
- Governance is concerned with controlling the way policies and laws are established.

The second part of the definition suggests that the purpose of governance is to influence or affect the activities, state, or behavior of the subjects being governed. Hence, governance affects and regulates its subjects through the administration of policies.

Scoping Authority over Subjects

The definition of governance specifies that governance exercises legitimate authority over the subjects being administered. We need a way to describe the boundaries of the subjects and activities being governed, as well as the boundaries of the area of jurisdiction over which the governing entity will have legitimate authority. Furthermore, we know that people are subject to multiple governing bodies, such as national and local governments, as well as the organizations where they work. It is therefore necessary to describe multiple authority hierarchies and the relationships across these levels.

A governance scope represents a set of entities and relationships that are subject to acts of governance. Governance scope is hierarchically decomposable so that it can capture the hierarchical nature of society and business organizations. However, in order to represent multiple overlapping hierarchies, a governance scope can belong to more than a single hierarchy. In principle, a scope can identify organizations, suborganizations, processes, activities, roles, and artifacts; it can then establish the boundaries over the entities that are governed. In the context of corporate governance, the scope would be the entire organization and its activities. In the case of IT governance, the scope would be the IT organization, processes, activities, roles, and resources. According to Cantor and Sanders (2007), it is often useful to express the scope of governance in terms of processes within organizations, since there are many existing standards that consistently decompose the entire activities of organizations into processes and activities. Examples of such standards include CobiT and ITIL.

A governing body, sometime referred to as the government, represents the set of roles that have the right to exercise authority over the governance scope. Within social and business organizations, it is common to find multiple governing bodies, each of which focuses on different kinds of scopes and is concerned with different governance needs. It is therefore useful to think about the arrangement of governing bodies in hierarchies and to align them with the hierarchies of governance scopes. By doing so, we can express the delegation of legitimate authority between governing bodies across the organization hierarchy, and the fact that legislation enacted by one governing body needs to conform, or at least not conflict with, legislation done by another governing body higher in the governing hierarchy chain. For example, a local government cannot create laws that violate national and federal laws. Within business organizations, it is common to find a hierarchy of governing bodies based on an organizational structure. We also consider process owners as governing bodies who are given authority to exercise control and legislation within the scope of their processes. Figure 1 illustrates the hierarchical nature of governance scopes and the relationships between these and the governing bodies.

There is a large body of political science literature that talks about types of governments (e.g., democracy, monarchy), how they are established,

Figure 1. Modeling governance scopes and governing bodies

and the accountability of the governors to their constituents. The current version of our model does not address those elements of political models of governments.

Goals of Governance

According to the second part of the definition, the purpose of governance is to influence the activities, state, or behavior of the subjects being governed. The need to influence the subjects in the first place often stems from external forces that place constraints or requirements on the activities within the governance scope. For example, state government regulations place constraints on organizations that do business within the jurisdiction of the state. Another example is the need to establish or update service delivery policies based on new security policies established by the larger organization. A final example is an IT organization that needs to control costs or improve performance based on business needs.

Hence, the context represents the overall situation and set of internal and external relationships in which a governance scope exists and in which its activities take place. The context sometimes acts as the driver or source of requirements for the act of governance.

A governance goal represents the desired state that the initiative or act of governance is trying to achieve within the governance scope. A goal needs to be measurable and provide a clear indication of how success and failure will be assessed. Governance goals are hierarchically decomposable, allowing the nesting of sub-goals. In this case, the success criteria of a high-level goal can be expressed as functions of the success criteria of the sub-goals. An example of a governance goal in business organizations is "ensuring that the organization performs effectively and efficiently against the requirements and imperatives coming from its context, and to ensure the delivery of the expected outcome." It is useful to express the governance goals in the terminology of the context; this enhances the communication between different stakeholders by providing a common vocabulary.

Governance Mechanisms

Based on our governance definition, governance requires the means to "control, direct, or strongly influence the actions and conduct" of the governed subjects. A governance mechanism represents an abstraction of the possible mechanisms that can be used to regulate, influence, or control the actions and conduct of elements described within the governance scope in order to achieve some governance goal. There are many kinds of governance mechanisms that have been suggested and categorized by academia, industry standards, and vendors. Weill and Ross (2004) highlight three categories of mechanisms: decision-making structures, process alignment, and communication mechanisms. CobiT focuses on mechanisms to control processes, and identifies policies, procedures, practices, and organizational structures as means of control. IBM identifies two major groups of mechanisms that are established in the governance process (Chulani et al., 2006; Ericsson, 2007):

- **Static mechanisms:** Chains of responsibility, authority, and communication (decision rights);
- **Dynamic mechanisms:** Measurement, policy, standards, and control mechanisms.

All these definitions are compatible and cover more or less the same types of mechanisms, although the organization and focus are sometimes different. The following are several examples of these mechanisms and how they influence the governance scope:

- Decision rights mechanisms are the means through which an organization can establish, charter, and communicate the roles and

responsibilities for particular management and decision-making processes. Typically, the decision rights are documented and communicated in a policy, such as a spending policy that allows a first-line manager to approve spending up to $3000 without a senior manager's signature. A RACI matrix (Hallows, 2001) is an example of a structured way to describe decision rights.

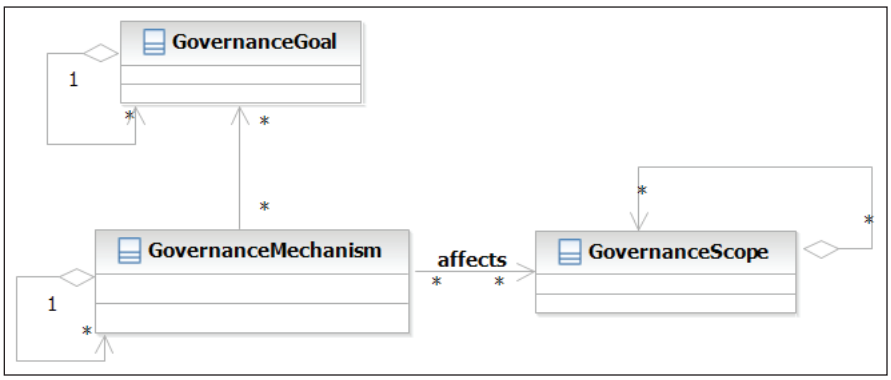
- Policies, procedures, guidelines, practices, and standards mechanisms all instruct the subjects under governance at varying level of formalism and strictness of the desired behavior or how to conduct their activities. Controls, measurements, and decision authority are often documented and communicated in policies and procedures.
- Control and measurement mechanisms provide the means for people with decision-making rights to control and monitor the activities for which they are responsible. Decision checkpoints, incentives, and policy assertions are examples of controls. For example, a project funding approval checkpoint is a control in the project funding process. An ROI measurement is a mechanism used to measure the return of investment in an asset. Another example is the measurement of estimated versus actual development time for software development tasks. Note that measurement has a dual role: it enables monitoring but also acts as an influencing mechanism that drives the behavior of the subjects.

The governance mechanism should provide a clear statement of its desired effect on the governance scope via one or more governance goals. Furthermore, governance mechanisms can be hierarchical, allowing governance goals to be met by a hierarchy of governance mechanisms. Figure 2 shows the part of the model that describes governance goals, scopes, and mechanisms. A governance mechanism affects a governance scope to realize a governance goal. In addition, a hierarchy of governance mechanisms can realize a hierarchy of governance goals.

Governance Points and Observables

In order for a governance mechanism to control and monitor an activity within the governance scope, it is necessary to identify the exact situation in the governance scope and the exact condition under which the governance mechanism should operate. This identification also serves as the specification for how to implement and deploy the governance mechanism. A governance point represents a specified location and situation within

Figure 2. Modeling governance scopes, mechanisms, and goals



the governance scope to which a governance mechanism should be applied. For example, a policy that enables a first-line manager to approve vacations that do not exceed two consecutive weeks creates a governance point. This point is the set of situations in which first-line managers in the governance scope should decide upon vacation approvals.

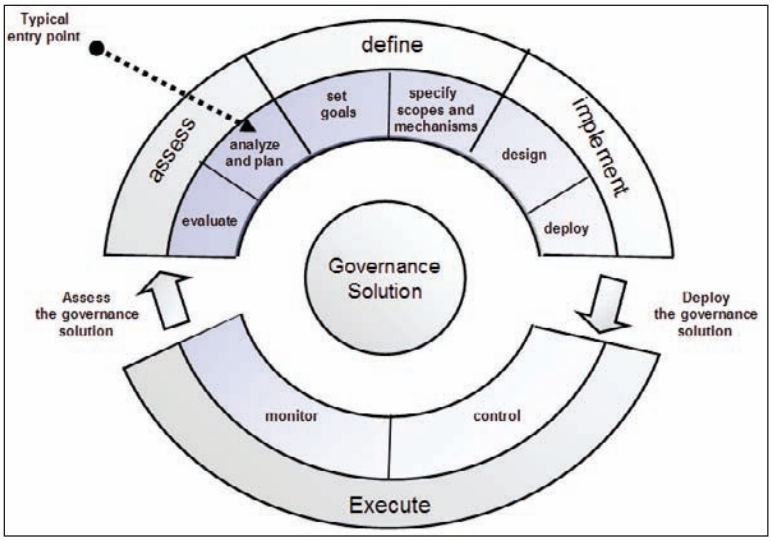
From an operational perspective, it is useful to express governance points in the context of artifact lifecycles, where events, activities, and state transitions of the artifacts act as potential points to which governance mechanisms can be applied. This creates a common structure for the definition of governance points. It also supports the implementation and integration of the governance mechanism into the processes and software automation of the activities described in the governance scope.

A governance observable represents a metric, event, piece of information, or artifact metadata that can be observed by a governance mechanism at a governance point. This provides the means to characterize the behavior of the governance scope by identifying observable information that could be used to help achieve the governance goals. It also allows the identification of specific properties within the governance scope that are relevant to achieving a governance goal. For example, such properties may include an event or attribute that are used for calculating a metric.

Governance Solutions and the Governance Process

So far we have shown how governance mechanisms can be associated with governance scopes to achieve governance goals. Often, sets of mechanisms, scopes, and goals collectively have some significance from the perspective of an organization, process, or initiative. In such cases, it is useful to refer to them as a group. A governance solution represents the collection of governance mechanisms applied to a set of governance scopes to achieve a set of related governance goals. For example, an IT governance solution is the set of governance mechanisms that are applied in the scope of an IT organization, its processes, and activities, to achieve the IT governance goals. Note that the term governance solution is commonly

Figure 3. The governance lifecycle (adapted from Cantor & Sanders, 2007; used with permission)



used (e.g., Cantor & Sanders, 2007) to denote the specification of the mechanisms, scopes, and goals. However, as we discuss next, a governance solution has its own lifecycle and it is necessary to discuss the state of the solution at specification time as well as at other phases of its lifecycle.

As presented in the definition, governance is an ongoing process. In fact, it is an iterative process through which the governance solution is established and evolved. In Figure 3, we present the lifecycle of that process and typical activities that are likely to take place in each phase of the lifecycle. Among different lifecycle views, such as the plan–do–study–act (PDSA) cycle (Tague, 2004), we have chosen to adapt the approach of Cantor and Sanders (2007) to governance lifecycle. This approach emphasizes the separation between activities to establish and evolve a governance solution, and those relating to the execution of the governance solution.

The governance process has four major phases:

1. **Assess:** The current governance solution is evaluated and new requirements for the governance solution are analyzed and planned. This includes measuring governance effectiveness metrics, assessing key performance indicators against previously defined governance goals, and planning how to address new governance needs arising from the context, such as new regulations.
2. **Define:** The governance solution is defined. The governance goals are captured and governance effectiveness measurements are defined. The scopes to bring under governance are determined and the governance mechanisms are specified.
3. **Implement:** This phase includes all the steps necessary to realize the defined governance specification and prepare it for execution by the organization. This phase could include process reengineering, automation and tool support, education, infrastructure deployment, policy announcement, and so forth. The governance model presented here does not focus on the artifacts generated in this phase.
4. **Execute:** The solution has already been deployed in the organization and management is expected to execute the governance solution. Managers and other specified roles are exercising their decision rights and playing a role in controlling and monitoring the scopes under their responsibility.

The governance lifecycle shows a clear separation between activities done to establish and evolve a governance solution and those that are done while executing a governance solution. This observation can be useful for understanding the relationships between the roles of governors and managers. It can be said that governors are responsible for establishing a governance solution while managers are responsible for executing the governance solution. Moreover, a governing body will sometimes assign decision rights to itself; in those cases, the governing body is also an actor in the execution of the governance solution. Similarly, some managers may sit in governing bodies; in those cases, they assume multiple roles of both governor and manager.

The governance solution can be viewed as having states that correspond to the governance process phases. It is interesting to note that there is always some version of a governance solution that is in the state of "executing" for any given scope. In each iteration of the lifecycle, the governance process can modify an executing governance solution by defining, implementing, and deploying a new version of that solution. Furthermore, some steps of the Assess phase of the governance lifecycle may also be running continuously by monitoring the executing governance solution.

A governance execution result represents the result of applying a governance mechanism at a particular time. It is a measurement that relates to the governance scope, but is used in the context

of the governance assessment phase. Examples of such measurements might be compliance records/status or governance performance indicators.

Figure 4 illustrates the model of the governance solution. A governance mechanism can be used to affect some behavior within a governance scope to realize some governance goal. The governance mechanism can be applied at specific governance points within the governance scope to affect or observe some behavior within the scope. The result of applying the mechanisms is stored in a governance execution result that is produced by the mechanism.

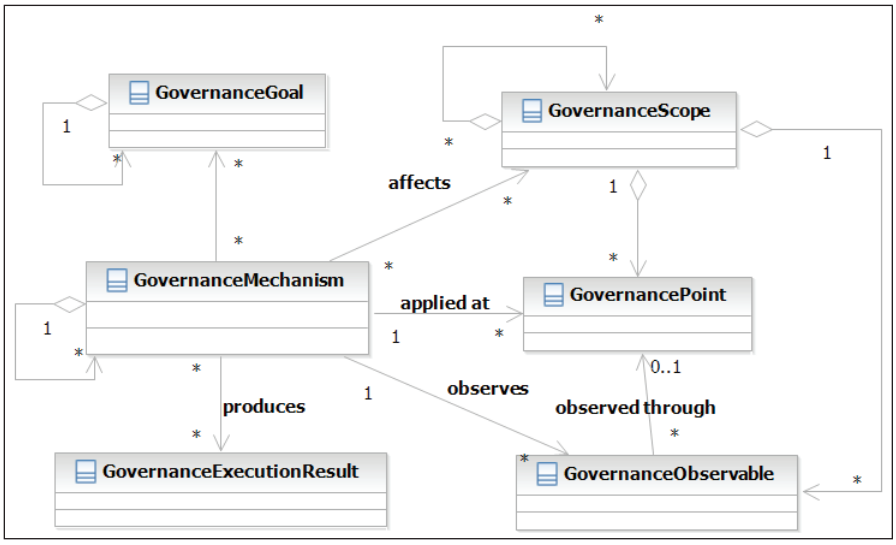
Systems of Governance Solutions

We are seeing a proliferation of governance solutions established by multiple governing bodies to cover a wide range of governance scopes. How are governance solutions related and how can the solutions be orchestrated to scale up when governing a large organization?

To answer this question, we make the following observations:

- There are multiple governance processes that are executed asynchronously by different governing bodies. Each has its own lifecycle and the governance solution of different governing bodies can be in different states. Furthermore, the cycle time may not be the same in all governance processes. Some processes may have a one-year cycle, while others have a quarterly cycle, depending on how adaptive and responsive the governance should be to the changing scope and context.
- Governance solutions have relationships. For example, governance decisions made by the large organization will have an effect on the governance solutions established for smaller organization scopes. In fact, the former can be viewed as part of the context of the latter. For example, a larger organization can define a policy stating that all sub-organizations should be ISO-certified within two years. This imposes a requirement for each organization to initiate a governance solution focusing on ISO certification.

Figure 4. Modeling the governance solution



- Governance solutions can be defined for varying granularities of scope. For example, governance solutions that are established by the board of directors and apply to an entire organization may coexist with a governance solution that focuses on development policies for a 30-person agile project.

To summarize, while the governance solution can autonomously execute for any given scope and goal, it can also link to other governance solutions either through the context or by establishing governance mechanisms that affect other governance solutions. These two characteristics ensure the scalability of the governance model.

TRANSITION TO AGILE SCENARIO: A GOVERNANCE PERSPECTIVE

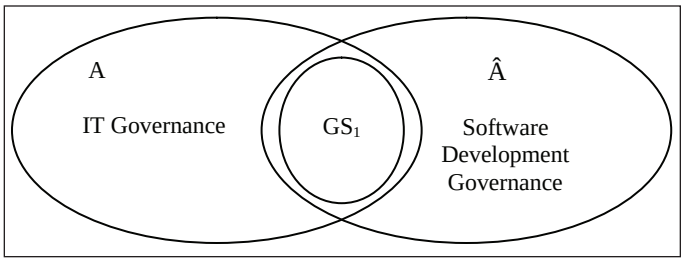
In this section, we present some of the data that was gathered in two different organizations that underwent a transition to agile development. The first (denoted by A) is a financial organization using software developed by an agile team, which is part of the organization's IT department. The team actually works for another organization (denoted by Â) and is outsourced to organization A to develop and maintain its software products. The second organization (denoted by B) is a global company that manufactures devices with embedded software. Several distributed teams, one of which has started to use agile methods, develop the software. The data was gathered by observations in planning sessions and development activities, consultation to higher management, and by guiding the retrospective process of the agile team.

We use the governance concepts described in the previous section to present the case of software development governance and analyze the transition-to-agile processes in the two organizations.

Governance scope. In both organizations, the transition to agile development began with one project. The management of organization Â decided to improve the delivery time of software projects and selected the project in organization A as an experiment for the agile approach. The intention of the management of organization Â was to extend use of the agile approach to more of its software projects. Examining the governance scope in this case, we denote by GS_1 the scope that contains the project team and its activities. Figure 5 schematically shows GS_1 as an inner scope in the two different hierarchies of organizations A and Â. In organization A, GS_1 is part of the IT governance; in organization Â, GS_1 is part of the software development governance. The teammates are the employees of organization Â outsourced to A.

In organization B, the project team and its activities are defined as the governance scope, which is within the hierarchy of the software development governance in this organization. In this case, the project manager together with his

Figure 5. Hierarchy of governance scopes in organizations A and Â



team leaders learned about the agile approach and decided to start the transition in their jurisdiction. In parallel, they started the process of convincing their upper management that it was worthwhile. This was different from organization Â, where the direction of governance is top-down.

Governing body. The governing body in the case of GS_1 included governors from both organizations A and Â. The governors from organization A were the CIO and the domain expert that served as the onsite customer. This expert was responsible for directing the team according to the release vision, giving them the requirements for each iteration, and prioritizing the requirements. The CIO and the domain expert could delegate authority to others in organization A, such as the people responsible for the infrastructure and those who tested the system as end users. The governors from organization Â continuously monitored this process in order to learn about its benefits and drawbacks. They worked together with the governors of organization A, who agreed to cooperate in implementing a new approach to software development.

In organization B, the project manager and team leaders served as the governing body. As part of the transition process, the role of methodologist was suggested. This person was in charge of maintaining and enhancing the methodology (Dubinsky & Hazzan, 2006). Although other roles that are concerned with the transition (e.g., tracker) were rotated among teammates, the person who performed this role did it consistently and continued to learn about agile methods. She also took upon herself to educate other teams in the organization about agile concepts. As a result, she naturally joined the governing body and is involved in every decision this body makes.

Governance goals. The governance goals of organization A are different from the governance goals of organization Â. Though they share the same scope, the context is different. The governing body of organization A is concerned with the needs of the IT users inside the organization and who use the software to support the business activities of this organization. In contrast, the governing body of organization Â is concerned with the kind of contracts it signs with its customers (in this case, organization A) and how these can be improved to increase business benefits as well as provide high quality products. This difference in governance goals on the same scope requires special attention when dealing with the mechanisms that should be used in this compound solution.

In organization B, the governance goals were derived from previous experience of the governing body in running software projects in this and other organizations. The goals refer on the one hand to the professional aspects of software production and on the other hand to the way the project is viewed in the context of the organization. Hence, one goal is to improve the way software requirements are dealt with and to shorten the time-to-market. Another goal is to follow the software development process used in this organization and published in an internal handbook. The decision to implement the agile approach to cope with the first goal implied that the governing body should communicate to higher management the changes caused by the agile implementation, especially these that do not fit existing procedures. They would also need to reconcile the governance solutions used inside the team and in its relations with the rest of the organization.

Governance mechanisms. The adoption of an agile approach implied several governance mechanisms. The most conspicuous was the work procedure that required short development iterations. In both organizations A and B, a release contains about eight iterations of two weeks each. When uncertainty increased, usually towards the end of the release, the iterations were shortened to one week. An iteration of two weeks was composed of one day of presentations and planning, and nine days of development. During the day of presentations and planning, the team presents the artifacts of the previous iteration to the customer and, together with the customer, plans the

functionality to be developed in the next iteration. During the nine days of development, the team develops the required functionality and no new requirements are accommodated.

Another example of a mechanism that was derived from the agile approach is the policy that states who the customer is and the definition of this role. In both organizations A and B, before the transition-to-agile process, the project manager played the role of the customer in setting the functionality developed by the team, along with the priorities and schedule. This behavior caused an on-going negotiation between the project manager and the real customer. The project manager generally refused to change requests that the real customer prioritized as important and continued to distribute work to the team as seemed necessary. The agile approach set the rules clearly: the customer is the one who provides the software requirements, decides what the team will develop in every iteration, and the priorities of these requirements. Of course, the customer can and should receive all the professional advice the team and the project manager can give. The customers should commit themselves to the process of development, be available during the iteration, particularly in the presentations where they gave feedback and in planning sessions where they reviewed the progress. The project manager should manage the development process and people so that a high quality software product will be developed.

The agile metrics are used in both organizations as the measurements of the process and product. Each team contains a tracker who is responsible for collecting the data required by the metrics and for communicating them at the end of the presentation of the iteration artifacts. The agile metrics can be used as governance observables. One measurement that was used by both teams is the calculation of estimated time of completed tasks versus the actual time that was invested to develop them. Next, we present governance observables that illustrate this measurement.

Governance points and observables as part of the governance lifecycle. The notions of governance scope, governing body, governance goals, and mechanisms are part of the Define and Implement phases of the governance lifecycle (see Figure 3). The governance points and observables exist in the Execute phase. The following are two kinds of governance mechanisms that are found in both organizations and that provide observables data:

- The measurement of estimated time of daily-completed tasks versus the actual time that was invested to develop them.
- The policy of conducting one-hour retrospectives at every iteration (Talby, Hazzan, Dubinsky & Keren, 2006).

These mechanisms belong to specific goals that are common in processes of transition to agile in general and were specifically set as goals also in our two cases.

- The first goal was to shorten delivery time. One of the mechanisms that serve this goal is measuring team velocity, which can be perceived as the amount of productive work units per iteration (Beck & Fowler, 2000). The agile approach recommends small releases of two to three months, each of which consists of short iterations of two to four weeks. Measuring team velocity per iteration enables ongoing visibility of the progress information as well as the ability to make decisions on how to continue.
- The second goal was to continuously improve the process by gradually adopting agile practices. One of the mechanisms that serve this goal is when teammates reflect on their activities (Hazzan, 2002; Kerth, 2001; Schön, 1983) after every iteration, before they start planning the next iteration. This is done as part of a retrospective process that enables individuals and teams to share ideas

about the major issues that emerge in their software development environments, think about ways to improve, and make decisions to support these improvements.

The data on team velocity and retrospective processes can be presented as governance observables that emerged in the Execute phase and are used as part of the Assess phase of the governance lifecycle. We present these observables in the following sections. We note that there are further issues that are relevant to the transition to agile scenario, such as testing and quality assurance, simplicity as a concept, and the role scheme, which are not addressed here.

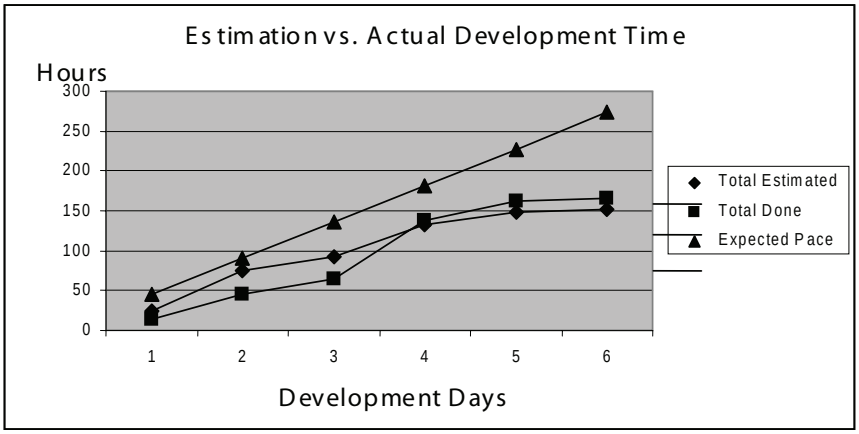
Team Velocity

The first governance observable is the graph of estimated time of completed tasks versus the actual time that was invested to develop them. One associated governance point occurs every development day when the tracker displays the graph during the stand-up-meeting that starts the team's workday. This is done in order to trace the team's daily progress. Another governance point that uses the same observable occurs every two weeks in the presentation of the iteration artifacts. This is done in order to trace the team's iteration progress. The daily progress is measured against the iteration commitment. The iteration progress is measured against the release commitment. We used this data to better understand the agile process. From the governance perspective, we can decide if this mechanism can assist us in the Assess phase to follow up on the performance of the governance solution.

Each day, in each of the teams, the tracker added two new points to the graph. The "total estimated" point represented the cumulative estimations of all tasks that were completed by the previous day and the "total done" point represented the cumulative actual time devoted to those tasks. A completed task was counted when the developer in charge completed the coding, unit testing, and integration with the entire developed system.

Figure 6 shows the graphs of estimations versus actual time in the third iteration for the team in organization A. The third (linear) line provides the expected pace according to available time. As can be observed, there is a significant difference between the time that is available for development and the time that is actually used for development. This phenomenon also happened in the case of the team in organization B. There are several reasons that may cause this behavior. Firstly, only

Figure 6. Estimation vs. actual development time in iteration 3 (team A)

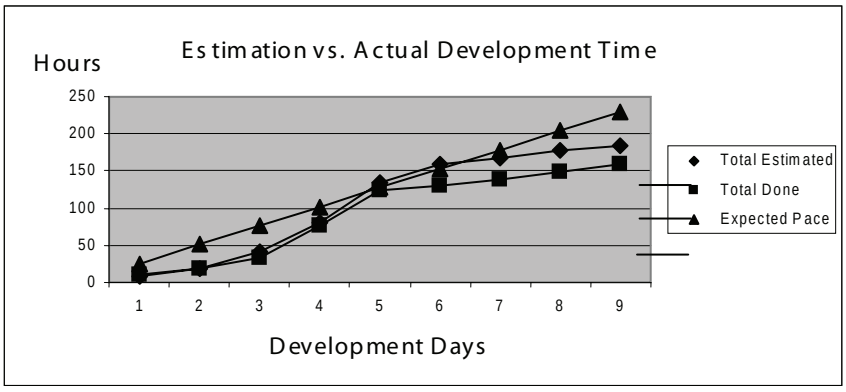


completed tasks are calculated. Although some teammates had invested time in other tasks, this time was not taken into consideration if the task was not complete before the end of the iteration. Secondly, there is often time invested in urgent tasks that come up, such as support service for end users who work with modules that are in production. Thirdly, some developers, whose time was taken into account, may have been absent.

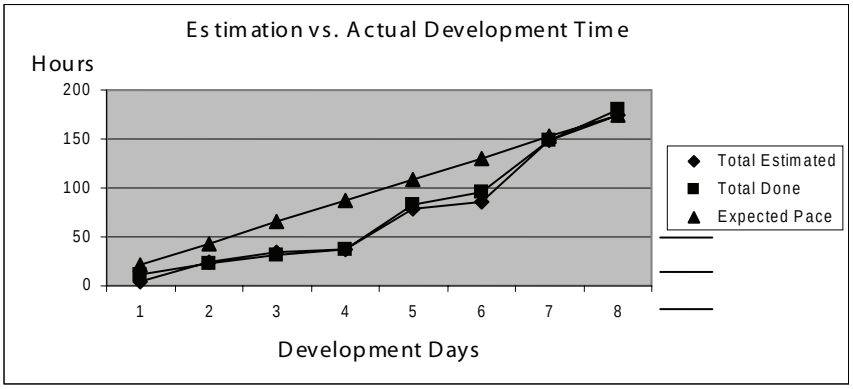
Figure 7 shows the graphs of estimations versus actual time in the second (Figure 7a) and forth (Figure 7b) iterations of the team in organization B. The Expected Pace line is the ratio between the total working hours of all teammates in the iteration and the number of days in the iteration.

We observe that at the end of the second iteration (Figure 7a), the amount of time actually spent on completed tasks (159 hours) was 30% less than the available time according to the expected pace (229 hours). This can be explained by the fact that tasks in progress that were not completed in this iteration were not counted. In the fourth iteration (Figure 7b), however, all tasks were completed. In such cases the total-expected point unites with the expected pace point since this was the amount of hours that was considered in the work planning.

Figure 7. Estimation vs. actual development time in iterations 2 and 4 (team B)

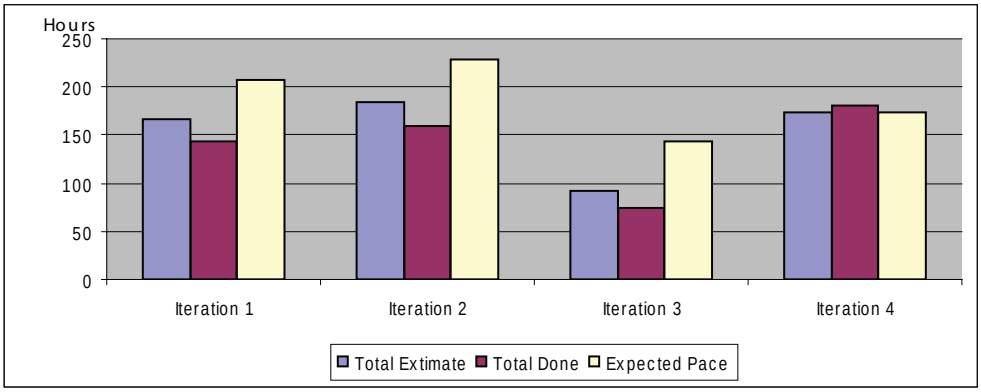


a) Iteration 2



(b) Iteration 4

Figure 8. Estimation vs. actual development time in the first 4 iterations (team B)



We further observe that in both iterations, the distribution into tasks was reasonably good. Too many dependencies between tasks can delay their completion, causing a nearly flat total-done line until close to the end of the iteration and then a sudden increase when many tasks are completed together.

Figure 8 summarizes the estimation versus actual times and the expected pace for each of the first four iterations for this team. We observe that estimates are too high in the first three iterations: 14% in the first (167 hours estimate vs. 144 actual) and second iterations (184 hours estimate vs. 159 actual) and 20% in the third (92 hours estimate vs. 74 actual). In the fourth iteration, in contrast, estimates were low by 4% (174 hours estimate vs. 180 actual).

In the three first iterations, the total-done time was less than the expected pace. In the first two iterations, the gap was 30% (144 hours vs. 207 and 159 hours vs. 229), and in the third iteration the gap was 48% (74 hours vs. 144). In the fourth iteration, the gap was –4% (180 hours vs. 174), which implies a certain improvement in the quality of the estimations.

Another issue that affected these measurements was the variability in team size. The reasons for the drop in the expected pace in the third iteration are personnel changes, travel of several teammates, and sick leave for two teammates.

Retrospective Process

The second governance point that we present concerns the retrospective process that guides the software development process. The agile approach use reflection sessions and a retrospective process as an internal practice (Beck & Andres, 2004; Salo, 2005; Talby et al., 2006). The teams in organizations A and B adopted the practice of one-hour reflection between the presentation of the artifacts of the previous iteration and the planning of the next iteration (Talby et al., 2006).

A reflection session was conducted in organization A between the first two releases of the transition-to-agile process. Teammates filled out an anonymous individual questionnaire containing questions mainly about the characteristics of the previous release and the expectations from the next one. We review some of the data that was collected during the discussion that followed. Reflecting on "the best thing that happened in the first release," these were the teammates' comments:

- "Focus on the goal with the customer's global view"
- "Cooperation"
- "It takes less time to develop tasks compared with the previous method"
- "End to end [development] shortens processes and integration"
- "A platform to talk about problem was created, sit together and hear problems"
- "Good communication between team and customers, there is someone to approach with questions"
- "People started new things, like modules"
- "Setting priorities gives focus"

Reflecting on "what can be changed in the next release," teammates generated a list and then voted for the following as the most important:

- Improve the integration process
- Adopt the methodology into the QA process
- Perform better follow-up

One of the first reflection sessions in organization B was dedicated to the relationships between the team and the organization. Teammates filled out an anonymous individual questionnaire containing questions about the organization's goals and values, existing policies, and the way the team could contribute to the organization and vice versa. One of the questions asked them to rate their level of agreement with several statements on the organization's existing policy on software quality. Table 1 shows the teammates' answers; the number in each cell represents the number of people who gave that answer. Based on this and similar data, we suggest that the reflection sessions can be considered as a governance mechanism that is activated in the Execute phase and feeds the Assess phase of the governance lifecycle.

In a broader perspective, the data that emerges from the retrospective process, together with other governance observables, can assist the governance follow-up in the Assess phase. During the Assess phase, a complete perspective on the governance solution lifecycle is gained. Specifically, we can follow up the transition-to-agile process and continuously steer it according to the governance information.

CONCLUSION AND FUTURE DIRECTIONS

Starting from a comprehensive definition of governance and its components, we presented a high-level governance model, which includes the main components and the relationships between them. To validate the model framework, we showed how to conceptually instantiate it for both IT governance and software development governance, in the context of transition-to-agile software development in large organizations.

Table 1. Teammates reflection on the organizational policy on software quality (majority is marked with grey)

Statement	1 Strongly disagree	2	3	4	5 Strongly agree	No answer
I'm familiar with the policy		2	1	4	5	
I follow the policy in my project	1		6	3	2	
Most projects in the organization follow the policy		3	2	4		3

We are now developing a governance lifecycle platform based on the model presented here. It should serve as a single point of administration for the governance of software development activities. The main parts of the governance solution platform are the governance module, the data module, the scheduler, and the user interface.

In brief, the governance module manages the governance lifecycle by supporting the governing body and relevant roles. The data module contains a data adapter that mediates between the application and the database. The database includes all the information from the different data sources available in software development environments:

- Software development artifacts such as code, test, specifications, models, and bug list
- Software management artifacts such as task plans and estimation graphs;
- Activity indicators that capture the state of the activities and tasks being performed; and
- Governance observables such as measures, policies, decision rights, and roles

The scheduler is responsible for scheduling tasks for governance mechanisms that are used within the governance solution. The user interface presents views appropriate to each of the different roles that are involved in the governance process.

In light of the development of the governance lifecycle platform, we suggest extending the development component of existing governance tools according to our model. This way, the model presented in this chapter can be used to augment existing IT governance models (e.g., CobiT and ITIL) to close the gap between the IT governance model and the governance of software development activities.

ACKNOWLEDGMENT

We would like to thank Clive Gee and Duncan Clark for their significant contribution to the UML model. We would like to thank Murray Cantor, Duncan Clark, Clive Gee, John Falkl, Steve Graham, Christine Draper, Greg Rader, and Calvin Powers for numerous discussions and ideas.

Orit Hazzan participated in consulting for one of the organizations. We would like to thank her for fruitful discussions.

Chapter 1.24
Domain-Specific Language for Describing Grid Applications

Enis Afgan

ABSTRACT

Grid computing environments are dynamic and heterogeneous in nature. In order to realize application-specific Quality of Service agreements within a grid, specifications at the level of an application are required. This chapter introduces an XML-based schema language (called the Application Specification Language, ASL) and a corresponding modeling tool that can be used to describe applications in grid computing environments. Such application descriptions allow derivation of guided and autonomic service developments for installation and invocation routines throughout the grid. In order to promote the language and ease the application description process, a domain-specific tool is also introduced. Based on our experience, the ASL in combination with higher level models improves, simplifies and promotes the grid application deployment process while simultaneously minimizing tedious and error-prone tasks such as manual application description composition.

INTRODUCTION

Grid computing (Foster, Kesselman, & Tuecke, 2001) has gained popularity as the emerging architecture for next-generation high performance distributed computing. Grid computing provides ubiquitous access to distributed high performance computing (HPC) resources that are shared between multiple organizations through virtualization and aggregation. This is realized through a layer of software (e.g., grid middleware), thus

making grid applications extremely software-intensive systems where the value of software is equivalent to the value of the underlying infrastructure. Grid middleware provides a standard set of services for authentication, authorization, resource allocation and management, job scheduling, submission, monitoring, and data transfer and management (Berman, Hey, & Fox, 2003b). Software packages and tools based on open-source/open-standard approaches such as Globus Toolkit (Foster & Kesselman, 1997) have enabled the deployment of "production quality" computational grids. Several domain-specific grids are currently operational, for example, Grid Physics Network (GriPhyN) (GriPhyN, 2006), Network for Earthquake Engineering Simulation (NEES-Grid) (NEES, 2006), International Virtual Data Grid Laboratory (IVDGL) (IVDGL, 2006), Open Science Grid (Grid, 2007), and Particle Physics Data Grid Collaboratory Pilot (Grid2003) (PPDG, 2006). Grid computing has offered researchers enormous computing and data storage capabilities by providing seamless access to geographically distributed resources through the creation of virtual organizations (VOs).

Despite the many benefits of grid computing, the grid itself does not provide a novel programming paradigm for developing new applications. Furthermore, no formal methodology exists for porting existing legacy applications to the grid. Most of the applications developed for the grid are based on traditional HPC or distributed computing principles. Typical HPC applications are developed using implicit parallel programming techniques (e.g., compiler-based automatic parallelization and directive-based parallelization) or explicit parallel programming techniques (e.g., threads and message-passing). After an HPC application is developed and tested on local resources, it is then deployed; that is, the entire application (source code, dataset, scripts) is transferred to a remote site, compiled on a remote host, and made available for execution.

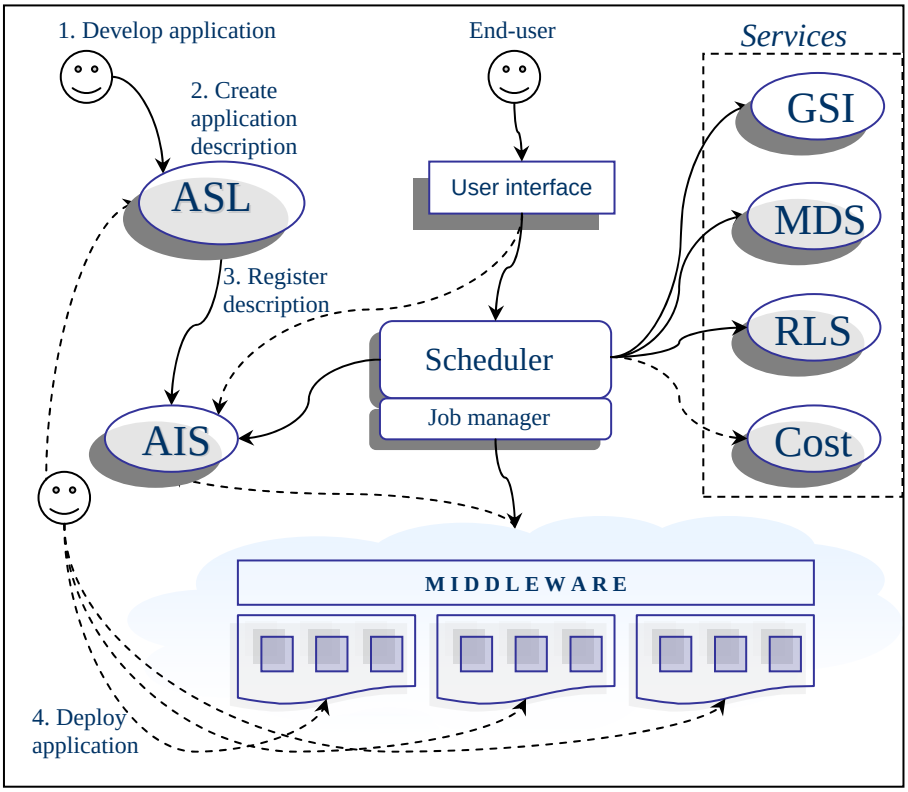
Deploying an application on the grid requires additional steps that involve user intervention, great insight into the internal structure of the application, as well as familiarity with the various grid computing technologies and toolkits. In addition, the progressive steps of application execution and job submission may involve many additional steps required from the end-user, not necessarily found in a typical application. Due to this inherent complexity and difficulty using the grid, several approaches have attempted to simplify grid deployment and configuration by developing technologies such as Web portals (Gannon et al., 2003), workflow systems (Aalst & Hee, 2002), and component assembly (Armstrong et al., 1999). The ultimate goal of such efforts is to enable the adoption of grid technologies and applications to a wider group of end-users who are not familiar with programming languages and the lower level grid infrastructure. The potential impact for improving grid accessibility to such users is significant (e.g., applied science researchers, distributed organizations, and organizations with variable computational requirements).

To tailor the complexities of a user's view of the vast amount of grid software by addressing the goals of end-user accessibility, there is a need to standardize and simplify the process of application deployment on the grid. As part of the contribution of this chapter, we present a new language called the Application Specification Language (ASL) (Afgan & Bangalore, 2007) that can be used by application developers and end-users to describe details of a given application. The ASL allows an application to be represented in the heterogeneous world of the grid by capturing its functionality, options and differences as compared with other applications found in the grid. Through the use of ASL, application descriptions can be made available for immediate use or further advancements among applications such as job schedulers, automated interface generators and application-specific on-demand help provisioning. The ASL

can also be used to describe how an application is combined with other matching services and software. The ability to specify the composition of services can facilitate the creation of new and added functionality, as well as enable further advancement of existing tools that can take advantage of the provided information.

To ease the process of collecting application description data and the description generation, a domain-specific modeling language (DSML) has been designed to assist in automating the grid application description and deployment processes. We believe that higher level models will improve, simplify and promote the grid application description and deployment process while minimizing tedious and error-prone tasks such as manual composition of application descriptions. The process of using the ASL and DSML within the context of grid deployment is shown in Figure 1, which outlines the major steps required for grid application development, publication and deployment. This figure highlights the global interaction between grid components and summarizes the ideas presented in this chapter. Upon development of an application, the developer can provide an application-specific description of a new application in the language described in this chapter. The application is registered by a service that can subsequently be queried by users, schedulers, or other tools. Information in the application description provides necessary data to enable automated integration with other available tools and services (e.g., Grid Security Infrastructure (GSI) (Foster, Kesselman, Tsudik,

Figure 1. Architecture using existing grid middleware technologies coupled with the technologies introduced throughout this chapter to enable improved application description and deployment



& Tuecke, 1998), Monitoring and Discovery Service (MDS) (Czajkowski et al., 1998), Resource Specification Language (RSL) (Czajkowski et al., 1998), Application Information Service (AIS)) as well as services still in development (e.g., cost). The focus of this chapter is on step 2 in the figure, whose addition to the global picture provides missing but beneficial functionality in the overall infrastructure. The dotted lines in the figure indicate possible interaction with a set of external events.

The rest of this chapter is organized as follows. The next section introduces grid computing concepts and provides a taxonomy of grid users. This is followed by a section that builds on grid technologies and provides examples of grid application development and deployment through a sample scenario outlining some of the difficulties with the current grid technologies. These issues are addressed in the section entitled *Application Specification Language*, which provides an introduction of a new language. The construction of this language is eased by a support tool based on metamodeling technology introduced and described in the *Modeling Wizards to Generate ASL* section. The end of the paper presents future trends and conclusions.

AN OVERVIEW OF GRID COMPUTING

Grid computing represents one of the new frontiers of computing. As the grid matures, many existing technologies will have to be revised and adopted to incorporate new ideas and concepts required by this evolving environment. Furthermore, many new technologies will arise as the result of emerging opportunities. This section introduces basic concepts of grid computing and presents a user categorization within this paradigm.

Grid Computing Background

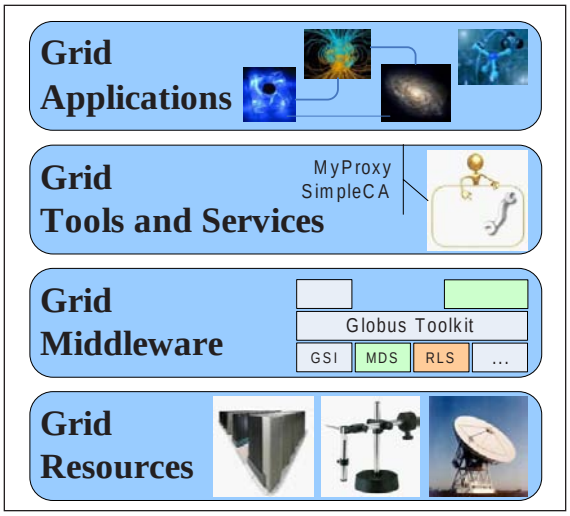
The grid community has witnessed increased adoption over the past several years as the emerging architecture for next-generation high performance distributed computing. Grid computing is a culmination of distributed computing (Tanenbaum & Steen, 2002) and high-performance computing (Kumar, Grama, Gupta, & Karypis, 1994). The grid integrates networking, communication, computation and information to provide a virtual platform for theoretically unlimited compute power and data management (Berman, Fox, & Hey, 2003a). It is designed to provide ubiquitous access to the vast number of resources and enables sharing between multiple organizations providing desired resource virtualization and aggregation. Virtual Organizations (VO) (Foster et al., 2001) represent aggregations of communities that may share national and international boundaries but have common objectives. Through VOs, grid computing is capable of aggregating heterogeneous resources that belong to different administrative domains to create a unique and valuable resource for the scientific community.

The VOs that are available in the grid are enabled through the use of middleware that provides a standard set of services for authentication, authorization, resource allocation and management, job scheduling, submission, and monitoring. Through this model, individual resources within an organization are virtualized into a common pool of accessible resources. The Globus Toolkit (GT) (Foster & Kesselman, 1997) is the most popular grid infrastructure framework for enabling the creation of grid applications. The GT offers all the basic technologies required for setting up a grid environment to support user creation, job submission and monitoring that span traditional boundaries (e.g., single institution environment setup). The technologies associated with the GT include:

- Grid Security Infrastructure (GSI) (Foster et al., 1998) is used for user authentication;
- Global Resource Allocation Manager (GRAM) (Czajkowski et al., 1998) assists in remote resource job management;
- Monitoring and Discovery System (MDS) (Czajkowski, Fitzgerald, Foster, & Kesselman, 2001) offers information discovery and state of resources; and
- GridFTP (Allcock et al., 2001) provides file transfer capabilities in the grid environment.

On top of the low-level grid middleware tools, an additional layer of grid system software packages provides an abstraction layer that hides complexities such as authentication, resource discovery, and file transfer. These intermediate layers offer direct interaction with the grid middleware allowing communication at a higher level of abstraction. Examples of such packages are portals (Gannon et al., 2003; Novotny, Russell, & Wehrens, 2004) and application schedulers (Afgan, 2004; Buyya, Abramson, & Giddy, 2000; Huedo, Montero, & Llorente, 2004) that provide a solid layer for using the grid as well as many options to develop grid applications.

Figure 2. Layered structure of grid computing



The top-most layer found in grid computing is the application layer that interacts directly with an end-user. A grid application is considered to be any application that is capable of exploiting grid resources through the use of grid middleware. The possibilities for using the grid are restricted only by the usability of the system as a whole. The end-result is a highly software-intensive system where, on top of the middleware functionality, lays the unlimited layer of application software offering a myriad of options and combinations to be explored by application developers as well as end-users. Figure 2 shows the overall layered structure of grid computing.

Because the grid is still an emerging technology, applications that were originally developed to run in more traditional environments may be adopted to take advantage of the benefits offered by grid technologies. The process of converting an existing legacy application to make use of the grid is called *application deployment* or *grid enablement*. The primary benefit an application gains, once grid-enabled, is the ability to use compute power more efficiently. Another benefit is that long running jobs can be broken up to execute in parallel on multiple resources to decrease turnaround time or increase efficiency. Additionally, larger data sets can be stored as well as processed without putting the load on any single system. By evolving a legacy application, the heterogeneity of the grid can be exploited to benefit the application as a whole by executing different application segments on separate (i.e., heterogeneous) systems making each segment take maximum advantage offered by underlying hardware, and in the end, gain maximum benefit for the application as a whole (Chase, 2005). With the diverse pool of available resources and the wider pool of available applications, ensuring mutual compatibility and maintainability becomes a major challenge. Some of the difficulties arise between the involved parties because individual requirements are not

stated in a standard, clear, and concise way and thus provide no opportunities for automation or standardized reliability.

GRID USER CATEGORY CLASSIFICATION

This section provides an overview of the roles and goals of individual grid users. The section identifies the specific requirements that are imposed by each user category, as well as the provisioning tools that accommodate their needs. The categories of users introduced in this section are middleware developer, application deployer, application developer, resource owner, and end-user. In some cases, a single person may play multiple roles (e.g., application developer and deployer).

Middleware Developer

As the interconnecting fiber of the grid, middleware represents the mechanism that facilitates the management of underlying resources as well as development of grid applications. Grid middleware is capable of delivering and sharing compute and data resources over secure channels while hiding intrinsic platform differences among the available resources. The middleware developers are key participants in the grid ecosystem and are closely connected to all other user categories. Middleware developers consider feature requests from user groups and participate in the design and implementation of the middleware standards that shape the way the grid operates. Examples of grid middleware include: the Globus Toolkit, Message Passing Interface (MPI) (Forum, 1998), Condor (Litzkow, Livny, & Mutka, 1988), Storage Resource Broker (SRB) (Baru, Morre, Rajasekar, & Wan, 1998), Web portals (GridSphere (Novotny et al., 2004), and the Open Grid Computing Environment (OGCE) (Gannon et al., 2003).

Application Deployer

An application deployer has the responsibility of performing the necessary work to grid-enable a legacy application. Due to the well-known possibility of high costs and challenges of application modification, the community focus is not on modifying the source code, but rather adopting the application through creation of wrappers that convert the entire application into a grid-enabled solution (Afgan, Sathyanarayana, & Bangalore, 2006; McConnell, 1996). The deployment process and wrapper creation for one of the five strategies is performed using a combination of the following techniques:

- Create script interfaces for command-line tools.
- Program directly to the Globus Toolkit using an available C API.
- Use a commodity toolkit such as Java CoG kit (Laszewski, Foster, Gawor, & Lane, 2001).
- Use the Grid Application Toolkit (GAT) (Allen et al., 2005).
- Use Grid Services (Sotomayor & Childers, 2005).

Because the application deployer is working with an existing application that may have several peculiarities, as well as the heterogeneity of grid resources, many issues may arise offsetting expected application performance or even correct execution. One of the causes of the evolution problem is the lack of standardized application information (Ulrich, 2002). The application deployer must placate the existing user base and should not modify the original application requirements to address the grid-related concerns. If any modifications are required during the deployment process, to better accommodate needs of either end-user or the resource owner, currently, there

is no effective way to convey the modifications that took place (as compared to the descriptive information pertinent to the original application) to either of those users categories.

Application Developer

As the grid gains acceptance, more applications will be custom tailored to take advantage of the benefits offered by the grid. Traditional programming techniques and methodologies (i.e., sequential or parallel) have their own set of challenges. Incorporating the grid into a legacy application poses a new set of accidental complexities. Most of the programming techniques and application types available when developing grid applications come from the HPC area or traditional distributed computing.

Grid services, which are based on the Service-Oriented Architecture (SOA) (Foster, Kesselman, Nick, & Tuecke, 2002a), represent the future of grid application development. However, grid services are hard to develop and deploy, as evidenced by the following steps that are required to develop a single, standalone service (Sotomayor & Childers, 2005):

1. Define and specify the service's interface so clients know how to invoke it.
2. Implement the given interface for the service; implement any related libraries.
3. Define the deployment parameters to indicate the specifics of the service.
4. Deploy the service to a grid service container.
5. Register the service so it can be discovered by other services.

In addition to coding difficulties, other issues arise when developing grid applications. These issues include security, licensing, job management, and synchronization. Another major step in application development is aggregation of newly created services or already existing ones through library calls and advanced programming techniques. Application creation will need to be tailored to extract maximum benefit from the grid for a wider community of users. Examples of such use include advertising application requirements (e.g., service name, installation instructions, license requirements), as well as minimum hardware requirements (e.g., CPU speed, underlying network infrastructure, memory consumption). Unfortunately, current methods do not provide an adequate solution to address these issues.

Resource Owner

Resource owners and providers assist in running the most basic layer of the grid multitier architecture, which consists of the resources (e.g., networks, computer, storage nodes), the middle-tier (e.g., middleware, certificate authority, portals), and the clients (e.g., GT clients, GUIs). Resource owners are responsible for maintaining their respective resources by meeting hardware requirements for individual applications, installing those applications, obtaining relevant libraries and compilers, maintaining applications, and enforcing policies. Beyond the initial cost of installing the grid environment, there is the natural cost of running individual clusters, as well as keeping licenses, subscriptions, and libraries up to date. The resource owners must also be cognizant of the Quality of Service (QoS) agreements between participating users (e.g., compatibility, application versioning, standardization). In order for grid computing to move further into the mainstream, resource providers must be able to reduce their operating costs, increase resource utilization and find a benefit in sharing their resources with the wider community.

End-User

The role of the resource owners is aligned to the bottom of Figure 2. At the top of Figure 2 are end-users who rely upon the results of a grid

application. In order for the grid to become a commodity computing technology, there is a need to attract a wide variety of users. Some of the issues preventing widespread adoption are the complexities and dynamics involved in job submission and job management, which are not yet tailored for lay-persons (i.e., those who are not computer savvy). Consider the following scenario that exemplifies the manual steps needed to submit a job on the grid:

1. Select the resources needed by an application.
2. Create a proxy certificate (e.g., grid-proxy-init).
3. Copy the necessary source code and input files to a remote host (e.g., globus-url-copy).
4. Create a Resource Specification Language (RSL) (Czajkowski et al., 1998) string.
5. Submit the job for execution (e.g., globus-job-run, globus-job-submit).
6. Copy output files generated from the remote host to local machine (e.g., globus-url-copy).

Although the general concept of the above steps exists in many distributed contexts, the introduction of the grid manifests as an additional obstacle toward application usage. As such, the grid requires a level of computer expertise that is not within the skill sets of general end-users. The complexities of manual job submission, typified by the above six steps, can be ameliorated by the following user-friendly approaches:

- Write a client using a commodity toolkit (e.g., Java CoG Kit (Laszewski et al., 2001)).
- Write an interface to a grid service.
- Use a portal (e.g., OGCE (Gannon et al., 2003) or a grid-port (Thomas, Mock, Dahan, Mueller, Sutton, & Boisseau, 2001)).
- Use a workflow systems (e.g., Chimera (Foster, Voeckler, Wilde, & Zhao, 2002b)).
- Use a component framework (e.g., Armstrong et al., 1999).

All of the above techniques are viable choices and present gradual improvements in usability, customization and acceptance. Whichever layer of abstraction the above techniques provide, one common goal is to simplify job submission by abstracting grid resources from the end-user.

From the grid user classification and description, there are numerous requirements imposed by each of the user groups. This point is further complicated when user roles are combined and intertwined with a need to provide an effective way to address individual user concerns from application development and registration to application usage. By helping to solve this problem, users will be empowered to create and use grid applications while improving overall grid acceptance and resource utilization.

GRID APPLICATION DEPLOYMENT SCENARIO

Software engineering researchers have introduced many helpful principles (e.g., information hiding (Parnas, 1972)) and best practices (e.g., design patterns (Gamma, Helm, Johnson, & Vlissides, 1994)) with the goal of simplifying the development process. Despite the improvements offered by traditional software engineering principles, there still remain many open questions when it comes to new technologies such as the grid. For example, developing applications to execute in parallel computing environments changes some of the underlying assumptions; this is due to the focus of performance as the primary concern, rather than maintainability, evolution, and changeability. Parallel computing (Kumar et al., 1994) is based on a set of models primarily governed by the communication patterns between algorithmic iterations within an application. The following categories represent various types of parallel programs based on communication patterns (full

details and descriptions of the individual sections are provided in the section entitled *Application name and description*):

1. Sequential applications
2. Parametric Sweep applications
3. Master-Worker applications
4. All-Worker applications
5. Loosely coupled parallel applications
6. Tightly couple parallel applications
7. Workflow applications

Development of parallel applications entails coordination between computation and communication as limited by the underlying hardware architecture. Depending on the problem type, one communication pattern may be a better choice over another based on the constraints of a specific application context. Once developed, the application is deployed on a targeted architecture. Occasionally, hardware-specific optimizations are performed to customize the code for optimal execution. Developing applications for parallel computing environments is guided by the concept of overlapping communication with computation, thus maximizing the use of resources. Although the optimal solution of any application is rarely achieved, the actuality of the application executing on a single, dedicated resource results in a reasonably understood platform to build upon. On the other hand, developing the applications for the grid under the constraints of parallel computing introduces new obstacles and complications. The execution resource becomes a virtual entity occasionally available and with a high failure rate. The communication between iterations and application modules is not only exponentially slower but also highly unstable. The development of such applications raises the complexity considerations to a higher level and introduces a whole new field of application deployment as a significant part in the application lifecycle.

Most current grid environments are based on the concepts embodied in Service-Oriented Architecture (SOA) (Foster et al., 2002a) and Web Services (Gottschalk, Graham, Kreger, & Snell, 2002). Applications deployed on existing grids are submitted as grid services, which are Web services with extended functionality to include support for stateful behavior, lifecycle management, and notifications (Foster et al., 2002a). The development of a grid service proceeds in several steps requiring expertise in many fields (Sotomayor & Childers, 2005). When developing traditional parallel applications, it is required for individual subtasks to work toward a common goal. The same idea transfers to the context of the grid, but additional difficulties arise because many applications that already exist and conform to this subtask model are not grid-aware, which requires major reengineering. The bottom line is that many existing software applications developed by the parallel applications community will not be rewritten to comply with the grid model, but will rather be adopted by the use of wrappers. This introduces new obstacles because different user categories must interact to achieve the common goal. Originally, an application developer was able to develop an application and deploy it on a resource because they possessed the required expertise. By adopting the grid, the requirements related to application deployment have risen and require new expertise, often not readily and easily available due to the involved complexities. This implies the need for a new domain expert (i.e., a grid specialist) who possesses deep understanding of the technology and is able to transform traditional applications into grid applications. The drawback to this solution is that additional communication is necessary at the development level, which prolongs the application development. Furthermore, the delivery process is perplexed with new possibilities to introduce errors due to miscommunication or misunderstanding.

The application deployment process on a grid is a nontrivial task. The user must first determine what resources are available and then decide the most suitable resource for a particular applica-

tion. It is important to differentiate the application development process from the application deployment process. As stated earlier, typical HPC applications are developed using a specific programming language and parallel programming paradigm (e.g., compiler directive-based, threads, message-passing, combination of threads and message-passing) and often the programming paradigm chosen decides the application deployment platform. If the application uses a shared-memory programming paradigm then the application can be deployed only on a shared memory system, whereas an application developed using the message-passing paradigm can be deployed on both distributed memory and shared memory systems. Furthermore, applications might have specific requirements (e.g., processor architecture, amount of memory, disk space, interconnection network, libraries, operating system) to deliver desired performance and scalability. An application developer could describe these requirements using application deployment descriptors, or hints could be added about various performance implications and space/time tradeoffs. For commercial software packages, information about licensing and subscription could also be provided by the deployment descriptors. An application scheduler may use these descriptors to select a suitable resource and schedule the application for execution.

As a concrete example showing the full process of application deployment, we will outline the options and necessary steps required to enable an application such as the Basic Local Alignment Search Tool (BLAST) (Altschul, Gish, Miller, Myers, & Lipman, 1990), a frequently used bioinformatics application to perform sequence similarity searches, to execute on a local campus grid, such as UABGrid (Gemmill & Bangalore, 2005). Portions of the following steps assume the availability of grid middleware such as the Globus Toolkit (GT) (Foster & Kesselman, 1999). This sample scenario assumes that a user authentication system is in place and that the user is able to access available resources using middleware tools. The following represents the scenario:

1. Obtain a valid user authentication proxy.
2. Manually log into each of the available resources and download BLAST.
3. Install BLAST individually on each resource.
4. Create a wrapper application that is responsible for necessary file transfers, iterative job submissions, job monitoring and notification using a grid middleware API or a commodity toolkit such as the Java CoG Kit (Laszewski et al., 2001). The wrapper developer must be aware of the method of interapplication communication and design the wrapper to accommodate for the appropriate task parallelization and communication methods with respect to the grid middleware. Also, additional levels of parallelization can be introduced at this level as is the case with a locally developed wrapper (Afgan et al., 2006). If a scheduler is not available for task scheduling among grid resources, this feature should also be included as part of the wrapper functionality.
5. Create a user interface where the application can be invoked. This can range from a set of command-line tools to a Web-based portal.

As can be seen from the given scenario, the process of enabling an application to execute on the grid requires a significant effort and high-level of expertise from the application deployer. Depending on the complexity of the wrapper, it may turn into a completely new application developed to maximize the potential of the original application in this new environment. One of the drawbacks is the requirement of the deployer to have a reasonably deep understanding of the application to ensure that the wrapper is correctly implemented.

APPLICATION SPECIFICATION LANGUAGE

Motivation and Background

A goal of an application developer is to see their solution adopted quickly by a large group of end-users. However, the typical path to adoption requires frequent interaction with end-users to address numerous questions, such as: how to install the application, how to invoke it, the purpose and function of the available options and arguments, as well as how to improve performance for a specific platform configuration. Through the lifetime of the application, additional documentation is created to address such common questions. However, with a new version of the software, much of this work needs to be discarded and redone. Avoiding this pipeline of events is challenging, but through gradual and systematic adoption of the technique proposed in this chapter, it is possible to provide more automated support for the end-user.

Computing has evolved from a user-centric context (where every detail of code execution needed human attentiveness and interaction) to a global service-driven view (such as Web Services, where complex, data dependent, goal seeking interactions and computations of independently developed components can be achieved with absolutely no human intervention). From this progression, we observe the common approach where automatic communication between programs is enabled. This is generally accomplished through definition of standard languages that specify protocols observed between applications. The following languages represent efforts within the grid community to automate specific deployment tasks:

- **Job submission description language (JSDL) (Anjomshoaa et al., 2005):** A recently completed standard from the Job Submission Working Group (JSWG, 2007) within the Open Grid Forum (OGF) (OGF, 2007). The JSDL is a specification of an abstract and independent language used for describing requirements of computational jobs in grid environments. It contains a vocabulary and normative XML schema that builds on the idea of standardizing a language to accommodate a variety of job management systems, which alleviates the problem of heterogeneity in the grid. By having a standard language available, a job submission description can enable diverse job management systems to communicate and complement job description in a more simplified manner.
- **Resource specification language (RSL) (Czajkowski et al., 1998):** Provides a common interchange language to describe resources and jobs to run on them. It is a language developed by the Globus Toolkit Project (Foster & Kesselman, 1999) and is represented by various <*name, value*> pairs that are used by the Grid Resource Allocation Manager (GRAM) (Czajkowski et al., 1998) to perform complex resource descriptions in cooperation with other components in the system. RSL preceded JSDL, so RSL can be seen as an earlier scaled-down version of JSDL.
- **Resource description language (RDL) (Anjomshoaa et al., 2005):** A language that is part of the JSDL standard document for describing underlying grid resources in terms of CPU speed, number of CPUs, and main memory. Even though not yet realized, the concept of this language has been propagated through other tools such as Condor and ClassAds (Solomon, 2004) and the necessary information (e.g., current resource status) can be obtained from MDS (Czajkowski et al., 2001) and Ganglia (Massie, Chun, & Culler, 2004).

The above mentioned languages have been developed to enable standardized exchange of

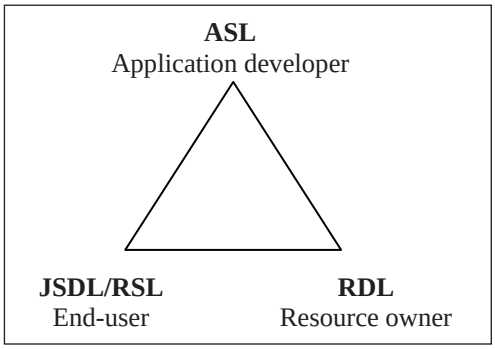
information between grid resources and provide support for direct and concrete communication between these resources. By defining documents specified by these language constraints, one can rely on automated negotiation during the job submission process without regard for the heterogeneity of the underlying hardware and software. When mapping the above mentioned languages to individual grid user categories, the JSDL and RSL map most favorably to the end-user category (where the user is mainly interested in adopting the grid as a pool of resources). The JSDL and RSL enable users to limit and perform resource selection. At the same time, RDL can be classified as a language for allowing resource owners to describe the capabilities of their resources and advertise that information for wider use through mechanisms such as MDS and Ganglia. What is evidently missing is the need to support the application developer. Once an application is developed, there is no standardized way to publicize the name and capabilities of the application in a manner that can be accessed by other tools. Rather, the application developer and the end-user are forced to interact in an interrogative manner, perhaps using a wiki or similar tools to advertise the availability of an application.

By supporting a method for capturing the core purpose of the application, requirements, and options, the end-user is provided with specific information that describes the application. After successful installation, the second most important feature enabling application use is the interface that the application provides to its users. With respect to grid applications, the most appropriate way to interact with an application is through a Web-based interface that requires no local installation of the application. A Web-based interaction may also provide special tools and knowledge to access available resources (Gannon et al., 2003; Hernandez, Bangalore, Gray, Guan, & Reilly, 2006). By providing a default standardized interface to the given application automatically, a resource owner may reuse the interface rather than implement their own. The benefit for the end-user is that the interface stays constant across different providers. An additional benefit is a reduction of possible errors in interface generation originating from the resource provider due to possible misunderstanding or lack of application knowledge. The Pasteur Institute Software Environment (PISE) (Letondal, 2000) is an example of previous work where this idea has been adopted in practice. PISE is a transformation tool that receives as input a PISE-DTD compliant XML document and interprets the document to create any of the suite of interfaces ranging from HTML to CGI and IPSH (Letondal, 2000). A scalable core is also provided by PISE that can be extended to add additional interface interpreters as needed. PISE currently contains a database of over 200 XML documents corresponding to interfaces for various applications that are primarily focused on bioinformatics. By leveraging ideas and technologies such as those provided by PISE, many of the accidental complexities associated with grid application deployment can be removed.

Description of the Language

To address the challenges raised in the previous sections, we present a new language called the Application Specification Language (ASL) (Afgan & Bangalore, 2007). As a new approach toward application specification that focuses on the needs of grid users and grid applications, the ASL is able to capture essential application information. Through standardized protocols, tools can be passed the information about an application that is specified in an ASL description. ASL is a language for describing any application's requirements, attributes, and options. The ASL directly supports the ability to capture application-specific information that is not necessarily found in the general pool of available description tags. Through the use of ASL, factors such as software and hardware requirements, data constraints, and algorithm complexity can be provided to a user. As

Figure 3. ASL-RDL-JSDL/RSL triangle showing direct communication paths between corresponding user categories



can be seen in Figure 3, the ASL may be composed with other groups of established grid languages (e.g., JSDL/RSL, RDL). The interactions implied in the triangle connect all perspectives and user categories of a grid environment, which enable communication to take place over well-designed paths to facilitate further communication, refinement, contract creation and the possibility of higher QoS for all participants.

ASL is applicable before and during installation, during job scheduling, during job execution, and even after the job has completed. It can be complemented and modified as knowledge about an application increases. The ASL can be used with legacy applications (requiring adaptation), or with newly developed applications designed specifically for the grid (often called "Smart Applications"). By providing a standardized way to describe application requirements, the ASL enables an automated capability to compare applications. Without ASL, such comparisons are very hard to perform manually because of their subjectivity. Such comparisons can be useful in numerous cases, such as application scheduling and software cost estimation (Afgan et al., 2006).

In essence, ASL is an extended application version of RSL. It provides a set of specialized tags used to capture application-specific details and thus provide a description of an application. The goal of this language is to use *application-specific descriptions* that enable deployment, maintenance, and execution of an application in a standardized and simplified way. The structure of the language is intended to describe entire, operational applications rather than individual components of an application or other software that may subsequently be composed into an application. The intent of ASL and individual ASL documents is to enable needed communication between heterogeneous resources in the grid through standard interfaces. Just like ASL's sister languages JSDL and RSL, ASL is not a grammar-based language, but rather a specification language establishing and defining a standard interface needed for heterogeneous grid resources to communicate with each other. A grammar-based language refers to a language that is defined and constrained by a context-free grammar. A schema-based language is rooted in an XML schema and is constrained by the tags defined in the associated schema.

By providing the appropriate set of tags, ASL enables application comparison and interface generation. Because every grid application is custom built to meet a certain need, the implementation details may be difficult to describe. Many of the options available during application specification often require significant human intervention as well as use of human language descriptions that cannot be modeled and captured by a general-purpose computer language (e.g., Java or C++). Providing a standardized set of tags to capture information about an application in a concise and precise manner is difficult. The requirements imposed when selecting a given set of tags must focus on capturing the core set of characteristics describing any application and then provide an extended set of tags that allow unique application components to be specified. Our first attempt at defining this set of tags considered existing languages such as JSDL and RSL, which capture job

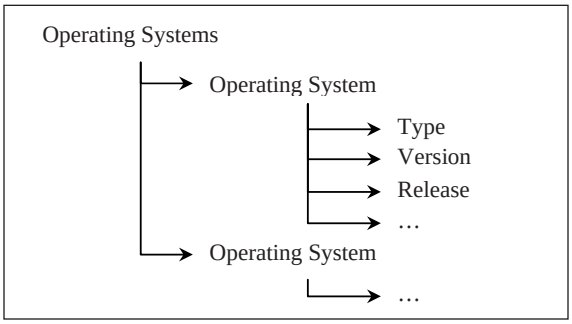
submission requirements that map onto resource and application requirements. Examples of such tags include numerical values (e.g., CPU speed and amount of main memory required), as well as a predefined set of values (e.g., operating system and CPU architecture type).

Additional tags were created by a systematic analysis of characteristics that describe an application but were not required for application invocation (e.g., max number of CPUs an application scales to). Many of these tags are simple in nature, allowing the definition of a range of valid values that can be used to validate data entered by the end-user. The more difficult set of requirements deals with values that are dependent on each other, but can be viewed individually as containers of simple values. Thus, these tags were organized in groups where subelements define individual pieces of the larger component. An example is the operating system requirement. An application may be suitable for many operating systems as well as different versions of an individual operating system. Thus, creating higher level elements that contain equivalent subelements allows different version dependencies to be specified (please see Figure 4).

One concern with adopting ASL, especially when viewed from the perspective of a developer creating the ASL document, is the requirement of the document syntax to be specified correctly (i.e., equivalent tags may have a different meaning when placed in different element groups). The most difficult part of describing an application concisely occurs with tags that cannot be constrained to a set of predefined values (e.g., tags that represent a human readable text string, such as copyright policy). The obvious impediment with such tags is the lack of precision needed for formal interpretation. However, the additional information provided within these tags can benefit end-user understandability of the application. The use of the tags for all types of descriptors (e.g., simple, complex groups and natural language) helps to partition the entire document and provide guided help for natural language descriptors. A further benefit of such tags is the possibility of developing additional translators to generate application Web documentation automatically.

The completed ASL document consists of several parts (discussed in subsequent sections of this chapter) each focusing on a particular portion of an application deployment lifecycle. With the blend of the formal tags (i.e., computer readable) and informal tags (i.e., end-user understandable), the ASL assists in application description from different perspectives and provides user support in multiple formats. Examples of interpretation include an application description Web page with installation and invocation instructions, script generation for automated application installation, as well as optimal system requirements for job submission.

Figure 4. Grouped set of elements and subelements with appropriate tags



Structure of the Language

An ASL document consists of four distinct yet related sections that are described in XML. By dividing the document into these distinct sections, an ASL document is more modular and allows for easier initial generation and later modification. With the use of appropriate tools, each section of the document can have its own permissions, which allows the document to be modified in-

dependently and securely. As the application receives a wider user base, additional information may become available from its users. As a result of multiple executions of an application, additional information can be gathered, such as profiles of application performance, unexpected behavior, or suggestions for future enhancements. Beyond the collection of application information, the segregation of the document into appropriate sections allows for shorter search times among users allowing them to focus on sections of the document of most interest. To provide segregation of information collection and retrieval, an ASL document consists of application name and description, installation requirements, job invocation requirements, and hints.

The sections are not directly connected to each other, but the data is stored only once per ASL document. Because of this, inadvertent references to information provided in other parts of the document may exist. These sections are correspondingly mapped to XML with appropriate tags. Each of the sections is described below and the schema is provided for the given section.

Application Name and Description

The application name and description section contains the most basic information about an application and acts as the application identification component. It specifies the name and version of the application as can be found in an application repository. This section also contains subelements such as the application description describing the application in a human readable format. The description identifies the problem the application solves and maps the application to an application category. The application category element is limited to a predefined set of values as described below. It is intended to offer better understanding of the application deployment process on the grid and it is essential in classifying different types of applications deployed in a grid environment. The majority of the applications typically deployed in a grid environment can be classified into the following categories:

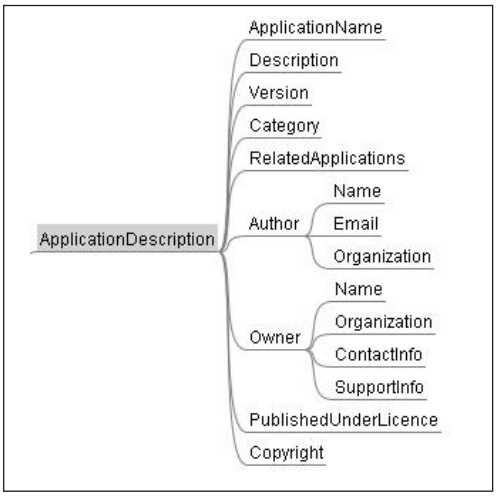
1. **Sequential applications:** Traditional applications developed to execute on a single node machine. For the applications that require larger resources (e.g., more memory, disk, or faster CPUs), the grid will also provide redundancy, fail-safe capability, and excess capacity.
2. **Parametric sweeps:** Multiple copies of sequential jobs using different input datasets or parameters. These applications are often submitted independently by a single user in an effort to reduce overall task execution time. Benefits of using the grid are the same as sequential applications with the addition of multiple instance coordination performed by grid tools and middleware.
3. **Master-Worker applications:** Master-worker or bag-of-tasks model (Kumar et al., 1994), where a master process distributes work (either statically or dynamically) to a set of worker processes and aggregates the results at the end. Many financial and bioinformatics applications fall into this category, each in constant need of surplus compute resources. The main differences between parametric sweeps and master-worker applications is that the individual tasks do not have to be executing the same code, but a workflow system can be in place with the master-worker model possibly delivering a more complex application functionality. The coordination between the worker nodes and task assignment must be handled by the master process.
4. **All-Worker applications:** Similar to the master-worker model, except that each process involved, including the master, share the workload equally and data is exchanged between individual processes in some pattern (point-to-point or group communication).

5. **Loosely coupled parallel applications:** Parallel applications (e.g., coupled fluid flow and wave models) that exchange data occasionally through files during execution (e.g., beginning and ending of an outer iteration).
6. **Tightly coupled parallel applications:** A single Message Passing Interface (MPI) (Forum, 1998) application distributed across multiple systems sharing data during the execution, possibly at frequent intervals, through passed messages. It requires interoperability between different MPI libraries or an MPI library such as MPICH-G2 (Karonis, Toonen, & Foster, 2003).
7. **Workflow applications:** A model connecting many individual applications executing at different geographically distributed locations, which are chained together to perform a complex simulation. For an application to be classified as a workflow application, additional information is needed to identify dependencies with other applications in terms of input and output data streams.

When selecting the application category for an ASL specification, the following considerations should be examined by a user composing the document. Applications that belong to categories (1) and (2) can be distributed and scheduled across any available computational resource on the grid because there is no synchronization or coordination required between individual tasks. However, applications in categories (3) and (4) must be scheduled on a single computational resource and cannot be distributed across multiple resources. This does not imply that the application may not use additional, distributed resources. If an application has been developed specifically for the grid, it can utilize middleware components to enable cross-resource task execution. In that case, task scheduling is the responsibility of the application itself because it would be deployed on a dedicated resource. Applications in categories (5) and (6) expect that the individual applications are distributed and assume that the individual tasks are scheduled to execute at the same time (through advanced reservation or mutual agreement with the resource providers). Workflow applications (category 7) assume that the scheduler can trigger the execution of one or more applications as described by the workflow. Because most of the existing schedulers (Berman et al., 2001; Casanova, Obertelli, Bernan, & Wolski, 2000; Huedo et al., 2004; Venugopal, Buyya, & Winton, 2005) do not handle advance reservation, the use of workflow applications is limited and intended mostly for future generations of applications and grid schedulers.

The remaining elements in this section are illustrated in Figure 5. *Category* element set has a predefined set of values from which a user must choose. The remaining elements found in this schema section do not have their values predefined, but can be defined by the person creating the document enabling desired application description.

Figure 5. Application description section schema

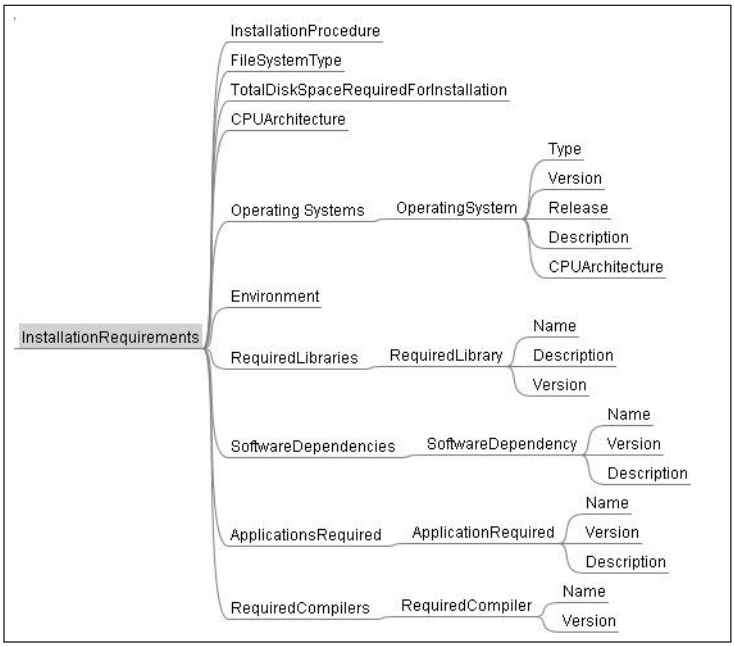


Installation Requirements

The installation requirements section of an ASL document contains a set of required elements that describe the pre-installation requirements as well as the installation procedure. Some of the examples of this type of element set include minimum processor speed, processor architecture, minimum amount of memory needed for installation of the application, libraries, applications required for the installation procedure (e.g., compilers, (un)packaging tools), licenses needed for application installation, network requirements, and required amount of disk space for the installation. The tags used are simple declarations that specify the value of a predefined type (e.g., string, integer). Even though this model may result in unnecessary inconsistencies between application descriptions, we believe at this stage of ASL development and definition this variability is necessary to allow for the correct words to be selected from a constrained set of choices. The full schema of the installation requirements section is given in Figure 6.

Among the elements defined in the installation category are *SoftwareDependencies* and *Applications Required* tags. The information these tags contain is intended strictly to be used during the installation procedure. The *SoftwareDependencies* tag refers to any other software that will be needed for the application execution. This can be viewed as a prerequisite for the installation; that is, in case software packages declared within this tag are not installed, the application cannot be expected to execute. Examples of such software dependencies would include Perl (Wall, Christiansen, & Orwant, 2000) with certain libraries and Postgres database (Momjian, 2000). With respect to installation, the *ApplicationsRequired* tag refers to other complete applications required to perform the installation. These applications may be invoked during the installation procedure, such as unpackaging and installation tools (e.g., Ant, make).

Figure 6. Application installation section schema



Job Invocation Requirements

The job invocation requirements section focuses on providing a user with the information needed to execute the application. Starting with the executable name, it also provides the available switches and minimum hardware requirements, as well as allows the developer to specify the number of input and output files with examples of their respective formats. This section does not represent a duplication of effort found in JSDL/RSL, but it is alternatively used to specify requirements for the entire application. Such specification is needed not only when executing a single job, but to describe the available options and how to use them. Rather than specifying exact input files and other job-specific parameters, the category defines application requirements, such as: the required input files, required format of those files, any output files and corresponding format of the output files, libraries required to invoke the application, and licenses needed to run the application. This capability can be viewed as a more detailed version of *man* pages in UNIX. This category allows the developer to be shielded through a contract-like document; that is, if any of the requirements are not met, the application cannot be expected to execute correctly.

The majority of the application description is provided in this section of the ASL document, so it is natural for a set of tools to be based on this category. An example tool is a translator that formats the appropriate information into a Web page allowing the information to be read through a browser, or a correct and application-specific job submission interface. Another example tool serves as a data verification tool that ensures input files are in the correct format. The complete schema is shown in Figure 8 on the next page. Similar to the installation section, the application invocation section has elements *SoftwareDependencies* and *RequiresApplications.* In this context, software dependencies refer to any software packages that are necessary and will be used as part of the ap-

Figure 7. Hints section schema

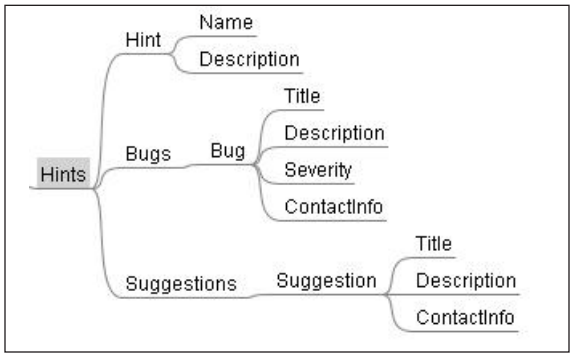


Figure 8. Application invocation section schema

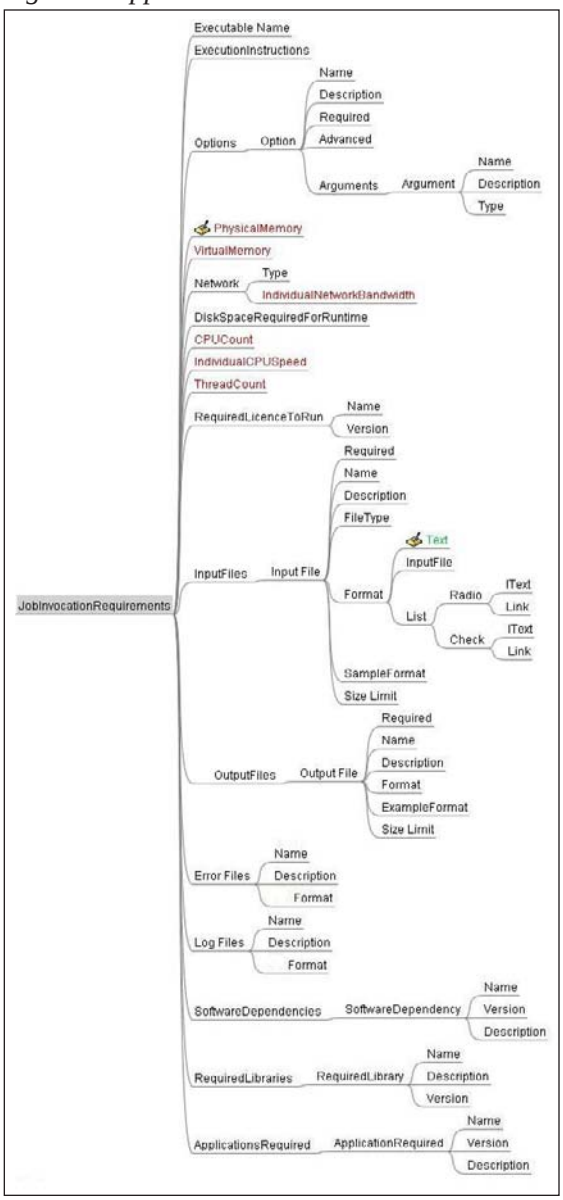


plication during its execution. An example would include a call to a Perl module. The description of the application requirements tag is similar to the description from the application installation section of ASL, where it specifies any other applications that may be invoked during this application's execution. This tag can be used to specify the requirements for a workflow, even though any further enforcement and coordination during execution must be done within the given application.

Hints

Due to the inherent variability of applications, information describing an application may not be adequately captured in the preceding sections of ASL due to noncompliance and uniqueness of the application. Also, the succinctness of available options in ASL tags or already existing data may prevent additional and possibly more complete application information to be stored. In order to accommodate for these possible shortcomings, there is an additional section found in every ASL document, which is entitled *Hints.* This section contains instructions and comments, mostly in natural language, which provide additional information about the application. The purpose of this information is to allow detailed descriptions for areas of high application complexity, either for the users of the applications or other developers who may use this application as a base layer for development. Another important goal behind this section and its element set is that it can be accessed and edited by a wide user group. Performance information may be stored in this section to specify the optimal parameters on a particular hardware architecture.

Depending on application type (e.g., sequential, embarrassingly parallel, MPI-based application), certain input parameters (e.g., size of input file, input file format, number of processors) may alter application performance and thus information found here could be useful for the resource owner, end-user and even the scheduler developer. By giving permissions to a wide range of users, known bugs as well as suggestions for future advancements can be documented. A large portion of its use can be found in troubleshooting an application where expected errors can be explained. Figure 7 shows the current Hints section schema.

Example ASL Documents

This section demonstrates the use of ASL to describe an initial set of applications that show the ability of the language to specify and distinguish applications. In these examples, ASL was manually generated by providing the values associated with appropriate tags as defined in the schema. This generation is quite straightforward, which provides the user variability in selecting the tags to be defined depending on the application. The rest of this section provides snippets of ASL documents with their respective applications. Differences between applications are outlined and the ability of ASL to capture these differences is discussed.

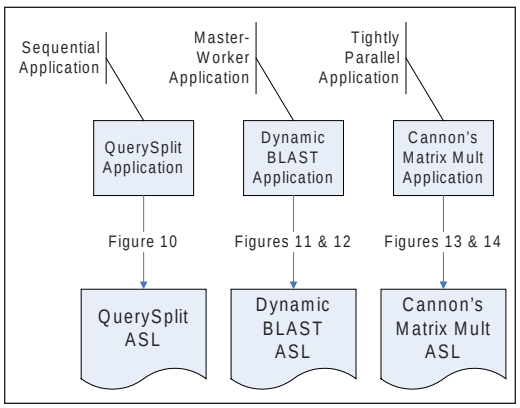
Application Descriptions

To show the ability of ASL to capture descriptions of applications belonging to different categories, three applications are specified, each from a different application category. The first two applications correspond to the sample scenario described in the *Grid Application Deployment Scenario* section. The first application is a sequential application implemented in Perl called *QuerySplit* that performs segmentation of the BLAST input query file (please see Figure 10). The *QuerySplit* application takes a text file as a parameter, which contains query sequences of variable length. It then proceeds to analyze the file and create several smaller files, each containing a number of queries so that the overall size of all the files is as close to each other as possible. This application

is used by the second application called Dynamic BLAST, a master-worker type application (Afgan et al., 2006) (please see Figure 11 and Figure 12). Dynamic BLAST is a custom-built application intended to maximize the use of small, distributed, readily available resources found in the grid to minimize the time needed to perform BLAST searches (Altschul et al., 1990). It uses established grid protocols for communication and task coordination while the custom scheduler handles task allocation and data transfers. The final application for this chapter is a parallel implementation of matrix-matrix multiplication using Cannon's algorithm (Cannon, 1969) (please see Figure 13 and Figure 14). Figure 9 illustrates relationships between application categories, applications, and corresponding ASL documents.

ASL is a schema and tag driven language enabling a new type of communication between heterogeneous grid resources. As indicated earlier by Figure 3, ASL enables capturing of application developer specific information and subsequent communication between other existing languages. In this context, the information that needs to be communicated is the information that can be compared to information already existing in other, currently available languages. In the grid environment, the goal of such information is to mitigate inherent heterogeneity of underlying resources, and thus the information needs to be capable of representing individual components of communicating systems that are the cause of this heterogeneity.

Figure 9. Relationship between application categories, applications and shown ASL documents



ASL Document Snippets

This section provides selected snippets with essential parts of the application descriptions outlining the capabilities of ASL to capture application information and how dependencies can be drawn between applications, software packages and required libraries.

Figure 10 is an example of a complete ASL *JobInvocationSection* for the *QuerySplit* application described in the previous section. This description starts off by capturing all the basic application run-time information (lines 2 through 9), such as the application invocation method, the minimum amount of memory required for the application to run, as well as the minimum speed of a host CPU. The most significant part of the provided example is to show how to describe an input file for an application. Lines 10 through 39 point out that the given application requires one input file to be provided in plain text (i.e., ASCII) and should be formatted according to the comments available in lines 17 through 33. In particular, lines 18 and 19 indicate that the properties input file must contain two plain text fields with user name and job name, respectively, followed by a pointer to another input file. The format of the contained input file is described as being in FASTA format (FASTA, 2006) whose sample is also provided in the *format* tag. The tags used for capturing necessary information (e.g., text) map favorably to individual components of a job submission interface (e.g., HTML). By analyzing the available tags and provided information, enough details are available to fully automate creation of a job submission interface by a higher level tool with items such as text boxes, radio buttons and drop-down menus with entries predefined in the ASL

document. Through this approach, an application-specific job submission interface can be generated directly from the application description, thus properly directed by an application developer rather than an application deployer.

Figure 11 provides an example of how an application developer can provide all the available values for a selected application invocation option, even within an input file. The XML snippet describes an application's single input file argument options. These are listed in lines 8 through 15, which limit the user's choice to any single value when invoking the application. This is an additional example of how ASL information can be applied in dual context for automated interface generation denoting that this information belongs to a single list and can be organized into a radio button group.

Figure 12 is a continuation of the ASL document for a Dynamic BLAST application. This snippet highlights the application, library, and software dependencies that Dynamic BLAST depends on or requires. As can be seen from the XML, a Dynamic BLAST application depends on being able to correctly invoke two other applications, namely GridWay (Huedo et al., 2004) and *QuerySplit*, whose description was provided in Figure 10. This idea, although simple to comprehend, has a significant potential in terms of application dependency visualization and installation tools. Through the use of this formalized method of declaring direct dependencies, much automation can be achieved. The remainder of the application description, shown in lines 11 through 15, indicates that Dynamic BLAST requires a specified library. Finally, lines 16 through 25 denote other software packages required to run Dynamic BLAST.

Figure 13 also shows the job invocation section of a parallel matrix-matrix multiplication. Line 3 specifies the format of the invocation command with several options. Lines 5 through 11 point out the necessary details about the first argument (e.g., description, whether it is required or optional). The remainder of the argument descriptions is omitted for brevity, but the information provided shows the ability of ASL to structurally and formally capture such information while allowing the user enough freedom to describe each of the arguments at the desired level of detail.

Finally, Figure 14 points out two more interesting points supported by ASL. Lines 4 through 6 deal with network requirements. Because this application is an example of a tightly coupled parallel application, the communication patterns are frequent throughout the algorithm iterations and thus the message passing requires the existence of a fast-speed, local network. Although this requirement can be built into an ASL definition and made a default requirement for all applications of this type, advances in message-passing technologies are enabling the communication to take place across administrative domains (e.g., MPICH-G2 (Karonis et al., 2003)), which would make this a possible hindrance to future applications. To avoid this limitation, the network type tag accepts "single" as its value denoting this application can be executed only on a local network, limited to a single resource. There are other possibilities here, but these options would all require relationships to be made between parts of an ASL document. The final interesting feature found in this part of the sample ASL document is the use of formulas as part of the application description (line 2). This information can be used by a scheduler when the input data is already known to perform not only application-specific but also data-specific scheduling.

Application of ASL Documents

The previous section provided an overview of ASL, its schema, and its sample use for various application categories. The examples demonstrated the capability of ASL to capture needed information as well as provide concrete samples for its creation. The use, possibilities, extensions, and limitation of the language will be explored

over time as its use becomes more widespread and tools emerge. Some examples of possible functionality and tools that can make use of ASL, either by complementing existing technologies or enabling new ones, are outlined in the *Future Trends* section of this chapter. In addition, this section introduces several projects with different goals and how adoption of ASL would improve them.

GridBench (Tsouloupas & Dikaiakos) is a project that focuses on providing a core set of benchmarks that characterize grid resources. Use of such benchmarks allows prediction of performance and scalability of compositions of applications on desired systems. The proposed framework supports collecting, archiving, and publishing collected data. The goal of GridBench is to provide a collection of kernels representative of applications and application categories that can be used to benchmark and characterize components that affect performance of applications and resources, allowing comparisons to be made. Use of ASL in this context to describe applications and subsequently include performance information into an ASL document enables automated sharing of performance associated with individual application and resources. Additional projects similar to GridBench that could use ASL are STAPL (Thomas et al., 2005), Prophesy (Taylor et al., 2000), and application performance predictors such as Downey (1997), Gibbons (1997) and Smith, Foster and Taylor (1998).

GridWay (Montero, Huedo, & Llorente, 2006) aims at supporting the "submit and forget" ideology where the user is abstracted from the grid middleware details by supporting easier and more efficient job execution on the grid. GridWay works on top of the Globus Toolkit and provides a job manager-like interface for its user where a job can be submitted, status checked, and results retrieved. Use of ASL in this context is broad and could include enablement of application-specific information to be presented to the user when selecting among several applications to execute, matching of performance of selected application to available resources, as well as fully automating application invocation parameters and options. Additional examples of grid resource brokers that could benefit from ASL in similar ways as GridWay include Nimrod/G and its parametric job description language (Steen, 2004), Condor-G (Frey, Tannenbaum, Foster, Livny, & Tuecke, 2001) and incorporation of ASL into ClassAds.

The dynamic nature of workflow systems demands the need for Grid services to be automatically generated according to the execution environment and resources available for execution. GridDeploy (Guan, Velusamy, & Bangalore, 2005) is a toolkit for automatically deploying applications as Grid services, and providing the necessary infrastructure for other applications to invoke them. Integration of ASL into GridDeploy would enable more streamlined generation of needed services because ASL provides needed descriptions of applications and corresponding performance on various resources. Use of standardized protocols to combine information available in ASL along with information from JSDL and MDS can enable user and job-oriented service composition by tools such as GridDeploy.

MODELING WIZARDS TO GENERATE ASL

There are several accidental complexities that emerge when using XML as a specification language. For example, an XML file is embodied as linear text, which makes it difficult to capture hierarchical structures that are shared across a document. To represent hierarchy, it is often the case that an XML document contains multiple links to other parts of the document. This reduces the comprehensibility of the XML document because it requires the user to search through the whole file for the desired section link. This becomes unfeasible as the size of the XML file grows. Furthermore, the extensive tags that de-

lineate the sections of an XML document make it very verbose, which introduces another degree for error in terms of the syntactical correctness of the document. In essence, XML serves as an excellent machine readable format due to its formal structure, but has many limitations as a human-centered language. This section introduces the approach we adopted that allows an end-user to specify properties about their grid application from higher level abstractions using a graphical modeling language. These models serve as input to a translator that assists in generating the ASL specification. An overview of domain-specific modeling is presented in the next section, followed by a description of a modeling language that generates wizards for extracting information required in an ASL specification.

Domain-Specific Modeling: Reducing the Effects of Platform Dependency

Model-driven Engineering (MDE) (Schmidt, 2006) represents a design approach that enables description of the essential characteristics of an application in a manner that is decoupled from the details of a specific technology (e.g., dependence on specific middleware or programming language). Domain-Specific Modeling (DSM) (Gray, Tolvanen, Kelly, Gokhale, Neema, & Sprinkle, 2007) is an MDE methodology that generates customized modeling languages and environments from metamodels that define a narrow domain of interest. In this context, a model corresponds to an abstraction whose concrete syntax is rendered in a graphical iconic notation that assists domain experts in constructing a problem description using concepts familiar to them. A model compiler can be associated with a specific modeling language to generate different artifacts (e.g., source code or deployment files) from a model. DSM has been shown to offer specific technical advantages in supporting rapid evolution of computer-based systems when the hardware and software configuration is tightly coupled and must frequently evolve to a new configuration schema (e.g., retooling an automotive factory (Long et al., 1998), or reconfiguring an avionics product-line (Gray, Lin, & Zhang, 2006)).

A benefit of DSM is the ability to describe properties of a system at a high-level of abstraction and in a platform-independent notation, which protects key intellectual assets from technology obsolescence. Initial research in DSM offers a contribution to end-user programming by supporting experts who may not have software development skills (e.g., physicists and avionics engineers) with a visual notation for expressing domain concepts in a specific *problem space*; thus, hiding the accidental complexities of using a general-purpose programming language. In DSM, models and model transformations are first-class entities in the development process and represent the initial point for generation of low-level details in the *solution space*.

The goal of providing new language abstractions appropriate to the specific programming task and user has been a common objective of language researchers for several decades (Floyd, 1979) and shares a common vision with another new approach called intentional programming (Simonyi, Christerson, & Clifford, 2006). Furthermore, the DSM philosophy of narrowly defined modeling languages can be contrasted with larger standardized modeling languages, such as the UML, which are fixed and whose size and complexity (France, Ghosh, & Dinh-Trong, 2006) provide abstractions that may not be needed in every domain, adding to the confusion of domain experts. The concept of "little languages" (Bentley, 1986), or similarly named Domain-specific Languages (DSLs) (Deursen, Klint, & Visser, 2000; Wile, 2004), share the same intent of DSM, but with different concrete syntax (i.e., DSLs are typically textual languages rather than graphical).

The Generic Modeling Environment (GME) (Balasubramanian, Gokhale, Karsai, Sztipanovits, & Neema, 2006) is the metamodeling tool

that we used in our approach to DSM. The next sections present our use of the GME to provide a modeling language that generates wizards for constructing an ASL specification.

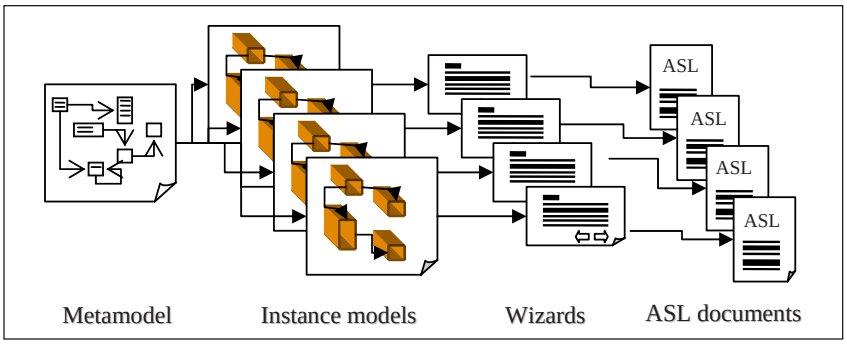
ASL Wizard Metamodel

The use of a higher level graphical modeling language to create ASL specifications consists of constructing the necessary modeling elements describing an application and filling in the parameters that describe the corresponding application feature. This method would help to remove many of the errors in formatting an ASL document to ensure that the document was created correctly (i.e., the application developer would be alleviated of a lot of typing and checking the correctness of XML tags). However, ASL is a language that has a one-to-one mapping between a value and tag pair (i.e., XML tag and the associated value). Because of this, the benefits of adopting a modeling language specifically for ASL are minimized. We realized that a much more significant improvement could be offered by guiding a user in creating an ASL document through wizards. The subsequent challenge became the specific technique to generate the implementation of the wizard.

Depending on the application type, entire element sets available in ASL may not make sense for a particular application. Non-savvy users may find themselves overwhelmed with the number of available options when creating such a document, resulting in slower acceptance or rejection of the ASL. There is a need to ease this transition and provide tools enabling quick and guided creation of such documents. Unfortunately, due to the need to have many possible variations of individual wizards to handle different application categories and variations within these categories, a single wizard would fail to accommodate all the needs. Generating many wizards is prohibitive due to the possibly large number of wizard variations, as well as their temporary lifespan. To accommodate for these variable needs, we have realized a method to generate custom wizards using high-level, domain-specific models. The approach considers the desired components found in ASL and connects them into a meaningful event-driven workflow. The result is a customized wizard that assists in creating a complete ASL document. Figure 15 shows the generation pipeline: a metamodel defines the wizard modeling language, from which specific instance configurations are created; from the instance models, the specific wizard is created (either in HTML, or some other technology); the generated wizards then create the corresponding ASL based on the user response to the wizard interaction.

There are two levels of indirection that are illustrated in Figure 15. The first level is specified in the instance models, which describe the essential elements of each wizard page and the control flow

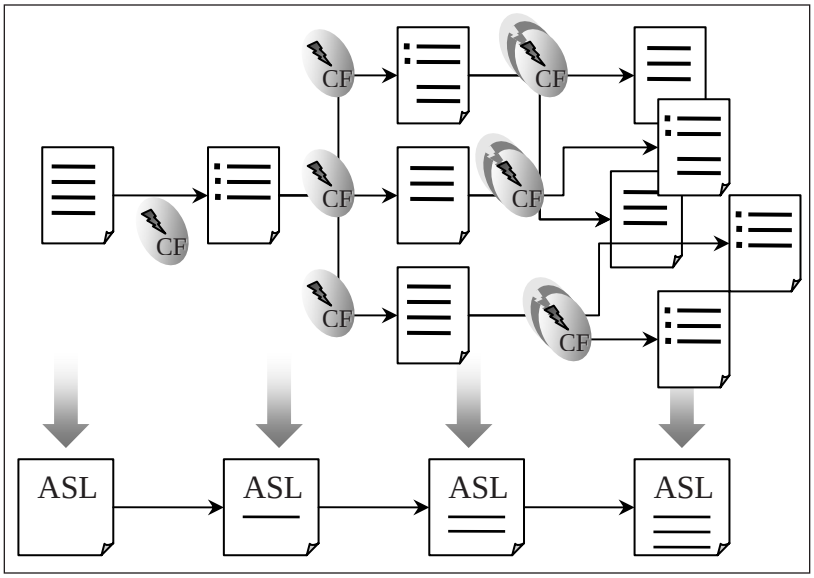
Figure 15. Three-level modeling stack used to generate ASL



(CF) between each page based on user interaction. The instance models must handle creation of objects composing the wizard being generated and must also process all of the possible choices available to adjust the control flow of the wizard. The second level of indirection is built into the generated wizard pages. The wizards are responsible for the actual generation of the ASL document. The control flow captured by the wizards must format the output of an ASL document and store the necessary data in the ASL document. The wizards must also pass any needed information among the wizard pages. To summarize, there are two levels of generation: the generation of wizard pages from the instance models, and the generation of ASL from the wizards; in essence, the process represents a generator of a generator, a unique concept within the area of DSM.

Figure 16 is a diagram showing the possible branching of the wizard pages depending on the user input. The first key observation is the possibility of any single page to be used at multiple levels of the wizard by several parent pages. The second observation is the number of required locations where automatic handling of the control flow and ASL document generation must take place. The model must allow the user accessibility and connectivity to individual pages between different stages of the wizard. This is handled through multiple levels of wizard generation within the model where the same level pages are all viewed on the same aspect within GME. Connections are allowed to be made between compatible objects at appropriate levels through the use of constraints. Connections between individual pages are then made accordingly by the user. The difficulty raised by this approach is the size of the instance model as well as the multiplicity of possible connections resulting in an instance model that is difficult to comprehend. The major obstacle in change adoption and correct execution of the composed wizard comes from the fact that the generator needs to be capable of handling multiple instances of control flow. Each connection that is made at the instance model level must be handled automatically by the generator to provide correct

Figure 16. Wizard flow showing multiplicity of generated wizard pages and control flow (CF) at each junction as the ASL document is being generated



execution flow. Beyond making static connections between wizard pages, additional code must be generated that is model-specific and corresponds to the choices the user is presented at each stage of the wizard.

Generating a Wizard

To highlight the challenges involved in constructing the ASL-driven wizards, this section provides a short scenario to illustrate the multiple levels of control the models must represent. From the perspective of the model user, the elements provided by the modeling language (i.e., the constructs defined in the metamodel) correspond to portions of an ASL document. These are classified as individual components ranging from high-level components (e.g., an entire job invocation section) down to low-level components (e.g., tags such as the application executable name). The iconic representation of these modeling elements, as viewed from a user perspective, are shown in Figure 17.

The end-user is considered to be the domain expert who helps create a model representing the wizard control flow. This is the first difficult task to be handled by the metamodel and subsequently the code generator within the model compiler. The challenge arises from the need for the connections to be made between wizard pages when the initial wizard code is generated, as well as the additional code that needs to be incorporated to handle user choices. This implies that group components that exist in the metamodel (that correspond to equivalent structures in the ASL), such as a drop down menu with many options, must be decomposed into individual pieces and conditional connections made to subsequent pages of the wizard from each of these options. This presents an inherent burden on the model user due to the large number of possible combinations as well as coordination of model layering where complying pages can be reused. The solution is found in the composition of ASL wizard pages. Instead of coupling all of the ASL sections onto a single page, the wizard and corresponding pages can be split into a form. As such, the scope of the ASL is reduced, thus limiting the number of elements, connections and choices the user must consider in the model. The downside to this solution is that equivalent pages within the wizard may belong to a different scope and cannot be reused. Because the division is starting from the most general concepts and progressing into

Figure 17. Available model components describing ASL wizard pages

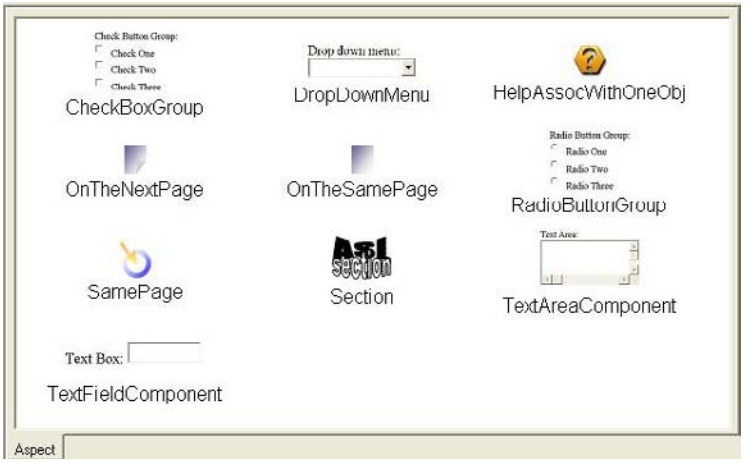


Figure 18. Model view of an ASL document skeleton

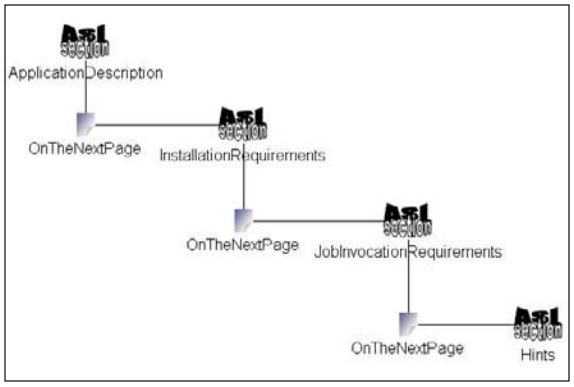

Figure 19. The details of the Application Description element set

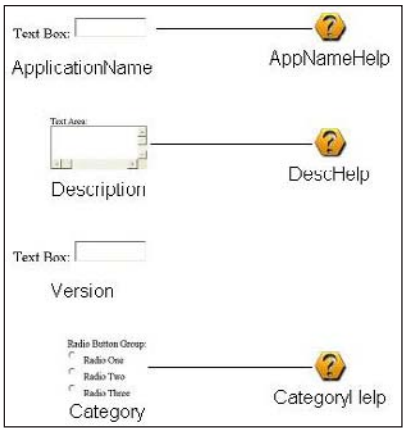


more detailed elements of an ASL document, this behavior should be minimized.

Figure 18 shows the skeleton of a typical ASL document with the indication of the necessary connections at this level for the generating wizard. The top-down scoping of the wizard can also be seen in this figure. Because the goal of the project is to simplify ASL generation, individual sections of the model (and thus wizard) directly map to the resulting ASL document. After a given layer of the wizard is fully generated (as shown in Figure 18), the user can provide further details on each individual section. This is accomplished by double-clicking the desired section (i.e., GME model) and opening a new set of model options. This step can be seen in Figure 19 where further details of the *ApplicationDescription* section are provided. The components used at this level map directly to the interface of the generated wizard (except the *Category* section, which is a model requiring individual elements to be provided by accessing the lower layer). This is primarily an example of a two-layer composition where wizard interface components were provided immediately, although additional layers could also be created requiring more pages and connections to be made, as they map to the appropriate page.

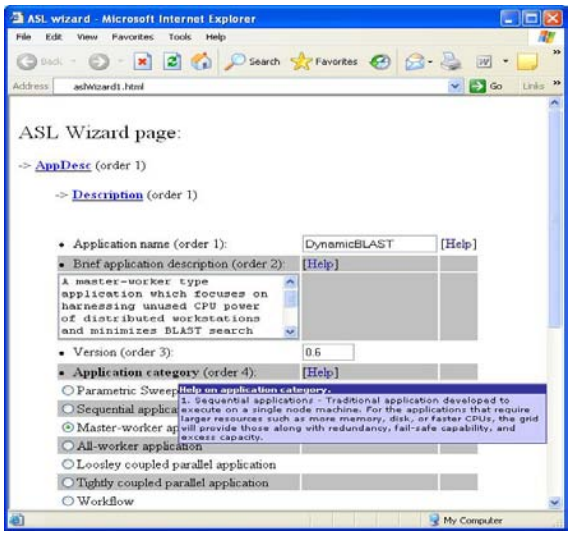
The model compiler that performs the transformation from the model to the generated wizards is presented with a challenge to deliver the requested code among the possible variations. This considerably complicates the code generator within the model compiler. The most difficult part of developing the metamodel and model compiler is the control flow component of the wizard where the connecting pages of the wizard must execute additional connection point code to handle storage and passing of the necessary information between wizard pages. The method of message passing is not defined by the user but rather implied by the generated model. This logic must be customized to the particular wizard and be completely transparent to the end-user. Beyond making the necessary connections at the page level, the generator must be capable of composing necessary code, including page scoping.

To illustrate this idea, a sample workflow can be followed: Upon generation of the wizard, a user instantiates it and provides some data to the wizard. The wizard advances to a subsequent page where the user is asked for more data, this page may branch off into several possible pages,

and so forth. Selection of the subsequent page is determined from a user's input at run-time. As each page may branch into multiple subsequent pages, and even though the paths to individual pages may differ, some of the pages may be equivalent in context. At each step of the wizard, control flow code logic must be provided by the wizard generator to accommodate for this variability and workflow coordination. In addition, the code for data storage that incrementally constructs the resulting ASL document must be generated by the wizard.

We have written a model compiler that generates HTML to represent the wizard pages. This model compiler creates and formats the necessary HTML forms for each wizard page. The compiler also generates the control flow and how the data is passed between each wizard page (i.e., using CGI POST, GET). As the ASL document is being created from multiple levels within the wizard, an additional concern is the correctness of the created document with respect to the generation of proper tags for each ASL element. As discussed in the previous section, ASL contains tags that are lexicographically equivalent. If the tags are placed outside of the correct context, an application interpreting the ASL specification would not be able to disambiguate the ASL. All of these difficulties must be handled in a generic manner within the generated code to accommodate the numerous permutations that may arise. A sample HTML-based wizard can be seen in Figure 20. The generated HTML page is part of the wizard and has been automatically created by the model compiler. The HTML is generated by the *ApplicationDescription* section of the model presented in Figure 18 and Figure 19. Each of the individual components has properties associated with them; thus, the ordering and layering of the wizard is based on the ordering property provided by the user when creating an instance model. Each of the components can also have help information, which appears as a text balloon in the generated wizard.

Figure 20. Sample page of generated wizard to collect initial application information



We have found that describing an application from a higher level of abstraction reduces the learning curve for a new technology such as ASL, but it has drawbacks in that it requires a new tool to be added in the repertoire of an application developer. The only related tool that accomplishes a similar idea of composing wizards from a higher level specification targets the .Net platform and generates MS Windows forms wizards (Actipro, 2006). However, integration of interoperable tools that share a single interface can advance the productivity of a software developer. An example is the Grid Automation and Generative Environment (GAUGE) (Hernandez et al., 2006), which also reduces accidental complexities of grid development through adoption of DSM. Because the development process within GAUGE takes place within GME, its extension to include concepts introduced by ASL represents a possible integration opportunity. By incorporating and extending an intelligent agent used for the application development process, data can also be extracted automatically to populate sections of the corresponding ASL document, thus reducing the

work required by the application developer. The integration with GAUGE represents future work that can ease the path of ASL adoption.

FUTURE TRENDS

As the general adoption of the grid moves from the research labs and campus infrastructures into mainstream industry (with the goal of offering high-levels of Quality of Service), many components (in terms of pervasive availability, secure use of systems, and seamless access) must still be provided. Many of the individual components and additional functionalities are being addressed by many researchers. The following is a list of research issues and further advancements that remain open in the context of this chapter as it fits into the larger picture of the grid:

- The initial schema and corresponding ASL documents have been constructed to ensure the language is capable of representing applications. The ASL schema should also be able to define individual components that comprise an application. The differences between two applications should also be discernable from the respective ASL specifications. Many more applications need to be described with the goal of adjusting the ASL schema to address new application categories.
- Publicizing the benefits of the ASL is necessary to promote adoption by the wider grid community. The current focus considers the standardization of the ASL within the Open Grid Forum. This is following a standardization path similar to JSDL.
- Additional tools are required to promote generation of ASL, such as the modeling approach described in this chapter.
- Tools that make use of ASL are of significant importance. Many tools can be adapted to make use of ASL documents but standardization is required before these actions can take place. Examples of such tools include the following:
  - *Application information services* (AIS), which represent a suite of services where registration, discovery, and monitoring of an application could take place at the level of a VO. Through a set of interfaces, the users would be able to discover services and applications, and obtain help documentation.
  - *Automated HTML application help generator*, which would be an application to interpret ASL documents and generate application-related information. This can be as simple as a static Web page being generated as the default help documentation or a more advanced on-demand search-and-match custom page generation based on user queries of problem identification to include the latest available information.
  - *GridRPM*, would be an application to take advantage of installation and dependency information available through the mesh of ASL documents (as available in AIS) and automatically construct descriptor files before proceeding with automatic application installation and deployment.
  - *Grid scheduler applications* could utilize the ASL information to perform application-specific scheduling without the need to keep historical application execution data.
  - *Accounting and software license accountability* is an area of the grid currently in its initial stages but will advance quickly in response to the high demand of grid services from industry. This area provides a vast number of options where relevant information

can be stored into ASL documents and later used through automated billing and license verification.

CONCLUSION

This chapter provides an overview of developing intensive software applications in a grid computing environment along with the taxonomy of grid users. For each user category the specific responsibilities, roles, and requirements were described. A sample application scenario was provided to illustrate the interaction required among the different user categories and the grid middleware. The functionality provided by the grid middleware to accomplish the successful deployment of the sample scenario was presented and difficulties with the current solutions were also outlined. To further illustrate the complexity involved in deploying grid applications, the grid applications were categorized into seven major categories. For each deployment category the various steps involved in the deployment process were discussed. It was noted that there is no support currently available for the application developer category to describe the requirements and capabilities of an application. In order to accommodate this need, a new language was presented–the Application Specification Language (ASL)–that supports the description of applications in a grid environment. Examples outlining the capabilities of ASL were provided using the sample application scenario. Finally, the chapter described a supporting modeling language for generating ASL documents from a higher level specification, which minimizes the effort of an application developer and deployer.

ASL enables the application developer to describe the application requirements and capabilities. Using domain-specific modeling for the creation of ASL documents reduces some of the accidental complexities encountered in the grid application development and deployment process. Metamodeling techniques could be further extended to provide additional tools for applying information available in ASL to other areas of grid computing (e.g., automated user interface generation for job registration, submission, and monitoring). The work presented here takes a bottom-up approach to solving some of the problems in information availability and standardization between grid entities (e.g., applications, users, and resources) in the heterogeneous environment. Through the adoption of technology presented here, individual pieces within a complex grid system can communicate through a common language and at the appropriate level of granularity permitting context-controlled information delivery in a range or formats. Overall adoption of the domain-specific modeling ideas into the area of grid computing as an effective tool to leverage some of the grid-inherent difficulties may result in shorter application development and deployment times by reducing complexity and expertise required.

Chapter 1.25
Performance Analysis of a Web Server

Jijun Lu
University of Connecticut, USA

Swapna S. Gokhale
University of Connecticut, USA

ABSTRACT

With the rapid development and widespread use of the Internet, Web servers have become a dominant source of information and services. The use of Web servers in business and critical application domains imposes stringent performance requirements on them. These performance requirements cast a direct influence on the choice of the configuration options of the hardware and the software infrastructure on which a Web server is deployed. In addition to the selection of configuration options, for a given level of load and a particular hardware and software configuration, it is necessary to estimate the performance of a Web server prior to deployment.

INTRODUCTION AND MOTIVATION

The World Wide Web (WWW) has experienced an exponential growth in the last 10 years and today Web servers are important sources of information and services. Web servers, which are typically based on the HTTP protocol running over TCP/IP, are expected to serve millions of transaction requests per day with acceptable performance, which may be defined in terms of transaction throughput and latency experienced by the users (Van der Mei, Hariharan, & Reeser, 2001). The stringent performance requirements imposed on Web servers have a direct influence on the configuration options of the hardware and software infrastructure used for deployment. Hardware configuration options may include the capacity and the number of processors and caching strategies. Software configuration options may include the number of server threads/processes to serve client requests, the buffer size, and the scheduling discipline. Prior to deployment, for a given level of load, it is necessary to determine the hardware and software configuration options that would provide acceptable server performance.

One of the ways of estimating the performance of a Web server is by conducting actual measurements. While the measurement-based approach may be viable to estimate the performance for a given set of configuration options, it is cumbersome and expensive for "predictive" or "what-if" analysis and for an exploration of a set of alternative configurations. Model-based analysis, which consists of capturing the relevant aspects of a Web server into an appropriate model, validating the model and then using the validated model to predict the performance for different settings is an attractive alternative to the measurement-based approach.

Web servers receive and process a continuous stream of requests. As a result, a vast majority of their time is spent waiting for I/O operations to complete, making them particularly apt to fall under the category of I/O intensive applications (Ling, Mullen, & Lin, 2000). The performance of such I/O intensive applications (responsiveness, scalability, and throughput) can be improved dramatically if they are provided with the capability to process multiple requests concurrently. Thus, modern Web servers invariably process multiple requests concurrently to enhance their performance and to fulfill their workload demands. Considering the concurrent processing capability, we propose the use of a multiserver *M/G/m* queue to model a Web server with an I/O intensive workload. The performance metric of interest is the response time of a client request. Since there is no known analytically or computationally tractable method to derive an exact solution for the response time of the *M/G/m* queue, we use an approximation proposed by Sakasegawa (1977). We validate the model for deterministic and heavy-tailed workloads using experimentation. Our results indicate that the *M/G/m* queue provides a reasonable estimate of the response time for moderately high traffic intensity. The conceptual simplicity of the model combined with the fact that it needs the estimation of very few parameters makes it easy to apply.

The balance of the article is organized as follows: First, we present the performance model of a Web server. We then discuss the workload characteristics used for the experimental validation of the model, followed by a description of the experimental infrastructure used for validation. Subsequently, we present and discuss the experimental results. Research related to the present work is summarized next. Finally, we offer concluding remarks and directions for future research.

PERFORMANCE MODEL

We describe the performance model of a Web server in this section. Towards this end, we first provide an overview of the software architecture of a Web server. Subsequently, we discuss the rationale for modeling a Web server using an *M/G/m* queue and present an analytical expression to compute the approximate response time.

Web Server Software Architecture

Modern Web servers implement concurrent processing capability using a thread-based, a process-based, or a hybrid approach (Menasce, 2003). An example of a thread-based server is the Microsoft IIS server (Microsoft Corporation, n.d.), a process-based server is the Apache HTTP server 1.3, and a hybrid server is the Apache HTTP server 2.0 (Apache Software Foundation, n.d.).

In both the thread-based and process-based architectures, to avoid the overheads of forking a process/thread for every request, the Web server can fork a pool of processes/threads at start-up. If all these threads/processes are busy, either additional threads/processes can be forked or the request waits in a queue. In the former case, the size of the thread/process pool changes dynamically, whereas in the latter case the size of the thread/process pool is fixed and a new request

waits in the queue if all the threads/processes are busy.

Queuing Model

We assume that the Web server consists of a static thread/process pool, with the number of threads/processes in the pool or the pool size, denoted *m*. Requests arrive at the server according to a Poisson distribution and the request service time is exponentially distributed. In most Web servers, the capacity of the queue to hold requests when all the threads/processes are busy is typically very large to ensure low probability of denying a request. Thus, for the purpose of modeling we assume the queue size to be infinite. The queuing model that coincides with these characteristics of a Web server, capable of processing requests

Figure 1. M/G/m queuing model

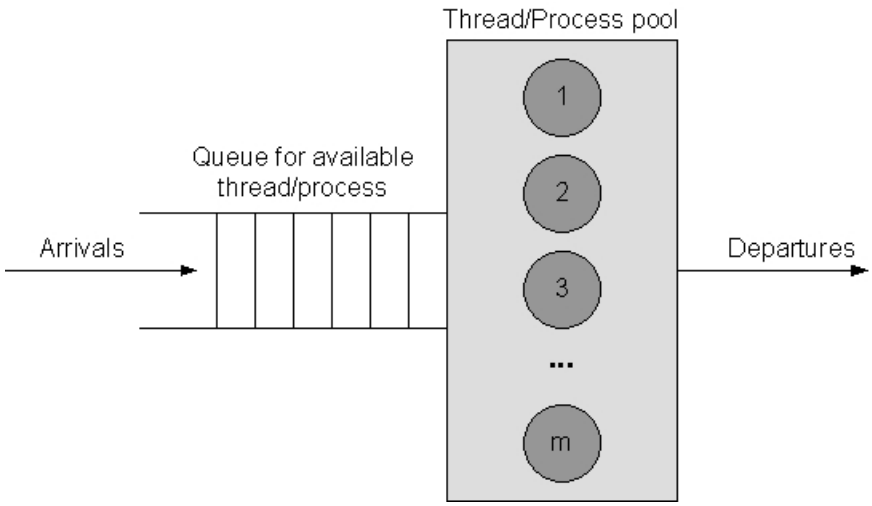

Table 1. Parameters of the M/G/m queuing model

Symbol	Meaning
R	Response time
m	Number of servers
λ	Arrival rate
μ	Service rate
c_s	Coefficient of variance of service time (ratio of standard deviation to the mean)
ρ	Traffic intensity $\rho = \lambda/(m\mu)$

concurrently is an *M/G/m* queue. We note that since the model is based on the existence of concurrent processing capabilities, and not on the specific implementation of concurrency, it is general and equally applicable to a thread-based, a process-based or hybrid architecture.

Figure 1 shows a pictorial depiction of the *M/G/m* queue. The arrival process is Poisson with rate and there are *m* parallel servers serving the requests. The service times of the requests are independent and identically distributed random variables, with a general distribution that has a finite mean μ^{-1} and a finite coefficient of variance c_s (the ratio of standard deviation to the mean). Specifically, for deterministic service times, c_s = 0; for exponential service times, c_s = 1; and for heavy-tailed service times, $c_s \to \infty$ (Lipsky, 1992). Let $\rho = \lambda/(m\mu)$ denote the traffic intensity, also known as utilization factor (Lipsky, 1992). For a stable system $\rho < 1$ and the queuing discipline is first-come-first-served (FCFS). Table 1 summarizes the parameters of the *M/G/m* model.

The performance metric of interest is the expected or the average response time of a client request denoted *R*. Except for certain special cases, there is no known analytically or computationally tractable method to derive an exact solution for the response time of the *M/G/m* queue. Several approximations have been proposed (Hokstad, 1978; Kimura, 1983; Sakasegawa, 1977; Yao, 1985) and among these we consider the one by Sakasegawa (Sakasegawa, 1977) since it requires very few parameters and involves straightforward computations. Using this approximation, the mean number of requests in the queue for the *M/G/m* model is given by:

$$L_q \approx \frac{(1+c_s^{\,2})}{2}\frac{\rho^{\sqrt{2(m+1)}}}{1-\rho} \qquad (1)$$

Equation (1) indicates that the queue length increases as ρ increases. Further, for a service time distribution with high variability (where c_s is high), such as in the heavy-tailed distribution (Crovella, Taqqu, & Bestavros, 1998), the queue length will increase very rapidly.

Using Equation (1), the mean response time for the *M/G/m* queue as per Little's law (Kleinrock, 1976) is:

$$R_{M/G/m} \approx 1/\mu + \frac{L_q}{\lambda} = 1/\mu + \frac{(1+c_s^{\,2})}{2\lambda}\frac{\rho^{\sqrt{2(m+1)}}}{1-\rho} \qquad (2)$$

Since a single server queue is commonly used to model a Web server (Cao, Anderson, Nyberg, & Kihl, 2003; Nossenson & Attiya, 2004; Squillante, Yao, & Zhang, 1999), we compare the mean response time of a multiserver *M/G/m* queue to the response time of a single-server *M/G/1* queue, which is given by:

$$R_{M/G/1} = 1/\mu + \frac{(1+c_s^{\,2})}{2\lambda}\frac{\rho'^{2}}{1-\rho'} \qquad (3)$$

where $\rho' = 1/\mu = m\rho$. Notice that $R_{M/G/1} > R_{M/G/M}$ holds for $\forall m \geq 2$.

WORKLOAD CHARACTERISTICS

We consider service scenarios where each request is for a single static file and the server responds to the client with the file. Since the file size is demonstrated to be heavy-tailed (Crovella et al., 1998), we consider two types of workloads, namely, deterministic and heavy-tailed, which are described next.

Deterministic Workload

For a deterministic workload, all the requests are for the same file size in a single experiment. We consider four deterministic workloads with file

sizes of 64 KB, 128 KB, 256 KB, and 512 KB. The smallest size considered is 64 KB due to the measurement granularity, which is 10 *msec* for our test bed (described in the next section). We note that even for a deterministic workload, in which the file size in every request is the same, the service time on an experimental test bed/real system will fluctuate (Lipsky, 1992), implying that $c_s \neq 0$ in Equation (1). Since the magnitude of these fluctuations is expected to be small compared to the actual service time, we use the term *deterministic workload* to indicate a relatively stable workload compared to the heavy-tailed one described next.

Heavy-Tailed Workload

In this section we discuss how the heavy-tailed workload was generated based on the Pareto distribution, which has been widely used to model such characteristics in a variety of phenomena including inter-arrival times (Paxson & Floyd, 1995), burst sizes (Charsinski, 2000), topological properties (Faloutsos, Faloutsos, & Faloutsos, 1999), workload properties (Crovella et al., 1998), and error rates (Goseva-Postojanova, Mazimdar, & Singh, 2004).

The Pareto distribution is characterized by a shape parameter α and a scale parameter k. The probability density function (pdf) of the Pareto distribution is given by:

$$f(x) = \alpha k^{\alpha} x^{-\alpha-1} \quad (4)$$

where α, $k > 0$ and $x > k$. The cumulative distribution function (CDF) of the Pareto distribution is given by:

$$F(x) = 1 - k^{\alpha} x^{-\alpha} \quad (5)$$

When $\alpha > 1$, the Pareto distribution has a finite mean which is given by:

$$E[X] = \frac{\alpha k}{\alpha - 1} \quad (6)$$

A series of numbers following the Pareto distribution can be generated by computing the inverse of the CDF presented in Equation (5) as below (Jin & Bestavros, 2005):

$$x = F^{-1}(u) = k(1-u)^{-1/\alpha} \quad (7)$$

In Equation (7), if α and k are known, then for random variates u_i's generated from the uniform distribution $U(0,1)$, $\{x_i\}$'s following the Pareto distribution can be generated. Note here $x_i > k$ for every i. It is expected that most $\{x_i\}$'s will have values close to k, with a small number being extraordinary high. When the shape parameter α of the Pareto distribution is fixed, the scale parameter k for a given mean $E[X]$ can be obtained as follows:

$$k = E[X]\,(1 - 1/\alpha) \quad (8)$$

We set the value of the shape parameter α to 1.36, based on prior research (Crovella, Taqqu & Bestavros, 1998). Four different mean file sizes, namely, 120 KB, 150 KB, 180 KB, and 200 KB were considered, and for each mean file size, using the preselected shape parameter α, the scale parameter k was obtained using Equation (8). Using the (α, k) pair, the CDF F_{S_i} of file size S_i is obtained. The probability of each file size is then computed as:

$$P_{S_i} = F_{S_i} - F_{S_{i-1}} \quad (9)$$

The individual file sizes considered are 64 KB, 128 KB, 256 KB, 512 KB, 1 MB, and 2 MB and the distributions of these file sizes in the four workloads are reported in Table 2.

EXPERIMENTAL INFRASTRUCTURE

In this section, we describe the experimental infrastructure used for model validation. We also

describe the process used to estimate the mean service time for each file size.

Test Bed Description

The experimental infrastructure comprises of a single server and a single client, with configurations summarized in Table 3. Both computers are connected via a 100M Ethernet across a LAN.

In a multithreaded server, as the size of the thread pool increases, each thread may experience some performance degradation. However, when the thread pool size is below a threshold, this degradation is negligible (Xu & Bode, 2004). As a rule of thumb, to ensure negligible degradation, the size of the thread pool should be twice the number of CPUs on the host machine (Ling et al., 2000; Richter, 2000). Thus, for the single processor server in our test bed, the size of the thread pool is set to 2. The configurations of the Web server used in the experiments are summarized in Table 4. Since the maximum queue length used is very large as compared to the number of threads, the assumption of infinite queue length needed to apply the *M/G/m* model is reasonable.

Service Time Estimation

Table 4. Web server configurations

Parameter	Value
CPU	1
Thread	2
Web caching	No
Network Bandwidth	100 Mbps
Maximum queue length	3000

Table 5. Mean service time of each file size (msec)

File size (S_i)	Service time ($\bar{T}_{S_i}$)
64 KB	10.00
128 KB	16.25
256 KB	32.85
512 KB	69.13
1 MB	133.03
2 MB	286.38

To compute the mean response time of a workload based on the *M/G/m* model using Equation (2), the mean service time for the workload needs to be obtained. The mean service time of a workload will depend on the distribution of the file sizes in the workload and the mean service time for each of those file sizes. Thus, to obtain the mean service times of the workloads, the mean service times of the file sizes in the workload need to be obtained.

To obtain the mean service time for a single file size, client requests at a very low arrival rate such that the traffic intensity is low (less than 0.4%) were presented to the server. For each file size, the average response time was computed using response time measurements for 200 requests. The low traffic intensity causes negligible queuing delay and the response time mostly consists of the service time. Thus, the mean service time was approximated by the response time under very low load, which for each file size is summarized in Table 5.

RESULTS AND DISCUSSION

In this section we present and discuss the results of the experimental validation of the *M/G/m* model. Several experimental scenarios for both deterministic and heavy-tailed workloads were considered, with each scenario comprised of a single workload (deterministic or heavy-tailed). For the deterministic workload, all the client requests were for the same file size. For the heavy-tailed workload, requests were generated according to the file size distribution for a given mean file size. In each scenario, request arrivals were generated according to a Poisson distribution with varying rates, chosen to maintain the condition $\rho < 1$ necessary for a stable system. Due to the high variability of the arrival rates of the Poisson process and for the file size distributions, the steady state mean queue length given by Equation (1) increases with ρ (Lipsky, 1992). The traffic intensity is considered to be low for $\rho < 0.3$, medium for $0.3 \leq \rho \leq 0.5$, and high for $\rho \geq 0.5$ (Lipsky, 1992; Nossenson & Attiya, 2004).

For each arrival rate, using the measured response times of 200 requests, the average response time was obtained. The mean response times were computed for the *M/G/m* model from Equation (2) and *M/G/1* model from Equation (3) using MATLAB. For each workload, the traffic intensity ρ for each arrival rate is also reported.

Deterministic Workload

The measured and the computed response times along with the traffic intensities for deterministic workloads of 64 KB, 128 KB, 256 KB, and 512 KB are reported in Tables 6, 7, 8, and 9, respectively. The results indicate that the response time predicted by the *M/G/m* model is very close to the measured response time for low to moderately high loads, with value of ρ around 0.5. The predicted response time is lower than the measured, and the deviations are within 7–8% for low and medium traffic intensities. As the traffic intensity increases, greater deviations occur. However, the deviation is within 10% even for high traffic intensities, with ρ close to 0.6. For the arrival rates and file size distributions, the system is already heavily loaded when $\rho \geq 0.5$ (Nossenson & Attiya, 2004) which cause these deviations.

The results also indicate that the response time predicted by the *M/G/1* model is always higher

than the response time predicted by the *M/G/m* model. As the arrival rate increases, the rate at which the predicted response time increases is much higher for the *M/G/1* model as compared to the *M/G/m* model. Further, as the arrival rate λ approaches service rate μ while maintaining λ < μ, the response time predicted by the *M/G/1* model deviates significantly from the measured response time. When μ < λ < 2μ, the response time of the single-server *M/G/1* model is not meaningful since it leads to ρ′ > 1, resulting in an unstable system. The *M/G/m* model, however, still represents a stable system for 0.5 < ρ < 1 and hence provides meaningful predictions of response time. Thus, a single-server queue is not adequate to represent a Web server equipped with concurrent processing capabilities.

Heavy-Tailed Workload

To compute the average response time for a heavy-tailed workload using Equation (2), the mean service time for the workload with a given mean file size can be computed using:

$$\overline{T}_{\overline{S}_i} = \sum_i \overline{T}_{S_i} P_{S_i} \qquad (10)$$

where S_i denotes the file size, $\overline{T}_{S_i}$ the mean service

time of file size S_i, P_{S_i} the probability of requesting a file of size S_i, and $\overline{T}_{\overline{S}_i}$ the mean service time of a workload with mean file size $\overline{S}_i$. As discussed earlier, the mean file sizes considered are 120KB, 150KB, 180KB, and 200KB. The mean service times of these workloads computed using the service times and probabilities reported in Table 2 and Table 5 respectively, are summarized in Table 10.

The measured and the computed response times for the heavy-tailed workload for different mean file sizes are summarized in Tables 11, 12, 13, and 14. The trend in the deviation between the predicted and measured response times in this case is similar as in the case of the deterministic workload. The predicted and the mean response times are within 10%, with the predicted one being lower than the measured for low and medium traffic intensities ($\rho < 0.5$). As indicated earlier, for the arrival rate and file size distributions, the system is already heavily loaded when $\rho < 0.5$ (Nossenson & Attiya, 2004) which cause these deviations. We note, however, that the difference between the computed and measured response time is around 12% even for moderately high traffic intensity with ρ close to 0.6. The response times predicted by the M/G/1 model follow similar trends as in the case of deterministic workload.

configurations, communication protocols, and interconnect topologies. Kamra, Misra, and Nahum (2004) present a control-theoretic approach that achieves dual objectives, namely, preventing overload and enforcing absolute response times. Cao et al. (2003) use an *M/G/1/K*PS* queuing model to model the performance of a Web server. Nossenson and Attiya (2004) introduce a new *N-Burst/G/1* queuing model with heavy-tailed service time distribution for Web server performance modeling. Squillante et al. (1999) employ a *G/G/1* queue to model high-volume Web sites. Liu, Heo, and Sha (2005) provide a model of a three-tiered Web services architecture, where each tier is modeled by a multistation queuing center. Kant and Sundaram (2000) present a queuing network model for a multiprocessor system running a static Web workload. Hu, Nanda, and Yang (1999) measure and analyze the behavior of a Web server driven by benchmarks and propose techniques for performance improvement. Hardwick, Papaefstathiou, and Guimbellot (2001) use a performance modeling framework, to create a performance analysis tool for database-backed Web sites. Kohavi and Parekh (2003) offer several useful, practical recommendations for supplementary analyses. Iyengar, Challenger, Dias, and Dantzig (2000) present techniques to be used at popular sites to improve performance and availability based on two case studies.

Previous works mostly use a *single* server queue to model a Web server. However, modern Web servers typically have multiple processes/threads that work independently and simultaneously to service requests. Thus, it is appropriate to consider this system a multiserver system, as in the *M/G/m* model in this article. While being an accurate representation of the characteristics of a modern Web server, the *M/G/m* model is simple to comprehend, needs the estimation of very few parameters, and involves straightforward computations, which makes it easy to apply. Since the model is not tied to a specific implementation of concurrency, it is equally applicable to a thread-based, a process-based, or hybrid architecture.

CONCLUSION AND FUTURE RESEARCH

In this article we propose the use of an *M/G/m* queue to model the performance of a Web server capable of processing multiple requests concurrently. The performance metric of interest is the response time of a client request. We validate the model experimentally for deterministic and heavy-tailed workloads. Our results indicate that the *M/G/m* queue provides a reasonable estimate of the service response time for low to moderately high traffic intensities. It is a more accurate representation of modern server characteristics, is conceptually simple, requires the estimation of very few parameters, involves straightforward computations, and is hence easy to apply.

Our future research includes extending the methodology to: (i) consider general arrival processes in performance analysis (Nossenson & Attiya, 2004), (ii) apply the methodology to model the performance of an application server in a three-tier Web services architecture, and (iii) consider QoS provisioning and overload control.

Chapter 1.26
Software Modernization of Legacy Systems for Web Services Interoperability

Chia-Chu Chiang
University of Arkansas at Little Rock, USA

INTRODUCTION

Software maintenance is an inevitable process due to program evolution (Lehman & Belady, 1985). Adaptive maintenance (Schenidewind, 1987) is an activity used to adapt software to new environments or new requirements due to the evolving needs of new platforms, new operating systems, new software, and evolving business requirements. For example, companies have been adapting their legacy systems to Web-enabling environments of doing business that could not have been imagined even a decade ago (Khosrow-Pour & Herman, 2001; Werthner & Ricci, 2004).

To understand software modernization of legacy systems for Web services, it is necessary to address how legacy integration has evolved from centralized computing to distributed, component-based computing due to the advent and widespread use of object-oriented and client-server technologies. Legacy systems were typically developed on a centralized, terminal-to-host architecture. Users usually accessed their legacy systems through terminals that included character-based menus and data entry screens. Consequently, legacy systems built on the central mainframe are inaccessible remotely without adaptations.

Component-based middleware technologies, such as Java RMI, common object request broker architecture (CORBA), and component object model/distributed component object model (COM/DCOM), provide solutions to support the interoperability of legacy systems in a heterogeneous and distributed environment (Chiang, 2001). Unfortunately, the technologies have proved to be insufficient in application integration solutions for several reasons (Stal, 2002). Although the technologies share common communication architectural foundations, the implementation of each technology differs in several aspects, including the object models provided, the communication protocols, and data marshaling/demarshaling. Due to the proprietary implementations of the technologies, they do not interoperate well with

each other. Obviously, existing component-based middleware only partially solves the interoperability problems of legacy systems. More effort is still required to make the legacy systems totally interoperable in a heterogeneous and distributed environment.

BACKGROUND

Web services have been widely considered as a better solution to legacy integration for software interoperability using open standards that include extensible markup language (XML), the simple object access protocol (SOAP), the Web services description language (WSDL), and the universal description, discovery, and integration (UDDI) (Chung, Lin, & Mathieu, 2003; Stal, 2002; Zhang & Yang, 2004). Service requesters and providers follow the Web service standards for message exchanges. When a service provider has a service for public exposure, it must write a description of the service in WSDL and register the service description with UDDI to a global repository. A service requester can then query the repository using UDDI to retrieve the service description. The service requester uses the service description in WSDL to send requests, and the service provider replies to the requests under SOAP.

LEGACY MODERNIZATION FOR WEB SERVICES AND CHALLENGES

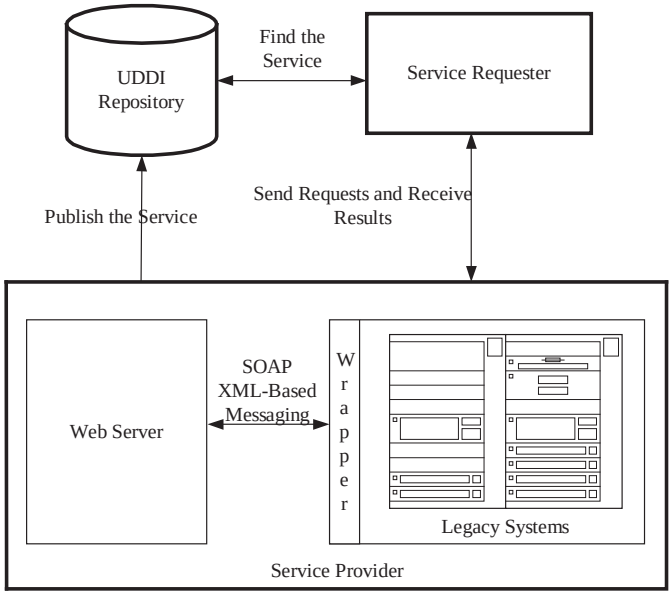
There are three main reasons for modernizing legacy systems: to reduce the system evolution risk, to recoup the investment on the systems, and to make the system distributed and scalable for business-to-consumer and business-to-business, as well as making it highly available to Web users.

Companies usually have two approaches to turn their legacy systems into Web services: wrapping and reengineering. Wrapping provides a cost-effective way to integrate legacy systems with Web services into a heterogeneously distributed computing environment. Unfortunately, the wrapping approach requires the whole legacy system to be exposed to the public as a Web service, which fails to properly abstract the system (Vinoski, 2002; Vogels, 2003). Furthermore, the wrapping approach increases the difficulty of maintaining the legacy system in the long run. Thus, the wrapping approach is generally a temporary solution, rather than a strategic one. The reengineering approach applies reverse engineering techniques to legacy systems to recover business rules, and develop Web services from the extracted business rules. This approach streamlines legacy systems but is highly dependent on the success of recovery on the business rules from legacy systems.

Wrapping legacy systems for Web services can be performed through wrappers or adapters. A wrapper is built to encapsulate a legacy system and provide access to the legacy system through the encapsulation layer. This layer exposes only the methods with parameter attributes to remote service requesters. In addition, the wrapper must resolve the incompatible communication issues between the legacy systems and the Web server using SOAP/XML messaging. Therefore, programmers are required to write a wrapper to reconcile the issues, as well as a WSDL for public exposure. Unfortunately, a wrapper is difficult to maintain, inefficient, and error-prone (Engelen, Gupta, & Pant, 2003). A sample Web service architecture via a wrapper is shown in Figure 1.

Turning legacy systems in middleware-based components into Web services is slightly different from the technique described above. Because the legacy system has already been wrapped in middleware, companies may be unwilling to unwrap their systems in order to turn the system into a Web service. Fortunately, there are Web services toolkits available to turn middleware-based componentized legacy systems into Web services (Engelen, Gupta, & Pant, 2003). First, the toolkits translate the interface definition of a

Figure 1. A Web service architecture to access legacy systems via wrappers

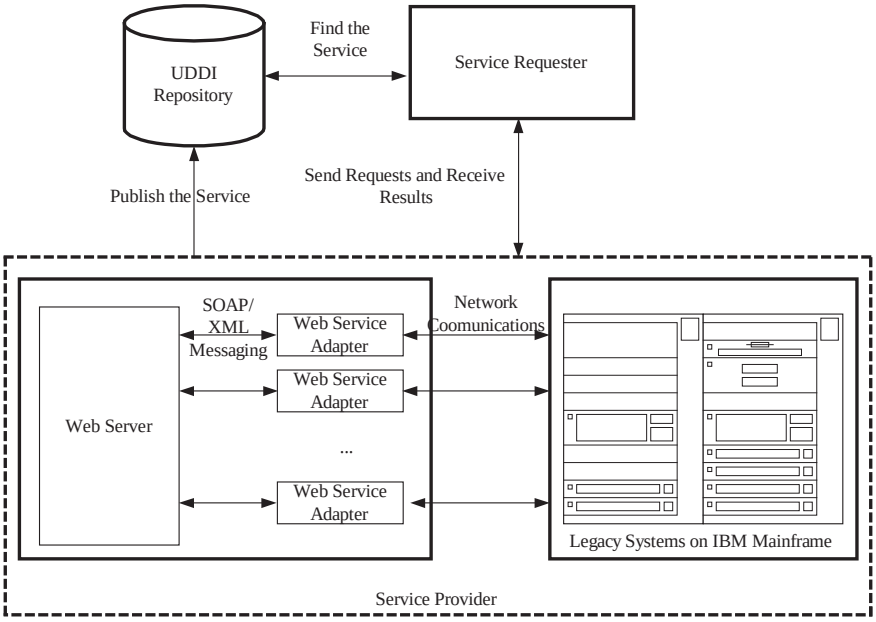


component in the interface definition language (IDL) into a service description in WSDL for public exposure. These toolkits then provide a wrapper component that enables distributed access to the component as a Web service through SOAP. A service requester can then find the WSDL in the registry and interact with the component as a Web service. Using the Web services toolkits, the creation of a wrapper component can be simplified. However, the technique could quickly reach design limitations as legacy systems continue to evolve. One limitation is that the operating system and programming language support in middleware is totally dependent on the development and deployment platforms that are offered by middleware vendors. In many situations, the platforms supporting the legacy systems may not be available for the development of middleware. An alternative to solve this problem is to create an adapter on an available platform and use some other strategy.

An adapter can resolve the language and platform dependency through inter-language binding, inter-process communications, and network communications. Compared to a wrapper, the adapter provides a better and more flexible solution to encapsulate legacy systems by reducing some degree of platform, operating system, and programming language dependency. However, an adapter may create an additional point of failure introduced by a service provider. A sample architecture of using an adapter is shown in Figure 2, and an application of this architecture is the IBM Web Services Technologies (Barcia, Hines, Alcott, & Botzum, 2004; Kreger, 2001).

In Figure 2, a Web service adapter is developed for each service invocation. The connection between the legacy systems and the adapter can be

Figure 2. A Web service architecture to access legacy systems via adapters



any communication protocol that includes TCP/IP and CICS supported by the backend server hosting the legacy system. The Web service adapter may call one single backend system per SOAP service request. It is also possible for the adapter to transform one SOAP request to multiple requests to one or more backend systems. The combined results of the backend requests are composed into one SOAP response, which is then passed back to the server requester.

Unlike the wrapping approach, the reengineering approach develops business rules from legacy systems into Web services. Legacy systems are first thoroughly analyzed for understanding. Code corresponding to the business rules is identified and extracted into a library for the creation of Web services as shown in Figure 3.

Next, the interface of the extracted code as a Web service is constructed for creating the Web service in WSDL. The WSDL specification is then compiled into a skeleton of a service provider as shown in Figure 4. Whenever a service requester sends a request message to the service provider, the skeleton automatically demarshals the request and invokes the service. When the service provider returns the results, the skeleton marshals the results into a response message and sends the response back to the service requester.

The WSDL specification of a service provider is also used to create a stub of a service requester for the invocation of the service remotely. The WSDL specification is retrieved from a UDDI repository, and a description of the remote procedures is created from the WSDL specification. The description of the remote procedures is then compiled into a stub of the service requester for marshaling and demarshaling request and response messages at runtime. The development

Figure 3. Code extraction from legacy systems

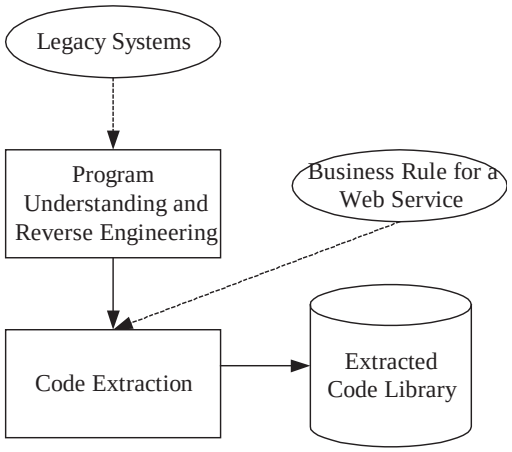


Figure 4. Creation of skeletons via a WSDL compiler

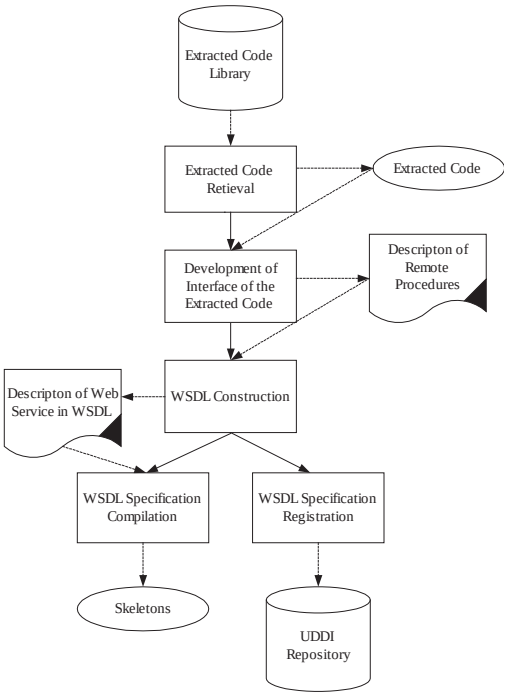

Figure 5. Construction of service requester and provider executables

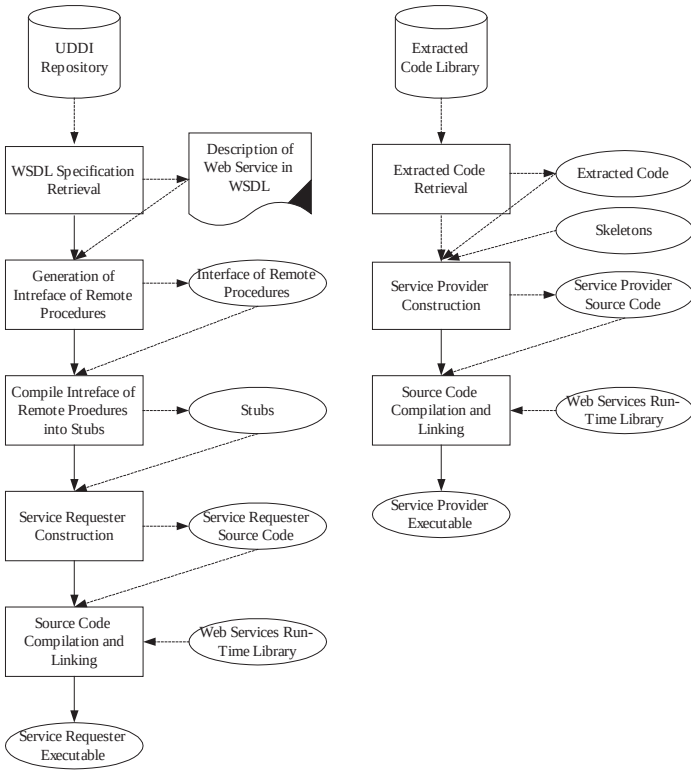

strategy of constructing executable files of a service requester and provider for Web services is illustrated in Figure 5.

In this approach, a WSDL specification does not define any language bindings. This allows stubs and skeletons to be constructed in any programming languages, such as C, C++, Visual Basic, Perl, and Python. Because a service provider's skeleton leaves the implementation of the service unspecified, the extracted code from the legacy system can be inserted into the skeleton to make the concrete implementation of the service. This approach is more than just converting code from one language to another. It is the conversion of an entire system architecture into a Web services architecture, including the user interfaces and database structures. The approach to developing Web services takes the same development strategy as the middleware approach for the development of distributed applications. The proxies are automatically generated from a WSDL specification describing the interface of the service. The extracted code from the legacy system fills in the concrete implementation of the service. Samples of the reengineering approach can be found in references (Engelen, Gupta, & Pant, 2003; Graveley, 2001). Two primary Web services architectures supporting the reengineering approach are the Java 2 platform Enterprise Edition (J2EE) and the .NET platform (Erl, 2005). The J2EE platform is a development and runtime environment based on the Java programming language. The .NET platform (MacDonald, 2003) is a proprietary development and runtime environment developed for use with Windows operating systems. The .NET platform provides unified support for a set of programming languages including Visual Basic, C, C++, and C#.

Web services identification plays an important role in the reengineering approach. It starts with program understanding. Program understanding via reverse engineering provides different views of abstraction of legacy systems which are helpful for identifying services. The code corresponding to the services is extracted from the legacy systems in terms of the business rules defined in the systems. Several techniques used for supporting reverse engineering and design recovery activities have been cataloged in various collections and surveys (Arnold, 1994; Bellay & Gall, 1997; Zvegintzov, 1997). Program slicing techniques (Huang et al., 1996; Sneed & Erdos, 1996; Wang, Sun, Yang, He, & Maddineni, 2004) are used to extract source code corresponding to the business rules from legacy systems. The extracted code may be used as a candidate for Web services. Due to the inherent complexity of the system and the language in which it is written, existing program slicing techniques cannot be fully automated yet. Therefore, human interventions are required to filter the candidates and should be kept to a minimum. Clustering techniques (Wiggerts, 1997) can be used to group the relevant extracted code into classes in terms of the attributes that provide promising candidates for Web services.

Despite all its promises and glories (Arsanjani, Hailpern, Martin, & Tarr, 2003), software modernization of legacy systems for Web services is not free of associated risks and challenges (Tilley et al., 2002). From a business perspective, there are issues of cost, manpower, management, maintenance, personnel pressure, and return on investment that must be examined when considering the integration of legacy systems to a Web services computing environment. The immaturity of these technologies may also offer technical challenges. The current generation of Web services infrastructures and tools has problems of large space consumption and performance degradation. Tools of reverse engineering and program slicing are not mature enough to be fully automated. These issues need to be addressed as these technologies evolve. In order to make a rational decision on the potential of each technology, one must assess the costs, limitations, and risks (Seacord, Plakosh, & Lewis, 2003; Ulrich, 2002). The issues, problems,

and limitations of modernizing legacy systems for Web services interoperability are summarized as follows:

- **Economics of modernizing legacy systems:** Inability to assess the costs of each approach
- **Security:** Maintaining secure and safe systems and keeping unauthorized user access out
- **Performance:** Degrading the system's performance due to the migration from one environment to another or from one language to another
- **Quality:** Failing to attain the quality of the system due to a poorly designed quality plan or unforeseen results from the migration
- **Acceptance:** Rejection of the system by users due to lack of knowledge of the Internet and its usefulness
- **Exposure points:** Risks associated with accessing the firm's systems remotely
- **Privacy and confidentiality agreements:** Addressing an individual's right to privacy and the sharing of confidential information
- **Automated tools:** Effective tools that reduce user intervention during the migration

FUTURE TRENDS

Companies will continuously modernize their legacy systems from centralized to distributed and Web-enabled environments due to the needs of evolving business requirements. Companies may choose to outsource the legacy modernization process for Web services to another company that specializes in such tasks. Automated tools used for extracting business rules from legacy systems will be continuously required for construction of Web services. Web service support tools that migrate middleware-based components into Web services will continue to improve the technology for reliability and transactional guarantees.

CONCLUSION

The applications of the World Wide Web (WWW) are used not only for information gathering, but also as an exciting technological breakthrough providing companies with new opportunities for conducting their businesses. Business applications must respond to changing business requirements quickly to combat conflicts resulting from having heterogeneous computing environments. Modernizing legacy systems for Web services plays a key role for companies to achieve their system integration. The critical issues discussed in this paper provide many implications and challenges to the companies. These issues must be dealt with before new issues arise as Web services technologies continue to evolve.

KEY TERMS

Reverse Engineering: Reverse engineering is the process of discovering the functions and their interrelationships of a software system as well as creating representations of the system in another form or at a higher level of abstraction.

SOAP: The W3C definition of SOAP is "a set of protocols governing the format and processing rules of SOAP messages."

Software Maintenance: Software maintenance is the process of enhancing and adapting a software product after delivery as well as correcting faults.

Software Reengineering: Chikofsky and Cross define software reengineering as "the examination and alternation of a software system to reconstitute it in a new form and subsequent implementation of that form."

UDDI: UDDI is a Web services registry and discovery technology for strings and retrieving Web services interfaces.

Web Services: The W3C definition of a Web service is "a software system designed to support interoperable machine-to-machine interaction over a network. It has an interface described in WSDL. Other systems interact with the Web services using SOAP messaging defined in the WSDL specification."

WSDL: The W3C definition of WSDL is "an XML format for describing Web services interfaces, message types, operations, and protocol mappings."

Chapter 1.27
Approaches to Building High Performance Web Applications:
A Practical Look at Availability, Reliability, and Performance

Brian Goodman
IBM Corporation, USA

Maheshwar Inampudi
IBM Corporation, USA

James Doran
IBM Corporation, USA

ABSTRACT

In this chapter, we introduce five practices to help build scalable, resilient Web applications. In 2004, IBM launched its expertise location system, bringing together two legacy systems and transforming the employee's ability to find and connect with their extensive network. This chapter reviews five of the many issues that challenge enterprise Web applications: resource contention, managing transactions, application resiliency, geographic diversity, and exception perception management. Using the IBM expertise location system as context, we will present five key methods that mitigate these risks, achieving high availability and high performance goals.

INTRODUCTION

In this chapter, we introduce five practices for building scalable, resilient Web applications. First, we briefly review the context in which IBM launched its internal expertise location system in 2004. We then introduce the challenges we faced in implementing the business requirements and present five key methods that mitigated risks to achieving our high availability and performance goals.

Specifically, we will look at:

- caching strategies for high availability Web applications: beyond storing copies of HTML (Challenger, Dantzig, & Iyengar, 1998; Iyengar & Challenger, 1997);
- asynchronous task processing within Web applications: removing non-essential linear logic from high-volume transactions (Grand, 2002);
- building self-reliant autonomous behavior: encapsulating through services achieving tight integration with *true* loose coupling (Birman, van Renesse, & Vogels, 2004);
- client-side Model View Control (MVC): moving MVC to the browser supercharging the response times and getting a "wow" user experience (Murry, 2005; Sun Microsystems, 2002);
- graceful degradation: keeping users thinking and feeling "fast," "reliable," and "always on" (Florins & Vanderdonckt, 2004).

Caching Strategies

Caching strategies are a core part of high-performing Web experiences. In many cases (Amiri, Park, & Tewari, 2002; Candan, Li, Luo, Hsiung, & Agrawal, 2001; Liebmann & Dustdar, 2004; Rodriguez, Spanner, & Biersack, 2001), the assumption is that caching occurs at the edge of the network, the closest point to the consumer and the furthest from the data or application. Another somewhat overlooked approach is object caching.

Davison (2001) provides a wonderful primer on Web caching that illustrates the principles of caching and highlights some of the issues that may arise due to its use. Edge caching, or Web caching, is focused on storing and managing Web pages (static or dynamic) to help speed up transaction times. As the complexity of Web architecture evolves, applications have become more distributed. Edge solutions exemplify this, placing caches of content, sometimes fragments of executable code, in multiple geographical locations.

In recent years, object caching has enjoyed a revival and is now seen as a more desirable component of Web application architecture. Caching objects and sharing them across an infrastructure is a compelling capability. Often, the cost associated with building an object is considered quite high. The difference with an object cache mechanism is that it often resides at the Web server (Jadav & Gupta, 1997), the Web application, or as a middleware between the data and the Web application logic. Once an object is built, it can be cached, distributed, and managed for future reuse; it delivers performance at the application layer, whereas edge caching offers performance benefits to the delivery of data.

The strategies and issues found in edge caching are very similar to those encountered in object caching, and understanding their roles can offer a more complete view of a caching strategy. If it is possible to reuse an object (whether it is HTML or an object created from multiple data sources), an opportunity exists to increase performance. Caching takes advantage of predicting what resource might be required in the near future and storing a copy for later use. Later in the chapter, we explore approaches to managing custom object caches and situations where they can provide impressive benefits.

Asynchronous Processing

Asynchronous processing is often thought of as multithreaded computing or parallel computing, both of which are far more technical than intended. A common trap in transaction processing is the preconceived notion that all processing has to be linear. There are opportunities to move non-critical or batch-oriented logic out of the critical path of handling a transaction. However, this often introduces a level of complexity that surrounds the execution of tasks that are not time-critical.

For example, Reynal (2005) offers a palatable introduction to failure detectors, a common component of an asynchronous system. Failure detectors help the system decide when activity is not behaving as it should. For instance, an asynchronous task might connect to an XML feed to refresh a local data cache. Obviously, a simple rule such as *all transactions must take no longer than one minute* to be considered healthy might suffice. At the other end of the spectrum, a failure detector might consider many variables such as historical averages or current operating features like a process' memory usage. Asynchronous processing offers the opportunity to offload activities that are less time-sensitive and speed up a given transaction. While it introduces a different level of management, it can be done very effectively and contributes to the overall performance of a system.

Resilient and Autonomic Behavior

In recent years, resilient and autonomic behavior has been posited as one of the next great evolutions in computing, driven primarily by the need to reduce maintenance and administration of increasingly large and distributed systems (Kephart, 2005). The goal is to embed the capability for an entire system, including hardware, middleware and user facing systems, to take a proactive approach towards maintaining a level of performance and reliability with little or no human intervention. At the core of this motivation is the need to build resiliency and autonomic capability into the component portfolio itself. Service-oriented architecture (SOA) is seen as an opportunity to provide systems with more resilient and autonomic features (Gurguis & Zeid, 2005). The increased dependency on Web services as a critical part of an application's building blocks introduces a new requirement of availability. Birman et al. (2004) discuss making Web services highly available through extending the base standards with high assurance, enhanced communication, and fault detection, an insightful collection of capabilities that enable more consistent performance. While SOA offers loose coupling, problems in one part of the system can have ripple effects on others. Availability, resiliency, and self-management are core attributes to a high performance system.

Client-Side Model View Control

Within the last year, a great deal of focus has been placed on richer Web application front ends (Paulson, 2005; Weiss, 2005). Web 2.0 or Ajax (Asynchronous JavaScript and XML) offer compelling user experiences by delivering the model view control (MVC) design paradigm to the browser. The Web client can update its data without end user action or refreshing the user experience. The current page does not need to reload to pull new data. It uses JavaScript and the browser's XMLHttpRequest object to connect back to the server. The server might be running a Web service, but it is not required. The document format does not have to be XML, though it often is. Using the Ajax approach to build user interfaces for Web applications delivers a more responsive user experience. Later in the chapter, we examine the use of the Web 2.0 model to deliver a high performance Web experience to bandwidth-constrained geographies. Delivering a fast end-user experience can be the key to persuading users that they are working with a superior application.

Graceful Degradation

Andoni and Staddon (2005) offer a unique approach to notifying users that their status with application is about to change. They describe how a user might have access to a certain level of content, but are delinquent on the payment of a bill, thus jeopardizing access to the service. Andoni and Staddon offer an example of graceful degradation where the service not only delivers a less optimal experience, but links the warning

of their eminent status change to the content that they are viewing. The idea is that the user gets less and less value out of the content; for example, video content becomes choppier (Andoni et al, 2005). The key to graceful degradation is in altering the user experience to communicate that some features are not available while maintaining the overall performance and availability of the application. All too often, applications are built with hard dependencies on certain features that do (but should not) prevent users from benefiting from the other unaffected capabilities. Building high performance applications involves offering a system that can temporarily modify itself to maintain an acceptable level of performance while setting expectations, so that end users are subtly aware of any issues but are not helpless.

Using each of these approaches, we will identify the circumstances that lead the architectural and design changes, review the relevant design patterns, discuss the real-world implementation, and consider the before and after results. While IBM's expertise solution offers many opportunities for innovative thinking, the concepts discussed in this chapter are generally applicable when reviewing or designing Web applications for high load, high availability and fast performance.

SETTING THE CONTEXT

Web application design and architecture have matured greatly in recent years. Numerous books and articles discuss everything from design patterns and enterprise architecture to solution deployment strategy and high availability infrastructure (Alur, Crupi, & Malks, 2001; Eckstein, 2003; Fowler, 2000; Gamma, 2002; Grand, 2002; Schmid & Rossi, 2004). The current art grew out of the need to provide highly scalable and fast Web experiences to match the growing sophistication of end users (Burns, Rees, & Long, 2001; Goodman & Kebinger, 2004; Iyengar & Challenger, 1997; Malveau & Mowbray, 2001; Schmid & Rossi, 2004; Zhang & Buy, 2003). One area lacking in the current literature is a real-world strategy for applying appropriate design patterns and architectural approaches that improve the performance and reliability of today's enterprise Web experiences. In addition, intranets often impose additional constraints, budgets, legacy systems, network bandwidth limitations, and the general desire to do more with less (Appel, Dhadwal, & Pietraszek, 2003).

Intranets are a fertile ground for trying new approaches in the hope of solving real problems. The payoff for finding the right architecture or design is that it often leads to solutions that perform to expectations, are easily maintained and, most importantly, help transform the business. Popular examples of this are expertise location systems (AskMeCorp, 2005; Autonomy, 2005; Entopia, 2005; Tacit, 2005). These systems allow users to find people or answers to questions in a fast and efficient way. Helping employees in an enterprise to find each other or other knowledge repositories has a direct impact on the company's ability to draw from its network in real-time.

Example: *Amy is a sales representative with Acme, Inc., and is at a client's location pitching her products. The client has introduced a new requirement, integrating two technologies with Acme's solutions. Amy quickly does a search across the company for people with knowledge of the technologies in question. She gets twenty results, including three senior level technical architects and two that have actually worked with the client in the past. Amy holds her own, saying that there are experts in the company with those technologies, and we could certainly revisit and explore how it might come together. During the break, Amy chats with her colleagues to get more background, sends email to a few of them, and creates a group so she can refer to them at a later time. Amy is able to demonstrate responsiveness and strong ties to her company for the rest of the client visit.*

In 2004, IBM redesigned its internal corporate directory, "BluePages," to include extensive profiling information, updated search capabilities, real-time connection and common Web services. Some of the challenges included managing an increase in data (10-fold), a demanding world-wide target population, and a geographically-dispersed infrastructure. These are the somewhat typical issues architects face today, and the 2004 redesign proved several best-practice approaches to high performance Web application design.

CHALLENGES IN BUILDING HIGH PERFORMANCE WEB APPLICATIONS

Data-Driven Web Applications Drive Contention to the Data Source

Over the last few years, Web applications have moved from basic content presentation with a few dynamic elements to more advanced content personalization and collaboration capabilities. Regardless of where a given application lives on that spectrum, most aggregate data and every request to the Web application incurs at least one hit to a data source. This introduces some obvious opportunities to manage transactions, while ensuring that the contention to the data source is minimized. Among the many ways practitioners address this space are connection pooling, data source replication, and resetting expectations to redefine requirements.

Pooling

Connection pooling is the primary tool for ensuring fast transactions to data sources. Object pools are collections of already created and initialized objects (Grand, 2002). The pool often limits the number of possible objects to maintain resource predictability and force a level of resource management. Objects are created beforehand to eliminate the performance cost associated with creating and initializing the objects for use. In the case of a database connection pool, a series of database connection objects are created that maintain a connection to the database. This eliminates the need to create a connection or initialize any required parameters. Many application platforms provide database connection pooling as part of their design: however, object pools are fairly straightforward to implement and are required when there is no "out of the box" solution. In the end, connection pooling is all about making the transaction perform so well that any contention for a managed resource is minimized.

Replicate the Data Source

Enterprises often have guidance and standards for reuse and data mart creation and management. The goal is often to minimize redundant data in multiple places. The side affect of centralizing data is that many exploiting applications are requesting the same data source. If deployed properly, this is a suitable strategy: Each exploiter is given access to a specific number of connections, reducing one application's impact on another. An issue is still not resolved when databases are geographically separate from the exploiting application. Database connection pools and database connection tools usually connect to databases over a network protocol that carries all the risk of network latency and instability. One method of mitigating this variable is to replicate the data source to the same subnet as the application server (Pacitti & Simon, 2000). By collocating the data source with the Web application, the number of issues introduced by the network is greatly reduced. If there was an issue with contention or network performance, they are addressed. As with many of these solutions, contention can still exist (Abbadi & Toueg, 1989; Pacitti & Simon, 2000), but by addressing the performance of every link, contention is minimized.

Do Less, Simplify Views, Reduce Functionality

A requirements document is an architect's best friend. It clearly specifies both functional requirements (i.e., users need to be able to send pages from the Website) and non-functional requirements (i.e., needs to handle 200 concurrent users per second). Therefore, the client has a clear understanding of what he/she/it is asking and what the service provider is committing to deliver. There are times when requirements are accepted even with little knowledge of what will be required to fulfill the commitment. This is very common when the team either lacks the experience necessary to size appropriately or when it is breaking new ground. During these times, practitioners often return to their customers, presenting the issues of the moment and convincing everyone that the right thing to do is revisit the requirements document. If there is too much occurring in a given user scenario (impacting the ability to support a certain service level), the team must consider whether it should be doing less, simplifying view or reducing functionality. Sometimes this *really* is the only option; after all, ambitious customers ask for the world, and it is the service provider's job to help realize that vision as best he/she/it can.

Transaction-Based Systems Tend to Do Too Much

In the early days of the Web developer, applications were often created as Fast-CGIs hooked into Web servers, persistent in memory and performing functions on each request. The more promising applications often provided considerable value, but increased in complexity. Application design went through a period of linear programming and with the maturation of application models such as J2EE, developers were able to branch out into an object-oriented world where solutions were created by pulling together modular components. Unfortunately, the practitioners did not evolve at the same rate as the technology. All this is to say, developers of transaction-based systems often do too much in one area of the application, reducing flexibility and manageability.

The Servlet Controller

One of the common approaches to structure a Web application is to use a servlet controller (Alur et al., 2001), which handle all the requests into an application. They often perform some very basic request preparation and then forward the transaction to other servlets to perform specific tasks. Servlet controllers act as the gate keepers to the application, providing a single face to the end user while maintaining the flexibility and modularity of specialized servlets that handle only the function required at any one time.

STRUTS

One of the most popular implementations employing a servlet controller is STRUTS from the Apache Software Foundation (Apache Foundation, 2005). STRUTS is a very robust framework that allows Web applications to be built based on some of the best design patterns (Sun Microsystems, 2002). STRUTS includes several features that address the transition from a single bloated application to a highly modular system.

Deal with Slow Performance by Adding Servers /Over-Scale

There are times when a change to the requirements document is not an option. The next favorite solution is to scale the application horizontally. "We will just add more hardware" is what we often hear. This traditional approach usually means you have enough servers to handle peak loads, and during the lower traffic hours the application is over-provisioned. Adding hardware to solve an architectural or design problem is a tactical solution which only masks the problem. Adding

hardware often helps address load issues, but the increase in resource brings an increase in complexity. There is a balance to be found between budget, hardware capability, and application architecture and design.

Complex Applications Need Tender Loving Care

Even the simplest applications have a tendency to become complicated. Companies often have legacy systems, a variety of existing hardware, software and processes, and the integration task can therefore be daunting. Even the most skilled, well-funded projects have weak points. These Achilles heels often require constant monitoring.

Some systems integrate with in-shop or third-party monitoring systems, allowing systems administrators to be notified when issues arise. The basic checks include making a request to the application, and as long as there is a response, trouble goes unnoticed. Some systems are more proactive, looking for errors and response times. However, with the desire to mask errors or erratic behavior from end users, monitoring tools have a difficult time relying on the basic tests. The Web application may be performing fine, while the database is down.

Savvy developers build in special servlets that perform end-to-end tests of their Web application. These test servlets make a series of calls to ensure that all is right from the application's perspective. However, this level of development is often unfunded because the value it provides is seen only when there is a problem, and even then it simply quickens the time to resolution instead of eliminating it. Applications with a myriad of dependencies, network files stores, LDAP (Lightweight Directory Access Protocol) servers, databases, and Web services require monitoring as well. To an end user, an unresponsive or non-functioning application is as good as no application (Goodman et al., 2004).

The Platform and Plumbing Can Impact Perceived Performance

Managing end user perception is a key task in achieving high customer satisfaction. With the continual push for a service-oriented architecture and componentization, the dependency list keeps growing. Exposing services also means providing consistent, reliable service; impacting and exploiting applications in acceptable ways. One of the problems is that not everything is managed in the application architecture layer. Platform and network plumbing can have serious impacts to perceived performance.

Applications are often made up of many components and software stacks. Each component contributes to the overall application platform, and it is possible to combine modules that work better or worse. This fact often drives solution providers into single-silo approaches, embracing a single vendor or a specific recipe of vendors to deliver solutions. A more mature approach is to realize the need for standards-based solutions to ensure that components are easily mixed and matched without impacting the exact implementation of the application.

Network conditions have an obvious effect on applications, especially when a global audience is considered. A fast application in North America (.25 - .50 ms response time) can become slow in Asia Pacific (5-15 sec). Some of these challenges arise simply because of the amount of content being shuttled across networks. Some delay can be minimized through caching edge servers, better network backbones, and globally-distributed solutions.

Unexpected Errors Happen, but Who Needs to Know?

Application developers are told to handle errors with grace, but the definition of "grace" often varies in meaning and context (Nielsen, 2003; Preece, 1994; Raskin, 2000). If an application

supports a very small audience, it might be preferred not to spend a lot of time on exception handling. In most cases, though, applications are meant to benefit a larger population and, often, a demanding user.

The most basic approach to handling errors is to employ custom error pages, so that at least the error looks like it was intended to be read and responded to. This is the minimal amount of effort required to keep up appearances.

Some developers have resorted to irrational behavior to confuse the user. If an error occurs when submitting a form, some applications redirect the user to a different page, possibly unrelated, in the hopes of confusing or at least giving the appearance that the user might have actually been at fault. "When in doubt, redirect to the home page" is a motto no one should be fond of, but it happens.

More sophisticated developers include a clear and direct message acknowledging the error. Sometimes an alert is generated for the benefit of the systems team; other times, the Web applications present the message to stop any further complaint. These approaches often tailor errors with reasonably coherent messages. Instead of ERROR 500, it might read "We're sorry! The application is currently having difficulty handling your request."

APPROACHES TO BUILDING MORE RESILIENT WEB APPLICATIONS

Numerous challenges face application developers and architects developing scalable Web applications that also maintain performance and reliability. In the previous section, we covered five scenarios that often plague Web applications: data source contention; performing too many tasks; care and maintenance; platform and network capability; and exception handling. With each of these areas, we explored some of the popular approaches for addressing the problem space.

In this section we examine alternative approaches to these problems that have proven best practices in our own architecture and application design. We will cover:

- Caching strategies for high-availability Web applications: beyond storing copies of HTML (Challenger et al., 1998; Iyengar et al., 1997)
- Asynchronous task processing within Web applications: removing non-essential linear logic from high-volume transactions (Grand, 2002)
- Building self-reliant autonomous behavior: encapsulating through services achieving

Table 1. Sample non-functional requirements (NFR) for an enterprise application

	Target	Measured By
Scalability	Up to 250 requests per second	Application stability
Performance	- For 95% of the transactions < 7 seconds - For 5% transactions < 10 seconds	Probe tools measuring response times at different geographies
Availability	99.96% during schedules service hours	Tools measuring availability metrics

tight integration with *true* loose coupling (Birman et al., 2004)
- Client-side Model View Control (MVC): moving MVC to the browser supercharging the response times and getting a "wow" user experience (Murry, 2005; Sun Microsystems, 2002)
- Graceful degradation: keeping users thinking and feeling "fast," "reliable," and "always on" (Florins et al., 2004)

High-Availability Application Layer Caching

One of the challenges that busy Web applications and Web portals face is the need to perform data source queries to deliver features and functions to end users. As we reviewed earlier, this often drives contention to the data source. One overlooked approach is to design smart caching strategies to minimize calls to the data source. This aversion is well warranted, as the decision to cache often has implications in terms of high availability, data freshness, synchronization challenges, and real-time management. The following section reviews two strategies for caching: database-driven caching and more dynamic LDAP caching.

Database-Driven Caching

Typically, relational databases comprise a mix of static lookup-type tables and dynamic or updatable data sets. Each of these offer opportunities for application layer caching. To help provide context to these situations, we will use the IBM expertise location system as an example.

Static Table Data Cache

One of the popular aspects of an employee's profile is the contextual information which we display alongside the more central content. A drastic change from the previous version is the area of the profile that depicts organization structure. When this profile view was initially designed, the pages were getting response times around 850-1000 milliseconds and were driving, on average, six times more LDAP operations to our enterprise

Figure 1. Example of a BluePages profile view with reporting structure (right)

directory than the second most common function of viewing employee records.

While there are several factors contributing to the performance attributes, the primary one was the introducing of the reporting structure on every profile. To help address both of these undesirable characteristics, we designed a cache holding reporting structure information for all users, using a local database as the source. Obviously, there is huge performance gain by replacing three LDAP operations with three lookups in a local memory object. Reusing the application data source to build the data structure alleviated any additional work from the corporate LDAP directories.

Caching lookup tables and other relatively stable areas of the database is easy and reduces the workload on the database and the application. It is a simple way of maintaining the user experience while improving performance.

Dynamic Table Data Cache

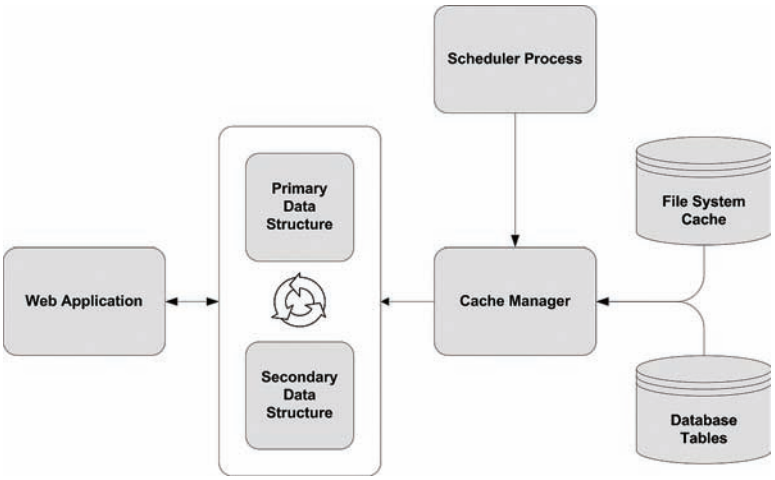
Static data is an easy and obvious caching opportunity, one that many architects and developers can easily apply to existing or new applications with very little investment. Obviously, things get challenging when caching occurs at the application layer, and the data has the possibility of being updated. Suddenly, maintaining appearances to an end user has to be well thought-out.

With the move to a modern Web application, IBM's expertise location exposed several common services and introduced an unexpected load. Caching at the service layer played a very important role in sustaining the growing popularity of service-oriented architecture and Web services.

In this type of cache, we need to deal with a table data which gets updated continuously by the Web application.

There are three key parts of this design (Figure 2): the scheduler, cache manager (Grand, 2002), and high-availability data structure. The scheduler initiates the cache manager and, in follow-on versions, also manages any message queues and events that trigger cache management features, such as changing the schedule for refresh. It performs most of the critical operations managing the cache data structures. Obviously, the cache manager is responsible for making calls to a Data Access Object (Alur et al., 2002) to load the

Figure 2. Highly-available data cache



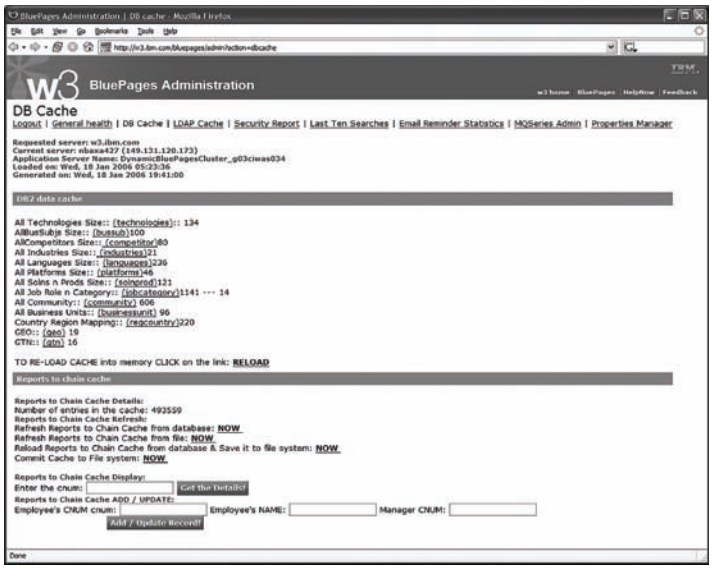
cache. This might be from the database or from the file system, depending on the configuration. The file system was used to eliminate start-up lag at risk of displaying stale data. For example, the reports-to chain cache (organizational) data object in BluePages is approximately 18MB size. It takes enough time that cycling the application produces undesired load and delay. By automatically committing the data structures in memory to disk, the cache manager can load instantly and update as needed.

The cache manager works with two data structures, the primary and secondary caches. Various data structures operate slightly differently and, often, some level of synchronization is required when performing manipulations. To eliminate contention of the data cache, a second one is created by the cache manager. It uses the second one to perform any management operations (add, update, delete) and sets a Boolean flag to immediately put it into play. The other cache can then be deleted or saved depending on the refresh strategy. For example, if the database is designed with time-stamps on changing data, deleting the cache is somewhat wasteful. There might be only five changes, and there is really no need to transfer all of the other data. By selecting only the items that changed and updating those in memory cache, updates can happen frequently and take effect more promptly with less resource churn.

One of the major undertakings for BluePages was the introduction of Web-based management for key subsystems (Figure 3). The cache management is one example of these Web-based management systems.

Web-based management of the cached object allows us to monitor the data that is in memory. For the reports-to chain cache, it shows data for an employee's reporting structure. It also allows an administrator to manage the data in memory (create, update, delete), commit those changes to the file system or database, and reload the cache, if necessary. Providing administrators with management capabilities to key subsystem

Figure 3. Data cache Web-based administration



components removes the specialists from having to perform more risky manual tasks in support of an application. It also allows the application to appear more responsive by supporting more real-time management instead of code changes or manual application restarts.

By using strategic caching, BluePages was able to see a reduction of 800 milliseconds in response time. Approximately 750 milliseconds were due to the reports-to chain cache and ~50 milliseconds were associated with database calls. Currently the same page delivers a 70ms server-side response time.

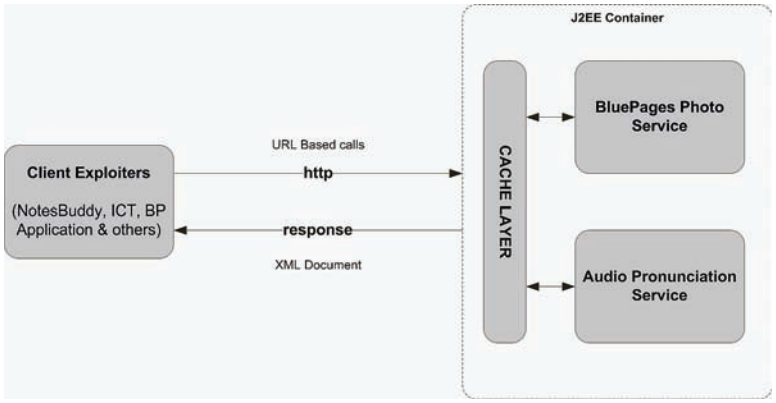
Another situation in which dynamic data caching plays an important role is the design of service implementations. Most services (Web services, XML-RCP, URL APIs, etc) take a considerable amount of overhead to process a request. For example, in Web services, a decent amount of XML is being manipulated; this in turn creates a considerable amount of garbage. Consider that overhead on top of the need to actually service the request by hitting data sources or performing calculations. BluePages receives approximately 3.2 million service calls per day and supports a response time of a few milliseconds for service exploiters. To achieve this level of efficiency, caching was employed to enable smarter transaction processing.

The key to smarter transaction processing is providing a proxy between the transaction request and the service logic, or process. The proxy determines if the request should pass into the process stage or if the request for whatever reason deserves a cached, static, or predefined response.

In the BluePages architecture, this "service cache layer" pre-fetches basic information related to the service and decides if it has enough information to respond. More specifically, BluePages offers a URL API to access a user's personal photo. The cache layer stores all the unique IDs and uses this information to short-circuit the request. If the request is for a user that does not have a photo, a redirect to a default image can be sent. The redirect is used instead of a full photo to keep the transaction light and to ensure that browsers get an opportunity to cache the default image for faster rendering.

In BluePages, this cache avoids over one million service calls from reaching the processing

Figure 4. Using caching to avoid unnecessary transactions



phase of the service. That translates into over one million database calls while improving overall response times.

Dynamic LDAP Caching

Sometimes caching all the data in RAM is just a waste of space. LDAP caching with some level of detail is probably not the best candidate to load into RAM. Presumably there is a high level of caching at the LDAP server, so it is best not to add another layer. Therefore, a cache is needed that builds based on usage, and some general rules about how memory can be reclaimed and which entries are always a "good idea" to have.

The typical reporting view includes a list of individuals related to the current profile. While one LDAP connection can be established with multiple queries executed, the transaction itself is still somewhat intensive. We think of the transaction time with LDAP as being very fast, and it is; but when you deal with so many transactions, general queuing theory and rendering speed tend to get the better of us. A read from RAM is simply much faster than a transaction to LDAP.

This view is supported with the lazy loading (Grand, 1999) dynamic LDAP cache. At least three levels of the chain already exist, and the subsequent entries are cached for future use.

The LDAP Cache Controller servlet acts as the central management point. It delivers the subsystem management views, and Web applications use a static method to access the Cache Manager (Grand, 2002). The Cache Manager is the object that populates the cache and fails over to LDAP as needed. It keeps track of metrics and performs any regular updates based on the Data Refresh Scheduler.

As with the other cache subsystem, the LDAP cache has a management interface. The main difference is the cache statistics view. With a database view, the hit rate is not relevant. In many cases, it is 100%. In the case of a dynamic cache where you are building it based on usage, hit rates are

Figure 5. BluePages reporting structure tab

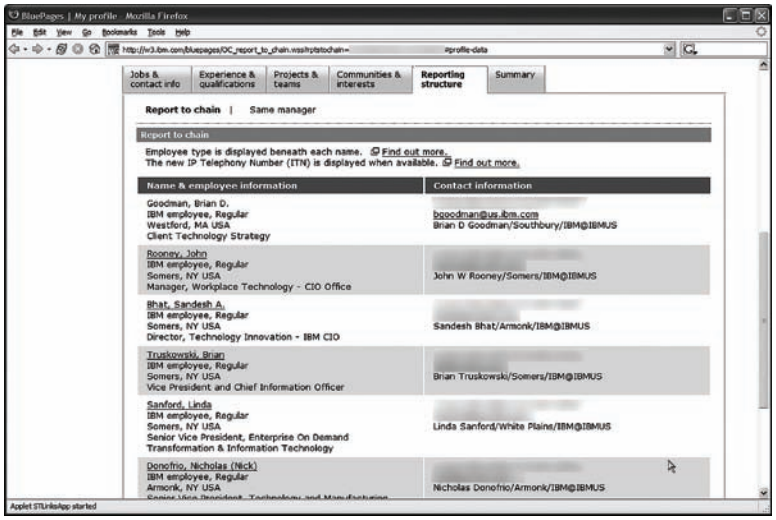


Figure 6. Dynamic LDAP cache

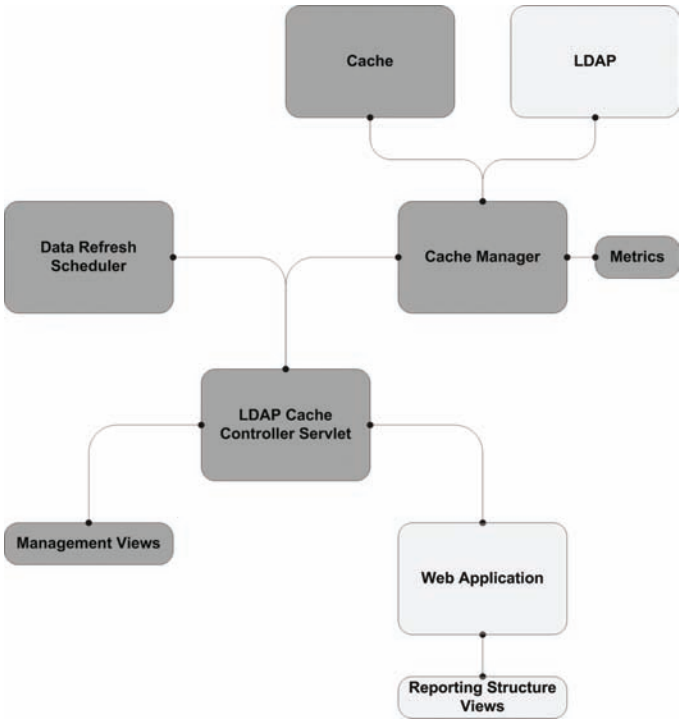

Figure 7. Dynamic LDAP cache Web administration

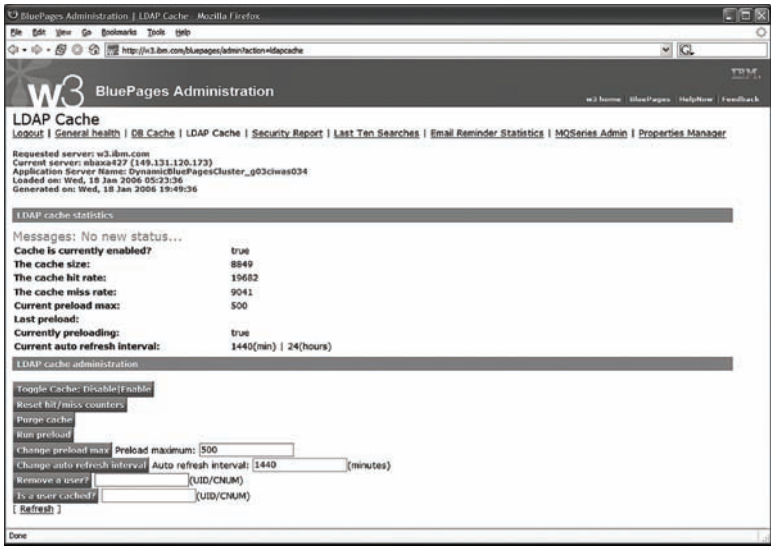

everything. When you consider that the only views driving this usage are organization structures (the third most accessed view), it is astounding that we experience an 80% hit rate.

In order to avoid the added traffic, caching was used. On some pages, we save up to 6 seconds—an eternity in Web time.

- Cache hit rate is 80% with a peak size of 80K entries stored
- Total LDAP call reduction by ~792K per day (240K queries vs. 48K queries)
- Avoiding up to ~6-10 LDAP operations and a response time of ~1000-1500 milliseconds on each organizational page

Asynchronous Task Processing

Making Transactions Non-Linear

One of the themes that this chapter raises is the notion that many operations can happen asynchronously (Grand, 2002). However, many architects and developers do not take the time to think about how to build their system to support it. Often implementing function wins out over responsible use of resources. A typical Web transaction is performed through a GET or a POST to a servlet or CGI. The servlet or CGI processes the request and returns a response. In many ways this is linear programming. If you use message

Figure 8. BluePages Web administration view of last ten searches

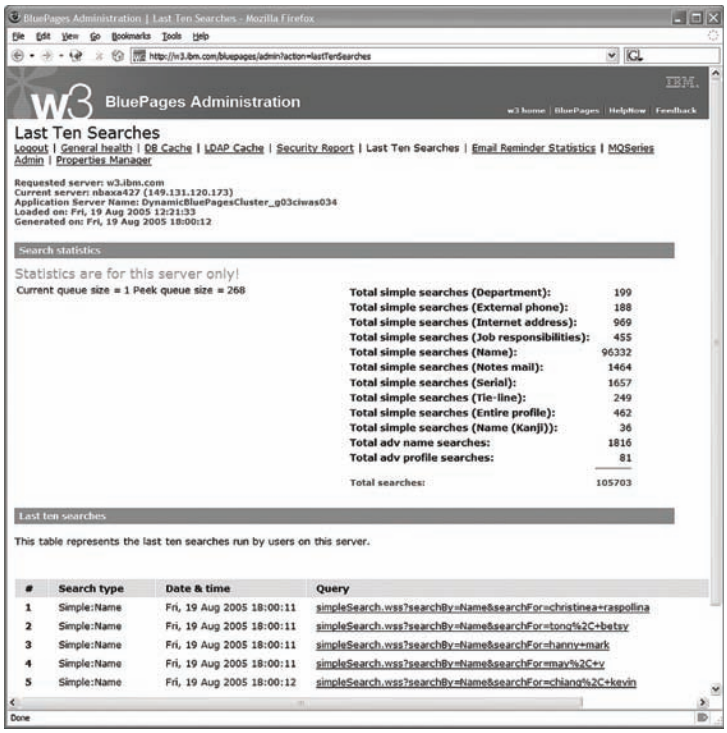

Figure 9. Blocking queue class diagram

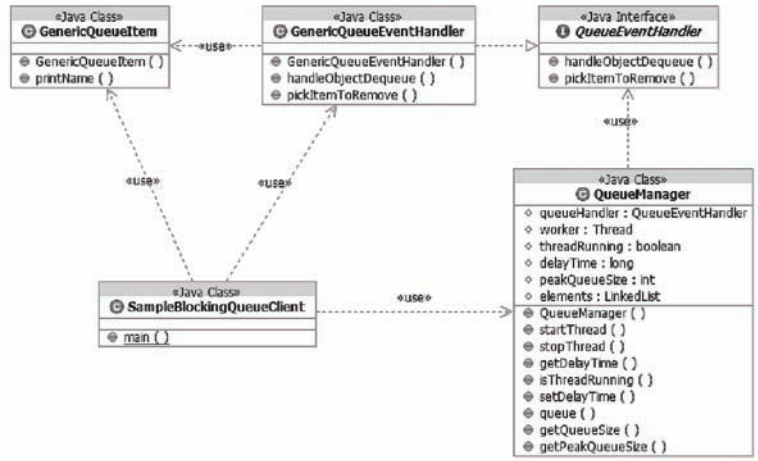

queuing systems in your Web applications today, then you might already know the wonders of responding without necessarily completing the entire transaction. To help illustrate this design point, BluePages offers a couple of examples, all based on the same pattern.

One of the design criteria for the online administration page was to track operation statistics in real-time: Who were the last ten users to log-in (success/failure), what were the last ten searches, and so forth. One of the more costly aspects of collecting such performance statistics is that it takes cycles away from performing the user facing operations. The problem to solve was how to perform the tasks as part of a transaction without constantly having a locked state around a data structure, or processing requests while we should be sending back results.

The basic solution is based around a blocking queue design pattern (Grand, 2002; Kabutz, 2001) dequeueing only when there are objects present in the queue. This avoids spinning extra cycles with no operation. In the class diagram (Figure 9), SampleBlockingQueueClient is a client/component exploiter of QueueManager. QueueManager manages the thread and message brokering. QueueManager is initialized with a QueueEventHandler and uses that interface to interact with other implementations of handling the queue. For example, some queues need to be priority-sorted or dequeued based on some other criteria. The GenericQueueItem happens to be the object being enqueued and dequeued. It is a very simple and effective design pattern.

An example from BluePages illustrates the real-world use further. BluePages provides a keyword search to employee profiles. A user might search for other employees in the company who know about a certain client and a technology. The servlet processes the request and enqueues a value object to the queue with minimal amount of data (i.e., the query terms, the URL, the user ID, a time-stamp, etc.) and then respond with the search results. Asynchronously, a thread uses a QueueEventHandler object to decide which item in the queue should be dequeued and then passes

that object to get handled. The object performs any calculations (number of searches, list management, and clustering or trend-type calculation) and stores the data to be presented and used in other ways. An example of where this data can be used is in the popular, "what are other people searching for right now" capability. Even though the insert is synchronized (we used a Java ArrayList), they take more precedent because there are more enqueues than dequeues at any given time. You can see in the sample screen shot of the BluePages administration interface that the peak queue size for this specific server instance is 268, so we know the approach is working.

In some cases, a soft-queue is not sufficient, and a real message queue subsystem is required. The proposal of this section is simply to raise the issue that not all aspects of a transaction need to complete during the duration of handling a request. There are times when it is not encouraged, and specifically for J2EE, it is suggested to be incorrect. For example, when performing database transactions asynchronously, a transaction is preferred for all the security context concerns (Brown, 2005). Asynchronous beans helps alleviate some of this limitation, as discussed in the next section.

Asynchronous Beans in J2EE

Spinning new threads from a servlet for asynchronous task processing is a common design approach until recent times. Some of the drawbacks of this approach include: The transaction loses container security, transaction scope, and lack of failover during critical failures.

J2EE came up with a standard solution to solve this problem, in which the servlet request places the task information as a message in queue, and message-driven beans (MDB) read this message. A *message-driven bean* is an enterprise bean that allows J2EE applications to process messages asynchronously. It acts as a JMS message listener, which is similar to an event listener except that it receives messages instead of events. The messages may be sent by any J2EE component, an application client, another enterprise bean, or a Web component, or by a JMS application or system that does not use J2EE technology. MDBs process the task in an asynchronous way within the container, taking advantage of all the container's built-in features. As soon as the request message is processed, the MDB can place a response on the response queue. Servlet requests can keep polling the response queue for the status of the request submitted to let the end user know the results of the asynchronous task.

Business Grid Computing

Web application architectures often require batch processing of some of the maintenance tasks. It is not uncommon to have developers rewriting code with stand-alone applications or scripts to perform these operations outside of the Web container. This results in code redundancy and, obviously, such implementation loses the application server container advantages. Advanced J2EE containers such as IBM WebSphere Extended Deployment, allow asynchronous task processing by allowing batch, long-running or compute-intensive tasks to run within the container; the best application is chosen for this task based on resource utilization.

The business grid function in WebSphere Extended Deployment extends the WebSphere Application Server to accommodate applications that need to perform long-running work alongside transactional applications. Long-running work might take hours or even days to complete, and consumes large amounts of memory or processing power while it runs.

While IBM and other companies have advanced application platforms to help with the task of batch processing as an architect or application designer, it is important to ensure that your applications have a strategy to minimize the duplication of code and fragmentation.

Application Resiliency

As more applications are designed to participate in Service-Oriented Architectures, they increase their dependency on resources outside of their control. Applications make calls to external interfaces, such as databases, LDAP, messaging servers, SOAP-based Web service calls, or even HTTP-based services. Suddenly, the performance of an application depends on the external interfaces of other applications and services (Krishnamurthi & Bultan, 2005). The availability or poor performance of external services potentially impacts the availability of the dependent exploiting applications. This section will look at how applications can employ a more autonomic, resilient approach to these situations.

Human Required: The SOAP Fault Specification

For Web Services, W3C built the SOAP Fault (W3C, 2003) to represent the availability status of the service providers. The information provided by SOAP Fault is similar to the reason-phrase provided by HTTP (Internet Society, 1999) which underscores the nature of the problem (Table 2). One of the problems with these approaches is that system designers end up using generic issue codes, making it almost impossible to know what is really going wrong. Issues can be detected, but a human is still required. What if the dependant hosting environment has problems? This could result in Web application servers accepting requests, filling queues, and in turn affecting the entire infrastructure. This becomes even more unattractive if the hosting environment provides shared hosting or manages entry through proxy servers. A SOAP Fault indicates that an issue occurred with that transaction; however, it places the next step back onto the calling application, which may very well keep making service calls and impacting the overall application performance.

Communicating Availability

Transaction or session-specific errors often indicate that something is wrong, but a hung socket

Table 2. Example of SOAP fault

```
<?xml version="1.0" encoding="UTF-8"?>
<soap:Envelope
 xmlns:soap="http://schemas.xmlsoap.org/soap/envelope/" >
  <soap:Body>
    <soap:Fault>
      <faultcode>-1000</faultcode>
   <faultstring>Database is unavailable.</faultstring>
   <detail/>
   </soap:Fault>
   </soap:Body>
   </soap:Envelope>
```

connection or a cascading error may never return a satisfactory message to allow an exploiting application to respond appropriately. In order to provide a higher level of resiliency, real-time status is required. UDDI servers can identify several end points, which may allow a Web service client the opportunity to use a different system to accomplish the same task. The problem is that any one of those services may be having problems. To help address this situation, system availability is included as part of the interaction between the service consumer, service discovery, and service provider.

This model (Figure 10) provides a level of service availability above and beyond the typical transaction-based error. Service clients can be advised of issues through simple calls to an independent third party, which allows appropriate logic to take place to maintain a higher level of service. This technique is similar to network dispatcher models, where a single service provides a feedback loop to ensure that servers in a cluster are available before being dispatched. For example, an asynchronous process may test the availability of an externally-dependant service through the central availability system. The response will provide information similar to typical faults; however, it is received outside of a transaction with the provider. This eliminates hung sockets or other variables that are only visible to the provider. Updates to availability status can be made from other enterprise monitoring tools, allowing for an integrated knowledge base of service availability.

In Figure 11, Enterprise Directory is a service provider. In this case, the service provider makes use of Tivoli Service Management to monitor its services. ED Monitor is one such service monitoring tool. BluePages monitors the health of the enterprise directory to failover or degrade service as necessary. Applications cannot perform in autonomic ways without being informed about

Figure 10. Service availability system for more predictable operations

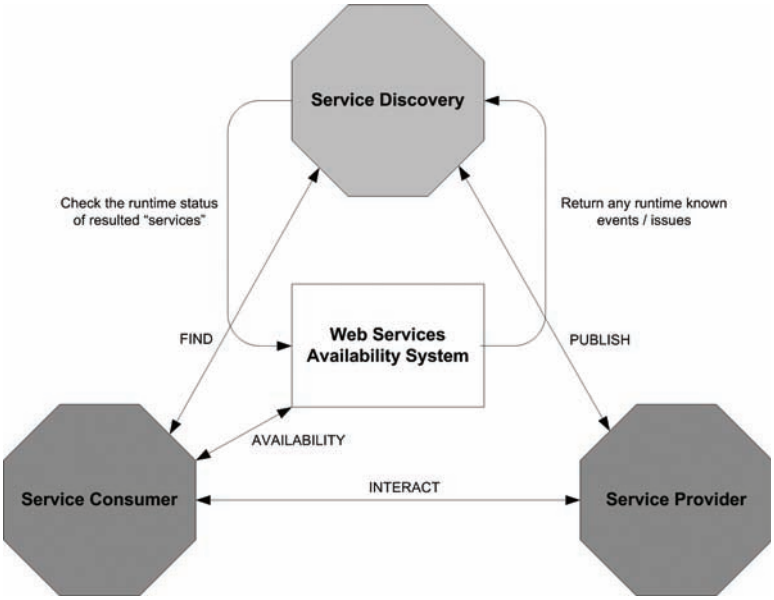

Figure 11. BluePages system checking availability of enterprise directory

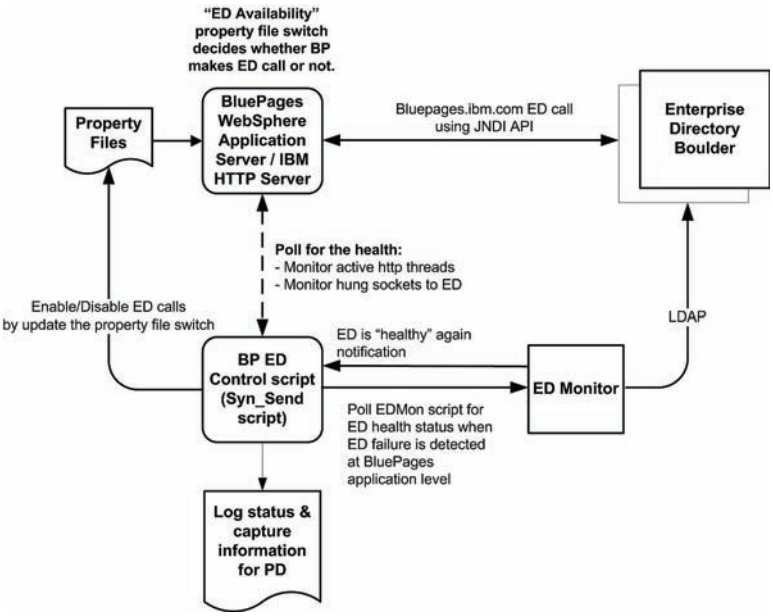


their state, the state of the environment and, more importantly, the state of the systems and services on which it depends.

Client-Side Model View Control (MVC)

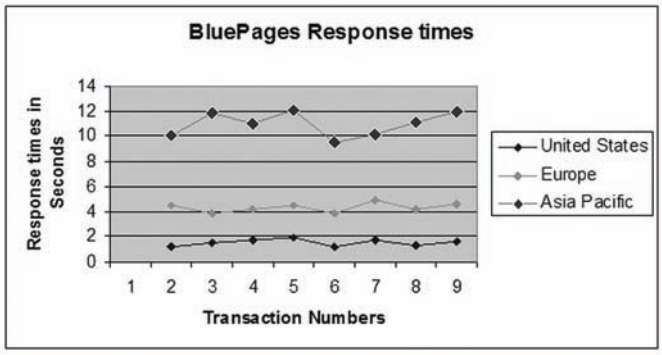
The Model View Control (Sun Microsystems, 2002) design pattern is a very popular approach to Web application design. Its one limitation is that the view is created server-side and must be transmitted to the client for interpretation. Moving MVC to the client truly separates the view from the middleware. The need for such activity is rooted in the desire for richer interactions and faster transactions. This section addresses client-side MVC and getting that "wow" user experience.

Common challenges for any enterprise Web application include internationalization and a variety of hosting issues that may impact responsiveness. While there are frameworks for addressing language translation among a diverse group of end users, the system deployment is often centrally located, resulting in poor performance for locations with limited bandwidth or congested links. BluePages is a real-world example of an enterprise application offering internationalization while being hosted from a single geography.

Figure 12 charts response times for the same page for Asia Pacific, Europe, and the United States. BluePages is deployed in the United States and, as the chart depicts, the performance of the application degrades as the end user's location moves further away.

The problem with the traditional (server-side) MVC design pattern is that it renders the entire view at the server, and makes the application and infrastructure components transmit the data to the Web clients. Web applications end up sending a

Figure 12. BluePages response time comparison



considerable amount of HTML back to the client Web browsers to achieve a rich user interface.

Consider users that rely on client-installed applications (VB-based, Lotus-based, or even Oracle forms), which query for information from a server. The amount of data transferred is the smallest possible, as it is no longer transmitting the view. The client-side applications display the data using the front-end logic held at the client. The client server model helps illustrate the benefits of a client-controlled view; however, it brings all the negative issues that drove the Web revolution. The ideal situation is a richer client side view that is managed via the Web.

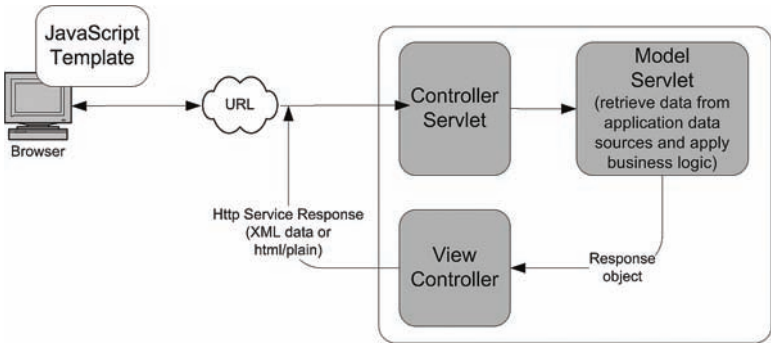
The decision regarding whether to use client-side MVC or server-side MVC may depends on several factors, including the kind of application, end user connectivity, or even how much data is being transferred to the client browser and what impact it has on the overall performance of the Web application. There are two approaches to client-side MVC: JavaScript Templates and the XMLHttpObject.

Client-Side MVC: Using JavaScript Templates

Using the JavaScript Template design pattern places all the rendering of the user interface into client-side cacheable assets. In this design pattern, the Controller Servlet invokes a Model Servlet. The Model code executes business logic, including actions such as retrieving information from database systems or other external services. The Model servlet passes values to the View Controller to render an XML document or HTML/plain text response. The View Controller decides which JavaScript template should be invoked for a particular service response. Once the response reaches the client browser, the JavaScript template specified by the View Controller renders the information retrieved by the service call. All the necessary HTML logic needed to display a rich GUI Web page is already built into the JavaScript templates.

This design pattern is dependent on how JavaScript files are cached by the Web browsers.

Figure 13. Client-side MVC, JavaScript templates



When a JavaScript file is requested through the browser, it is also accompanied by HTTP header directives that tell the browser how long the object can be considered fresh. Freshness translates to how long the resource can be retrieved directly from the browser cache instead of making calls to the originating end point. Since the browser represents the cache closest to the end user, it offers the maximum performance benefit whenever content can be stored there. Another consideration is that the JavaScript templates need to change infrequently to support a longer client-side timeout. Using this design pattern, BluePages shows a ten-fold improvement.

Client-Side MVC Using XMLHttpObject

Every modern Web browser has some form of XMLHttpObject that provides a socket connection to the originating server. This provides the opportunity to make subsequent asynchronous calls. Coupled with Dynamic HTML (DHTML), the user interface can be updated without a browser refresh. Avoiding the browser refresh provides a richer user experience because the context of the interaction is maintained. This is a popular approach and is often referred to as "Asynchronous JavaScript and XML" (AJAX) (Murry, 2005). The most popular examples are found from Google

Table 3. Sample search results response time comparison

Search Keyword	Number of Results	Server-Side MVC Design Response Times	Client-Side MVC Design Response Times
Smith, Chris	30	14.12	1.482
Linda	28	8.32	1.803
Kline	42	8.47	2.093
Kile	8	6.43	1.172
Inampudi	3	6.17	1.042

Figure 14. Client-Side MVC using XMLHttpObject

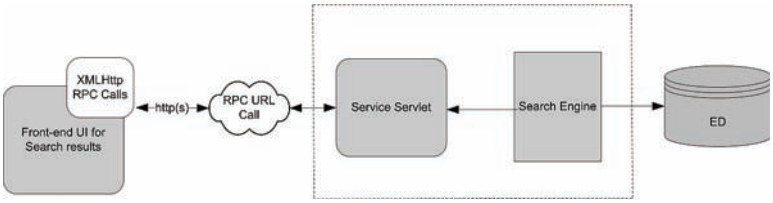


Figure 15. BluePages type ahead engine using XMLHttpObject

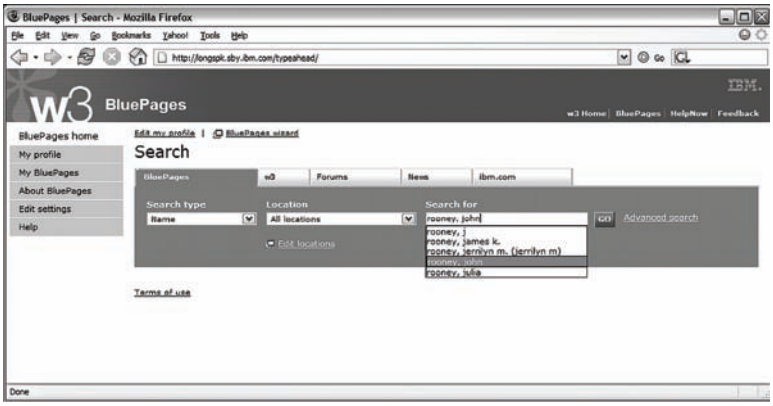


(GMail, Google Suggest, and Google Maps) (Google, 2005a, 2005b, 2005c).

In this design, pattern applications make asynchronous HTTP calls using XMLHttpObjects via JavaScript. A server-side service returns a response object. The response could be SOAP, XML, plain text, or JavaScript. The response text is then processed by the logic in JavaScript methods. Using DHTML, the content is displayed on the Web page.

Another use of this design pattern is depicted in Figure 15. As the user enters the employee's name for the search, the type-ahead engine makes a service call to retrieve matches from BluePages user dictionary. The list of potential names is displayed in the pull-down list based on the retrieved matches. As the user types more characters, the search is refined. In this scenario, it is important that the list retrieval is faster than the end user's typing speed.

Network Bandwidth Savings

Client-side MVC has another important advantage: network bandwidth savings. Since client-side MVC makes use of static templates to render the

Table 4. BluePages search performance using JavaScript template design pattern

ED Search	Current Implementation	BPv6 Implementation
Page size	77.9KB (Search on "kline" 25 results/page)	18.7KB (Search on "kline" 25 results/page)
Data transfer / day	77.9 GB	18.7 GB

user interface, the look and feel for an application can be cached in the client browser. The data that gets transferred to the client browser becomes much smaller.

While client-side MVC introduces some additional design complexity for Web applications, it can be worthwhile to achieve richer interfaces and more responsive Web experiences. There are sure to be many perspectives on the advantages and disadvantages of client-side MVC before it is universally accepted, but it has the potential to address some of the long-standing issues of Web application architecture.

Graceful Degradation

Most degrees in computer science and information technology do not require a class in human-computer interface design. It is not uncommon for an application to let the end user know that there was an error, for example, that it could not write to the memory and thus had to halt. The developer might have thought that the error would never occur, but even some of the common issue messages are unfriendly.

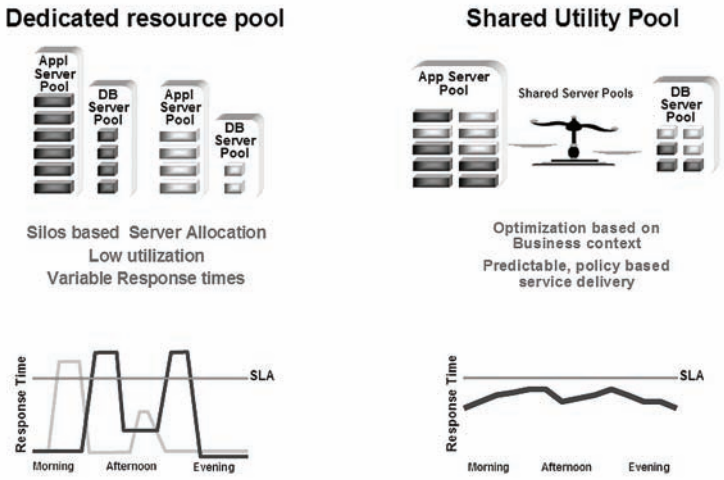
While there has been plenty of discussion over making exceptions appear informative and friendly (Nielson, 2000; Preece, 1994; Raskin, 2000), there is less focus around graceful degradation (Andoni et al., 2005; Florins et al., 2004; Herlihy & Wing, 1987). The driving principal is that an application can go beyond responding with friendly errors and actually disable features and functions until the environment stabilizes. Web applications in particular are vulnerable to an increasing number of dependencies: Web services, databases, LDAP directories, and file systems. Any single dependency can bring a Web application to a halt, and an unresponsive Web application might as well be a dead application. A simple method to address some of these issues is to place a timeout on the transaction, forcibly breaking the process to return an error to the end user. It is better to say something is broken than to be truly unavailable. This is really the first step. The second step is to prevent future access to the resource until a successful transaction indicates that the resource is again available. The challenge is to monitor your dependencies and code against the availability of those resources. If a database becomes unavailable, a backup might be used or menu items might be disabled, with ample indication to the end user that some of the features to which they may be accustomed have been disabled temporarily.

The BluePages Web application has many dependencies on external resources, and this provides an excellent real-world example. As part of the application, a service interface exposes read access to a back-end data store. Simple requests

to the service return a person object in the form of a DSML XML document. It happens that the full-text search engine requires XML documents to be written on a file system. This allows the file system to be the primary data source with the database as a backup. The added resources and processing required for reading a record from the database and returning an XML document are less preferable than serving up a static XML document. A simple servlet proxies requests to the appropriate data handlers by referencing a Boolean flag. This flag is used as an availability indicator of the primary data source. This indicator is set in two ways. First, any transaction which fails accessing the file system will set the flag so subsequent calls are routed to the secondary method. Second, an asynchronous process periodically checks the primary resource and proactively sets the flag in the hope that it will catch the issue before a failing request does. Additionally, this process sets the flag back when its periodic test no longer fails. From an exploiter's perspective, the service rarely fails. At most, there is a slight slowdown in performance, which is undesirable, but better than failing altogether. Adding a proxy layer between the requestor and the actual data access method lets the application short-circuit a potentially grave situation early, preserving the rest of the application.

Another example includes a typical dependency on a database or LDAP directory. BluePages provides both directory lookup and free text search. The truth is that the free text search can provide similar search results to that of the directory query, but the results are not exactly the same. Based on the previous example, it is easy to imagine the monitoring system provided in the application. The difference here is that if there is a problem with the LDAP resource, the current deployment has no effective way for failover. Instead of simply sending an error or notifying the user that the LDAP servers are causing a problem (not exactly something the average user understands), a subsequent query is automatically performed using the free text search. An unresponsive directory message might imply that the

Figure 16. Dedicated resources vs. shared utility



Web application itself can no longer perform any useful function. In our case this is not accurate, but end users should not have to figure this out. The search results are not perfect, but often they will suffice. Moreover, it is a single step to an end user; they cannot use the application improperly. Even if they do not see the general message that some features are disabled, the query is handled and results are provided as best as possible. The results are labeled appropriately, and the error messages are well communicated, while the user maintains access to the information. In this case we alter the behavior of the application slightly to support a more satisfying application experience. Failure is communicated, and next steps are clearly provided.

The principal of graceful degradation means that, as an application begins to fail, it does so in a way that is not jarring to the end users or other components or subsystems. If a single feature is broken, disable the components that rely on that feature, provide a method for resuming work, or failover to a backup method. There are times where budget, design limitations, or schedule restrict the ability to implement applications in this way, but the benefits are quite significant. Applications that gracefully degrade and re-enable as possible are easier to manage and maintain. They change the mode of application instability to monitoring, instead of scrambling to reboot and provide service. In some ways, we are talking about building smarter systems. At the heart of any autonomy is a core system that can indicate for it and others that a problem exists.

FUTURE TRENDS

Just as software design and architecture continue to evolve, underlying infrastructure and middleware continue to provide an ecosystem within which applications can execute. Key to maximizing future infrastructure advances is the ability for an application to tolerate and to exploit many of these advances. Recently, autonomic computing technologies have advanced to the point where grid-like technologies can be delivered, without the need for disruptive approaches to be embedded within application designs. By having a middleware environment that provides the needed abstraction layer around the underlying physical deployment topology, applications can be managed against a set of predetermined policies. These policies, while enforcing against a breach of their predefined goals, will provision and de-provision instances of an application, all without having the application or pre-mediation of the event.

Given today's large dynamically-configurable operating systems/hardware, applications should provide ample opportunities for the hypervisor to capitalize on parallelism. Key to this ability is having applications designed with clear units of work spawning threads which are then separately managed and driven to their logical conclusion. Just as loosely coupled applications need to understand their dependencies on downstream processing, highly threaded applications need to understand and take steps to ensure that they provide exception handling, for the non-serialized processing that is likely to occur.

In focusing on the maturing of the infrastructure and middleware, a key strategy within the industry is to deliver computing resources as a dependable, scalable, and transparent commodity which applications exploit through standard development and interface models. This strategy is squarely focused at delivery of the infrastructure as a utility.

Utility Computing

Utility computing is a provisioning paradigm in which a service provider makes computing resources available to a consumer as needed. Infrastructure management and the ability to charge for specific usage, rather than the traditional fixed rate model, are central to the value proposition.

The utility computing vision makes several promises revolving around reducing IT complexity, pricing based on usage and decreasing operating, and capital costs to the enterprise. Adapting an infrastructure to a utility computing model is not simply about making changes to IT infrastructure; people and business process changes are also critical for future success (Whatis.com, 2005)

A sub-strategy of utility computing is directly associated with consolidation. In a shared utility computing model, a service provider looks to centralize its computing resources to serve a large audience reducing overhead while maintaining business resiliency. The value proposition for utility computing can be difficult to express, but the following points to help articulate it:

- **Efficiency yields cost savings:** In accordance with industry observations, the average machine utilization of datacenter systems is between 15 and 25 percent (Coulter, 2005).
- **Abstraction and virtualization yields flexibility:** A dynamic infrastructure allows the environment to proactively respond to changing application loads (Chase, Anderson, Thakar, Vahdat, & Doyle, 2001). Through virtualization, transparent provisioning of system resources is performed against a constantly reevaluated set of policies. As load decreases and the likelihood of a policy breach is diminished, systems are de-provisioned and reallocated to other services. This increases the overall utilization of assets and saves money through less upfront infrastructure.
- **Standardizing the infrastructure stack speeds implementation:** By having a utility computing mindset, individual applications are freed from the overhead of having to procure, setup, and test dedicated infrastructure, which typically has long lead times and capital expenditure associated with it. This process is typically repeated numerous times within an enterprise portfolio, and little if any economies of scale are leveraged. By driving standardization into the infrastructure stack and a predictable set of services, applications can execute against a set of assumptions and deploy into a shared resource pool without unique and dedicated resources.

In order to support this utility computing services model, many fundamental infrastructure services are needed, such as the ability to meter, bill, provision, and de-provision the infrastructure. Niche industries will focus on these core services with much of the discussion around virtualization centers on increasing the utilization of assets. Standardization is key to a successful business in utility computing.

As the industry continues to move toward the utility delivery model, application architectures will need to evolve to a platform agnostic perspective where the MIPS and GIGs are of interest, rather than which level of operating system or service pack exists. Additional planning and specification will be required to externalize how an application is to be scaled, depending on the real-time operating characteristics.

Today's visualization tools allow the management of entire resource pools and proactively manage its utilization (IBM, 2005b). Virtualization is a journey in which applications and middleware are abstracted from progressively greater layers of the machine physical characteristics.

In a utility computing environment characteristic, workloads are highly distributed; applications instances must be allocated and de-allocated frequently and with minimal overhead and latency. Without this on-demand provisioning scheme, it will be difficult to maximize the efficiency of the core infrastructure. Currently, low utilization rates continue as a result of massive infrastructure build-outs. These build-outs are a direct result of static, fixed computing limitations and, quite

frankly, over-funded approaches to guarantee application availability; maintaining high utilization rates in all resources is critical if utility providers are to be profitable. Understanding how utility computing impacts their work is critical to architects, developers, and strategists catching the wave the first time around.

CONCLUSION

Every enterprise application has special considerations to achieve functional and non-functional requirements. As practitioners, we all look for a common platform to help alleviate some of our woes. It is not uncommon for people to say, "We will just add more servers," or "CPUs are getting faster and RAM is getting cheaper." It is true that application platform and server management can contribute substantially to success. The key to successful Web applications is the approach taken to application design and architecture while providing the necessary abstraction layers to allow exploitation by an ever-maturing systems management set of technologies. A well-designed application will thrive in future computing environments, but no amount of autonomics will efficiently deliver a poorly-designed application.

This chapter reviewed five common challenges in enterprise Web application design: resource contention, managing transactions, application resiliency, geographically-diverse and exception/perception management. Using our experiences with IBM's expertise location system, we presented five key methods:

- High-availability application layer caching
- Asynchronous task processing
- Self-reliant, autonomous behaviors
- Client-side MVC
- Graceful degradation

Finally, looking at trends that will continue to change and impact enterprise application design and architecture offers some insight to upcoming challenges. While the approaches in this chapter are somewhat generic, they are by no means the only way to address these issues. However, over the last 18 months, we have witnessed their immense contribution to the resilience, scalability, and overall performance from transaction time to network throughput and bandwidth usage.

Chapter 1.28
A Survey of Development Methods for Semantic Web Service Systems

Terje Wahl
Norwegian University of Science and Technology, Norway

Guttorm Sindre
Norwegian University of Science and Technology, Norway

ABSTRACT

Semantic web services (SWS) hold the promise of enabling dynamic discovery of candidate web services fitting a particular specified need. One interesting question is what impact this will have on software and systems engineering methods – will mainstream methods like RUP still be suitable, or will new or adapted methods be needed? This article surveys the state-of-the-art in methods specifically tailored for the engineering of SWS systems, looking at development methods trying to cover the entire lifecycle as well as methods covering only one or two phases. Some of the surveyed methods are specifically meant to deal with semantics, others are for the engineering of service-oriented systems in general. The survey reveals that there are many proposals being made in this area, some extensions of mainstream methods like RUP, others more experimental. [Article copies are available for purchase from InfoSci-on-Demand.com]

INTRODUCTION

During recent years, the software industry has increasingly acknowledged that using discrete building blocks of software provides an effective way of engineering such systems (Stojanovic & Dahanayake, 2005). The 1990's saw an increased use of component based development (CBD), but this is now giving way to the increasingly popular technologies of Web Services and Service Oriented Architectures (SOA) (Stojanovic & Dahanayake, 2005). In the future, Semantic

Web Services (SWS) may provide an even more powerful way of rapidly building flexible and advanced Service Oriented Systems (SOS).

Technology versus Development Methods

When information systems are developed based on some specific technology, this implies the use of some underlying basic concepts such as *service, requester,* and *provider,* and a certain way of thinking about the structure and organization of the information systems. Hence, it is important that the system engineering methods match the underlying technology, to be able to create systems of high quality in a more effective manner. To effectively develop or adapt methods for engineering of SWS systems, there is a need for understanding what special concerns arise when engineering these systems. New engineering methods or adaptations of general methods may be desirable if special concerns are to be taken into consideration.

The service concept elevates the abstraction level and aims at empowering business users to create and execute software systems based on SOA (Erl, 2005; Stojanovic *et al*., 2004). Many technology standards for SOS and Web Services-systems have emerged, but little attention has been given to methods for modeling and designing such systems (Cabral *et al*., 2004). The amount of new technology is growing and it changes over time, making development complex and error-prone. As a result, increased application adaptability, widespread reuse and commercialization is slowed without proper support from methods and development tools (Cabral et al., 2004).

Motivation and Purpose

This article surveys the current state-of-the-art in engineering methods specifically tailored for the requirements specification, modeling, design and development of SWS systems. Methods may also be in the form of specially designed tools for supporting the development of SWS systems. The motivation for providing such a survey in terms of its utility for the reader is as follows:

- Giving an overview of methodological differences that have been envisioned between SWS systems development and current mainstream software development.
- Giving an overview of, and some comparison of, different methods and techniques that have been proposed to deal with the specific challenges of developing SWS systems, so that the reader can more easily navigate the plethora of existing proposals and possibly find a method which is useful in the reader's own context (whether this be research or practice).

We try to analyze what makes the development of SWS systems different and unique compared to the development of other kinds of information systems. From the survey we also try to identify what special concerns the methods take into consideration, and compare these concerns in the analysis. We perform a simple classification and comparison of the different methods and tools. In the end, we identify some suggested areas for future research into methods and tools supporting the engineering of SWS-based systems.

Scope

This article focuses on requirements specification, modeling, design / development, and testing / evaluation methods for creating SWS-based systems for end-users. It does not focus on methods for developing new technologies or frameworks for such systems, but rather attempts to look at what becomes important if assuming that the proper technical infrastructure is in place. As a result, we are focused on methods that involve users, with more or less technical skills, to see what systematic approach, actions, processes and

tools are required to create a system for end-users based on an existing infrastructure framework.

Engineering of SWS systems may be seen from two perspectives: Engineering of individual SWS (as a service provider), or engineering of SOS utilizing SWS (SWS-based systems, as a service requester). When building the latter kinds of systems, there is often a need for simultaneously developing services - not only utilizing existing ones. This article tries to cover both these perspectives. On the other hand, the design, development and utilization of general domain ontologies are important aspects of developing SWS systems, but are considered beyond the scope of this article.

Many methods for engineering of information systems in general or SOS in general, e.g., (Stojanovic et al., 2004) might be useful for the engineering of SWS systems. This might especially be true for methods supporting modeling and elicitation of requirements, such as interviewing, workshops, etc. These methods are however considered beyond the scope of this article.

Research Questions and Methods

The research questions of this study are as follows: 1) What methods have been proposed specifically for the development of semantic web service systems? 2) How mature are these methods, e.g., in terms of empirical evaluations and tool support?

In the framework of (Glass *et al.*, 2004) the research method of this article would be classified as Literature Review / Analysis. In a more recent taxonomy by (Mora *et al.*, 2008) where IS research is divided into four quadrants according to the dimensions conceptual / empirical and behavioral / design, this article would fall into the category conceptual behavioral research, as it does not design anything new, rather reviewing existing proposals, and this review is on a conceptual level rather than performing empirical comparisons of various software engineering methods. As discussed by (Kitchenham, 2004) there are two types of reviews, the *traditional* / *conventional* and the *systematic*. Systematic reviews have several advantages in terms of the thoroughness of procedure and confidence in the final result, but also disadvantages in a much heavier workload due to its formality, therefore requiring much longer time. The review reported in this article would not fully satisfy all of the strict criteria for a systematic review as formulated by Kitchenham, but has many aspects of a systematic review in that it makes an unbiased analysis of a large collection of works rather than considering a more limited and biased collection of sources.

The literature search for this study was performed by searching in Thomson ISI, IEEE and ACM Digital Libraries, and Google Scholar with phrases “web service” and “service-oriented” combined with development stage terms such as “analysis”, “requirements”, “design”, “development”, “composition”, and “testing”. The sources that emerged from this search were quickly evaluated by reading the abstract or browsing through the full paper (if available) to determine its relevance to our study. The most relevant ones were then selected for further analysis, the inclusion/exclusion criterion being whether the paper really proposed or discussed a *method* for service-oriented systems development (rather than merely discussing advantages of service-orientation or proposing components or architecture of such systems). The reference list of found papers was also used to harvest further papers that for some reason did not pop up in the initial search.

Organization of this Article

Section 2 presents related work and explains how the current article is different from previous surveys in the field. Section 3 discusses the special challenges in the engineering of SWS systems, emphasizing how this is different from more traditional software development, and motivating why specific methods are needed although mainstream

development methods can partially be used or adapted to this purpose. Section 4 presents the surveyed methods and tools, which are compared and discussed in section 5. Section 6 concludes and suggests further research directions.

RELATED WORK

Some work has been done on surveying the state of the art in SWS technologies and frameworks, e.g., (Cabral et al., 2004), and for the underlying technologies of service-oriented architecture, there is a thorough survey in (Papazoglou & van den Heuvel, 2007). (Küngas & Matskin, 2006) perform a survey of commercial and governmental web services to see which data they use, but this is more an investigation of the services as such, not of software development methods related to semantic web services.

(Srivastava & Koehler, 2003) have performed a survey of current solutions and open problems regarding web service composition. They focus on solutions used in industry vs. solutions proposed by academia. (Rao & Su, 2004) make a survey of automated approaches to service composition, referencing some of the same articles as this one, but of course missing those published after 2004. (Zimmermann *et al.*, 2005) discuss analysis and design techniques for service-oriented development in a survey-like manner, however, with fairly few references the paper is more a survey of issues than of sources in the field. (Ramollari *et al.*, 2007) present a survey of service-oriented development methodologies. The survey is most focused on the analysis and design stages, but does not focus specifically on semantic web services.

Hence, the main differences of the current survey compared to these previous ones is a more specific focus on engineering methods for SWS systems without restricting ourselves to any specific development stage, as well as looking at a broader range of methods.

SEMANTIC WEB SERVICES AND SOFTWARE ENGINEERING

Potential Benefits of Semantics

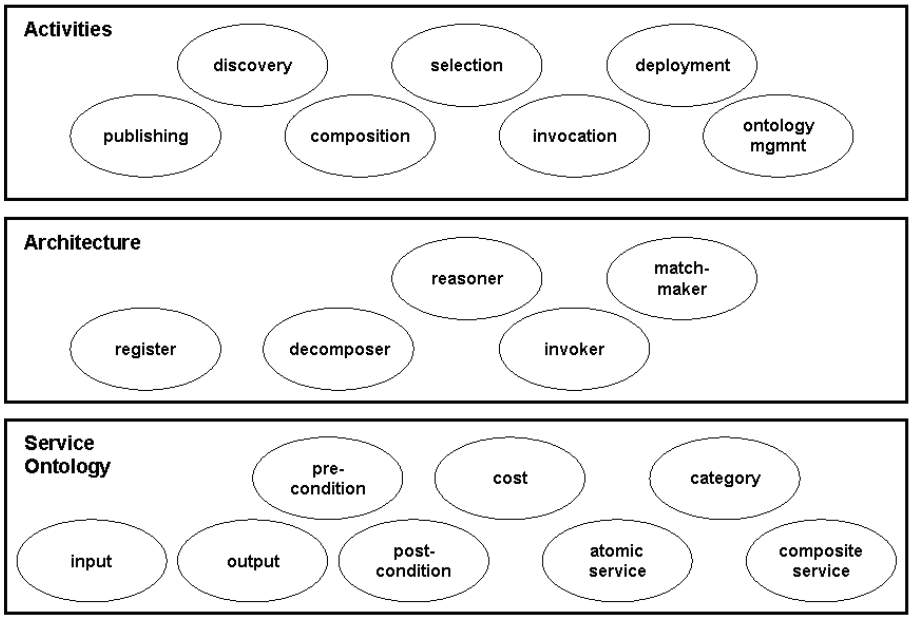
Existing technologies for traditional web services only allow descriptions at the syntactic level (Cabral *et al.*, 2004). This makes it difficult for requesters and providers to understand the meaning of the inputs and outputs and the real functionality of the service. This limitation may be overcome with the use of SWS. Semantic descriptions of web services are needed to enable automated discovery, composition and execution across heterogeneous users and domains (Cabral et al., 2004). Each SWS is described in a service ontology, enabling machines to understand its capabilities and reason over it related to other domain knowledge.

According to (Cabral et al., 2004), SWS infrastructures can be described along three different dimensions, as shown in Figure 1: *Usage activities*, *architecture* and *service ontology*. These dimensions are about the business, physical and conceptual level requirements for SWS respectively.

Special Lifecycle Concerns for SWS Systems

(Blake, 2007) discusses lifecycle issues in the development of service-oriented systems. Two different lifecycles are proposed. The development of single services is seen as similar to more traditional development, thus possible to do within mainstream lifecycles, for instance of RUP-like conceptualization and analysis, followed by iterative cycles of design, development, and testing, and finalized by deployment and retirement. However, the development of larger systems composed by such services, called service-centric software systems management, is seen as quite different,

Figure 1. SWS infrastructure dimensions, adapted from (Cabral et al., 2004)



thus needing a new kind of lifecycle with several different roles participating. Business-process engineers will be responsible for business-process conceptualization and domain analysis. Software engineers will then be responsible for the subsequent design stage. This has an iterative cycle much similar to the previous lifecycle, but the nature of the steps is different: service discovery, service composition, and evaluation. Finally, the operation stage is also different in nature, with the steps on-demand composition and rebinding, indicating a much higher dynamicity than for the traditional lifecycle.

(Gu & Lago, 2007) propose a more complex picture, illustrating the roles of several actors in one lifecycle picture. The main roles, however, are the service provider and application provider, which correspond to the two different kinds of lifecycle suggested by (Blake, 2007), and many similar aspects can be seen covered in both proposals. A somewhat more traditional lifecycle, much inspired by RUP, can be seen in (Papazoglou & van den Heuvel, 2006), identifying four different approaches to service-oriented applications: green-field, top-down, bottom-up, and meet-in-the-middle development.

(Tsai *et al.*, 2006) mention four challenges for service-oriented software engineering, namely decomposition challenge, utility challenge, quality challenge, and certification challenge, and state that service-oriented development has somewhat different methodological needs from the current mainstream focus on OOA / OOD with methods such as RUP and MSF. Yet, as pointed out by (Zimmermann et al., 2005) many of the general principles found in such mainstream methods still apply also in service-oriented software engineering, and extensions or adaptations of mainstream methods may therefore be one approach to better address service-oriented development. Some examples of RUP extensions are IBM's RUP for SOA (IBM, 2006) and the Service-Oriented Unified Process (Mittal, 2007). Sun's SOA RQ method (Sun, 2006) and the method proposed in

(Papazoglou & van den Heuvel, 2006) are also partly based on or have many similarities with RUP. Another example of a relationship between mainstream and service-oriented software development is OMG's effort to combine MDA with SOA, and to provide a meta-model for defining ontologies to help the construction of semantic web applications in an MDA context (OMG, 2006). The UML SOA profile proposed by (Johnston, 2005) can be seen as a related effort to align service-oriented development with mainstream techniques.

Another view on lifecycle can be found in situations where the idea is not to build new software but to offer services to a customer, for instance in a sourcing situation. The Information Technology Infrastructure Library, version 3 (ITIL v3) has made an increasing focus on service-oriented approaches in IT service management (Greiner, 2007; Keel *et al.*, 2007). From the perspective of the service-provider, the following lifecycle activities are envisioned: Service Strategy, Service Design, Service Transition, Service Operation, and Continual Service Improvement (Greiner, 2007). ITIL provides a common vocabulary for these activities, as well as guidelines to how they should be conducted.

Special Phase Concerns for SWS Systems

To find suitable specialized engineering methods, there is a need for understanding what special concerns arise when engineering systems based on SWS. On the requirements level, service-orientation poses both challenges and opportunities. The introduction of a new architectural paradigm might mean that some traditional development methods are no longer appropriate, and that new methods are needed. On the other hand, the presence and possible reuse of existing services might make requirements engineering easier (Jones *et al.*, 2005) – for instance, functionality of available services might inspire stakeholders to become clear about requirements they were not aware of, and could also enable rapid prototyping for elicitation and validation purposes.

Moreover, requirements engineering challenges can be found on two different levels, requirements for single services (which should, for instance, be as generic as possible to make the service competitive for usage in a wide range of applications), and requirements for applications or systems composed of various services, where the goal is to satisfy the needs of the stakeholders of that particular application. This is quite similar to the old distinction between development for reuse and development with reuse (Sindre *et al.*, 1995).

To understand challenges in design and later development stages we need to know what parts of a system must be implemented if we assume that there already exists a suitable infrastructure framework on which to build the system? Answering this question requires us to analyze what components and functions of the system are (or are envisioned to be) fully automated elements that need no involvement from the (business) user or system developer that are creating the end-user system.

All the *architecture* components for SWS (as shown in Figure 1) are meant to be automatic functions in an SWS framework. For example, *reasoning* is supposed to be performed without human intervention. Regarding the *activities* performed in an SWS system, most of these are clearly desired to be automatically performed, e.g., *publishing* and *invocation* of services. However, some of the activities may need to be performed manually or at least semi-automatically, depending on the complexity and type of system. This especially applies to *composition* and *selection* of services (D. Martin *et al.*, 2004). A system performing simple tasks within a well known domain may perform fully automated service composition and selection if the underlying framework is sufficiently robust and advanced (D. Martin et al., 2004). But some tasks may be so complicated

that they require a user to manually specify how different services are to be composed, or manually select desired services from lists of possible matches. In addition, sometimes users will want to be able to influence the composition process, e.g., if they only have a basic overall idea of their requirements for the system (Kim & Gil, 2004). One method of manually specifying a composition may be to define a process flow for the execution of a combination of different activities.

The *service ontology*, describing the service extensively, will usually have to be manually specified. This is done when implementing a service as a service provider, and must assure that the capabilities of the service are aligned with its service description (its service ontology). When specifying requirements for a SWS system, an overall service ontology may be created manually to specify the goal and requirements of the system, or a business process may be manually created and service ontologies defined for each of the activities in the process.

Service-oriented systems also have special challenges in the testing and evaluation phase. As pointed out by (Offutt & Xu, 2004) the testing of web service applications is difficult because they are distributed applications with runtime behaviors that differ from more traditional applications. For instance, the fact that service providers may change the implementation of a service at any time, introduces new challenges to regression testing (Ruth, 2008) and quality evaluation (Bianculli & Ghezzi, 2007).

Empowering the End User

Since the first software systems were created, systems have been developed at an increasing level of abstraction, making it easier for non-technical users to participate. SOS engineering (including SWS systems engineering) takes aim at providing modeling, design and development methods that map high-level business requirements to the technical implementation (Stojanovic & Dahanayake, 2005). Doing this will empower end-users to specify, design and develop their own systems, and thus "bridge the gap between business and IT" (Stojanovic & Dahanayake, 2005). Hence it is important that the methods and tools require as little technical skills as possible. Properly set up, and assuming an adequate supply of various services from providers, it could be possible for non-technical users to develop SWS systems in a fashion similar to Model Driven Development (MDD).

OVERVIEW OF METHODS AND TOOLS

In this section we survey methods and tools that support the engineering of SWS systems. We focus on methods and tools from the user perspective, i.e. involving user interaction.

Requirements for SWS Systems

The EU-funded IP project "Service Centric Systems Engineering" (SeCSE) has addressed various aspects of the development of service-oriented applications, including the requirements process (Jones et al., 2005; Zachos *et al.*, 2007). This is envisioned as an iterative cycle between requirements formulation and searching for services. Starting with an incomplete requirements specification, some possible services may be found in a service repository, these may again provide ideas – either because of functionality they contain, or properties they are lacking – for more detailed requirements. Tool support is developed for the approach, including a requirements assistant (UCaRE), a service discovery tool (EDDiE), and a service exploration tool. An evaluation of UCaRE is presented in (Zachos et al., 2007), while the EDDiE tool is presented in more detail in (Dourdas *et al.*, 2006).

While the efforts around UCaRE have mainly addressed the requirements specification of larger

systems (to be composed of services), another effort within SeCSE has addressed the specification of single services (Walkerdine *et al.*, 2007). A faceted specification approach is used to aid the later retrieval and comparison of services according to system specification. Also here, tool support has been developed and evaluated through a case study.

(Barn *et al.*, 2007) propose a tool workbench (SOA-MDK) for model-based development of service-oriented systems. The approach is inspired by component-based development, and the development method starts by developing business process models and information models, which can be considered RE activities on the system level. These models are then factored, and services allocated to the various parts. Finally, WSDL specifications are generated for the various services. A somewhat similar approach, but considering use cases plus non-functional requirements rather than business process models in the early stages, is proposed by (Dexter *et al.*, 2007).

Modeling and Design of SWS

(Timm & Gannod, 2005) recognize that the learning curve for the OWL-S descriptions language is steep, and that the current state of tool support is limited. They have created an automated software tool that uses model-driven architecture (MDA) techniques to generate OWL-S descriptions. The manual input to this tool is the description of an SWS in the form of a UML model specified in a standard UML modeling tool. Conversion to OWL-S is done via an XML representation of the UML model and XSLT.

(Jaeger *et al.*, 2005) propose a methodology for developing OWL-S descriptions that consists of three main steps: Generation of an OWL-S template, identification of available ontologies, and performing classification. Tasks in this methodology that must be performed manually are adapting or designing an ontology that describes the relevant domain, and classifications of the service, its inputs/outputs and any optional additions.

(Elenius *et al.*, 2005) have created a development tool for SWS, in the form of an OWL-S editor which aims to be easy and intuitive. The editor is implemented as a plug-in to the Protégé OWL ontology editor, and allows for engineering of all aspects of SWS by providing specialized views and design features wherever deemed necessary by the authors.

(Scicluna *et al.*, 2004) discuss how the difficult task of developing an OWL-S specification can result in incorrect specifications of the description or lead the user to rather utilize some other type of description language. They have created the OWL-S editor tool *OwlsWiz*, which enables creation of OWL-S ontologies from a WSDL description by presenting the user to a step-by-step process of inputting information. It allows a fast way of creating SWS descriptions while using well known standards such as WSDL and UML Activity Diagrams. Their main objective with the tool is to abstract away the underlying complexity of the OWL-S format and offer a relatively user-friendly way of building complex descriptions.

(Klein & Koenig-Ries, 2003) present an approach to improving the usability of DAML-S (now named OWL-S) by suggesting a process and a tool. The process guides through the activities needed to create adequate SWS descriptions by introducing a layered ontology of services, consisting of an upper service ontology, an ontology for the service category, and several domain ontologies. Their graphical tool *DINST* implements this process and claim to offer a comfortable way of editing SWS descriptions.

(Heß *et al.*, 2004) state that manually creating semantic metadata for services is tedious and error-prone. They propose a semi-automatic tool (*ASSAM*) for assisting a user in creating semantic metadata for SWS in the OWL-S format. *ASSAM* consists of two parts; a WSDL annotator appli-

cation, and OATS (Operation Aggregation Tool for Web Services), a data aggregation/schema matching algorithm. The WSDL annotator application uses machine learning to provide the user with a point-and-click interface containing suggestions on how to semantically annotate a web service. The tools have been evaluated, and findings indicate their usefulness.

(Brambilla *et al.*, 2007) propose a framework for developing semantic web service systems cross-cutting several enterprises. The proposed approach utilizes several available techniques, such as BPMN for the specification of business process models and WebML for the development of web applications. WSMO ontologies are semi-automatically elicited from the design of the applications. Their model-driven design process is seen as consisting of four steps: process design, data design, hypertext design, and semantic description. For this approach, a CASE-tool has also been presented (Brambilla *et al.*, 2006).

Composition of Semantic Web Services

(Sirin *et al.*, 2004) have developed a goal-oriented and interactive composition approach that utilizes matchmaking algorithms to assist users in filtering and selecting services while building the composition. They have created a semi-automatic tool that uses OWL-S service descriptions and filters and selects services using matchmaking algorithms. The system has two separate components: One component is an inference engine that stores service requirements and processes match requests. The other is the composer that generates the service composition workflow. The composer communicates with the inference engine to discover possible matching services, and presents them to users that may create a workflow of services based on the choices presented at each step. Users enter constraints on the service parameters from a form generated by the system using the ontologies that define those parameters. Users make the final selection of the specific services at each step.

(Kim & Gil, 2004) have developed a framework for interactive composition of SWS that guide users in sketching a composition of services. They argue that users benefit when employing intelligent tools that help them specify complete and correct pathways, even if there is only a small number of services that need to be put together. Their approach is to first take existing service descriptions and extend them with domain ontologies and task ontologies that attend to various task types in the domain. Their analysis tool *CAT* (Composition Analysis Tool) then uses these ontologies when examining and giving specific suggestions regarding the user's solution. They demonstrate how *CAT* may be useful in a case study regarding the domain of earthquake science.

The Service Component Architecture (SCA) (Chappell, 2007) is a joint effort in by a number of American companies, defining a platform for how to program web services and how to assemble them. However, it focuses more on defining necessary standards and infrastructure, and less on software engineering methods.

IRS-III (Hakimpour *et al.*, 2005) is a framework for structured web service composition. Their approach is supported by a tool which automatically recommends candidate web services to satisfy the specified composition context.

Testing / Evaluation of Service-Oriented Systems

(Offutt & Xu, 2004) present an approach for automated generation of test cases for web service systems, based on data perturbation. Automated test generation is also the topic of (Sinha & Paradkar, 2006), proposing an approach based on finite state machines. In this approach, WSDL-S specifications are taken as input, hence utilizing some provided semantics of services.

(E. Martin *et al.*, 2007) presents a prototype tool for robustness testing of web service systems,

but this is for web services in general, not specifically for semantic web services.

(Ruth, 2008) presents algorithms for safe test selection when performing regression testing on web service applications. (Penta *et al.*, 2007) propose the usage of genetic algorithms to produce test data for examining whether web services adhere to service level agreements.

As for evaluation, (Bianculli & Ghezzi, 2007) propose an approach for run-time quality monitoring of conversational web services, based on algebraic specifications. (Zhu *et al.*, 2006) present an approach for model-driven generation of benchmarks to evaluate service-oriented systems.

Methods Spanning Several Development Phases

(Gomez-Perez & González-Cabero, 2004) propose a framework for design and semi-automatic composition of SWS at a language-independent and knowledge level. The framework is directly based on the stack of ontologies that describe all the features of SWS. The framework specifies how to create SWS with the capabilities required by an external agent or user, focusing on three models: An instance model (specifying the SWS at the knowledge level), a checking model (utilizing design rules - called axioms - to check that there are no inconsistencies or errors in ontology instances) and a translation model (translating the service modeled at the knowledge level into an SWS-oriented language such as OWL-S combined with WDSL/SOAP). A prototype tool called *ODE SWS* has been implemented as an integrated part of *WebODE*, which is a platform for ontology development. The tool allows users to manually design descriptions and compositions of services at a conceptual level using a graphical user interface. The service model and composition is automatically checked for errors before performing an automatic translation into the OWL-S specification.

(Howard & Kerschberg, 2004) recognize the need for a comprehensive and overarching framework that deals with the processing and workflow requirements of Virtual Organizations, maps these into a group of service-oriented activities, dynamically configures these activities from available services and manages the choreography and execution of these services. They propose such a framework, which they call the Knowledge-based Dynamic Semantic Web Services (KDSWS) Framework. The framework deals with specification of service requirements, mapping of these requirements to composable services, and coordination of the execution of services conforming to enterprise workflow requirements. The KDSWS Framework has a functional architecture containing a user layer. The idea is that users would visit a portal of the e-enterprise, compose their request as a high-level task, and cooperate with a planning agent to decompose the task into a plan that is automatically processed further. A framework implementation is planned in the future.

(Papazoglou & van den Heuvel, 2006) propose a method which is inspired by RUP, combined with business process modeling and component-based development, covering all phases from planning to deployment and execution of the service-oriented system. However, while all phases are mentioned, some of them (e.g., testing) are discussed in rather general terms, not containing any suggestions of specific service-oriented techniques for that phase. The development of an integrated tool set supporting the approach is mentioned as future work in the article.

COMPARISON AND DISCUSSION

In this section we perform a simple classification and comparison of the different methods and tools, and discuss the result.

Table 1 below gives an overview of the methods and tools identified in the survey dealing with stages before testing. It indicates what development phase the methods are intended for, whether tool support is documented for the method (the first Y/N in the Tool & Eval column), and if the usefulness of the method/tool is evaluated (the second Y/N in the Tool & Eval column). Note that an N in one of these columns does not necessarily mean that tool support or evaluations has not been established, only that this was not found documented in the publication. Furthermore, the "Lang" column indicates which modeling languages are utilized by the approach, and the final "Proc" column whether it makes any particular assumptions about the

Table 1. An overview of methods and tools supporting the engineering of SWS systems

Approach	Phase	Tool & eval		Lang	Proc
SOA-MDK (Barn et al., 2007; Dexter et al., 2007)	reqs	Y	Y	BPM, info. mod. Use cases	Inspired by CBD
SeCSE (Walkerdine et al., 2007; Zachos et al., 2007)	reqs, design, comp.	Y	Y	Use cases, Struct natural lang, WSDL	Extended RUP
(Timm & Gannod, 2005)	design	Y	N	UML, OWL-S	no
(Jaeger et al., 2005)	design	N	N	OWL-S	no
(Elenius et al., 2005)	design	Y	N	OWL-S	no
(Scicluna et al., 2004)	design	Y	N	OWL-S, WSDL, UML AD	no
(Klein & Koenig-Ries, 2003)	design	Y	N	OWL-S	no
(Heß et al., 2004)	design	Y	Y	OWL-S, WSDL	no
(Brambilla et al., 2007)	design	Y	Y	BPMN, WebML, WSMO	Own process
(Gomez-Perez & González-Cabero, 2004)	design, comp.	Y	N	OWL-S	no
(Sirin et al., 2004)	comp.	Y	N	OWL-S	no
(Kim & Gil, 2004)	comp.	Y	Y	WSDL	no
IRS-III (Hakimpour et al., 2005)	comp.	Y	Y	WSMO, UPML	no
(Howard & Kerschberg, 2004)	all	N	N	KDL, KDSPL	Own process
(Papazoglou & van den Heuvel, 2006)	all	N	N	BPEL	Inspired by RUP

overall development process, e.g., being related to RUP or component-based development (CBD). Note here that a "no" does not necessarily mean that the approach could not be used together with, e.g., RUP, only that the publication does not make any particular assumption about this. Hence a "no" here may in some ways be a disadvantage (no overall process provided) but also in some ways an advantage (the proposed technique can potentially be used with many different larger-scale development methods).

Table 2 similarly gives an overview of the surveyed approaches to testing and evaluation of service-oriented systems. The columns indicate what kind of testing the technique supports, what kind of specifications it takes as input, what it delivers as output, and what approach is used for the intermediate processing.

The list of methods might not be comprehensive, but despite of this it may be argued that much more research has been done on the enabling technologies of SWS than research regarding methods for requirements engineering, modeling, design and composition of systems based on these technologies.

Most of the methods (all but two) are accompanied by a software tool. This might indicate that the need for tool support is recognized and reckoned with. However, most of the tools are at an early stage of development and undergoing continued development, showing that this research area is still somewhat experimental and immature. Yet, there is a positive trend that publications from the last 2-3 years tend to include evaluations of the proposed methods, while earlier publications did not.

Several methods focus on modeling & design or composition or both phases of development, but only two of the methods focus explicitly on requirements specification for SWS systems. This may be because this has not received a lot of attention in research, or because more general methods apply well to specifying requirements for SWS systems. Many methods talk about cre-

Table 2. An overview of test and evaluation methods

Source	Kind of testing	input	output	approach
(Offutt & Xu, 2004)	functional	XML	test cases	Data perturbation
(Sinha & Paradkar, 2006)	functional	WSDL-S	Test cases	Extended finite state machines
(E. Martin et al., 2007)	robustness	WSDL	Test cases, test results	Java code generation
(Ruth, 2008)	regression	WSDL	Test selections	agents

(Zhu et al., 2006)	Performance / benchmarking	UML	benchmark	MDA

ating specifications of SWS systems, however it is important to note that a specification/description of a system is not the same as the system requirements.

Several of the suggested approaches underline the importance of user friendliness for the users that will make use of the methods and tools, by minimizing the needed amount of user input and the technical skills needed to provide it. This might point towards the underlying technologies being complex, and a wish for relatively non-technical business users to be able to create SWS systems in a fashion similar to Model Driven Development (MDD).

Most of the methods and tools utilize the OWL-S specification, indicating that it is very popular compared to other alternative technologies. Although most of the papers in this survey briefly rationalize the usefulness and argue the general benefits of their methods or correctness of their tools, only six of the methods have been evaluated for their usefulness. This hints at the relative immaturity of this research area, and a large potential for further research.

CONCLUSION AND SUGGESTIONS FOR FUTURE RESEARCH

Engineering of Semantic Web Services (SWS) systems include two important tasks that usually must be performed with input from a human user; requirements engineering, and modeling and design. In addition, manual input might often be needed when composing SWS into a workflow. Most of the other parts of SWS systems engineering are at least envisioned to be performed automatically. This indicates that engineering of SWS systems might become similar in fashion to Model Driven Development (MDD).

Our findings indicate that although some research have been done regarding methods for requirements engineering, modeling, design and composition of SWS systems, this research area is still somewhat experimental and immature. The need for tool support is recognized and reckoned with, and especially the approaches published in 2007 or later tend to come with working tool support, although this is often in the form of research prototypes that may not always be easily integrated with other mainstream software development tools. The OWL-S specification seems to be very popular in use compared to other alternative technologies. Methods for requirements engineering specifically aimed at SWS systems have not received a lot of attention. This might indicate that more general methods apply well to specifying requirements for SWS systems.

Research is being done to allow business users to be able to create SWS systems with as little technical knowledge as possible. This might also lead to engineering of SWS systems being performed in a fashion similar to MDD. There is also an evident convergence between business process modeling, enterprise application integration and service-orientation, for instance exemplified by the fact that many BPMS tools take a service-oriented approach. This convergence can also be seen in the survey, as languages such as BPMN and BPEL are included in several of the surveyed approaches in Table 1 and 2. The typical picture, however, is that the largest and most comprehensive tools tend to address service-oriented development in general, without any particular focus on semantics, while the tools that are ambitious on semantics tend to be smaller research prototypes with a more limited scope, dealing with only one or a few development phases. Hence, better tool support can be envisioned when ambitious semantic-based functionality also reaches the mainstream tools.

Future research is needed on methods for engineering of SWS systems. In particular, there is a need for further refinement of tools supporting the methods, and there is a strong need for research evaluating the usefulness of the proposed methods and tools. It will also prove valuable to do more research on requirements engineering for

SWS systems, to examine if general requirements engineering methods are adequate, or if more suitable methods can be found when considering the distinctive character of SWS systems.

ACKNOWLEDGMENT

This work was performed in the context of the project WISEMOD, funded by the Norwegian Research Council.

Chapter 1.29
Knowledge Management Software

Rodrigo Baroni de Carvalho
FUMEC University, Brazil

Marta Araújo Tavares Ferreira
Federal University of Minas Gerais (UFMG), Brazil

INTRODUCTION

Due to the vagueness of the concept of knowledge, the software market for knowledge management (KM) seems to be quite confusing. Technology vendors are developing different implementations of the KM concepts in their software products. Because of the variety and quantity of KM tools available on the market, a typology may be a valuable aid to organizations that are searching and evaluating KM software suitable to their needs.

The objective of this article is to present a typology that links software features to knowledge processes described in the SECI (socialization, externalization, combination, internalization) model developed by Nonaka and Takeuchi (1995). KM solutions such as intranet systems, content-management systems (CMSs), groupware, work flow, artificial intelligence- (AI) based systems, business intelligence (BI), knowledge-map systems, innovation support, competitive intelligence (CI) tools, and knowledge portals are discussed in terms of their potential contributions to the processes of socialization, externalization, internalization, and combination.

BACKGROUND

KM intends to be an area of research and practice that deepens the understanding of knowledge processes in organizations and develops procedures and instruments to support the transformation of knowledge into economic and social progress. In fact, different aspects of these issues have been studied for decades in many different disciplines as R&D (research and development) and innovation management, information systems management, information science, computer science, library studies, innovation economics, science and technology social studies, epistemology, and many others. Maybe one of the most important contributions of the KM concept is the creation

of a space (in academy and in the business world) where these many groups and points of view may discuss and work together.

KM studies analyze people, organizations, processes, and technology. Although technology is not the main component of KM, it would be naive to implement KM without considering any technological support. According to Stewart (1998), the intellectual capital of an organization has three dimensions: human capital, structural capital, and client capital. Structural capital is defined as the organizational systems and structures that store and transfer knowledge, and it includes the quality and extent of information systems, databases, patents, written procedures, and business documents. From this perspective, KM software should be considered as an important component of the structural capital of organizations.

This article assumes that IT has a supporting role, not the main role, in a KM program. According to Terra (2000), KM has seven dimensions: strategy, culture and organizational values, organizational structure, human resource skills, IT, measuring, and environmental learning. Therefore, IT is only one of the dimensions of KM, and technology alone does not transform information into knowledge. The KM ultimate challenge is to increase the chances of innovation through knowledge creation. The role of IT in this context is to extend the human capacity of knowledge creation through the speed, memory extension, and communication facilities of technology.

Nonaka and Takeuchi (1995) have analyzed the knowledge-creation process of Japanese organizations and developed a framework (SECI model). This model relates the knowledge creation of firms to four knowledge conversion processes.

- **Socialization (S):** the process of sharing tacit knowledge through shared experiences. As apprentices learn the craft of their masses through observation, imitation, and practice, so do employees of a firm learn new skills through on-the-job training.
- **Externalization (E):** where tacit knowledge is articulated into explicit knowledge with the help of metaphors and analogies. Externalization is triggered by dialog and collective reflection.
- **Combination (C):** the process of converting explicit knowledge into more systematic sets of explicit knowledge.
- **Internalization (I):** where explicit knowledge is converted into tacit knowledge. This usually occurs when explicit knowledge is put into practice. It is also related to shared mental models and work practices.

These interactions build a continuous spiral from the individual to organizational level. Ponzi (2004) used bibliometric techniques to analyze 2,240 source records obtained from scientific citation indexes. His research revealed that Nonaka and Takeuchi (1995) is the top most cited reference in the KM area and the most influential work. Due to this popularity, we have decided to use the SECI model to help individuals who already know this framework but need a better understanding of the KM software market.

There are some related works concerning KM software categorization: Barnes (2001), Bellaver and Lusa (2002), Davenport and Prusak (1998), Fernandez, Gonzalez, and Sabherwal (2004), Maier (2004), Malhotra (2000), Rollet (2003), Ruggles (1997), and Tiwana (2002). None of these academic works establish a direct relationship between the KM systems and the SECI model. The authors usually prefer to use their own KM framework to analyze the link between knowledge processes and KM systems. There is also another type of proposal for categorization, that is, Microsoft (2000), which has been developed by vendors and is very IT based. It is not the objective of this article to discuss the differences and the similarities among these proposals, but they have been considered in the development of the typology presented here.

MAIN FOCUS OF THE ARTICLE

The main objective of this article is to present a typology of KM solutions present on the market that comprehends 10 categories, each of which emphasizes specific KM aspects. It also intends to identify which of the knowledge-conversion processes (Nonaka & Takeuchi, 1995) is supported by each software category. This article concludes by presenting some trends in KM software development and suggesting some guidelines for the launching of KM programs supported by IT.

To accomplish our objective, it was necessary to explore the software market in order to classify KM tools. The major difficulty in accomplishing this task was the establishment of limits on a growing market. A sample of KM software was constructed through information collected on KM-related sites selected in Nascimento and Neves (1999), on advertisements in KM magazines (*KM World*, *KM Magazine*, and *DM Review*), and in digital libraries (http://brint.com). The exploratory research resulted in a list of 26 software vendors that were contacted, from which 21 sent folders, technical briefings, and demo versions of their software. The analysis of each KM system basically consisted of an installation and feature checkup. It was tested if the features advertised by the vendor were really supported by the KM system. After the analysis of these tools, it was possible to identify some common features among them, which originated the typology's first version. This version (Carvalho, 2000) was composed of eight categories.

After this period, Collins (2003), Detlor (2004), Firestone (2003), Kim, Chaudhury, and Rao (2002), and Raol, Koong, Liu, and Yu (2002) published research related to the evaluation of KM software and the emergence of knowledge portals. Due to the development of the KM software market and influenced by the previously mentioned works, this typology was reviewed and updated in 2004. As a result, two new categories have been incorporated: competitive intelligence tools and knowledge portals. The KM systems are then discussed in terms of their contributions to the four knowledge conversion modes developed by Nonaka and Takeuchi (1995).

As a result of this research, 10 KM software categories are presented as follows:

- Intranet-based systems
- Content management systems
- Groupware
- Work flow
- Artificial intelligence-based systems
- Business intelligence
- Knowledge map systems
- Innovation support tools
- Competitive intelligence tools
- Knowledge portals

Intranet-Based Systems

An intranet is an appropriate tool to systematize and add the explicit knowledge that is dispersed through departments. Intranets are organizational assets and an important part of the structural dimension of intellectual capital, as described by Stewart (1998). The communication in intranets is usually passive because the user has to pull the information. Nevertheless, the efficient usage of intranets is closely related to a wider comprehension of information management contribution to organizational performance. An intranet, like other systems described in this article, should be understood as a part of the organizational information context, and its usefulness is influenced by culture, values, and principles concerning strategic information management. This explains why, despite the wide and varied set of features made possible by intranets, they have been used in most organizations primarily for basic information access, that is, the retrieval of corporate documents (Choo, Detlor, & Turnbull, 2000).

According to Choo et al. (2000), intranets are quite helpful in promoting the externalization, combination, and internalization processes. The

combination process is supported by unified access to multiple content sources, and internalization occurs when there is a dissemination of success stories and best practices on the intranet. Part of the intranet content is generated by employees who have decided to document their experiences and externalize their knowledge. Web server software, such as Apache HTTP (hypertext transfer protocol) Server, offers the basic features for intranet deployment.

Content Management Systems

CMSs manage repositories of important corporate documents and contribute to the organization of the vast amount of documents generated by office activities. Paperwork is still a reality, and each document is a source of nonstructured information that could be lost if not well organized. According to Rollet (2003), existing paper documents are brought into the CMS through scanning, and optical character recognition (OCR) software analyzes the resulting image files and translates them into computer-readable text. Bennet (1997) states that CMSs provide more efficient retrieval, and better security and version control of documents. File Net and Excalibur Retrieval Ware are examples of CMSs. These systems have many features-cataloging, metadata, searching, versioning, and indexing-that were inherited from the traditional information retrieval (IR) systems, which are studied in the field of library science.

CMSs deal only with the explicit dimension of knowledge, supporting then the combination process. The focus of CMS is primarily on providing access to existing documents in any available media: fax, e-mails, HTML (hypertext markup language) forms, computer reports, paper, video, audio, or spreadsheets.

Groupware

Organizations are searching for flexible structures that can easily adapt to a changing environment. The need of cooperation between geographically dispersed work groups is a critical issue to global organizations. Groupware systems have a push style where information is sent to the user. Groupware is a blend of synchronous (like chat), asynchronous (like e-mail), and community-focused tools (like e-groups). Informal communication predominates in a groupware environment. Groupware systems are well suited to support communities of practice, where specialists of a given domain of knowledge, who may be dispersed all over the world, exchange their expertise in order to find solutions to specific problems.

According to Nonaka and Takeuchi (1995), the externalization of tacit knowledge is induced by dialog and collective reflection. Groupware helps this process by permitting collaboration and the exchange of nonstructured messages. Discussion groups and chats are common groupware features that make possible the gradual articulation of tacit knowledge. The development of technologies, such as videoconferencing and instant messaging, has contributed to a better quality of interaction among groupware users. These enriched virtual environments provide a suitable context for the socialization and internalization processes. Choo et al. (2000) present online apprenticeship as an example of socialization supported by groupware. The Microsoft groupware suite (MS Exchange, MS Outlook, MS Messenger) and the Lotus family (Notes, Sametime, Lotus Workplace) are examples of groupware packages.

Work Flow

Work flow systems support standardized business processes. These systems regulate the information flow from person to person, place to place, and task to task in processes that require ordered and structured information. The objective of work flow systems is to establish and accelerate the process flow, following its steps and tracking each activity that composes the process. They make explicit the knowledge that is embedded in standard pro-

cesses, mainly supporting the formal codification of existing knowledge (externalization).

Cruz (1998) defines the three basic elements of work flow, also called the three *R*s model.

- **Roles:** set of skills to execute a specific task
- **Rules:** features that define how the data should be processed
- **Routes:** logical paths for the knowledge flow through the process

Work flow systems, like ARIS Toolset, present features that support the graphical representation of existing processes. These systems are also used for business process reengineering (BPR) because they make explicit who does what in what order, and what products or services are produced. Another interesting feature of work flow systems is simulation, which permits the dynamic analysis of business processes. The simulation supplies information about the execution of processes, process weak points, and resource bottlenecks. Work flow systems are usually integrated with groupware and CMSs in order to provide an organized document flow across knowledge workers, supporting then the execution of a business process.

Artificial Intelligence-Based Systems

AI is the computer-science field that has produced the first studies relating information to knowledge. Expert systems, CBR (case-based reasoning) systems, and neural networks are some types of systems that use AI techniques. An expert system is built on the observation of a specialist at work and on the mapping of part of his or her knowledge into derivation rules.

As Davenport and Prusak (1998) explain, CBR systems support learning from a set of narratives or cases related to a problem. When a user has a problem, he or she can check in the case database in order to find if it is related to a problem that has already been solved. CBR systems use pattern matching algorithms to retrieve cases that are more similar to the problem stated before. The user can interact with the system by analyzing the solutions of existing cases and refining the search. CBR systems have been successfully used in help desk and call-center applications. They help contributors to externalize what has been learned from experience through the narrative of cases.

On the other hand, frequent users of the CBR system can internalize the knowledge that is represented into the system. This knowledge can also be restructured and represented in another manner. According to Rollet (2003), fundamental prerequisites for AI methods are suitable ways of representing knowledge, and automated reasoning typically uses highly formalized knowledge bases consisting of explicit rules, using, for instance, predicate logic. AI is also important for the development of software components, like intelligent agents, that can be used in a wide range of information systems, helping search and retrieval features.

Neural networks, like CA-Neugents, are more sophisticated systems that use statistical instruments to process cause-effect examples and to learn the relationships involved in the solution of problems. Neural networks are very flexible and intelligent systems because each new input results in an automatic reprogramming and consequent addition of new relationships.

Business Intelligence

Business intelligence is a set of tools used to manipulate a mass of operational data and to extract essential business information from them. BI systems comprehend the following:

- **Front-end systems:** They consist of a comprehensive set of data analysis tools like OLAP (online analytical processing), data mining, query, and reporting.

- **Back-end systems:** DBMSs (database management systems), data warehouses, and data marts.

DBMSs are the basis of a BI solution. First, the operational data generated by business transactions are extracted from the DBMS, filtered by some criteria, and then moved to the data warehouse. After this BI back-end loading step, the front-end tools are able to identify hidden patterns inside the data, and the user is free to build his or her own queries and strategic reports. BI systems, like Business Objects and Oracle 10g BI, provide end users with self-service access to information stored in data marts, data warehouses, and online transaction processing (OLTP) systems. As Choo (1998) explains, organizations are using analysis tools to reveal patterns that would otherwise remain buried in their huge operational databases; software for OLAP, a front-end BI tool, allow users to create multidimensional views of large amounts of data as they "slice and dice" the data in various ways to discover patterns and trends.

The focus of BI is decision making. BI systems excel in the job of sorting, categorizing, and structuring information, and facilitating the reconfiguration of existing information (combination) as well as creating new information.

Knowledge Map Systems

Also known as expertise locators, knowledge maps work like yellow pages that contain a "who-knows-what" list. A knowledge map does not store knowledge. The map just points to people who own it, creating opportunities for knowledge exchange.

A standard knowledge map is fed with profiles of competencies of the members of an organization. The knowledge map provides an expert locator feature that helps users to find the expert's best suited to work on a specific problem or project. A knowledge map categorizes an organization's expertise into searchable catalogs. By using a knowledge map, it is easier to identify people in terms of whom they know, what they know, and how proficient they are at a given task.

Human resource specialists use knowledge maps to match existing competencies with strategic targets and to identify what kinds of know-how, essential for growth, are currently available. According to Terra (2000), knowledge maps facilitate tacit knowledge exchange because they provide faster expert search and increase the chance of personal meetings. This approximation can probably result in face-to-face contacts that promote shared experiences and learning by observation, imitation, and praxis (socialization).

Innovation Support Tools

Amidon (2000) defines innovation as the application of new ideas to products or services. The result of innovation can be observed by the number of new patents, the design modifications of existing products, and the development of new products. Innovation support tools are systems that contribute to knowledge generation along the product design process. These tools intend to create a virtual environment that stimulates the multiplication of insights and are especially used in industrial R & D. An innovation support tool may include different features.

- A technical database where patents, articles, and research projects are recorded
- Graphic simulation features, which can facilitate internalization
- Combinatory tools, which help to consider unusual possibilities in the design of innovations

Innovation support tools, like Goldfire Innovator from Invention Machines, are generally based on a scientific content or patent database that allows users to conceive new products, correct

product defects, design feature modifications to existing products, identify technology trends and future product road maps, or improve production processes. The combination process is also supported because an engineer can combine existing explicit knowledge to generate new patents or product specifications.

Competitive Intelligence Tools

FULD & Company Inc. (2000) describes the CI cycle in five steps.

- **Planning and direction:** the identification of questions that will drive the information gathering phase
- Published information collection
- **Primary source collection:** information gathering from people rather than from published sources
- **Analysis and production:** the transformation of the collected data into meaningful assessment
- **Report and inform:** the delivery of critical intelligence in a coherent manner to corporate decision makers

FULD and Company Inc. (2000) has evaluated the CI software offered on the market and has concluded that they offer better support to the second and fifth steps of the CI cycle. The other steps are very human based and are only slightly benefited by technology. In the second step, software agents perform the automatic collection of timely information from news feeds and search the Internet and corporate intranets. In the fifth step, CI tools accelerate the dissemination of reports by sending e-mail reports according to users' preferences. CI tools concentrate on the combination process of the knowledge conversion spiral. They act like a probe on information sources: The information that is obtained is filtered and classified before dissemination so it is disseminated in an adequate format to facilitate combination. On the other hand, CI tools contribute to sense making, which is related to the internalization process. According to Choo (1998), organizations first have to make sense of what is happening in their environments in order to develop a shared interpretation that can serve as a guide to action.

Knowledge Portals

In an attempt to consolidate various departmental intranets, organizations are constructing corporate intranets or portals (Choo et al., 2000). A great contribution of portals is the integration of heterogeneous information sources, providing a standard interface to the users. According to the authors, a portal's primary function is to provide a transparent directory of information already available elsewhere, not to act as a separate source of information itself. Common elements contained in corporate portal design include an enterprise taxonomy or classification of information categories that helps to ease retrieval, a search engine, and links to internal and external Web sites and information sources.

The personalization feature of portals enables end users to organize their work by community, interest, task, or job focus. Besides providing personal access to knowledge, portals help users in the job of building community places. Online awareness and real-chat capabilities are available throughout the portal. Therefore, the user can see who is online, connect with them instantly, and get immediate answers.

But portals are evolving into more complex and interactive gateways so that they may integrate in a single solution many KM tools' features presented before. They are becoming single points of entry through which end users and communities can perform their business tasks, and evolving into virtual places where people can get in touch with other people who share common interests. Knowledge portals are the next generation of

EIPs (enterprise information portals). Knowledge portals support all knowledge processes described in the SECI model because portals are in fact the amalgamation of many KM systems presented before.

Table 1 presents the 10 classes of KM software discussed in this article, their main contribution to knowledge conversion processes, the disciplinary origin of their main concepts, and some examples. The examples are merely illustrative and do not represent a recommendation or preference for any technology vendor.

It is interesting to notice how KM software covers a large spectrum of features, information resources, and users. For instance, CMSs are made to retrieve documents while knowledge map systems exist to find people. Like CMSs, BI supports the combination process. However, CMSs deal basically with documents that are usually nonstructured and appear in a great va-

Table 1. Categories of knowledge management software: Summary table

Category	Dominating Knowledge Conversion Processes	Origin of Concepts	Examples
Intranet-Based Systems	Externalization, Combination, Internalization	Computer Networks (Web Technology)	Apache HTTP Server
Content Management Systems	Combination	Information Science	Excalibur Retrieval Ware and File Net
Groupware	Socialization, Externalization, Internalization	CSCW (Computer-Supported Cooperative Work)	Lotus Family (Notes, Sametime) and MS Suite (Exchange, Outlook, Messenger)
Work Flow	Externalization	Organization and Methods	ARIS Toolset (IDS Scheer)
Artificial Intelligence-Based Systems	Externalization, Combination, Internalization	Artificial Intelligence	Neugents (Computer Associates)
Business Intelligence	Combination	Database Management	Business Objects and Oracle 10g BI
Knowledge Maps	Socialization	Information Science and Human Resource Management	Gingo (Trivium) and Lotus Discovery Server
Innovation Support Tools	Combination, Internalization	Innovation and Technology Management	Goldfire Innovator (Invention Machines)
Competitive Intelligence Tools	Combination	Strategic Management and Information Science	Knowledge Works (Cipher Systems) and Vigipro (CRIQ/CGI)
Knowledge Portals	Socialization, Externalization, Combination, Internalization	Computer Networks and Information Science	Hummingbird and Plumtree

riety of formats, while the basic BI structure is a database record with specific attributes and a standardized format. Finally, the users of innovation support tools are usually technicians, engineers, or scientists who are involved in some creative design process inside an R & D department, while managers are BI's typical users.

FUTURE TRENDS

There seems to be a trend of functional convergence in KM systems. Preserving initial features, vendors are incorporating extra features from others categories described in the typology presented in this article, transforming their products into KM-integrated suites. For instance, a BI system may start to offer a knowledge map feature in a new version. So, it seems that increasingly, KM software will be classified in more than one of the presented categories, which can be alternatively considered as an array of features for KM systems.

The portal technology is the materialization of this convergence trend. Scientific research about portal features and types of KM systems seems to merge, following the movement of the KM software market. Collins (2003) and Detlor (2004) are examples of this recent approach. According to Collins, the knowledge portal's basic features are BI, collaboration, and content management. As a result, a basic portal will require the integration of at least four KM systems presented in this article: the intranet, CMS, groupware, and BI.

Integration can be a cumbersome task and may not be seen as a short-term project, especially in the case where there are heterogeneous systems scattered all over the organization. Firestone (2003) emphasizes the role of XML (extensible markup language) in portal architecture and presents relations between portal-integration efforts and the current research concerning EAI (enterprise application integration). The better choice is to consider a knowledge portal as a gradual project, allowing organizations to expand later the capabilities and functionalities delivered through the portal.

CONCLUSION

The wise selection of KM software requires a previous analysis of an organization's knowledge needs. Among the considerations to be addressed in some organizations is the fact, for instance, that a low level of socialization may be the critical point; in other ones, externalization may need to be improved.

As to the adoption process, it is interesting to notice the differences between KM software and ERP (enterprise resource planning) systems. ERPs are usually implemented in a top-down style, and the organization generally has to adjust its processes to the system in a short period of time. It is impossible to do the same with a KM system. The commitment and motivation of members are crucial to any KM program, much more than better KM software. KM requires a long term strategy to involve people and break paradigms. Also, policies referring to participation, flexibility, autonomy, and career evolution must surely be adapted.

KM software can be considered an interdisciplinary business because their development requires not only technical skills, but also a deep understanding of social and managerial aspects. In this sense, Choo et al. (2000) suggest that intranet designers look for the lessons learned from the field of CSCW. Recommendations include the need to ensure that everyone benefits from groupware, the need to understand the current work practice, and the involvement of users in design.

As a result of the research presented in this article, we conclude that KM software is evolving in order to offer an integrated platform for organizational knowledge conversion processes. But this does not mean that the resources of KM software are already well exploited by the orga-

nizations that have adopted them. As reported in literature and as we have ourselves learned from the study of two Brazilian organization systems (Carvalho, 2000), their potential is most frequently underevaluated and unexplored. In fact, their actual utilization stresses mainly their support of information access and retrieval, while their communication and collaboration dimensions are yet to be discovered.

The implementation of KM systems is a complex process. The KM software needs not only to be integrated to the existing IT infrastructure, but to the organizational culture, procedures, and human resource policy as well. The correct balance between managerial and technical aspects constitutes one of KM-tool adoption's greatest challenges. According to Detlor (2004), culture and user behaviors are the key drivers and inhibitors of internal sharing, and organizations should develop ways of stimulating people to use and contribute to KM systems.

Many organizations that are implementing KM programs focus exclusively on the conversion of human capital into structural capital. They think of KM as an opportunity to extract part of the knowledge of their employees and store it in knowledge bases. This approach misunderstands the dynamic and complex characteristics of knowledge, its tacit-prevailing nature, and the fact that, more than existing knowledge, the incessant creation of knowledge is the distinctive feature.

The KM concept has recently been severely criticized (Berkman, 2001), and one of the reasons for this may be the excessive emphasis on software and methodologies per se. This argument emphasizes the importance of considering technology in its context, that is, of relating it to the complexity of knowledge processes in order not to over (or under) estimate technology, or to miss the opportunity of bringing knowledge to where it belongs: the center of organizational attention.

KEY TERMS

Competitive Intelligence: Set of interrelated measures that aim at systematically feeding the organizational decision process with information about the organizational environment in order to make it possible for people to learn about it, to anticipate its evolution, and to make better decisions in consequence.

CSCW (Computer-Supported Cooperative Work): Branch of computer science dedicated to the study of groupware technologies.

Enterprise Information Portal (EIP): Single Web interface to corporate information.

Expert System: A special type of artificial intelligence system that contains a limited domain knowledge base, an inference mechanism to manipulate this base, and an interface to permit the input of new data and user dialog.

Groupware: Type of software that is designed to help teams that are geographically dispersed who need to work together.

Intelligent Agent: Software component capable of acting autonomously by perceiving the environment, evaluating choices, and deciding on actions without checking the user.

Knowledge Portal: A personalized interface to online resources for knowledge workers to integrate applications and data. It is an evolution of EIP.

Neural Networks: A system composed of a large number of software nodes connected by weighted links. The system learns by adjusting those weights through repetitive learning cycles.

OLAP (Online Analytical Processing): Front-end tool that allows the analysis of multidimensional data. It is commonly used in business intelligence systems.

Chapter 1.30
Malicious Software

Thomas M. Chen
Southern Methodist University, USA

Gregg W. Tally
SPARTA, Inc., USA

INTRODUCTION

Malicious software (malware) allows an intruder to take over or damage a target host without the owner's consent and often without his or her knowledge. Over the past thirty years, malware has become a more serious worldwide problem as Internet-connected computers have proliferated and operating systems have become more complex. Today, the average PC user must be more cognizant of computer security than ever before due to the constant threat of possible infection. Although exact costs are difficult to determine, there is little doubt that malware has widespread impact on equipment damages, loss of data, and loss of productivity. According to surveys, malware is one of the most common and costly types of attack on organizations (CERT, CSO, & ECTF, 2005).

In the early days of computing, malware was predominantly viruses and Trojan horses that spread among computers mainly by floppy disks and shared files (Grimes, 2001). The typical virus writer was a young male experimenting by himself and looking for notoriety. Today, malware is largely worms, viruses, spyware, bots, and Trojans proliferating through computer networks. Worms are a particular concern due to their ability to spread by themselves through computer networks. They can exploit weaknesses in operating systems or common applications such as Web and e-mail clients. They are often used as vehicles to install other types of malware onto hosts. Many thousands of worms and viruses are constantly tracked by the WildList (Wildlist Organization International, 2006) and antivirus companies.

Naturally, host-based and network-based defenses have also evolved in sophistication in response to growing threats. Surveys have found that organizations almost universally use antivirus software, firewalls, intrusion detection systems, and other means of protection (Gordon, Loeb, Lucyshyn, & Richardson, 2005). These defenses certainly block a tremendous amount of malware and prevent global disasters. However, their effectiveness is widely known to be limited

by their ability to accurately detect malware. Detection accuracy is critical because malware must be blocked without interfering with legitimate computer activities or network traffic. This difficulty is compounded by the creativity of attackers continually attempting to invent new methods to avoid detection.

BACKGROUND

Self-Replicating Malware

Malware can be classified into self-replicating or nonself-replicating. Self-replicating malware consists of viruses and worms. Fred Cohen originated the term virus after biological viruses for their manner of parasitically injecting their RNA into a normal cell, which then hijack the cell's reproductive process to produce copies of the virus (Cohen, 1994). Analogously, computer viruses attach their code to a normal program or file, which takes over control of execution of the infected program to copy the virus code to another program.

Polymorphism was a major development in virus evolution around 1990. Polymorphic viruses are able to scramble their form to have at most a few bytes in common between copies to avoid detection by virus scanners. In 1991, the dark avenger's mutation engine was an easy to use program for adding polymorphism to any virus. A number of other "mutation engines" were subsequently created by other virus writers.

A new wave of mass-mailing viruses began with Melissa in 1999. It was a macro virus infecting Microsoft Word normal templates. On infected computers, it launched Microsoft Outlook and e-mailed copies of itself to 50 recipients in the address book. It demonstrated the effectiveness of e-mail as a propagation vector, infecting 100,000 computers in 3 days. Since then, e-mail has continued to be a popular vector for viruses and worms because e-mail is used by everyone across different operating systems (Harley, Slade, & Gattiker, 2001). Mass-mailing worms today often carry their own SMTP engines to mail themselves and circumvent security features in e-mail programs.

Whereas viruses are program fragments dependent on execution of a host program, worms are standalone programs capable of spreading by themselves (Nazario, 2004; Skoudis, 2004). A worm searches for potential targets through a computer network and sends a copy of itself if the target is successfully compromised. Worms take advantage of networks and have proliferated as Internet connectivity has become ubiquitous.

One of the earliest and most famous worms was written by Robert Morris Jr. in 1988. Perhaps released accidentally, it disabled 6,000 hosts, which was 10% of the ARPANET (the predecessor to the Internet). A number of fast worms, notably Code Red I, Code Red II, and Nimda appeared in 2001. Two years later, another wave of fast worms included SQL Slammer/Sapphire, Blaster, and Sobig.F. The following year was dominated by MyDoom, Netsky, and Bagle worms (Turner et al., 2006).

Nonself-replicating malware classification of nonself-replicating malware into disjoint subcategories is difficult because many types of nonself-replicating malware share similar characteristics. Perhaps the largest category is Trojan horses defined as programs with hidden malicious functions. A Trojan horse may be disguised as a legitimate program to avoid detection. For example, a Trojan horse could be installed on a host with the name of a legitimate system file (displacing that file). Alternatively, the intention of the disguise could be to deceive users into executing it. For example, a Trojan horse could appear to be a graphic attachment in an e-mail message but in actuality be a malicious program. Trojans do not replicate by themselves but could spread by file sharing or downloading.

Remote administration or access trojans (RATs) are a well-known type of trojan horse

giving covert remote control to attackers. One of the first was Netbus written in 1998. It works in a client-server fashion with the server component installed on the target machine responding to the attacker's client. Another well-known RAT was Back Orifice released by Cult of the Dead Cow in 1998, which was later released as an open source version Back Orifice 2000.

A backdoor is software giving access to a system bypassing normal authentication mechanisms (Skoudis, 2004). Programmers have written backdoors sometimes to allow convenient access for legitimate testing or administrative purposes, but backdoors can be installed and exploited by attackers to maintain covert remote control after a target has been compromised. For example, the Nimda worm dropped a backdoor on infected hosts.

Relatively recently, bots such as Spybot and Gaobot have become a major problem (Turner et al., 2006). Bots installed on a group of hosts act as a large bot net to carry out a remote attacker's instructions which are typically communicated via Internet relay chat (IRC). Bot net sizes in the thousands to hundreds of thousands have been observed. Bot nets have been rented or sold as platforms for spamming, distributed denial of service, and other criminal activities (Lewis, 2005).

A rootkit is low-level software, possibly at the kernel level, designed to conceal certain files and processes. Rootkits are sometimes bundled as part of malware such as worms (Hoglund & Butler, 2006) because the concealment allows attackers to maintain longer control over their targets.

Spyware is software that collects and sends personal information through the network to a remote attacker (Evans, 2005). Spyware may be bundled with a legitimate program, and its presence may be mentioned in a end user license agreement (EULA). Commonly, a type of spyware called adware is bundled for the purpose of collecting information about user behavior to customize delivery of advertising. Accepting the EULA is considered explicit agreement to installation of the spyware, but many people neglect to read EULAs carefully. More pernicious types of spyware deliberately hide their presence and attempt to steal personal data by recording data to a file which is transmitted to or retrieved by a remote attacker.

MALICIOUS SOFTWARE

Malware involves an ongoing conflict between attackers and defenders. Worms are a prime example of a malware attack. Computers are typically protected by a combination of host-based and network-based defenses.

Self replication basics worms actively select and attack their targets through a network automatically. The capability for self replication is enabled by certain functions in the worm code (Skoudis, 2004). First, a function for target location chooses the next host for attack. The simplest algorithm chooses random IP address as pseudorandomly generated 32-bit numbers. Random target selection is not completely effective because the B and C class address spaces are more populated. Hence, some worms target B and C class addresses more often. Also, some worms favor targets on the same local area network as the victim because they are easier to reach. Another common way to identify targets is to harvest e-mail addresses from the victim host.

Second, a function in the worm code must contain the infection mechanism to compromise a selected target. The most common method is an exploit of a vulnerability. Most operating systems and applications software have vulnerabilities or weaknesses discovered over time. The most common type of vulnerability is a buffer overflow, which can lead to running arbitrary malicious code on a target host if attacked successfully (Foster, Osipov, Bhalla, & Heinen, 2005). When a vulnerability is discovered, the software developer is usually notified privately and given a chance

to develop a patch or update. The vulnerability may be publicly disclosed later along with the patch. Vulnerabilities are regularly published in Microsoft security bulletins, CERT advisories, Bugtraq, MITRE CVEs, and other places. This process allows users to update their systems before attackers can write the exploit code that takes advantage of the vulnerability. Other vulnerabilities may be discovered by attackers but not disclosed, in hopes of catching targets unprotected against so-called zero-day exploits.

Exploits are not the only way for worms to spread. Social engineering takes advantage of human gullibility to trick users into taking an action to help the worm (e.g., opening an e-mail attachment). Password attacks attempt to compromise a target by trying default passwords, easily guessed passwords, or cracking the password file. Another way to spread is to look for backdoors left by other worms.

Worms can easily include multiple exploits to compromise more targets faster. The Morris worm was an example using a combination of different exploits to attack targets: a buffer overflow exploit of the Unix finger daemon; an exploit of the debug mode of the sendmail program; and cracking the password file by a dictionary attack. Another prominent example of a blended threat was Nimda in 2001, using five different vectors.

A third function in the worm code enables replication of the worm to a compromised target. Replication might be combined with the exploit. For example, SQL Slammer/Sapphire carried a buffer overflow exploit and a copy of the worm within a single 404-byte UDP packet.

Finally, worm code may optionally contain a payload. The payload is executed on the target and might be virtually anything such as data theft, data deletion, or installation of other malware.

Host-Based Defenses

The most common suite of host-based defenses includes antivirus software, spyware detection software, and a personal firewall. Antivirus and antispyware software aim to identify specific malware, disinfect, or remove infected files, and prevent new infections if possible. Antivirus and antispyware programs largely work by signatures, which are sets of characteristics that will identify a specific malware (Szor, 2005). Signatures are preferred for their accuracy in identifying known malware, but new malware without a matching signature can escape detection. Antivirus software typically include heuristic rules to detect suspicious new malware based on their behavior or construction. For example, behavior blocking looks at the behavior of programs and raises a warning if the behavior appears suspicious. The disadvantage of heuristics is a possibly high rate of false positives (false alarms).

Another defense against malware is software patching. Software developers often publicize new vulnerabilities along with patches for them. This works for known vulnerabilities but not all vulnerabilities are known by the developers. Also, it can be inconvenient for users to keep up with regular patching.

Host-based intrusion detection systems are processes that observe system activities and raise alarms for suspicious activities. For example, if someone fails several consecutive login attempts, that would be a suspicious activity suggesting that the person does not know the correct password.

Lastly, computers typically include personal firewalls, implemented as software at the network interface. Incoming and outgoing traffic is blocked according to the firewall policies. There might be firewalls on the perimeter of a user's network, but a personal firewall allows packet filtering to be customized to individual preferences.

Network-Based Defenses

Compared to host-based defenses, network-based defenses have the advantage of providing broad protection to groups of users without any special requirements on hosts (Nazario, 2004).

Firewalls are perhaps the best known network defense (Northcutt, Zeltser, Winters, Fredrick, & Ritchey, 2002). Firewalls apply filtering rules to block malicious traffic including malware. Rules are often based on fields in packet header fields such as source and destination addresses, source and destination ports, and protocol.

Routers with access control lists (ACLs) can block traffic similarly to firewalls. Routers must process packet headers for the purpose of forwarding packets along the correct routes. ACLs are simply additional rules to specify which packets are dropped.

Network-based intrusion detection systems (IDS) are specialized equipment to observe and classify traffic as normal, suspicious, or malicious. IDS raise alarms for suspicious traffic but do not take active actions (intrusion prevention systems have that additional capability to block malicious traffic). Like antivirus software, IDS typically work by a combination of signature-based and behavior-based detection (also called misuse and anomaly detection). Signatures are traffic characteristics that unique identify malware traffic and are preferred for accurate detection. However, not all malware traffic is known, and therefore malware might escape signature-based detection (Riordan, Wespi, & Zamboni, 2005). Behavior-based or anomaly detection aims to identify all suspicious traffic that deviates in some sense from normal traffic.

Honeypots are decoy computers intentionally set up to look vulnerable to attackers (Spitzner, 2003). They are not used for legitimate services so all traffic received by a honeypot is unsolicited and inherently suspicious. Their general purpose is to learn about attacker behavior but can be configured to collect malware, particularly worms that choose their targets automatically and randomly. The risks associated with malware impose the necessity for special precautions to limit possibly compromised honeypots from spreading malware to other computers.

CHALLENGES

New vulnerabilities are constantly being discovered in operating systems and applications software, giving rise to new exploits for malware. Turner et al. (2006) reported an average of 10 new vulnerabilities discovered per day. Accurate detection of new exploits requires signatures, but signatures usually takes a few hours to days to develop. In the absence of a signature, the effectiveness of defenses will depend on the accuracy of anomaly (or behavior-based) detection. Anomaly detection based on unique behavioral traits of worms is an active area of research (Al-Hammadi & Leckie, 2005; Gu, Sharif, Qin, Dagon, Lee, & Riley, 2004; Kawaguchi, Azuma, Ueda, Shigeno, & Okada, 2006). For example, random worms might be inferred by the observation of a large number of failed connection messages (Berk, Bakos, & Morris, 2003). Another active research problem is automated defenses after detection such as automatic generation of worm signatures (Newsome, Karp, & Song, 2005; Simkhada, Tsunoda, Waizumi, & Nemoto, 2005) or dynamic quarantine (Moore, Shannon, Voelker, & Savage, 2003).

The situation is complicated by the many means of self-preservation that malware today often use. First, malware attempts to be stealthy through polymorphism or rootkit techniques. Second, malware can actively attack defenses. It is not uncommon for viruses and worms to disable antivirus software on targets by stopping antivirus processes and disabling registry keys. Third, malware has the capability to dynamically download new code or plug-ins, changing its functionality.

FUTURE TRENDS

Malware is always seeking new propagation vectors in addition to the Internet. Recently, malware

has begun to spread via wireless networks to mobile devices such as cell phones and PDAs and is increasingly targeting instant messaging (Turner et al., 2006). E-mail and social engineering will continue to be popular propagation vectors.

The changing nature of payloads, increasingly towards remote control and data theft, suggests that malware is become more used for cybercrimes. Malware for profit has been called crimeware. This trend is also suggested by increasing use of stealth techniques.

Finally, worm outbreaks have become faster than humans can respond. For example, SQL Slammer/Sapphire is reported to have infected 90 percent of the vulnerable hosts within 10 minutes. This trend means more dependence on automated defenses in the future. However, the effectiveness of automated defenses will depend on a solution to the problem of accurate detection.

CONCLUSION

Current defenses based on signatures and anomaly detection are imperfect. Signatures are preferred for accuracy but take time to develop and distribute. On the other hand, anomaly detection has the difficult challenge of differentiating normal from malicious behavior. In the future, malware attacks will be carried out faster, and we will depend more on automated defenses. These defenses will need solutions to automating signature development and making anomaly detection more accurate.

Finally, users are an important part of security. Since malware often use social engineering, user education and awareness of secure practices (such as patching and antivirus updating) are essential. Just as with anything valuable, users must be constantly vigilant to protect their computers and data.

KEY TERMS

Antivirus: Software to detect viruses and worms, clean infected files, and prevent new infections.

Exploit: Software written to take advantage of a specific vulnerability.

Firewall: A device or software to selectively filter packets.

Intrusion Detection System: A device or software to detect suspicious or malicious activities.

Malware: Software intended to perform a malicious action.

Rootkit: Low-level software designed to avoid detection on a compromised host.

Spyware: A type of malware that collects personal user information and transmits to a remote attacker.

Trojan Horse: A type of malware with a hidden malicious function.

Virus: A type of self-replicating malware that infects other files or programs.

Vulnerability: A security weakness in operating system or application software.

Worm: A standalone program capable of automated replicating itself through a computer network.

Chapter 1.31
Current Challenges in Intrusion Detection Systems

H. Gunes Kayacik

A. Nur Zincir-Heywood
Dalhousie University, Canada

INTRODUCTION

Along with its numerous benefits, the Internet also created numerous ways to compromise the security and stability of the systems connected to it. In 1995, 171 vulnerabilities were reported to CERT/CC © while in 2003, there were 3,784 reported vulnerabilities, increasing to 8,064 in 2006 (CERT/CC©, 2006). Operations, which are primarily designed to protect the availability, confidentiality, and integrity of critical network information systems are considered to be within the scope of security management. Security management operations protect computer networks against denial-of-service attacks, unauthorized disclosure of information, and the modification or destruction of data. Moreover, the automated detection and immediate reporting of these events are required in order to provide the basis for a timely response to attacks (Bass, 2000). Security management plays an important, albeit often neglected, role in network management tasks.

Defensive operations can be categorized in two groups: static and dynamic. Static defense mechanisms are analogous to the fences around the premises of a building. In other words, static defensive operations are intended to provide barriers to attacks. Keeping operating systems and other software up-to-date and deploying firewalls at entry points are examples of static defense solutions. Frequent software updates can remove the software vulnerabilities, which are susceptible to exploits. Firewalls provide access control at the entry point; they therefore function in much the same way as a physical gate on a house. In other words, the objective of a firewall is to keep intruders out rather than catching them. Static defense mechanisms are the first line of defense, they are relatively easy to deploy and provide significant defense improvement compared to the

initial unguarded state of the computer network. Moreover, they act as the foundation for more sophisticated defense mechanisms.

No system is totally foolproof. It is safe to assume that intruders are always one step ahead in finding security holes in current systems. This calls attention to the need for dynamic defenses. Dynamic defense mechanisms are analogous to burglar alarms, which monitor the premises to find evidence of break-ins. Built upon static defense mechanisms, dynamic defense operations aim to catch the attacks and log information about the incidents such as source and nature of the attack. Therefore, dynamic defense operations accompany the static defense operations to provide comprehensive information about the state of the computer networks and connected systems.

Intrusion detection systems are examples of dynamic defense mechanisms. An intrusion detection system (IDS) is a combination of software and hardware, which collects and analyzes data collected from networks and the connected systems to determine if there is an attack (Allen, Christie, Fithen, McHugh, Pickel, & Stoner, 1999). Intrusion detection systems complement static defense mechanisms by double-checking firewalls for configuration errors, and then catching the attacks that firewalls let in or never perceive (such as insider attacks). IDSs are generally analyzed from two aspects:

- **IDS deployment:** Whether to monitor incoming traffic or host information.
- **Detection methodologies:** Whether to employ the signatures of known attacks or to employ the models of normal behavior.

Regardless of the aspects above, intrusion detection systems correspond to today's dynamic defense mechanisms. Although they are not flawless, current intrusion detection systems are an essential part of the formulation of an entire defense policy.

DETECTION METHODOLOGIES

Different detection methodologies can be employed to search for the evidence of attacks. Two major categories exist as detection methodologies: misuse and anomaly detection. Misuse detection systems rely on the definitions of misuse patterns, which are the descriptions of attacks or unauthorized actions (Kemmerer & Vigna, 2002). A misuse pattern should summarize the distinctive features of an attack and is often called the signature of the attack in question. In the case of signature based IDS, when a signature appears on the resource monitored, the IDS records the relevant information about the incident in a log file. Signature-based systems are the most common examples of misuse detection systems. In terms of advantages, signature-based systems, by definition, are very accurate at detecting known attacks, which are included in their signature database. Moreover, since signatures are associated with specific misuse behavior, it is easy to determine the attack type. On the other hand, their detection capabilities are limited to those within signature database. As the new attacks are discovered, a signature database requires continuous updating to include the new attack signatures, resulting in potential scalability problems. Furthermore, attackers are known to alter their exploits to evade signatures. Work by Vigna, Robertson, Balzarotti (2004) described a methodology to generate variations of an exploit to test the quality of detection signatures. Stochastic modification of code was employed to generate variants of exploits to render the attack undetectable. Techniques such as packet splitting, evasion, and polymorphic shellcode were discussed.

As opposed to misuse IDSs, anomaly detection systems utilize models of the acceptable behavior of the users. These models are also referred to as normal behavior models. Anomaly-based IDSs search for the deviations from the normal behavior. Deviations from the normal behavior are consid-

ered as anomalies or attacks. As an advantage over signature-based systems, anomaly-based systems can detect known and unknown (i.e., new) attacks as long as the attack behavior deviates sufficiently from the normal behavior. However, if the attack is similar to the normal behavior, it may not be detected. Moreover, it is difficult to associate deviations with specific attacks since the anomaly-based IDSs only utilize models of normal behavior. As the users change their behavior as a result of additional service or hardware, even the normal activities of a user may start raising alarms. In that case, models of normal behavior should be redefined to maintain the effectiveness of the anomaly-based IDS. Similar to the case of misuse IDSs, attackers are known to alter their exploits to be recognized as normal behavior by the detector, hence evading detection. The general approach employed for evading anomaly detectors is based on the generation of mimicry attacks to perform evasion. A mimicry attack is an exploit that exhibits legitimate normal behavior while performing malicious actions. Methodologies exist to create mimicry attack automatically (Giffin, Jha, & Miller, 2006; Kayacik, Zincir-Heywood, & Heywood, 2007) or manually (Kruegel, Kirda, Mutz, 2005; Tan, Killourhy, & Maxion, 2002; Wagner & Soto, 2002).

In today's intrusion detection systems, human input is essential to maintain the accuracy of the system. In the case of signature-based systems, as new attacks are discovered, security experts examine the attacks to create corresponding detection signatures. In the case of anomaly systems, experts are needed to define the normal behavior. Therefore, regardless of the detection methodology, frequent maintenance is essential to uphold the performance of the IDS.

Given the importance of IDSs, it is imperative to test them to determine their performance and eliminate their weaknesses. For this purpose, researchers conduct tests on standard benchmarks (Kayacik & Zincir-Heywood, 2003; Pickering, 2002). When measuring the performance of intrusion detection systems, the detection and false positive rates are used to summarize different characteristics of classification accuracy. In simple terms, false positives (or false alarms) are the alarms generated by a nonexistent attack. For instance, if an IDS raises alarms for the legitimate activity of a user, these log entries are false alarms. On the other hand, detection rate is the number of correctly identified attacks over all attack instances, where correct identification implies the attack is detected by its distinctive features. An intrusion detection system becomes more accurate as it detects more attacks and raises fewer false alarms.

IDS DEPLOYMENT STRATEGIES

In addition to the detection methodologies, data is collected from two main sources: traffic passing through the network and the hosts connected to the network. Therefore, according to where they are deployed, IDSs are divided into two categories: those that analyze network traffic and those that analyze information available on hosts such as operating system audit trails. The current trend in intrusion detection is to combine both host-based and network-based information to develop hybrid systems and therefore not rely on any one methodology. In both approaches however, the amount of audit data is extensive, thus incurring large processing overheads. A balance, therefore, exists between the use of resources, and the accuracy and timeliness of intrusion detection information.

Network-based IDSs inspect the packets passing through the network for signs of an attack. However, the amount of data passing through the network stream is extensive, resulting in a trade off between the number of detectors and the amount of analysis each detector performs. Depending on throughput requirements, a network-based IDS may inspect only packet headers or include the content. Moreover, multiple detectors are typi-

cally employed at strategic locations in order to distribute the task. Conversely, when deploying attacks, intruders can evade IDSs by altering the traffic. For instance, fragmenting the content into smaller packets causes IDSs to see one piece of the attack data at a time, which is insufficient to detect the attack. Thus, network-based IDSs, which perform content inspection, need to assemble the received packets and maintain state information of the open connections, where this becomes increasingly difficult if a detector only receives part of the original attack or becomes "flooded" with packets.

A host-based IDS monitors resources such as system calls made by critical applications, logs, file systems, processor, and disk resources. Example signs of intrusion on host resources are unusual system call sequences, critical file modifications, segmentation fault errors, crashed services, or extensive usage of the processors. As opposed to network based IDSs, host-based IDSs can detect attacks, which are transmitted over an encrypted channel. Moreover, information regarding the software that is running on the host is available to host-based IDS. For instance, an attack targeting an exploit on an older version of a web server might be harmless for the recent versions. Network-based IDSs have no way of determining whether the exploit has a successful chance, or of using a priori information to constrain the database of potential attacks. Moreover, network management practices are often critical in simplifying the IDS problem by providing appropriate behavioral constraints, thus making it significantly more difficult to hide malicious behaviors (Cunningham, Lippmann, & Webster, 2001).

CHALLENGES

The intrusion detection problem has three basic competing requirements: speed, accuracy, and adaptability. The speed problem represents a quality of service issue. The more analysis (accurate) the detector, the higher the computational overhead. Conversely, accuracy requires sufficient time and information to provide a useful detector. Moreover, the rapid introduction of both new exploits and the corresponding rate of propagation require that detectors be based on a very flexible/scalable architecture. In today's network technology, where gigabit Ethernet is widely available, existing systems face significant challenges merely to maintain pace with current data streams (Kemmerer & Vigna, 2002).

An intrusion detection system becomes more accurate as it detects more attacks and raises fewer false alarms. IDSs that monitor highly active resources are likely to have large logs, which in turn complicate the analysis. If such an IDS has high false alarm rate, the administrator will have to sift through thousands of log entries, which actually represent normal events, to find the attack related entries. Therefore, increasing false alarm rates will decrease the administrator's confidence in the IDS. Moreover, intrusion detection systems are still reliant on human input in order to maintain the accuracy of the system. In case of signature-based systems, as new attacks are discovered, security experts examine the attacks to create corresponding detection signatures. In the case of anomaly systems, experts are needed to define the normal behavior. This leads to the adaptability problem. The capability of the current intrusion detection systems for adaptation is very limited. This makes them inefficient in detecting new or unknown attacks or adapting to changing environments (i.e., human intervention is always required). Although a new research area, incorporation of machine learning algorithms provides a potential solution for accuracy and adaptability of the intrusion detection problem.

CURRENT EXAMPLES OF IDS

Intrusion detection systems reviewed here are by no means a complete list but a subset of open

source and commercial products, which are intended to provide readers different intrusion detection practices.

- **Snort:** Snort is one of the best-known lightweight IDSs, which focuses on performance, flexibility, and simplicity. It is an open-source intrusion detection system that is now in quite widespread use (Roesch, 1999). Snort is a network-based IDS which employs signature-based detection methods. It can detect various attacks and probes including instances of buffer overflows, stealth port scans, common gateway interface attacks, and service message block system probes (Roesch, 1999). Hence, Snort is an example of active intrusion detection systems that detects possible attacks or access violations while they are occurring (CERT/CC ©, 2001).
- **Cisco IOS (IDS Component):** Cisco IOS provides a cost-effective way to deploy a firewall with network-based intrusion detection capabilities. In addition to the firewall features, Cisco IOS Firewall has 59 built-in, static signatures to detect common attacks and misuse attempts (Cisco Systems, 2003). The IDS process on the firewall router inspects packet headers for intrusion detection by using those 59 signatures. In some cases, routers may examine the whole packet and maintain the state information for the connection. Upon attack detection, the firewall can be configured to log the incident, drop the packet or reset the connection.
- **Tripwire:** When an attack takes place, attackers usually replace critical system files with their versions to inflict damage. Tripwire (Tripwire Web Site, 2004) is an open-source host-based tool, which performs periodic checks to determine which files are modified in the file system. To do so, Tripwire takes snapshots of critical files. Snapshot is a unique mathematical signature of the file where even the smallest change results in a different snapshot. If the file is modified, the new snapshot will be different than the old one, therefore critical file modification would be detected. Tripwire is different from the other intrusion detection systems because rather than looking for signs of intrusion, Tripwire looks for file modifications. Tripwire also offers a commercial version of the open source detector.
- **Stide:** Stide (Forest et al.,1996) employs a methodology based on immune systems where the problem is characterized as distinguishing self from nonself (normal and abnormal behaviors respectively). An event horizon is built from a sliding window applied to the sequence of system calls made by an application during normal use. The sequences formed by the sliding window are then stored in a table, which comprises the normal database. During the detection phase, if a pattern from the sliding window is not in the normal database, it is flagged as an anomaly. Recent work proposed improvements on Stide by employing finite state automata (Sekar et al., 2001), virtual path tables (Feng et al., 2003) and static analysis of the source code of the application (Wagner et al., 2001).

FUTURE TRENDS

As indicated above, various machine learning approaches have been proposed in an attempt to improve on the generic signature-based IDS. The basic motivation is to measure how close a behavior is to some previously established gold standard of misuse or normal behavior. Depending on the level of a priori or domain knowledge, it may be possible to design detectors for specific categories of attack (e.g., Denial of Service, User to Root, Remote to Local). Generic machine learning approaches include clustering or data-mining

in which case the data is effectively unlabeled. The overriding assumption is that behaviors are sufficiently different for normal and abnormal behaviors to fall into different "clusters." Specific examples of such algorithms include artificial immune systems (Hofmeyr & Forrest, 2000) as well as various neural network (Kayacik, Zincir-Heywood, & Heywood, 2003; Lee & Heinbuch, 2001) and clustering algorithms (Eskin, Arnold, Prerau, Portnoy, & Stolfo, 2002).

Naturally, the usefulness of machine learning systems is influenced by the features on which the approach is based (Lee & Stolfo, 2001). Domain knowledge that has the capability to significantly simplify detectors utilizing machine learning often make use of the fact that attacks are specific to protocol-service combinations. Thus, first partitioning data based on the protocol-service combination significantly simplifies the task of the detector (Ramadas, Ostermann, & Tjaden, 2003).

When labeled data is available, then supervised learning algorithms are more appropriate. Again, any number of machine learning approaches have been proposed, including: decision trees (Elkan, 2000), neural networks (Hofmann & Sick, 2003), and genetic programming (Song, Heywood, & Zincir-Heywood, 2003). However, irrespective of the particular machine learning methodology, all such methods need to address the scalability problem. That is to say, datasets characterizing the IDS problem are exceptionally large (by machine learning standards). Moreover, the continuing evolution of the base of attacks also requires that any machine learning approach also have the capability for online or incremental learning. Finally, to be of use to network management practitioners, it would also be useful if machine learning solutions were transparent. That is to say, rather than provide "black box solutions," it is much more desirable if solutions could be reverse engineered for verification purposes. Many of these issues are still outstanding, with cases that explicitly address the computational overhead in learning against large datasets only just appearing (Song, Heywood, & Zincir-Heywood, 2003).

CONCLUSION

Intrusion detection system is a crucial part of the defensive operations, which complements the static defenses such as firewalls. Essentially, intrusion detection is searching for signs of attacks and when an intrusion is detected, intrusion detection system can take an action to stop the attack by closing the connection or report the incident for further analysis by administrators. According to the detection methodology, intrusion detection systems can be categorized as misuse detection and anomaly detection systems. According to the deployment, they can be classified as network-based or host-based, although such distinction is coming to an end in today's intrusion detection systems where information is collected from both network and host resources. In terms of performance, an intrusion detection system gets more accurate, as it detects more attacks and raises fewer false alarms. However, no intrusion detection is infallible, attackers use detector weaknesses and blind spots to evade intrusion detection systems. Fortunately, penetration testing and ethical hacking became a part of the field of research.

KEY TERMS

Attack vs. Intrusion: A subtle difference—intrusions are the attacks that succeed. Therefore, the term *attack* represents both successful and attempted intrusions.

CERT / CC ©: CERT Coordination Center. Computer security incident response team, which provide technical assistance, analyze the trends of attacks, and provide response for incidents. Documentation and statistics are published at their web site: http://www.cert.org.

Exploit: Taking advantage of a software vulnerability to carry out an attack. To minimize the risk of exploits, security updates, or software patches should be applied frequently.

Fragmentation: When the data packet is too large to transfer on given network, it is divided into smaller packets. These smaller packets are reassembled on destination host. Among with

other methods, intruders can deliberately divide the data packets to evade IDSs.

Light Weight IDS: An intrusion detection system, which is easy to deploy and have smaller footprint on system resources.

Logging: Recording vital information about an incident. Recorded information should be sufficient to identify the time, origin, target, and if applicable, characteristics of the attack.

Machine Learning: A research area of artificial intelligence, which is interested in developing algorithms to extract knowledge from the given data.

Open Source Software: Software with its source code available for users to inspect and modify to build different versions.

Penetration Testing: A part of computer security research, where the objective of an "ethical hacker" is to discover the weaknesses and blind spots of the security software such as intrusion detection systems.

Security Management: In network management, the task of defining and enforcing rules and regulations regarding the use of the resources.

ABSTRACT

Finding the right software is often hindered by different criteria as well as by technology changes. We performed an analytic hierarchy process (AHP) analysis using Expert Choice to determine which data mining package was best suitable for us. Deliberating a dozen alternatives and objectives led us to a series of pair-wise comparisons. When further synthesizing the results, Expert Choice helped us provide a clear rationale for the decision. The issue is that data mining technology is changing very rapidly. Our article focused only on the major suppliers typically available in the market place. The method and the process that we have used can be easily applied to analyze and compare other data mining software or knowledge management initiatives.

INTRODUCTION

Based on the *knowledge life cycle* model, four stages of knowledge creation, knowledge storage/retrieval, knowledge transfer, and knowledge application have been proposed by Alavi and Leidner

(2001) and confirmed by Jennex (2006). "To be effective knowledge management systems, KMS, must support the various knowledge management functions of knowledge capture, storage, search, retrieval, and use" (Jennex, 2006, p.3). Knowledge discovery is generally one of the important stages or phases of KM. And while this incorporates identifying critical knowledge (this may also be what this stage is called), using data mining to aid in knowledge discovery is appropriate as being a useful KM tool.

Data mining is a promising tool that assists companies to uncover patterns hidden in their data. These patterns may be further used to forecast customer behavior, products and processes. It is important that managers who understand the business, the data, and the general nature of the analytical methods are involved. Realistic expectation can yield rewarding results across a wide range of applications, from improving revenues to reducing costs (Davenport & Harris, 2007; Porter & Miller, 2001). It is crucial to properly collect and prepare the data, and to check the models against the real figures. The best model is often found after managers build models of several different types or by trying different technologies or algorithms. This alone demonstrates the active role managers play in the data mining or other knowledge management processes.

Selecting software is a practical yet very important problem for a company (James, Hakim, Chandras, King, & Variar, 2004). However, not enough attention is given to this critical task. Current literature is quite limited because selecting software is such a complex problem, due to many criteria and frequent technology changes (Elder IV & Abbott, 1998; Giraud-Carrier & Povel, 2003). Haughton, Deichmann, Eshghi, Sayek, Teebagy, and Topi (2003) generally reviewed several computer *software packages* for *data mining, including* SPSS Clementine, XLMiner, Quadstone, GhostMiner, and SAS Enterprise Miner. Corral, Griffin, and Jennex (2005) examined the potential of knowledge management in data warehousing from an expert's perspective. Jennex (2006) introduced technologies in support of knowledge management systems.

Firstly, this article will take a brief look at data mining today, through describing some of the opportunities, applications and available technologies. We will then discuss and analyze several of the most powerful data mining software tools available on the market today. Ultimately, we will also attempt to provide an analytical analysis and comparison among the brands we have selected. Our selection is based, in part, on our own experience using data mining software as well as writing data mining code, SQL code and our work as relational database administrators. For our analytical comparison we will be using *Expert Choice* (Version 11) advanced decision support software.

DATA MINING SOFTWARE

Data mining software analyzes- based on open-ended user queries- relationships and patterns that are stored in transaction data. Available are several types of analytical software: statistical, machine learning and neural networks, decision trees, Naive-Bayes, K-Nearest Neighbor, rule induction, clustering, rules based, linear and logistical regression time sequence, and so forth. Along the lines of Mena (1998) and Martin (2005), the basic steps of data mining for knowledge discoveries are:

1. Define business problem
2. Build data mining data base
3. Explore data
4. Prepare data for modeling
5. Build model
6. Evaluate model
7. Deploy model
8. Results

Note: Each of these steps contains managerial issues which must be addressed.

The key to knowledge discovery is a true understanding of your data and your business. Without this understanding, no algorithm is going to provide you with a result in which you should confide. Moreover, without this background you will not be able to identify the problems you are trying to solve, prepare the data for mining, or correctly interpret the results. There are many tasks involved in the construction of a database: data collection, data description, selection, data quality assessment and data cleansing, consolidation and integration, metadata construction, and maintaining the database. In exploring the data, the manager must choose the appropriate hardware to accomplish this feat. The goal is to identify the most important fields in predicting an outcome, and determine which derived values may be useful. According to O Chan (2005), a good interface and fast computer response are very important in this phase because the very nature of your exploration is changed when you often have to wait up to 30 minutes for some graphs to be created.

Preparing data for modeling consists of four main parts: selecting variables, selecting rows, constructing new variables and transforming variables. The managerial decision in this case focuses on identifying key variables to examine, nonfully functional variables inclusive. The time it takes to build a model increases with the number of variables while blindly including extraneous columns can lead to incorrect models. The most important thing to remember about data model building is that it is an interactive process. Many alternative models may have to be examined to find one that is most appropriate in solving your business problem. A manager searching for a good model may go back and amend the data he or she is using or even modify his or her problem statement. In the evaluation and interpretation process, the accuracy rate found during testing applies only to the data on which the model was built. The accuracy may vary if the data to which the model is applied differ in important and unpredictable ways from the original data set.

Once a data mining model is built and validated, it can be used in two main ways. First, the manager may recommend actions based on simply viewing the model and its results. For example, the manager may look at the clusters the model has identified, the rules that define the model or the lift and ROI charts that depict the effect of the model. The second process involves applying the model to different datasets. The manager may use the model to flag records based on their classification or assign a score such as the probability of an action.

Data Mining Software Alternatives

As stated earlier in our introduction, there are numerous data mining software alternatives that vary in the number of modeling and visualization nodes as well as in price. We have elected the following eight software vendors for comparison due to a limitation of trial version of *Expert Choice* (Version 11):

- Clementine from SPSS
- DB2 Intelligent Miner from IBM
- Enterprise Miner from SAS
- GhostMiner by Fujitsu
- Insightful Miner V5.2 for Insightful
- Megaputer PolyAnalyst
- Microsoft SQL Server 2005 Enterprise Edition
- Oracle Data Miner

Although there are various other comparable programs available, we were limited in our selection. One of the limiting factors was the inadequacy of alternatives in our decision tools' evaluation copy.

Decision Tool

To aid in comparing our software choices, we used an evaluation copy of *Expert Choice* version 11, a leading software solution construed to analyze, categorize, prioritize, select, allocate and choose a selection based on relevant criteria (Expert Choice Inc, 2007). *Expert Choice* incorporates a process known as *Analytical Hierarchical Process* (AHP) into its software (Saaty & Vargas, 2006; Saaty, 1980, 1996, 2001, 2005). Research has demonstrated that AHP is a powerful decision-making tool that can help organizations avoid making costly mistakes caused by bad decisions (Hemaida & Schmits, 2006). AHP was developed by Saaty and Kearns and consists of four stages (Roper-Lowe & Sharp, 1990). The first stage is to construct a hierarchy where the primary objective, or goal, is at the highest level. Criteria, which can also be subdivided, follow in decreasing order. At the bottom of the hierarchy are the alternatives to be evaluated. The second stage calculates weights for the criteria using pair-wise comparisons. In the next stage, the alternatives are also compared to each other in respect to each criterion. Finally, all weighted scores are tallied to yield a final score. The alternative with the highest score is considered the best alternative.

SAMPLE PRODUCTS

In this section, we will analyze the various features and benefits offered by each of our software alternatives that are to be considered, as well as researching product reviews and professional opinions. The information gathered from this analysis will serve as the basis for the pair-wise comparisons of the software alternatives with respect to each of our criteria In other words, we will investigate how important one choice is over the other alternative given a specific criterion, when comparing any two software alternatives,

CART by Salford Systems

CART is an easy to use decision tree tool that uses the CART algorithm and boosting. Its main objective is to rifle through databases, identifying significant patterns and relationships, which are then used to generate predictive models. CART uses an exhaustive, recursive partitioning routine to generate binary splits by posing a series of yes-no questions. It searches for questions that split nodes into relatively homogenous child nodes. As the tree evolves, the nodes become more homogenous, identifying segments. CART supports more than 80 file formats, including SAP, SPSS databases such as Oracle and Informix, Excel spreadsheets, and Lotus 1-2-3 spreadsheets.

CART was formulated from the original CART code developed by Stanford University and University of California at Berkeley statisticians. The frequent addition of new features and capabilities continually enhances the procedure, strengthening the accuracy and reliability of the results. CART has a no-stopping rule, which makes it unique. This means that more data are read and compared, and it ensures that important data are not overlooked by stopping too soon. It produces an over-grown tree, and immediately prunes it back for the most optimal results. CART also uses a powerful binary split search approach. This means the trees are more sparing with data and detect more structure before too little data are left for learning. Next, CART uses automatic self-validation procedures, which are essential in avoiding the trap of finding patterns that apply only to the training data.

CART was designed for both technical and nontechnical users. It can quickly identify important data relationships. It offers users some flexibility, with the choice of how to split criteria. It also offers different models for scalability. The results are easy to read and understand, with decision tree diagrams drawn out. Salford Systems understands that expert and timely technical

support is a critical part of the business, which is why they offer many means of customer training and support. The company offers both public and private on-site instruction, user seminars, hand-on training courses, consultation services, and e-mail, NetMeeting, and phone support from offices worldwide.

SPSS—Clementine

Clementine data mining software by SPSS is useful for organizations using SPSS infrastructure as well as those with mixed platforms. This program supports both client and server platforms, including the Windows family of products and Sun Solaris, HP-UX11i, IBM AIX, and OS/400 server platforms.

With regard to reliability, Clementine by SPSS supports decision trees, neural networks, regression, self-organizing maps, clustering, and association rules (Lampe & Garcia, 2004). However, the author states that Clementine implements "a broad set of statistical algorithms, but fewer than in the SAS and IBM packages" (Lampe & Garcia, 2004, p. 18).

In the area of efficiency, Clementine works with SPSS, SAS and SQL and can export to C code and Predictive Model Markup Language (PPML) (Angus, 2006). It can also handle critical data preparation, rapid modeling, and model scoring tasks. These tasks are all performed using GUI graphical layouts, workflow diagrams, scatterplots, distribution, histogram, multiplot and Web charts (which are unique to Clementine (Haughton et al., 2003)).

Training and support for Clementine are available from SPSS in the form of online tutorials, downloadable overview and demos of the program, along with online technical support and excellent help screens. The price of Clementine starts at $75,000 (Angus, 2006).

Enterprise Miner by SAS

Enterprise Miner was developed by SAS Corporation, which was originally called Statistical Analysis System. Enterprise Miner is an integrated software product that provides widespread business solutions for data mining based on SEMMA (Sample, Explore, Modify, Model, Assess) methodology. It has many different statistical tools including decision trees, clustering, linear and logistic regression and neural networks. Data preparation tools include outlier detection, variable transformations, random sampling, and the partitioning of data sets into training, test, and validation data sets. Its advanced GUI allows you to review large amounts of data in multidimensional histograms with ease, as well as compare modeling results graphically.

Enterprise Miner includes several procedures that automate traditional analysis tasks, such as choosing the variables to include in a model and applying the appropriate transformations. The system also provides extensive visualization to help users explore the data to decide on additional manipulations that the system itself does not recommend. Enterprise Miners' graphical user interface and automated framework indicate that the user does not have to know how the tools work to use them. Release 8.2 provides cross-platform national language support that is especially important to international customers.

GhostMiner by Fujitsu

GhostMiner is a data mining software product from Fujitsu that not only supports common databases (or spreadsheets) and mature machine learning algorithms, but also assists with data preparation and selection, model validation, multimodels (like committees or k-classifiers), and visualization. GhostMiner provides a large range of **data preparation** techniques and a broad

scope of **selection of featured** methods. Choice of data mining algorithms and v**isualization techniques** are integrated.

GhostMiner offers several project features unique to their platform, which enables users to create simple interfaces for their specific needs. GhostMiner has a human machine interface (HMI) that is fairly user friendly and easy to start up right out of the box. The system is so easy to use that it actually has a feel of being too user friendly and may be missing some of the power of the larger server based data mining software tool such as Darwin IBM and Oracle. GhostMiner can be loaded directly onto a Windows based PC and is equally adept at data mining a system database as it is a series of spreadsheets, text or ASCII files.

GhostMiner contains both data preprocessing capabilities as well as data visualization capabilities. Data preprocessing includes data normalization, standardization and many preliminary statistical analysis functions, such as variance, standard deviation, mean and median across the entire database. GhostMiner does not have the inherent flexibility of some of the larger, more robust products, and also does not offer the same levels of support as the products offered by Oracle and IBM. GhostMiner is a product marketed to small to mid size users who are looking for a simple to use product at a lower price than some of its larger, well known counterparts.

Insightful-Insightful Miner

Insightful Miner is a cost effective data mining software program. The software has numerous model types, algorithms and visualizers, including decision trees, *Block Model Averaging*, linear and logistic regression, neural networks, Naïve Bayes, Cox proportional hazard models, K-means clustering and others. Insightful Miner offers highly scalable algorithms, which train models on very large data sets without the need for sampling or aggregation. Insightful also offers data preprocessing and data cleansing as well as exploratory data analysis and visualization. Insightful Miner's cost is typically $12,000.

According to a product review in *DM Review* (Lurie, 2004) the main strength of Insightful Miner is its ability to scale large data sets in an accessible manner. It provides the analytic tools required to transform fragmented raw data into "actionable knowledge" (Lurie, 2004, p. 88). Insightful Miner provides cutting edge analytics and reporting tools to identify patterns, trends and relationships in data. Insightfuls' simplicity allows users to quickly aggregate, clean and analyze data. Its powerful reporting and modeling capabilities allow users to deliver clear, usable analytics to designers and producers. Simple visual work maps make it easy for users to become productive relatively quickly. Insightful Miner provides excellent product support and its documentation is complete and easy to understand.

In another product review of Insightful Miner (Deal, 2004), the software was found to be a comprehensive data mining application that includes extensive data input, data manipulation, and analysis capabilities. Insightful Miner can efficiently process large amounts of data by using a chunking and processing algorithm that is intended to be scalable to the mass of data used for each analysis. Insightfuls' ability to integrate S-Plus strengthens and extends its functionality. Deal (2004) stated that Insightful Miner "is a very simple and intuitive process" (p. 46).

IBM-Intelligent Miner

IBM Intelligent Miner V7R1 is very user friendly software. It is an essential e-commerce tool, as it can aid in handling transactions as they come in. It has business intelligence applications, which allow it to make decisions that would be good for any business, large or small. The intelligence part of the software could cut costs and increase profits. The data screens help with decision making and improvement on processes that are out of

date. It also maximizes the business to customer relationship, because of the personalization the software can provide for each client. This software package is also compatible with Windows, AIX, Solaris and Linux servers.

IBM Intelligent Miner V7R1 has IM Scoring, in which the user has an advantage, because scores and ranks are done in real time. This means that as a new transaction takes place, it would then reorganize the scores/ranks of the customers' information. For example, when a customer buys an item off the Internet, the software would update for the payment due and when it should be posted. The same would apply for a dentist visit: after 6 months it would indicate that it is time for another checkup for the particular patient. As the appointment would approach, the higher the person would be on the list, that is, moving up the ranks. Another advantage with the IM Scoring is the high performance and scalability of mining functions, thus making sampling obsolete.

The best aspect of this product is its user friendliness. The whole staff would be content with it. It can also be updated easily, without any disruption to the business. IBM is currently promoting the DB2 Query Management Facility version 8.1, because in March 2006, IBM withdrew Intelligent Miner from all marketing and ended all its support for Intelligent Miner tools.

Megaputer-PolyAnalyst

Another data mining software package is PolyAnalyst (the newest version is 4.6) made by the Megaputer Company. This company is quite small, especially compared to some of the other companies we have profiled. Megaputer Intelligence Inc. is a leading developer and distributor of advanced software tools for data mining, text mining, and intelligent e-commerce personalization. The tools help reveal knowledge hidden in data. They add intelligence and insight to every step of the business decision-making process.

Because the Megaputer Company focuses primarily on data mining programs, they can offer a more comprehensive program than other companies who simply have a data mining component to existing products. They offer a vast array of algorithms from which a consumer can choose the ones they need specifically, making the product ready to be customized. The price for an older version of PolyAnalyst (the most recent pricing data found) is an affordable $2,300 for the base version and can go up to $14,900 with all the algorithms. Also, the developer kit for PolyAnalyst is available for $16,000.

PolyAnalyst can be run either on a stand-alone system or in a client/server configuration, where the server would handle the data processing. It only works with the Microsoft Windows O/S, which shows that it is not as portable as some other products analyzed. Also, Megaputer offers possible users a free evaluation version to decide if this is the software right for them. The program offers a rich set of features. PolyAnalyst by Megaputer seems to be a feature rich data mining software package. The price and ala carte feature set seem more suited for a smaller company that cannot afford to use a more expensive data mining solution that would require the use of highly trained employees.

Oracle–Oracle Data Mining

Oracle Data Miner is the graphical user interface for Oracle Data Mining (Release 10.1 and above) that helps data analysts mine their Oracle data to find valuable hidden information, patterns, and new insights. Oracle Data Mining is a powerful data mining software embedded in the Oracle Database that enables you to discover new information hidden in your data and helps businesses target their best customers and find and prevent fraud.

Oracle provides unique portability across all major platforms including Windows, Solaris, HP-

UX, IBM AIX, Compaq Tru64, and Linux and ensures that applications run without modification after changing platforms. There are two common ways to architect a database: client/server or multitier. Two basic memory structures are associated with Oracle software: the system global area and the program global area.

Oracle Data Miner facilitates interactive data preparation, data mining model creation, evaluation, refinement and model scoring. Oracle Data Mining provides the following supervised data mining algorithms: Naïve Bayes, Adaptive Bayes Network, decision trees, Support Vector Machines, and attribute importance. Unsupervised algorithms are: clustering, association rules, feature selection, anomaly detection, text mining and unstructured data, and life sciences algorithm. Mining Activity Guides provide structured templates for all users to explore and mine their data.

Oracle Data Mining (ODM) enables companies to extract information efficiently from the very largest databases, and build integrated business intelligence applications and support data mining problems such as: classification, prediction, regression, clustering, associations, attribute importance, feature extraction and sequence similarity searches and analysis. When the capabilities of Oracle Data Mining are combined with the ability of the RDBMS to access, preprocess, retrieve and analyze data, they create a very powerful platform for data analysis.

Oracle Data Mining can generate valuable new insights and reports that can help proactively manage your business, according to the Oracle Discoverer report. Oracle Data Miner models can be visualized graphically and can be display in tables, histograms, line graphs and pie graphs. Data may be in either Excel or the Database. Significant productivity enhancements are achieved by eliminating the extraction of data from the database to special-purpose data mining tools (Berger & Haberstroh, 2005).

Data size is unlimited. The expert analyst can adjust some or all of the parameters manually, but the option to allow the algorithms to optimize the parameters intelligently, with no intervention, is available. There are free demos available: Oracle Data Mining, Integration with Oracle BI EE, Spreadsheet Add-in for Predictive Analytics, and Text Mining. The tutorial Oracle by Example series and online training provides valuable hands-on experience, step-by-step instructions on how to implement various technology solutions to business problems. Oracle Data Mining significantly reduces the cost of data mining. Savings are realized in the avoidance of additional hardware purchases for computing and storage environments, redundant copies and multiple versions of the data and duplication of personnel who perform similar functions. Database analytics includes: engine, basic statistics (free), data mining, and text mining.

SQL Server 2005

SQL server 2005 is Microsoft's solution to database management and data mining. SQL Server database platform provides enterprise-class data management with integrated business intelligence (BI) tools. SQL Server 2005 combines analysis, reporting, integration, and notification. SQL server is closely integrated with Microsoft Visual Studio, the Microsoft Office System, and a suite of new development tools, including the Business Intelligence Development Studio (Bednarz, 2005).

Microsoft SQL Server series utilizes the Windows operating system and features four discrete algorithms. HMI features include a Windows' interface, as well as complete integration with the Microsoft Office suite. Reports that are served by the Report Server in Reporting Services can run in the context of Microsoft SharePoint Portal Server and Microsoft Office System applications such as Microsoft Word and Microsoft Excel (Fontana, 2005). SharePoint can be used to subscribe to

reports, create new versions of reports, and distribute reports. SQL Server 2005 also supports rich, full-text search applications. Query performance and scalability have been improved dramatically, and new management tools will provide greater insight into the full-text implementation.

SQL Server also features an online restore function, database encryption and a fast recovery option. It also has a system with built-in scalability features such as parallel partition processing, creation of *remote relational online analytical processing* (ROLAP) or *hybrid online analytical processing* (HOLAP) partitions, distributed partitioned cubes, persisted calculations, and proactive caching.

COMPARISON

We use *Expert Choice* in the evaluation process and will attempt to analytically quantify the aspects of data mining software that best define overall product quality. Before we describe the decision making process, we would like to present several assumptions on which our decision will be based:

1. In addition to our experience, we will rely on manufacture specifications, descriptions and described attributes, along with third party reviews where available.
2. We will base our needs on fundamental business goals such as business-related decision making and business-driven information analysis. Although this definition may seem overly broad, we will attempt to further limit our scope by eliminating research and development, educational and political as well as most human resource applications.
3. Because we are using a trial version of *Expert Choice* advanced decision making software, there will be limits with respect to importing and exporting data as well as with printing and possibly some advanced analytical tools. Therefore, we will utilize screen captures embedded into this document, and will manually write any necessary data as opposed to systematic imports or exports.

Criteria Revisited

Our selection process will be centered on the below mentioned software quality criteria. We will attempt to compare all of our selections based on the specified criteria. Using *Expert Choice*, we will make objective ratings of each product, comparing in a pair-wise manner, attributes that define each element.

- **Portability:** the amount of platform independence; the number of support platforms and supported software architectures as well as any software requirements needed to run the software.
- **Reliability:** the degree of completeness, accuracy and consistency, any stated warranty and support provided by the vendor. The number of data models and algorithms available with the software as well as any templates or custom models available for creation of projects.
- **Efficiency:** the degree of efficiency and accessibility; the degree in which the product supports the general business goal assumptions and the number of tools available for data preprocessing.
- **Human engineering:** how well the software interfaces and communicates with the outside world, plus the quality of the human machine interface (HMI). Testability – how well the software is structured; how results are displayed and how results are reintroduced into the process if applicable.
- **Understanding:** degree of self-descriptiveness; the degree of simplicity of the machine

interface, the use of graphical user interfaces, visual programming ability, summary reports, and data model visualization.

- **Modifiability:** the degree of augmentation ability and the ability to change over time and expand; the use of batch processing and any expert options as well as data size limitations.
- **Price, training and support:** price of product, availability of evaluation or demo versions, and the amount of post purchase support included in the package.

Evaluation Model

Our evaluation criteria, as entered in the Expert Choice, are as follows:

- Portability: evaluated in terms of:
  - Hardware platform (PC, Unix/Solaris workstation, etc.).
  - Software Architecture (standalone, client/server, thin client).
  - Software requirements (DB2, SAS, Base, Java/JRE, Oracle, and so forth.
- Reliability - evaluated in terms of:
  - What model classes does the tool support?
  - How many algorithms does the tool use?
  - Does the tool allow custom model creation or simply uses templates?
  - What is the reputation of the vendor supplying the tool?
- Efficiency evaluated in terms of:
  - How well does the product support our general business goal assumption?
  - Ability to perform data preprocessing.
- Human Engineering evaluated in terms of:
  - Simplicity of HMI (human machine interface)
  - Graphical layout
  - Visual programming ability
- Testability evaluated in terms of dissemination and deployment:
  - How well the results are reintroduced into the process "closing the loop"
  - How results are displayed
- Understanding in terms of evaluation and interpretation of data:
  - Are summary reports available?
  - Can the model be visualized graphically?
- Modifiability in terms of scalability and upgrades:
  - What is the data set size limit?
  - Are there expert options or batch processing?
- Training and support evaluated in terms of:
  - Is a free demo available?
  - Is any free training or support available with the purchase?
- Price (where available) – if pricing is not available we will note our evaluation as price neutral.

PROCEDURE OF EXPERT CHOICE

Let's use five products to demonstrate the whole process of *Expert Choice* on a small scale. We commence with pair-wise comparisons for each of our criteria. Figure 1 is a screen capture of our initial results of priorities. As can be seen in Table 1, we placed a great deal of importance on Human Engineering (weight of .220), slightly less on Training and Support (w=. 193) and then on Understanding (w=. 190). Our main driver was that for the software to be successful, people had to know and understand it. Our next highest priority was Reliability, with a relative weight of .142, followed by Portability, which is platform and hardware independence, with a relative weight of .128.

Next, we perform a pair-wise comparison of each software tool for each criterion; that is, we compare the components of each criterion on a case-by-case basis, assigning relative strengths and weaknesses to each product. Although this process is quite tedious, it provides an accurate measurement for each product. Table 2 shows an example of a pair-wise comparison for the contribution of hardware platform independence to overall platform independence, which is a contributor to overall portability within our quality structure.

Table 3 shows a graphical representation from the pair-wise comparison between all products for the hardware contribution, to overall portability. The screen capture shows a weight for each product with SQL Server as the best in class (with a weight of .269) and GhostMiner as last in class (with a weight of .109). These criteria are also weighted individually so as to roll up into the overall contribution toward portability.

Table 1. Weights assigned to criteria

Category	Priorities
Human Engineering	0.22
Training and Support	0.193
Understandability	0.19
Reliability	0.142
Portability	0.128
Modifiability	0.051
Efficiency	0.039
Testability	0.022
Price	0.016

Overall Results

Table 4 shows the overall results from *Expert Choice* advanced decision support software. From the first iteration of our selection process, the best solution for our chosen attributes and assigned priorities is the CART product, with an overall weight of .268, followed by SAS Enterprise with an overall weight of .223. We also performed several iterations, changing the weights of our criteria.

Table 5 shows the assigned weights of each category along with the overall score for all of the objects. This tool allows dynamic sensitivity

Table 2. Pair-wise comparison grid WRT hardware platform

	CART by Salford Systems	SAS Enterprise Miner	Oracle 8i	GhostMiner	SQL Server 2005
CART by Salford Systems		3.0	3.0	3.0	7.0
SAS Enterprise Miner			2.0	3.0	4.0
Oracle 8i				3.0	3.0
GhostMiner					4.0
SQL Server 2005					
Inconsistency: 0.73					

Table 3. Class weightings for overall hardware platform independence

Vendor	Class Weighting
CART by Salford Systems	0.268
SAS Enterprise Miner	0.223
Oracle 8i	0.215
GhostMiner	0.141
SQP Server 2005	0.152
Overall inconsistency: 0.28	

Table 4. Results from "Choosing a data mining software vendor"

Vendor	Overall Weight
CART by Salford Systems	0.191
SAS Enterprise Miner	0.215
Oracle 8i	0.222
GhostMiner	0.109
SQP Server 2005	0.263
Inconsistency: 0.73	

Table 5. Dynamic sensitivity analysis

Category	Category Weight	Vendor	Vendor Preference Weight
Portability	12.8%	CART by Salford Systems	26.8%
Reliability	14.2%	SAS Enterprise Miner	22.3%
Efficiency	3.9%	Oracle 8i	21.5%
Human Engineering	22.0%	GhostMiner	14.1%
Testability	2.2%	SQL Server 2005	15.2%
Understandability	19.0%		
Modifiability	5.1%		
Training and Support	19.3%		
Price	1.6%		

analysis with respect to changing priorities. We used this tool to look at how much a change in one weight changes the overall goal. Using this tool is similar to the sensitivity analysis performed in Excel Solver; however, instead of listed ranges the Expert Choice tool allows for dynamic manipulation. From the chart, we can see our weighted emphasis on Human Engineering (22%), Training

Table 6. Dynamic sensitivity analysis with different constraints

Category	Category Weight	Vendor	Vendor Preference Weight
Portability	0.1%	CART by Salford Systems	24.0%
Reliability	2.6%	SAS Enterprise Miner	18.5%
Efficiency	3.2%	Oracle 8i	17.1%
Human Engineering	5.8%	GhostMiner	20.8%
Testability	3.3%	SQL Server 2005	19.6%
Understandability	21.5%		
Modifiability	4.1%		
Training and Support	15.7%		
Price	33.5%		

and Support (19.3%) and Understandability. The window on the right shows which system best fits our stated criteria.

In Table 6 we change our requirements in order to verify the strength of our decision. We increase the importance of Price from 1.6% all the way up to 33.5%. We also change our Human Engineering requirement from 22% down to 5.8%, and also reduce Training and Technical Support, Portability, Reliability, Efficiency and Modifiability (flexibility) substantially and still came up with CART systems as our best overall choice (24% weight).

SCENARIO ANALYSIS

We now start to compare eight leading data mining packages based on seven criteria. Determining the best software is a multiple objective decision-making process because different companies may have completely different needs. An array of software may each be the best choice because their design and performance are defined within a certain type of institution. Usually, one data mining software cannot be the best for every scenario. This is because specific software cannot meet the expectations of every type of institution; therefore, the creation of scenarios is a very important tool in term of decision-making process.

In order to make this project more accurate and realistic, we have combined different scenarios. Factors, such as size, budget, type of business, and the type of data we have to manipulate, can affect the software we attempt to choose and the reasons why we choose it. Having simulated many scenarios, we found that size is a decisive factor. For instance, if we choose two companies with different sizes and follow a traditional reasoning, the tentative result may contradict with our intuition.

After researching all the alternatives, we used our decision tool, *Expert Choice*, to make pairwise comparisons for each of them. A total of 392

pair-wise comparisons were required to compare each of the alternatives with respect to each of the criteria (196 comparisons for each scenario). This was in addition to the 42 pair-wise comparisons required to assign weights to each criterion with respect to the goal (21 comparisons for each scenario). After completing all of the pair-wise comparisons the software synthesized all of the weights of the alternatives with the weights of the criteria and selected the best alternative of each of the two scenarios. Table 7 below summarizes the weights of the pair-wise comparisons for each of the alternatives with respect to each criterion. As with the weights of the criteria, there is also a direct relationship between the calculated weights in each column and the respective criterion. In other words, the higher a number is in a given column the more important that sized company views that particular software for that specific criterion.

Based on our research of all the alternatives and the weighted criteria calculated by our decision tool, the software has determined that for a small-sized company the top three alternatives are Insightful Miner, Megaputer PolyAnalyst, and SAS Enterprise Miner. These results were somewhat unexpected. We had anticipated that Insightful, Megaputer, and GhostMiner would

Table 7. Weights assigned to each alternative for both a small and large-sized company

Synthesized Weights - with respect to criteria	Efficiency		Human Engineering\ Understandability		Modifiability		Portability

be among the top three or four alternatives for a small-sized company, primarily because each of these vendors offer stand-alone versions of their software and are also the least expensive among all the alternatives. However, GhostMiner ranked lower than expected while SAS Enterprise Miner ranked higher. A closer analysis of the pair-wise comparisons shows that SAS was more efficient and had better human engineering than GhostMiner. Because of the weights given to these two criteria, SAS Enterprise Miner was able to beat all of the other alternatives despite its cost.

According to our decision tool, the top three alternatives for a large company are SPSS Clementine, followed by SAS Enterprise Miner and Insightful Miner. There was not one overwhelming choice for a large company. The differences in weight among the top three alternatives were relatively small (16.7%, 15.9%, and 13.5%, respectively). These results were also a little unanticipated. All of the software reviews that we have read rated SPSS and SAS among the top leading data mining software that are commercially available. We had not expected Insightful Miner to rank among the top three alternatives for a large company. We anticipated that Microsoft, IBM, or Oracle would round out the top three alternatives because these vendors offer enterprise class DBMS. Upon closer examination of the software analysis, Insightful Miner's visualization and modeling nodes were comparable to those of an enterprise class data mining software program such as Enterprise Miner and Clementine. In addition, a closer review of the pair-wise comparisons showed that Insightful Miner ranked higher than the other alternatives (with the exception of SAS and SPSS) in human engineering and efficiency. It also tied for top weight for Training and Support/Price. Table 8 below summarizes the results of the Expert Choice software.

Certainly, different companies may have different priorities, preferences, and prerequisites. We have explored a few individual scenarios.

Special Case 1: This is a large international company, with thousands of employees, doing business between U.S., Mexico and other countries in Latin America. It is an import and export company. The main goal of using data mining software is to determine the best distribution methods in order to maximize profits. Keeping costs down so it can compete with other companies is always a concern. The three main criteria this company is looking for in a software package are: Training and Support with multilingual support because of the language difference between the countries,

Table 8. Summary of synthesized results for each sized company

Synthesized Weights - with respect to goal	Large Company	Small Company
Clementine	0.167	0.138
Enterprise Miner	0.159	0.140

SQL Server 2005	0.102	0.092
Overall inconsistency ratio	**0.010**	**0.020**

Human Engineering to assure that employees in different countries with possibly different computer skill levels, will be able to adapt and use the software, and Portability because it is an established company with an IT department and different platforms that include Microsoft, IBM and Sun Microsystems, as well as a range of desktop operating systems that includes Windows 2000 and XP, Linux, and old legacy equipment. They must be certain that the software is compatible with all existing platforms. Because large amounts of data are processed, software must be robust and reliable as well.

- **Our goal is:** To find the best data mining software.
- **Our criteria are:** Listed seven factors. The three most important criteria are Training and Support, Human engineering, and Portability.
- **Our alternatives are:** Clementine, Enterprise Miner, Oracle, Microsoft SQL, IBM DB2, Salford CART, Megaputer, and Insightful Miner.

Criteria	Weights
Portability	.215
Modifiability	.181
Training and Support	.147

Enterprise Miner	.126
Oracle	.162
Microsoft SQL	.109
IBM DB2	.117
Salford CART	.123
Megaputer	.111
Insightful Miner	.117

Special Case 2: This is a large national corporation, between 500 and 1,000 employees, in the retail industry with many branches throughout the country. They already have an IT department and different types of platforms, including Unix Servers and Microsoft 2000 and 2003, as well as XP and 2000 Workstations. Portability is very important to make sure that the software is able to run with the platforms already in place. This company already has a well-established customer base, so the goal of choosing data mining software is to find the best way to maximize customer retention, while lowering costs. The three most important criteria that this company is looking for in a software package are: Portability, Efficiency to assure it supports the general business goal assumption, and Modifiability because it is a growing business, and they want to be sure that they can go back and customize the software if necessary.

Other Cases

Online Company/E-commerce

An online/e-commerce company in the recently growing industry: First of all, because an Internet company has both actual and potential customers, it needs a tool that can hold and analyze large amounts of data. Secondly, it might have engineers or a technical department, so it may not put weight on human engineering and training and support. Consequently, we put more weight on modifiability and less weight on engineering and support. As a result, Oracle would be the best tool for an online/e-commerce company because it scores the highest among eight tools. If Oracle is not available, IBM would be the second choice.

Educational Institutions

Data mining software is used worldwide in the educational industry. One of Megaputer's data mining software called PolyAnalyst gets a majority of its business from educational industry. Microsoft SQL came in first place with Ghost-Miner as the runner up.

Even though these scenarios can be used as references, they did not apply to every type of institution. Thus, it will be interesting to see what other choices are available in term of the best data mining software. What would be the best data mining software for a medical institution?

CONCLUSION

With the use of *Expert Choice* we were able to analytically evaluate eight products within a complex yet controlled environment. The detailed analysis included prioritizing our constraints, evaluating the contributing criteria, entering comparative data and performing relevant sensitivity analysis. The software, *Expert Choice,* performed the analysis, based on our definition, priorities and data.

Data mining technology is changing very rapidly. Our article focused only on the major suppliers typically available in the market place. There is no definite and explicit answer as to which tool is better suited to potential clients, mainly due to their unique priorities. As there are so many variables to quantify, the problem needs to be defined. Based on what approach the problem requires, then and only then can tools start being quantified. Certainly, the method and the process that we have used can be easily applied to analyze and compare other data mining software for each potential user. Although there is no pattern for pairing the correct software with the proper institution, with the use of this process, every institution should be able to determine which data mining software is the best for their operations.

ACKNOWLEDGMENT

We would like to thank Dr. Jennex, the *Edit-in-Chief of IJKM*, for his tremendous help and guidance during the period of revising our manuscript for more than one year. Dr. Jennex has suggested *Scenario Analysis,* a practical and wonderful idea, and offered many other specific suggestions.

Chapter 1.33
Intelligent User Preference Mining

Sheng-Uei Guan
Xian Jiatong-Liverpool University, China

Ping Cheng Tan
National University of Singapore, Singapore

INTRODUCTION

A business-to-consumer environment can be developed through software agents (Guan, Zhu, & Maung, 2004; Maes, 1994; Nwana & Ndumu, 1996; Wang, Guan, & Chan, 2002) to satisfy the needs of consumers patronizing online e-commerce or m-commerce stores. This includes intelligent filtering services (Chanan & Yadav, 2000) and product brokering services to understand user's needs better before alerting users of suitable products according to their preference.

We present an approach to capture individual user response towards product attributes including nonquantifiable responses. The proposed solution can capture the user's specific preference and recommend a list of products from the product database. With the proposed approach, the system can handle any unaccounted attribute that is undefined in the system. The system is able to cater to any unaccounted attribute through a general descriptions field found in most product databases. In addition, the system can adapt to changes in user's preference.

BACKGROUND

In e-commerce activities, consumers are confused by the large number of options and varieties of goods available. There is a need to provide on top of the existing filtering and search services (Bierwirth, 2000) an effective piece of software in the form of a product brokering agent to understand their needs and help them in selecting products.

Definitions

A user's choice in selecting a preferred product is often influenced by the product attributes ranging from price to brand name. This research will

classify attributes as accounted, unaccounted, and detected. The same attributes may also be classified as quantifiable or nonquantifiable. *Accounted attributes* are attributes that the system is specially customized to handle. A system is designed to capture the user's choice in terms of price and brand name, making them accounted attributes. *Unaccounted attributes* are not predefined in the system ontology. The system does not know whether an unaccounted attribute represents a product feature. Such attributes merely appear in the product descriptions field of the database. The system will attempt to identify unaccounted attributes that affect the user's preference and consider them as *detected attributes*. Thus, detected attributes are unaccounted attributes that are detected to be crucial in affecting the user's preference.

Quantifiable attributes contain specific numeric values (e.g., memory size) and their values are well defined. Nonquantifiable attributes on the other hand do not have any logical or numeric values, and their valuation could differ from user to user (e.g., brand name). The proposed system defines price and quality of a product in the ontology and considers them to be quantifiable, accounted attributes.

Related Work

One of the research goals among related work is to understand a user's needs before recommending products through the use of product brokering services. Due to the difference in complexity, different approaches were proposed to handle quantifiable and nonquantifiable attributes. One approach to handling quantifiable attributes is to compile these attributes and assign weights representing their relative importance to the user (Guan, Ngoo, & Zhu, 2002; Sheth & Maes, 1993; Zhu & Guan, 2001). The weights are adjusted to reflect the user's preference.

Much research aimed at creating an interface to understand user preference in the context of nonquantifiable attributes. This represents a more complex problem as attributes are highly subjective with no discrete metric to measure their values. Different users give different values to a particular attribute. MARI (Multi-Attribute Resource Intermediary) (MARI, 2007) proposed a "word-of-mouth" approach to solving this problem. The project split up users into general groups and estimated their preference to a specific set of attributes through the group each user belongs to. Another approach to handling nonquantifiable attributes involves requesting the user for preferred attributes. Shearin and Liberman (2001) provided a learning tool for users to explore their preferences before requesting them to suggest desirable attributes.

The problems in related work lie in the handling of nonquantifiable attributes, as the approaches are too general. Most work so far only attempted to catch user preference through generalization and stereotyping instead of understanding specific user needs. Another problem is that most works are only able to handle a specific set of attributes. The attributes to be handled are hard-coded into the system design, and the consequence is that it is not able to handle attributes that are unaccounted. However, the list of product attributes is often large. The approach used in related research may not be able to cover all the attributes, as they need to classify them into the ontology.

DESCRIPTION OF INTELLIGENT USER PREFERENCE DETECTION

The proposed approach attempts to capture user preference based on two quantifiable accounted attributes, price and quality. It learns incrementally any unaccounted attribute that affects a user's preference. If any unaccounted attribute is suspected, the system comes up with a list of candidate attributes and verifies their importance through a genetic algorithm (Haupt & Haupt, 1998). Thus, attributes that were unaccounted for

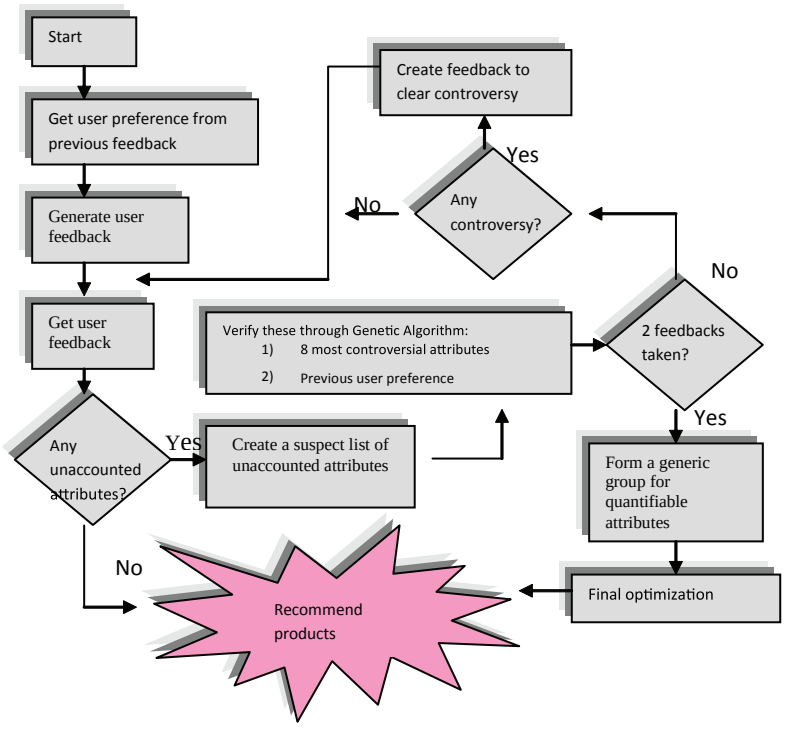
previously will be considered. The unaccounted attributes are derived from the general descriptions field of a product. The approach is therefore adaptive in nature, as the system is not restricted by the attributes it is designed to cater to.

The overall procedure is shown in Figure 1. The system first retrieves any captured information regarding the user from previous feedback and generates a list of products from the product database for the user to rank and investigates the presence of any unaccounted attribute affecting the user's preference. The system then compiles a list of possible attributes that are unaccounted for by analyzing the user feedback and rank these attributes according to their suspicion levels. The most suspicious attributes and any information captured from previous feedback are then verified using a genetic algorithm. If two cycles of feedback are completed, the system attempts to generalize any quantifiable attributes to form a generic group of attributes. The system finally optimizes the information collected by the genetic algorithm and recommends a list of products from the product database to the user according to the preference captured.

Tangible Score

In our application, we shall consider two quantifiable attributes, price and quality, as the basis in deriving the tangible score. The effect of these two attributes is always accounted for. The equation to derive this score is as shown in Equations 1-3.

Figure 1. System flowchart diagram



$$Score_{Price\ Competitive} = PrefWeight*(MaxPrice - Price)/MaxPrice \quad (1)$$

$$ScoreQuality = (1.0 - PrefWeight)*Quality \quad (2)$$

Equation 1 measures the price competitiveness of the product. PrefWeight is the weight or importance the user places on price competitiveness as compared to quality with values ranging from 0 to 1.0. A value of 1.0 indicates that 100% of the user's preference is based on price competitiveness. A product with a price close to the most expensive product will have a low score in terms of price competitiveness and vice versa.

Equation 2 measures the score given to quality. The quality attribute measures the quality of the product and takes a value ranging from 0.0 to 1.0. The value of "1.0 – PrefWeight" measures the importance of quality to the user. The final score given to tangible attributes are computed by adding Equations 1 and 2 as shown in Equation 3 below.

$$TangibleScore = Score_{PriceCompetitive} + Score_{Quality} \quad (3)$$

Modification Score for Detected Attributes

The modification score is the score assigned to all detected attributes by the system. These detected attributes were previously unaccounted for but had been detected by the system to be an attribute in the user's preference. These include all other attributes

$$Modificati\ on\ Score = \sum_{i=1}^{NoOfAttrib\ utes} (K_i - 1) * TangibleSc\ ore \quad (4)$$

besides price and quality. As these attributes may not have a quantifiable value, the score is taken as a factor of the TangibleScore derived earlier. The modification score is shown in Equation 4 whereby the modification factor K is introduced.

The values of each modification factor K ranges between 0.0 and 2.0. A value of K is assigned for each newly detected attribute. The modification factor K takes a value of 1.0 that gives a modification score of 0 when the detected attribute does not affect the user's choice. When K<1.0, there is a negative or penalty score for the particular attribute when the user has negative interest. When K >1.0, we have a bonus score to the attributes when the user has positive preference towards certain attributes. The final score for the product is as shown in Equation 5 as the sum of tangible and modification scores.

$$Final\ Score = Tangible\ Score + Modification\ Score \quad (5)$$

A Ranking System for User Feedback

As shown in Equations 1 and 2 earlier, there is a need to capture user preference in terms of the PrefWeight in Equation 1 and the various modification factor K in Equation 4. The system will request the user to rank a list of products. The system makes use of this ranked list to assess a best value for PrefWeight in Equations 1 and 2. In case when no unaccounted attributes affect the user's feedback, the agents will be evolved and optimized along the PrefWeight gradient.

Fitness of Agents

The fitness of each agent depends on the similarity between the agent's ranking of the product and the ranking made by the user. It reflects the fitness of agents in capturing the user's preference.

Unaccounted Attribute Detection

To demonstrate the system's ability to detect unaccounted attribute, the ontology will contain

only price and quality while all other attributes are unaccounted and remain to be detected, if they are relevant to the user. These unaccounted attributes include nonquantifiable attributes that are subjective in nature. The unaccounted attributes can be retrieved by analyzing the descriptions field of a product database thus allowing new attributes to be included without the need of change in system design.

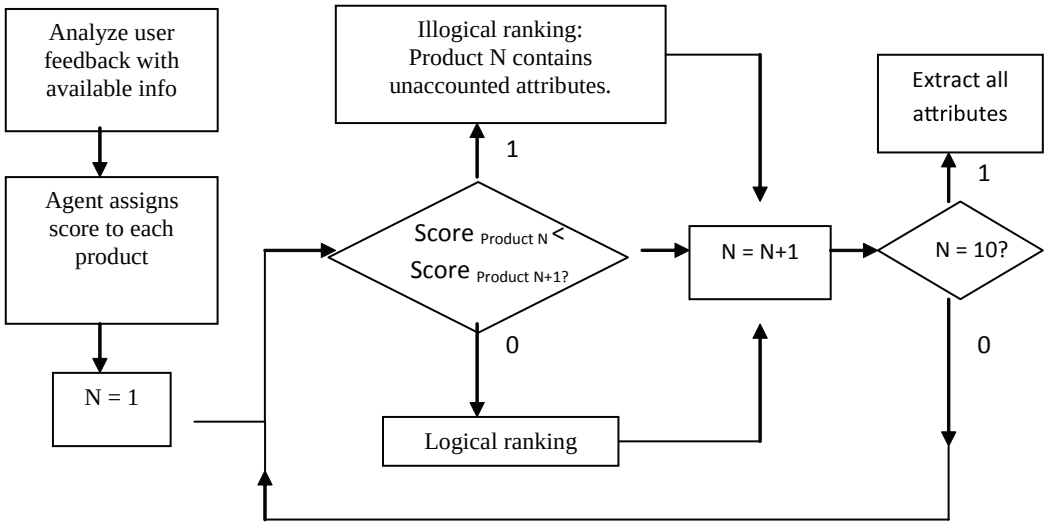
The system first goes through a detection stage where it comes up with a list of attributes that affect the user's preference. These attributes are considered as unaccounted attributes as the system has not accounted for them during this stage. A *confidence score* is assigned to each attribute according to the possibility of it being the dominant attribute influencing the user's preference.

The system will request the user to rank a list of products after that it analyzes the feedback according to the process as shown in Figure 2. The agents then attempt to explain the ranking by optimizing the PriceWeight and various K values. The fittest agent will give each product a score.

The system loops through the 10 products that are ranked by the user and compares the score given to products. If the user ranks a product higher than another, this product should have a higher score than a lower ranked product. However, if the agent awards a higher score to a product ranked lower than another, the product is deemed to contain an unaccounted attribute causing an illogical ranking. This process is able to identify all products containing positive unaccounted attributes that the user has preference for.

The next step is to identify the unaccounted attributes inside these products that cause such illogical rankings. The product descriptions for these products with illogical rankings are analyzed and tokenized. Each word in the product descriptions field is considered as a possible unaccounted attribute affecting the user's preference. Each token is considered as a possible attribute affecting the user's taste. The system will analyze the situation and modify the confidence score according to the cases as shown.

Figure 2. Chromosome encoding



1. The token appears in other products and shows no illogical ranking: deduction of points.
2. The token appears in other products and shows illogical ranking: addition of points.

Confirmation of Attributes

The attributes captured in previous feedbacks may be relevant in the current feedback as the user may choose to provide more than one set of feedback. The system thus makes a conjecture that the user's preference is influenced by certain attributes affecting him in previous feedbacks if available and eight other new attributes with the highest confidence score. The effect of these attributes on the user's preference is verified next.

Each agent in the system will estimate the user's preference by randomly assigning a modification factor ("K" value) for each of the eight attributes with high confidence score. Attributes identified to be positive are given K values greater than 1.0 while negative attributes would have K values less than 1.0. The PrefWeight and K values are optimized by a genetic algorithm to improve the fitness level of the agents.

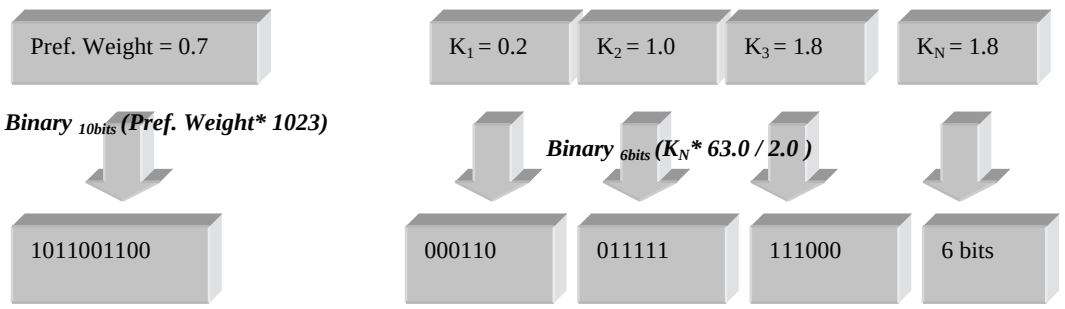
Optimization Using Genetic Algorithm

The status of detected attributes perceived by the agents and the most suspicious attributes will be verified here. The PrefWeight and various K values will be optimized to produce maximum agent fitness. As this is a multidimensional problem (Osyczka, 2001) with each new K value introducing a new dimension, we use a genetic algorithm to convert the attributes into binary strings. The agents are evolved under the genetic algorithm to optimize the fitness of each agent. The attributes of each agent are converted into a binary string as shown in Figure 3, and each bit represents a chromosome. In the design, 10 bits are used to represent the PrefWeight while 5 bits are used to represent the various K values.

Incremental Detection System

The system takes an incremental detection approach in understanding user preference, and the results show success in analyzing complex user preference. The system acknowledges that not all vital attributes may be captured within one set of feedback and thus considers refinement of

Figure 3. Process identifying products with illogical rankings



the results of previous sets. The attributes that affect a user's preference in one feedback become the prime candidates in the next set of feedback. In this way, the attributes that are detected are preserved and verified while new unaccounted attributes are being detected allowing the agents to learn incrementally about the attributes that affect the user's preference. However, some of the information captured by the system may be no longer valid as the number of feedback cycles increase. This creates a problem in the incremental detection system, as the information may not be relevant. To solve this problem, the system checks the validity of past attributes affecting the user's preference and delete attributes that are no longer relevant in the current feedback. Each set of feedback contains two feedback cycles.

Both feedback cycles attempt to detect the presence of any unaccounted attributes. In addition, the first cycle will delete any attributes that are passed from previous feedbacks and no longer relevant. These attributes should have a K value of 1.0 after we apply the genetic algorithm. Any controversial attributes detected by the first cycle will be clarified under the second feedback cycle.

IMPLEMENTATION OF INTELLIGENT USER PREFERENCE SYSTEM

A prototype was created to simulate the product broker. An independent program is written and run in the background to simulate the user. This program is used to provide feedback to the system and ranks the list of products on behalf of a simulated user who is affected by price and quality as well as a list of unaccounted attributes. The system is also affected by some generic groups of quantifiable attributes. It was observed that the performance of the system is closely related to the complexity of the problem. More complex problems tend to have lower overall performance. However, this is alleviated by providing multiple sets of feedback. The system was able to detect those attributes affecting the user's preference, and in the cases tested, the gap in performance was negligible. The system also demonstrated its ability to adapt to changes in user preference. This is important when multiple sets of feedback are involved as the user's preference may vary between feedback cycles.

FUTURE TRENDS

The current system generated user feedbacks to clarify any doubts on suspicious attributes. However, more than half of the feedbacks were generated in random to increase the chances of detecting new attributes. These random feedbacks were generated with products of different brand names having an equal chance of being selected to add to the variety of the products used for feedbacks. This could be improved by generating feedbacks to test certain popular attributes to increase the detection capabilities.

CONCLUSION

We have presented a solution in handling unaccounted attributes without the need of change in the ontology or system design. The results showed that the system is indeed capable of capturing the user's preferences even when unknown attributes were present. The system is also able to handle the presence of multiple unaccounted attributes and classify quantifiable attributes into a generic group. Given the possibility that unaccounted attributes could remain undetected during the process of mining, it could happen that a list of products recommended to the user has none matched against her preference or worse, that the user who makes a purchase based on available information and subsequently he discovers that

there were other products better meeting his needs. How to ameliorate such a situation is a challenging task, and it is on our future research agenda.

KEY TERMS

Accounted Attribute: A quality, feature, or characteristic that is listed in product specifications of a specific product.

Attribute: A quality, feature, or characteristic that some product has.

E-Commerce: Consists primarily of the distributing, buying, selling, marketing, and servicing of products or services over electronic systems such as the Internet and other computer networks.

Genetic Algorithms: Search technique used in computer science to find approximate solutions to optimization and search problems. Genetic algorithms are a particular class of evolutionary algorithm that uses techniques inspired by evolutionary biology such as inheritance, mutation, natural selection, and recombination (or crossover).

M-Commerce: M-commerce, or mobile commerce, stands for electronic commerce made through mobile devices.

Ontology: Studies being or existence and their basic categories and relationships, to determine what entities and what types of entities exist.

Product Brokering: A broker is a party that mediates between a buyer and a seller.

Software Agent: An abstraction, a program that describes software that acts for a user or other program in a relationship of agency.

Tokenize: The process of converting a sequence of characters into a sequence of tokens or symbols.

Chapter 1.34
Mining Software Specifications

David Lo
National University of Singapore, Singapore

Siau-Cheng Khoo
National University of Singapore, Singapore

INTRODUCTION

Software is a ubiquitous component in our daily life. It ranges from large software systems like operating systems to small embedded systems like vending machines, both of which we frequently interact with. Reducing software related costs and ensuring correctness and dependability of software are certainly worthwhile goals to pursue.

Due to the short-time-to-market requirement imposed on many software projects, documented software specifications are often lacking, incomplete and outdated (Deelstra, Sinnema & Bosch 2004). Lack of documented software specifications contributes to difficulties in understanding existing systems. The latter is termed program comprehension and is estimated to contribute up to 45% of total software cost which goes to billions of dollars (Erlikh 2000, Standish 1984; Canfora & Cimitile 2002; BEA 2007). Lack of specifications also hampers automated effort of program verification and testing (Ammons, Bodik & Larus 2002).

One solution to address the above problems is mining (or automatic extraction of) software specification from program execution traces. Given a set of program traces, candidate partial specifications pertaining to the behavior a piece of software obeys can be mined.

In this chapter, we will describe recent studies on mining software specifications. Software specification mining has been one of the new directions in data mining (Lo, Khoo & Liu 2007a, Lo & Khoo 2007). Existing specification mining techniques can be categorized based on the form of specifications they mine. We will categorize and describe specification mining algorithms for mining five different target formalisms: Boolean expressions, automata (Hopcroft, Motwani & Ullman 2001), Linear Temporal Logic (Huth & Ryan 2003), frequent patterns (Han & Kamber 2006) and Live Sequence Charts (Harel & Marelly 2003).

BACKGROUND

Different from many other engineering products, software changes often during its lifespan (Lehman & Belady 1985). The process of making changes to a piece of software e.g., to fix bugs, to add features, etc., is known as software maintenance. During maintenance, there is a need to understand the current version of the software to be changed. This process is termed as program comprehension. Program comprehension is estimated to take up to 50% of software maintenance efforts which in turn is estimated to contribute up to 90% of total software costs (Erlikh 2000, Standish 1984; Canfora & Cimitile 2002). Considering the $216.0 billion of software component contribution to the US GDP at second quarter 2007, the cost associated with program comprehension potentially goes up to billions of dollars (BEA 2007). One of the root causes of this problem is the fact that documented software specification is often missing, incomplete or outdated (Deelstra, Sinnema & Bosch 2004). Mining software specifications is a promising solution to reduce software costs by reducing program comprehension efforts.

On another angle, software dependability is a well sought after goal. Ensuring software runs correctly at all times and identifying bugs are two major activities pertaining to dependability. Dependability is certainly an important issue as incorrect software has caused the loss of billions of dollars and even the loss of lives (NIST 2002; ESA & CNES 1996; GAO 1992). There are existing tools for performing program verification**.** These tools take formal specifications and automatically check them against programs to discover inconsistencies, identify bugs or ensure that all possible paths in the program satisfy the specification (Clarke, Grumberg & Peled 1999). However, programmers' reluctance and difficulty in writing formal specifications have been some of the barriers to the widespread adoption of such tools in the industry (Ammons, Bodik & Larus 2002, Holtzmann 2002). Mining software specifications can help to improve software dependability by providing these formal specifications automatically to these tools.

MAIN FOCUS

There are a number of specification mining algorithms available. These algorithms can be categorized into families based on the target specification formalisms they mine. These include specification miners that mine Boolean expressions (Ernst, Cockrell, Griswold and Notkin 2001), automata (Cook & Wolf 1998; Reiss & Reinieris, 2001; Ammons, Bodik & Larus 2002; Lo & Khoo 2006a; Lo & Khoo 2006b; Mariani, Papagiannakis and Pezzè 2007; Archaya, Xie, Pei & Xu, 2007; etc.), Linear Temporal Logic expressions (Yang, et al. 2006; Lo, Khoo & Liu 2007b; Lo, Khoo & Liu 2008, etc.), frequent patterns (Li & Zhou, 2005; El-Ramly, Stroulia & Sorenson, 2002; Lo, Khoo & Liu 2007a; etc.) and Live Sequence Charts (Lo, Maoz & Khoo 2007a, Lo, Maoz & Khoo 2007b).

These mined specifications can aid programmers in understanding existing software systems. Also, a mined specification can be converted to run-time tests (Mariani, Papagiannakis & Pezzè 2007; Lo, Maoz & Khoo 2007a; Lo, Maoz & Khoo 2007b) or input as properties-to-verify to standard program verification tools (Yang, Evans, Bhardwaj, Bhat and Das, 2006; Lo, Khoo & Liu 2007b).

Preliminaries

Before proceeding further, let us describe some preliminaries. Specifications can be mined from either traces or code. A program trace is a sequence of events. Each event in a trace can correspond to a statement being executed, or a method being called, etc. In many work, an event is simply the signature of a method that is being called.

Traces can be collected in various ways. A common method is to instrument a code by inserting `print' statement to various locations in the code. Running the instrumented code will produce a trace file which can then be analyzed.

Mining Boolean Expressions

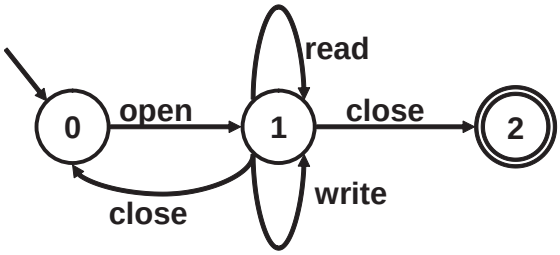
Ernst, Cockrell, Griswold and Notkin (2001) propose an algorithm that mines Boolean expressions from program execution traces at specific program points. Sample Boolean expressions mined are x=y+z, x>5, etc. The algorithm is based on a set of templates which is then matched against the program execution traces. Template instances that are satisfied by the traces above a certain threshold are outputted to the user.

Mining Automata

Simply put, an automaton is a labeled transition system with start and end nodes. Traversing an automaton from start to end nodes will produce a sentence, which will correspond to a program behavior (e.g., file protocol: open-read-write-close). An automaton represents a set of valid sentences that a program can behave. An example of an automaton representing a file protocol is drawn in Figure 1.

One of the pioneering work on mining automata is the work by Ammons, Bodik and Larus (2002). In their work, a set of pre-processed traces are input to an automata learner (Raman & Patrick, 1997). The output of the learner is a specification in the form of an automaton learned from the trace file. This automaton is then presented to end users for fine tuning and modifications.

Figure 1. File protocol specification



Lo and Khoo (2006a) define several metrics for assessing the quality of specification mining algorithms that mine automata. Among these metrics, precision and recall are introduced as measures of accuracy to existing specification miners producing automata. Precision refers to the proportion of sentences accepted by the language described by the mined automaton that are also accepted by the true specification. Recall refers to the proportion of sentences accepted by the language described by the true specification that are also accepted by the mined automaton. In the same work, a simulation framework is proposed to evaluate existing work on mining automaton-based specifications, which also help identify room for improvement.

Lo and Khoo (2006b) next propose an architecture using trace filtering and clustering to improve the quality of existing specification miners. The architecture pre-processes the traces by first filtering anomalies in the traces and then clustering them into similar groups. Each group is then fed separately to an existing specification mining algorithm to produce an automaton describing a partial specification of a system. These partial specifications are later merged into a unified automaton. It has been shown that the quality of the resultant specification mining algorithm after filtering and clustering are employed is better than before. In particular, in a case study on a Concurrent Versions System (CVS) application, the precision is doubled with a small reduction in recall.

Mariani, Papagiannakis and Pezzè (2007) use an improved automata learner (Mariani and Pezzè, 2005) and a Boolean expressions miner (Ernst, Cockrell, Griswold and Notkin, 2001) to generate regression tests of third party or Com-

mercial off-the-shelf (COTS) components. Their algorithm first learns an automaton and a set of Boolean expressions and then converts them to regression tests to ensure the compatibility of third party components when used together.

Other work on mining automata includes: (Archaya, Xie, Pei & Xu, 2007; Reiss & Reinieris, 2001; Cook & Wolf 1998; etc.)

Mining Linear Temporal Logic Expressions

Linear Temporal Logic (LTL) is a formalism for specifying precise temporal requirements. It models time as a sequence of states where each state is an event from a fixed set. The full description of LTL can be found in (Huth & Ryan, 2004). Here, we focus on 3 temporal operators of LTL namely G, X and F. The operator X refers to the next state, *F* refers to the current or a future state, and *G* captures all future states (globally). In software there are many requirements expressible in LTL, for example:

1. Whenever (globally when) *resource.lock* is called, (from the next state onwards) finally *resource.unlock* is eventually called
   Or
   G(*resource.lock*->XF (*resource.unlock*))
2. Whenever (globally when) a correct pin is entered and user requested money and the balance is sufficient, (from the next state onwards) finally an ATM eventually dispenses money
   Or
   G(*correct_pin*->XG(*request_money*->XG(sufficient->XF(dispense))))

Yang, Evans, Bhardwaj, Bhat and Das (2006) mine significant two-event temporal logic expressions stating "whenever an event E_1 occurs eventually an event E_2 occurs" from program execution traces. An expression is significant if it satisfies a minimum threshold of ``satisfaction rate''. The algorithm is limited to mining two-event temporal logic expressions due to the exponential complexity involved in mining expressions of arbitrary sizes. To capture behaviors involving more than two events, they proposed a partial solution where previously mined two-event expressions are concatenated to form longer expressions. However, not all more-than-two event expressions can be mined this way, and superfluous rules that are not significant might be introduced in this process.

Lo, Khoo and Liu (2007b, 2008) extend this work by devising an algorithm to mine significant LTL expressions of arbitrary sizes. An expression is significant if it obeys minimum thresholds of support and confidence. A novel search space pruning strategy is employed to enable efficient mining of rules of arbitrary size.

Mining Frequent Patterns

Li and Zhou (2005) use a closed itemset mining algorithm by (Grahne & Zhu 2003) in their proposed algorithm called PR-Miner to recover elements of a program (function, variable, etc) that are often used together in a code. These associations among program elements can be composed as rules that reflect implicit programming rules in code.

El-Ramly, Stroulia and Sorenson (2002) propose a new pattern mining algorithm to mine frequent user-usage scenarios of a GUI based program composed of screens – these scenarios are termed as interaction patterns. Given a set of series of screen ids, frequent interaction patterns capturing common user interactions with the GUI are obtained.

Lo, Khoo and Liu (2007a) propose a new pattern mining algorithm to mine frequent patterns of program behavior from program execution traces —these patterns are termed as iterative patterns. Patterns can occur repeatedly within a program trace and across multiple traces. These patterns follow some constraints of Live Sequence Charts (LSC), which is one of the standards in

Figure 2. A sample iterative pattern (of 32 events) mined from JBoss application server (note: diagram is read top to bottom, left to right)

Connection Set Up	TransactionManagerLocator.getInstance TransactionManagerLocator.locate TransactionManagerLocator.tryJNDI TransactionManagerLocator.usePrivateAPI	**Transaction Commit**	TxManager.commit TransactionImpl.commit TransactionImpl.beforePrepare TransactionImpl.checkIntegrity TransactionImpl.checkBeforeStatus TransactionImpl.endResources TransactionImpl.completeTransaction TransactionImpl.cancelTimeout TransactionImpl.doAfterCompletion TransactionImpl.instanceDone
TxManager Set Up	TxManager.begin XidFactory.newXid XidFactory.getNextId XidImpl.getTrulyGlobalId		
Transaction Set Up	TransactionImpl.associateCurrentThread TransactionImpl.getLocalId XidImpl.getLocalId LocalId.hashCode TransactionImpl.equals TransactionImpl.getLocalIdValue XidImpl.getLocalIdValue TransactionImpl.getLocalIdValue XidImpl.getLocalIdValue	**Transaction Disposal**	TxManager.releaseTransactionImpl TransactionImpl.getLocalId XidImpl.getLocalId LocalId.hashCode LocalId.equals

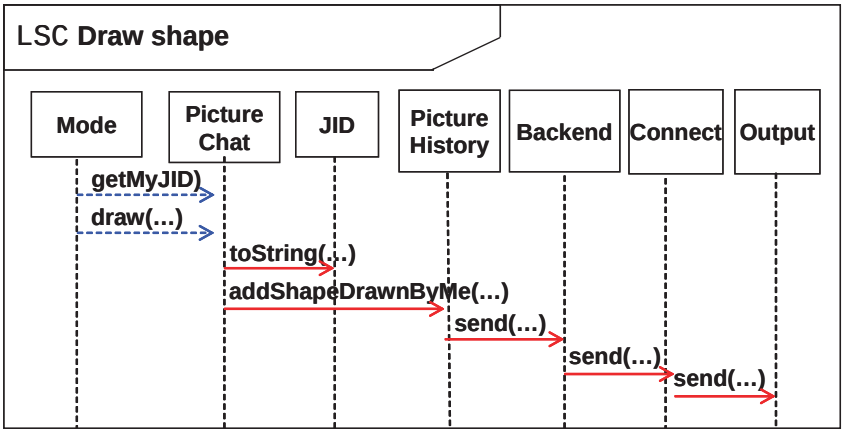
software modeling community. An example of a specification mined from the transaction component of JBoss Application Server is shown in Figure 2. It specifies that a series of connection setup events is followed by transaction manager setup events, transaction setup events, transaction commit events and eventually transaction disposal events.

Mining Live Sequence Charts

Lo, Maoz and Khoo (2007a, 2007b) extend the work on mining iterative pattern (Lo, Khoo & Liu, 2007a) and propose an algorithm to mine significant Live Sequence Charts (LSC) from program execution traces. A chart is significant if it obeys minimum thresholds of support and confidence. While iterative pattern follows some of the semantics of LSC they are not LSC. LSC is a formal version of UML sequence diagram with pre- and post- chart. An LSC specifies that when the behavior specified by the pre-chart occurs, the behavior specified by the post-chart will also occurs. Mined LSCs are also different from Linear Temporal Logic expressions mined in (Lo, Khoo & Liu, 2007b, Lo, Khoo & Liu, 2008) as the satisfactions of the pre- and post- charts conform to the semantics of LSC (Harel & Marelly 2003). Also for mining LSCs, an event in a trace is a triple (caller, callee, method signature). An example of a mined chart from Jeti instant messaging application (Jeti 2006) is shown in Figure 3. It describes a series of methods that are being called when a user of Jeti draws a line in the shared canvas with another communication party.

We have reviewed various approaches to mine different forms of software specifications. The specifications mined can aid user in understanding existing software and serve as input to other software engineering tasks, e.g., software verification, testing, etc.

Figure 3. A sample LSC mined from Jeti messaginge application (boxes, arrows, dotted arrows and solid arrows correspond to classes, method calls, pre-chart and post-chart respectively)



FUTURE TRENDS

As program traces can be huge, there is a need to improve the efficiency of existing techniques further. Further industrial case studies are also needed to adapt existing techniques to the industry. A comparison of existing techniques will do well to help users to better understand which technique works best in a particular situation. There is much room for further theoretical and practical contributions to the domain of mining software specifications.

CONCLUSION

Software is a ubiquitous component of our daily life. Documented software specifications are often missing, incomplete and outdated. This causes difficulties in understanding software systems. Program comprehension accounts for a significant proportion of total software cost. On another angle, programmers' reluctance and difficulty in writing formal specifications have been some barriers to the wide spread adoption of automatic program verification tools. Specification mining is one of the promising solutions to the above problems. It can provide candidate specifications to aid programmers in understanding existing programs. The specification can also be input to program verification tools and converted to run-time tests to aid program verification and bug detection. In the future, we look forward to more theoretical and technical contribution to this field, as well as more case studies and the availability of more open source tools.

KEY TERMS

Automaton: A labeled transition system with start and end nodes describing a language. A path from the start to an end node corresponds to a sentence in the language.

Linear Temporal Logic: Formalism commonly used to describe temporal requirements precisely. There are a few basic operations given with symbols G, X, F, U, W, R corresponding to English language terms 'Globally', 'neXt', 'Finally', 'Until', 'Weak-until' and 'Release'.

Live Sequence Charts: A formal version of UML sequence diagram. It is composed of a pre- and post- chart. The pre-chart describes a condition which if satisfied entails that the behavior described in the post-chart will occur.

Program Comprehension: A process of understanding a piece of software.

Program Instrumentation: Simply put, it is a process of inserting `print' statements to an existing program such that by running the instrumented program, it will produce a trace file reflecting the behavior of the program when the program is run.

Program Testing: A process find defects in a piece of software by running a set of test cases.

Program Trace: A series of events where each event can correspond to a statement that is being executed, a function that is being called etc., depending on the abstraction level considered in producing the trace.

Program Verification: A process to ensure that software is always correct no matter what input is given with respect to some properties, e.g., whenever a resource is locked for usage, it is eventually released.

Software Maintenance: A process of incorporating changes to existing software, e.g., bug fixes, feature additions, etc., while ensuring the resultant software works well.

Specification Mining or Specification Discovery: A process for automated extraction of software specification from program artifacts. We use artifacts in a liberal sense to include program traces, code, repository, data, etc.

Software Specification: A description on how a piece of software is supposed to behave.

Section II
Development and Design Methodologies

This section provides in-depth coverage of conceptual architectures, frameworks and methodologies related to the design and implementation of software systems and applications. Throughout these contributions, research fundamentals in the discipline are presented and discussed. From broad examinations to specific discussions on particular frameworks and infrastructures, the research found within this section spans the discipline while also offering detailed, specific discussions. Basic designs, as well as abstract developments, are explained within these chapters, and frameworks for designing successful software applications.

Chapter 2.1
Ontology Based Object-Oriented Domain Modeling:
Representing Behavior

Joerg Evermann
Memorial University of Newfoundland, Canada

Yair Wand
The University of British Columbia, Canada

ABSTRACT

An important step in developing the requirements for an information system is analyzing the application domain. In this step, conceptual models are used for representing an application domain. However, while languages for software design are available and widely used, no generally accepted language exists for conceptual modeling. This work suggests the use of object-oriented software modeling languages also for conceptual modeling. Such use can support a more accurate transition from domain models to software models. As software-modeling languages were not intended for modeling application domains, their constructs lack the required semantics. While previous papers addressed the representation of structural elements of domains using object concepts, this paper addresses behavioral aspects, related to change and interaction. The proposed semantics are based on a mapping between ontological concepts that describe behavior and object-oriented constructs related to dynamics. Based on these mappings, modeling rules are proposed to guide the modeler in creating ontologically well-formed models. The mappings and rules are exemplified using UML and are demonstrated using a case study.

INTRODUCTION

A good understanding of the application domain is necessary to develop the requirements for information systems (IS). Such understanding can be facilitated with the use of conceptual models. Conceptual modeling is the "activity of formally describing some aspects of the physical and social world for the purpose of understanding" (Mylopoulos, 1992).

Despite possible benefits to IS development of using conceptual models, no widely used formal or semi-formal language for conceptual modeling exists. In contrast, formal and semi-formal languages, notably object-oriented languages, are commonly used in software design. As reported in (Dobing & Parsons, 2006, 2008) and also found in our case study (Sec. 8), practitioners, for lack of a language specific to conceptual modeling, have been using software design languages for this purpose. However, this often occurs in an unguided way, possibly leading to confusion and difficulties in understanding. Without guidance, the support of UML for describing domains other than software is poor and this can lead to miscommunication (Smolander & Rossi, 2008).

Adopting widely used and well-accepted object-oriented languages, usually employed for software design, in a guided way and with clearly specified semantics for conceptual modeling, has several potential benefits: (1) It can provide a shared language to support better communication between analysts and software designers. (2) It can help mitigate translation problems between the conceptual and the software models, (also called "impedance mismatch" (Cilia, Haupt, Mezini, & Buchmann, 2003; Kolp, Giorgini, & Mylopoulos, 2002; Roe, 2003; Rozen & Shasha, 1989). More specifically, because the domain model is specified in the same language as software, the domain model can also serve as an initial model of the software system (Coad & Yourdon, 1991), which can subsequently be adapted to particular technologies. Such technology-driven refactoring is beyond the scope of this paper. The discussion in Section 9 will revisit this point in more detail. (3) A clear representation of application aspects can reduce possible confusion of business and implementation aspects in conceptual models (Parsons & Wand, 1997). (4) Assigning semantics to language constructs for domain representation purposes can provide modeling rules (Evermann & Wand, 2005a).

Because object-oriented languages were not developed for conceptual modeling, they lack application domain semantics. For example, while language constructs such as "Method" or "Operation" have clear meaning for software design, it less clear what they represent in the application domain. However, assigning application domain semantics to language constructs, while necessary for their use in application domain modeling, is insufficient. It is also desirable to identify *modeling rules* to ensure that the created models represent only really possible situations in the application domain. Modeling rules can improve the ability to communicate and reason about the domain by restricting the possible interpretations of a model (Hadar & Soffer, 2006), and hence can support convergence of the domain understanding among different stakeholders, a pre-requisite for development and implementation success. Therefore, such rules can improve the effectiveness of the created models as ways to communicate and reason about the domain (Reinhartz-Berger & Sturm, 2008).

Previous research (Evermann & Wand, 2005b) proposed the use of object-oriented design languages for modeling the structural aspects of application domains. That research proposed specific application domain semantics for the static structure constructs found in UML class diagrams, and suggested modeling rules to develop well-formed and meaningful (with respect to perceptions of the real world application domain) models. The present work addresses the behavioral aspects of conceptual modeling, focusing on constructs to describe change and interaction. We exclude use case related constructs as they describe external interactions with a system, whereas the remaining UML constructs describe the system itself.

Our approach is based on the use of ontology, a specification of concepts that exist in a domain. Previously, ontologies have been used mostly to *evaluate* modeling languages (Green & Rosemann, 2000; Opdahl & Henderson-Sellers, 2002; Opdahl, Henderson-Sellers, & Barbier, 1999).

This work extends the ontological approach to *prescribe* modeling rules for using constructs related to dynamic to model behavioral aspects of a domain. We use the Unified Modeling Language UML (OMG, 2005) as a specific instantiation of object-oriented software design languages, due to its wide acceptance (Dobing & Parsons, 2006, 2008).

The paper is organized as follows. Section 2 presents the research methodology, followed by an introduction to ontology and the specific ontology used for this research (Sec. 3). These introductions are limited to the analysis of behavior and interactions. The main sections (Sec. 4-7) develop the proposed semantics and modeling rules. The paper closes with a presentation of case study research that provides empirical support for the proposed semantics and rules (Sec. 8).

RESEARCH METHODOLOGY

To assign application domain semantics to object-oriented language constructs, we create mappings between language constructs and domain concepts. Domain concepts are specified in terms of an ontology. Ontology is an area of study that is "that branch of philosophy which deals with the order and structure of reality in the broadest sense possible" (Angeles, 1981). A particular ontology specifies what exists and how things behave in a domain. Ontological mappings are established by the following two steps (Wand & Weber, 1993):

1. Representation mapping: Assign each ontological concept a language construct with which to *represent* it.
2. Interpretation mapping: Assign each language construct an ontological *interpretation*.

Once ontological mappings have been established, the transfer of ontological assumptions and constraints to the language generates modeling rules. This transfer is based on the principle that relationships between ontological concepts should also hold between the language constructs that are used to represent them.

Our analysis is guided by the principle that the mappings should retain the existing relationships between language constructs, so as not to affect its software design semantics. For example, as associations can relate UML classes, there should be something that relates the ontological concepts to which UML classes are mapped. If this condition cannot be satisfied, then the assignment of semantics to object constructs cannot be accomplished without violating some fundamental design language aspects. Given this requirement, the mapping of one language construct has implications for the possible mapping of other, related ones. We address these interdependencies by using an iterative method, changing our perspective repeatedly between the representation mapping and the interpretation mapping. We begin by proposing an initial representation mapping for core ontological concepts (Section 4). Based on this mapping, we propose an interpretation mapping for related, as yet unmapped, language constructs (Section 5). We repeat this for a second time to cover all remaining ontological concepts and language constructs (Sections 6, 7). In this way, we ensure a mapping that is internally consistent and respects the existing dependencies between language constructs as much as possible.

This iterative methodology also addresses the problem of "correct" interpretation of the ontology and the language specifications. As both specifications are texts that must be read and interpreted, the iterative methodology follows the hermeneutic cycle (Gadamer, 1976; Ricoeur, 1976), recognized as essential in interpretive IS research (Boland, 1985; Chalmers, 2004; Myers, 1995; Prasad, 2002). This prevents premature assignment of meaning and allows the entire meaning of the language and ontology specifications to emerge.

Our work has the following limitations. First, it is not our purpose to suggest modeling rules for software design. The derived rules are appropriate for conceptual modeling but may not be so for software design. However, models that conform to our rules are valid software models, as we do not violate the existing software semantics of the language. Second, our rules do not guide us in how to perceive the world. Thus, we might suggest rules on how to use modeling constructs such as objects and classes, but not on how to identify them in the domain. For example, we do not offer rules that tell the modeler how to identify things in the domain. Instead, our rules are of the kind that, given the modeler has already identified a thing, the rules tell her how to model it in object-oriented terms. Third, it is beyond the scope of a single paper to examine all UML constructs, as several hundreds UML constructs exist. We restrict ourselves to the basic constructs commonly seen in UML diagrams. Furthermore, some language constructs serve a purely syntactic purpose or only have meanings in the software context and cannot be assigned any domain semantics (e.g. Pseudo State, Stub State). We consider these constructs not relevant for conceptual modelling. We also exclude use case related constructs, as they describe external interactions with a system, whereas the remaining UML constructs describe the system itself.

ONTOLOGY

The term *ontology* has seen increasing use in such areas as information systems, artificial intelligence, and knowledge engineering (Gruninger & Lee, 2002; Noy & Hafner, 1997; Uschold & Gruninger, 1996). The present research takes up the call for a return to philosophical ontology (Guarino & Welty, 2002; Smith & Welty, 2001). An ontology is taken to be a commitment to the belief in the existence of certain entities in external reality, for example the business and organizational world. A specific ontology is a set of assumptions about what exists or is perceived to exist in a domain. Adopting an ontology is a fundamental philosophical choice that cannot be justified *a-priori*. As any philosophy, it is the framework that enables one to carry out research (Kuhn, 1996), and the merits of its adoption can only be assessed based on the results of that research. Some reasons for our choice of ontology, based on previous research results, are given below.

The Bunge-Ontology

The specific ontology chosen for our purposes is based on the work of Mario Bunge (1977, 1979). We use this particular ontology for pragmatic reasons:

- It is based on ontological work done over a long period (Bunge, 1977, pg. xiii).
- It is an axiomatic system and formally represented in set theory notation.
- It has not been developed specifically for use in software development, but is instead based on "the ontological presuppositions of contemporary scientific research" (Bunge, 1977, pg. xiii). Thus, its use can help distinguish between domain and software concepts.
- It has been shown to provide a good benchmark for the evaluation of modeling languages and methods (Dussart, Aubert, & Patry, 2004; Evermann & Wand, 2005b; Opdahl & Henderson-Sellers, 2001; Parsons & Wand, 1997; Rosemann & Green, 2000; Soffer, Golany, Dori, & Wand, 2001; Wand, Storey, & Weber, 1999; Wand & Weber, 1989, 1993; Weber & Zhang, 1996).
- It has been used to assign ontological meaning to object concepts (Wand, 1989).
- It has been empirically shown to lead to useful outcomes (Bodart, Patel, Sim, & Weber, 2001; Cockroft & Rowles, 2003; Evermann & Wand, 2006; Gemino, 1999; Weber & Zhang, 1996).

The following paragraphs introduce the ontological concepts of Bunge's work (Bunge, 1977, 1979). This is necessarily an incomplete exposition of the entire ontology, including only the concepts relevant to this paper. A brief synopsis is presented in Table 1.

The world is made up of substantial *things* that exist physically in the world. Things can combine to form a *composite* thing. Things possess (substantial) *properties.* Properties in general are those possessed by a set of things, for example "color," "speed,, "salary," and so on. Individual properties, that is, properties of an individual thing, can be considered values of properties in general, (e.g., a specific thing is blue in color, and is traveling at a speed of 100 mph; a specific thing is a person earning a salary of $50,000). Intrinsic properties are those that a thing possesses by itself, whereas mutual properties exist between two or more things. Composites possess *emergent* properties, that is, properties not possessed by any component. A *law* is any restriction on the properties of a thing.

Any thing can be described by a set of *attributes,* which (Bunge, 1977) also calls *state functions.* A set of state functions is called a *functional schema* or *model.* A thing can be described by many different schemata. For example, a person may be described by height and weight, or described by location and organizational unit. The *state* of a thing is defined as the set of values of *all* state functions comprising a particular model. The *lawful state space* of a thing is defined by constraining the values of the state functions to those values consistent with the laws the thing adheres to.

Table 1. Concepts of the Bunge-ontology

Ontological Concept	**Explanation**
Thing	Fundamental concept. The world consists of things and only of things.
Property	Things have properties.
Intrinsic Property	Property of one thing.
Mutual Property	Property of two or more things.
Law	Restriction of or relation on properties.
Composition	Things can be composed to form composite things.
Emergent Property	Property of a composite thing that is not a property of one of its components.
State Function	Function describing a property of a thing. Synonymous with attribute.
Functional Schema (Model)	Set of state functions describing things. A model of things that are similar in some ways.
State	Value vector of state functions of a functional schema.
Natural Kind	Set of things adhering to same laws (common behavior).
Quantitative Change	Change of state of a thing.
Qualitative Change	Change of natural kind of a thing by loss or acquisition of properties.
Event	Change of state.
Process	Ordered set of events of one thing.
Lawful Transformation	Path in state space between an initial and a final state, where all points on the path are lawful states.
History	The states a thing traverses over time.
Action	A thing A acts on a thing B iff the state history of B depends on the existence of A.
Interaction	Two or more things acting on each other.

All things change, and every change is a change of things. A change may be *quantitative*, in which case the values of one or more state functions (and individual properties) are changed, or it may be *qualitative*, in which case state functions (and general properties) are acquired or lost. Concurrent with loss or acquisition of properties is the loss or acquisition of behavior as things lose or gain possible ways in which they can change. Change always involves the change of state of some thing. Since all things are changeable, every lawful state space contains at least two distinct states.

A discrete change is termed an *event*. An event can be described as an ordered pair of states. An event is defined for the state space of a *single* thing. A change in one thing may also be a change in another (e.g., changes of mutual properties). This is an interaction consisting of two distinct events in the two things. If the state space is non-denumerable, that is for continuous change, a change is represented by a triple (s_i, s_f, g) representing the initial state, the final state and a function g, the *lawful transformation*, which represents the path in the state space that the thing traverses. All possible changes must be in accordance with laws.

Interaction is defined through the state history of a thing: If the state history of one thing depends on the existence of another thing then the second is said to *act on* the first. Things interact, if each acts upon the other. Every thing acts on, and is acted on, by other things. Changes occur as a consequence of laws: If two properties are lawfully related and one changes, then the other may also change, depending on the laws that relate them. Since laws relate properties of one thing only, for a thing A to act on a thing B as the result of laws, there must exist a mutual property of A and B which is lawfully related to (intrinsic) properties of A and B. Furthermore, interaction may give rise to mutual properties. The interaction of a person enrolling at a university to become a student would give rise to the mutual property "tuition fee balance." Hence, some properties necessarily exist prior to interaction and some others may exist post interaction (Evermann, 2005).

REPRESENTATION MAPPING

We base our mapping process on the mapping of some fundamental concepts in existing research (Evermann & Wand, 2005b). These fundamental mappings are in agreement also with other work on UML and Bunge's ontology (Dussart et al., 2004; Evermann, 2005; Opdahl & Henderson-Sellers, 2001, 2002). Table 2 shows these mappings. With these fundamental mapping of Table 2 in mind, we begin our mapping of concepts related to change and behavior.

States and State Transitions

The central concepts of behavior in Bunge's ontology are states and state transitions. Object-oriented languages such as UML also provide states and state transition. We propose to represent ontological states by object-states and ontological state transitions by object-state transitions. Some consequences follow from this mapping.

In Bunge's ontology, a state is the *complete* assignment of values to the state functions, that is a vector of the values of *all* state functions. While the object-oriented literature has noted the connection between attributes and states (Booch, 1994; Coad & Yourdon, 1990; Jacobson, 1992; Rumbaugh, 1991), UML does not support modeling this connection. We therefore propose the following rule to preserve the ontological relationship between states and properties also in object-oriented languages:

Rule 1: *Every object-state must be defined by a specific assignment of values to a set of attributes of the object for which the state is defined.*

This rule ensures that appropriate attributes are modeled to be able to fully represent the dynamics

Table 2. Prior mappings of fundamental concepts

Ontological Concept	Object Construct in UML	Remarks
Thing	Object	
Property	Attribute	
Intrinsic Property	Attribute of 'ordinary' class	
Mutual Property	Attribute of association class	
Emergent Property	Class attribute	Attribute of an aggregate made of class instances.
Functional Schema	Class	
Natural Kind	Set of objects (extension of class)	Described by class.
Composition	Aggregation	
	Composition	Does not have an ontological equivalence. In ontology things exist independent of whether they are components or not.
	Association	Does not have an ontological equivalence. Implies interaction (Evermann, 2005).
A collection of mutual properties that are generated together	Association class	

allowed by the state space and the transitions within this space. For example, if a student in a university domain has two states, "passed" or "failed," this must be modeled using some attributes (for example "Course Credits" with different number of course credits defining each state, "passed" or "failed").

Ontologically, every change of state changes the value of at least one state function. For example, when a student passes a course (transitions from "failed" to "passed" standing), the changed value would be that of the attribute "Course Credits". Hence, from Rule 1 follows:

Corollary 1: *An object's state transition must change the value of at least one of its attributes.*

Interpretation Mapping (1st Iteration)

Sub-States

Object-oriented languages like UML allow the definition of a state hierarchy in which a state may contain sub-states. An object in a sub-state is also in the super-state containing that sub-state. In Bunge's ontology, states do not have sub-states. Hence, we must find an ontological interpretation for this object-oriented "shorthand" notation.

Ontologically, sub-states can be interpreted using two different functional schemata of the represented thing, spanning two different state spaces. For example, let a telephone answering machine have a state "Passive" and a composite state "Active" with sub-states "Greeting Recording," "Message Recording," and "Message Playback." States "Active" and "Passive" can be characterized by an attribute "Tape Speed" (zero for "Passive" and greater than zero "Active"). This is one model of the answering machine. Distinguishing among the sub-states of "Active" requires additional state functions, for example "Recording Source" (with values "Microphone" or "Telephone Line"), and "Mode" (with values "Recording" or "Playback"). Thus, the second model is defined by three attributes. In this model it is possible to distinguish between states such as "Message Recording" ("Tape Speed > zero," "Recording Source=Telephone Line," and "Mode=Recording"), and "Greeting

Recording" ("Tape Speed > zero," "Recording Source=Microphone," and "Mode-recording").

Formally, let state x (defined by a set of state variables $a=a_1$) be a point in state space sp_x, spanned by attribute a. Let sub-state y be a point in state space sp_y, spanned by attribute set a and a set of additional attributes b. Multiple points in sp_y, for example $<a=a_1, b=b_1>$, $<a=a_1, b=b_2>$, and so on can be mapped to a single point x in sp_x. State space sp_x is a *projection* of sp_y onto attribute set a. Based on the above example and this formal discussion we propose the following rule and corollary:

Rule 2: *Object-oriented sub-states are defined using attributes in addition to those defining the super-state.*

Corollary 2: *For an object transitioning among sub-states, the values of only those attributes change, that are not used to define the super-state.*

In object-oriented languages, two or more sub-states of the same super-state may be concurrent. In addition to the conditions on the super- and sub-states expressed by Rule 2 and Corollary 2 we require that, for two sub-states of a common super-state to be concurrent, the two higher-dimensional state spaces are independent:

Corollary 3: *Concurrent sub-states require mutually disjoint sets of additional attributes in the class description.*

The rules proposed in this section help to ensure that the attribute definitions for object classes are sufficient to support the desired behavioral characteristics of the object as expressed in state charts. Specifically, in UML, the proposed language rules relate elements of state charts with those of class diagrams.

Active States

Some object-oriented languages allow modeling of object states during which the object undergoes a change. In UML 1.x, these were called action states. In UML 2.0, actions and activities are separated from states. However, the notion of a state during which changes occur remains, as behavior can be associated with states in the form of a "DoActivity." This is incompatible with the ontological notion that a state is an assignment of values to attributes at a specific instance in time. Again, we must identify the proper ontological interpretation of this object-oriented "shorthand notation".

We build on our interpretation of object-oriented sub-states: If a change occurs while a thing is in a certain state, there must exist a state variable not employed for the state definition and that state variable may change. Hence, action states can be represented by means of sub-states:

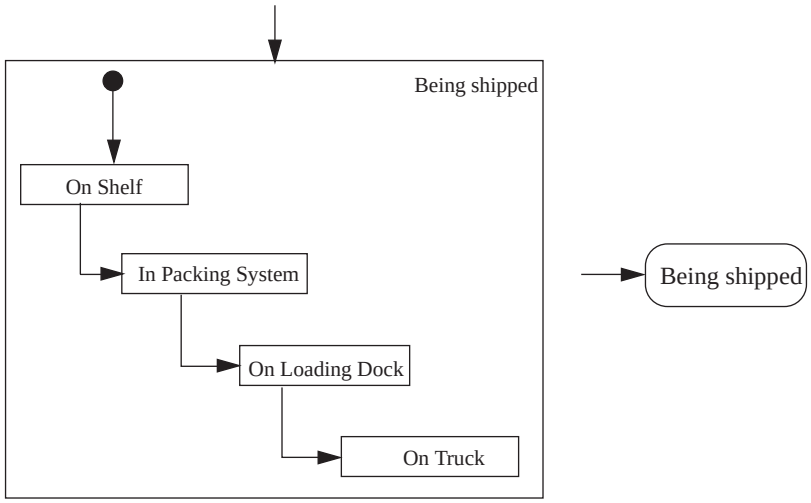
Rule 3: *Action states are composite states comprising a set of sub-states. The object transitions among the sub-states while in the action state. State charts and class diagrams must reflect this.*

For example, the situation in Figure 1A is equivalent to that in Figure 1B. An item that is in the action state of "being shipped" undergoes state transitions while being in that state, for example from state "On Shelf" to a new state "In Packing System" and so on.

Operations

Bunge's ontology provides no construct that is equivalent to methods or operations in object-oriented languages. It has been suggested that these are software related constructs that are without relevance for real-world models (Parsons & Wand, 1991, 1997) and thus need not be interpreted ontologically. However, as operations feature prominently in object-oriented modelling,

Figure 1. Action-states



this section shows how operations are related to state transitions, thereby gaining an ontological interpretation, and derives rules for their use in conceptual modeling.

Whereas operations specify behavior only in abstract terms, a method provides a specific implementation of an operation[2]. As Bunge's ontology expresses dynamics through states and transitions, we must use these concepts to assign domain semantics to methods and operations.

We note that in the object approach, the *entire* range of behavior of an object (except creation and reclassification, i.e. qualitative change) is determined by its set of operations. Ontologically, *every* change of a thing is describable in terms of state transitions. We therefore propose:

Rule 4: *The quantitative behavior of objects of a particular class (for each model) is entirely describable by a top-level state chart SC_0 associated with the class.*

Since the behavior of objects is limited to the operations defined on the object:

Rule 5: *Every object-oriented state-transition in SC_0 must correspond to an operation modeled for the class of objects that SC_0 is associated with and vice versa.*

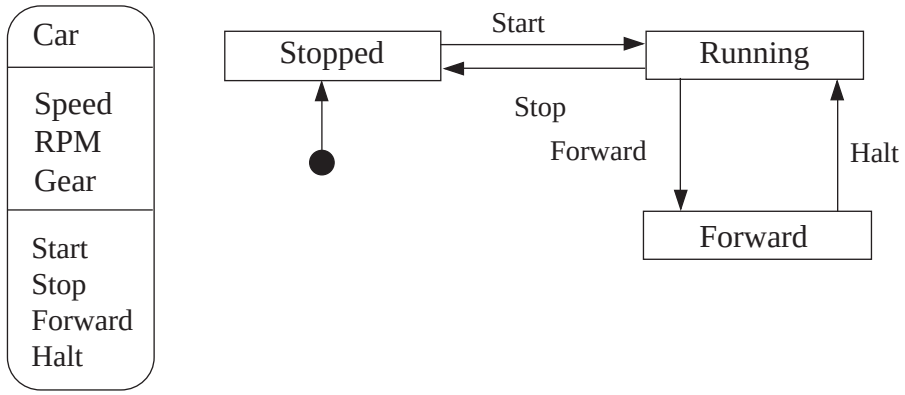
Since in our ontology every thing is able to change, we propose the following:

Corollary 4: *Every object must have at least one operation.*

Bunge's ontology, as adapted in (Wand & Weber, 1993, 1995), distinguishes among *stable* and *unstable* states. A thing can only leave a stable state due to interaction. In object-oriented descriptions, an object remains in a particular state until an operation is invoked on it. An operation reflects the complete response to this invocation; the object then awaits another operation to be invoked. Since we have proposed that operations are realizations of top-level state transitions, we add now the rule that top-level state transitions are transitions from and to stable states:

Corollary 5: *States in SC_0 represent stable states.*

Figure 2. Class definition and state chart



(A) (B)

The above rules and corollaries allow the modeler to identify operations that may have been missed in constructing the class diagram, or identify operations for which there are no corresponding state transitions. Such operations would be redundant. Figure 2 shows an example. Consider a car that can be in three states, engine "Stopped," engine "Running," and going "Forward." Assume the states of a car are defined as in Table 3. Then the class definition in Figure 2 (A) is consistent with the top-level state chart SC_0 depicted in Figure 2 (B).

Explicitly modeling the link between operations and state transitions provides the operation and method designer a way of ensuring that the full state description of a system is realized. It also helps ensure that operations do not implement change beyond that in the state description.

Behavior

In object-oriented languages such as UML, state charts may be used to specify the behavior that implements an operation. These state charts must follow some rules. In general, behavior represents lawful transformations that describe in greater detail the state transition represented by an operation. Hence, the beginning and end of the path in state space represented by a particular state chart must match the initial and final states of the operation whose behavior this state chart describes:

Table 3. Example state definitions

Stopped	(Speed = 0, RPM = 0)
Running	(Speed = 0, RPM = 1000, Gear = 0)
Forward	(Speed = 50, RPM = 3000, Gear = 1)

Corollary 6: *A state chart describing an operation must begin and end with the initial and final state of the transition in SC_0 that corresponds to the operation.*

Corollary 7: *The behavior represented by a state chart must modify the attribute values of the object in a way that corresponds to the values defined for the initial and the final state of the state chart.*

These rules and corollaries allow the modeler to identify incomplete state charts. If a state chart describing a particular behavior does not begin and end with the proper states, it may be incomplete. Corollary 7 can help design behavior specifications that conform to the state description by providing pre- and post-conditions of a method. For example, let the answering machine switch from state "Message Recording" to state "Passive."

The initial state is characterized by attributes and values "Tape Speed > 0," "Recording Source = Telephone Line," and "Mode = Recording" while the final state is defined by "Tape Speed = 0." A method implementing an operation corresponding to this state transition should assume the object representing the answering machine is in a state possessing attributes according to the initial state and must ensure the assignment of object attributes according to the final state.

REPRESENTATION MAPPING

In Bunge's ontology, interaction is represented by state transitions, rather than message-passing, as in object-oriented modeling. Ontologically, interaction arises because things adhere to laws that must be satisfied at all times: When an event in thing A changes a property that is lawfully related to a property of thing B (this relation must be via mutual properties), the property of thing B may need to adjust so that the law remains satisfied. Hence, interactions can, in theory, be derived from the knowledge of the laws, for example by means of constraint solving (Mackworth, 1977) or constraint programming (Van Hentenryck, 1989). We say "in theory" because these methods are not generally applicable and, except for special cases, not computationally efficient.

It is the object-oriented system designer's task to ensure that the modeled message-passing pattern satisfies all application domain laws (often termed business rules). It is often the case that such laws are only implicitly understood by analysts, rather than being explicitly stated and modeled. A rigorous ontological analysis of the domain can help explicate the existence of laws or constraints and suggest possible ways how laws (business rules) can be implemented via interactions (message passing).

The discussion of Bunge's ontology in Section 3 suggests that since laws constrain the state variables of only a single thing, changes between two things must happen by virtue of mutual properties. Thus, a change of a mutual property in one thing does not lead to a change in another thing but *is* a change in a property of another thing. Since mutual properties are mapped to association class attributes (see Table 2), we derive the following rule:

Rule 6: *For every two classes of objects between which message passing is declared, there exists an association class with at least one attribute.*

This rule can help the modeler to identify which messages need to be shown in a model and between which two objects an association class needs to be identified. This in turn can provide for a richer analysis of the application domain. The case study in Section 8 demonstrates that this is feasible as the number of relevant messages, and therefore the number of association classes, typically remains manageable.

The scope of the model and level of abstraction determines whether a particular thing and its mutual properties should be modeled. Clearly, one does not wish to model individual atoms and molecules even though they are ultimately the connected things. Scope and level of abstraction are determined based on the model purpose prior to modeling. For example, intermediate communication mechanisms such as communication systems are typically outside the scope of a model of a business (but not a technical) domain: A telephone line between two people possesses mutual properties with both the speaker and the listener. It is these mutual properties and the properties of the phone line (voltage, waveform, etc.) that undergo change. However, as the telephone line is typically outside of the model scope, it and its properties will not be included in the model. Instead, the interaction between the two individuals will be considered using properties shared directly between the individuals, such as shared beliefs, goals, and so on that may be affected by the interaction.

In Bunge's ontology every thing acts on and is acted upon by other things. Hence, there should be interactions originating from and terminating on the thing:

Rule 7: *Every object must be the receiver and sender of, or responder to, some message.*

This rule shows the need to critically examine the interactions or information flows. One could argue that things in the environment of a system may only send but not receive messages, for example a customer ordering a product, a student registering for a course, and so on. Nevertheless, even for these examples, the actions of ordering and registering are pointless unless the customer and the student also receive messages. This could be order acknowledgements or shipping details for the customer. For the student, the messages may involve tuition fee billing or textbook requirement messages. Neither customers nor students will only send messages without expecting to receive any. This rule also illustrates differences between software and domain models. Consider a `LineItem` object in a transaction application that might in a software model be shown as only receiving messages. However, as we wish to describe the domain, rather than the software, we require an interpretation of what a `LineItem` object represents. For example, it might represent a particular product being ordered by a particular customer. In that case, it is not a thing, but an event or activity, and should not be modeled as an object.

Often, a thing is made up of parts. In such cases, it is sufficient for any of its parts to receive and send some message to satisfy rule 7. The receiving and sending must not necessarily be done by the same part. For example, assume an object A with parts P_1 and P_2. If P_1 receives messages (is acted upon) but does not send any messages (acts on), and P_2 sends messages but does not receive any, we consider rule 7 to be satisfied, as the object A both receives and sends messages. In this case, some interaction necessarily exists between the parts P_1 and P_2 (which is not shown on the level of the composite object).

A specific instance of such a composite object is the domain environment. The necessarily limited scope of any model leads to some things interacting with things beyond the model scope, that is, with the environment. Rather than showing the individual objects comprising the environment (which are outside the scope), the modeler may instead choose to designate one thing as the environment, with the understanding that it is a composite object and subject to message passing amongst its parts.

In summary, while we suggest that message passing is not ontologically real, we advocate its use in conceptual modeling to represent interaction, with the understanding that the ontologically real interaction occurs by mutual properties and therefore requires association classes.

Interpretation Mapping (2nd Iteration)

Message passing is one of the core concepts of the object-oriented approach. It is the mechanism by which object interaction is realized. Messages can be interpreted in two ways, depending on the ontological status we ascribe to them:

- Messages are not things in the world. They are abstract concepts that serve as descriptions, illustrations, abstractions or representations of interaction (Wand, 1989).
- Messages are substantive things in the world. They are ontologically real.

There are two arguments against the second interpretation (Evermann, 2005). First, the message passing mechanism for interaction has previously been examined with respect to Bunge's ontology and found to be an unsuitable construct or mechanism for describing real world business domains (Parsons & Wand, 1991, 1997; Wand &

Weber, 1993). Consider the following examples:

– The machine sends a message to the machined item to move itself to a new location.
– The general ledger sends a message to an office desk to depreciate its value.
– A truck sends a message to the crate to load itself onto the loading dock.

While acceptable in software specifications, such messages are not likely to be observed between these things in the real world. Clearly, a machine does not send messages to machined items to move them. Instead, an operator moves items to and from the machine.

Second, if messages did represent real things in the world, they should be represented as objects (see Table 2). Instead of two objects interacting directly, one object would have to interact with a message object, which in turn would need to interact with the second object. This would lead to an infinite regress. Based on these two reasons, we interpret messages as abstract expressions of interaction, not as things. Consequently, they are mapped to the ontological concept of interaction, not to things.

In UML, messages are associated with value specifications (their arguments). Specifying message arguments implies that interaction occurs through changes to the value of properties represented by the message parameters. However, message arguments do not refer to attributes of either the sending or receiving object, and are therefore not interpreted as (mutual) properties.

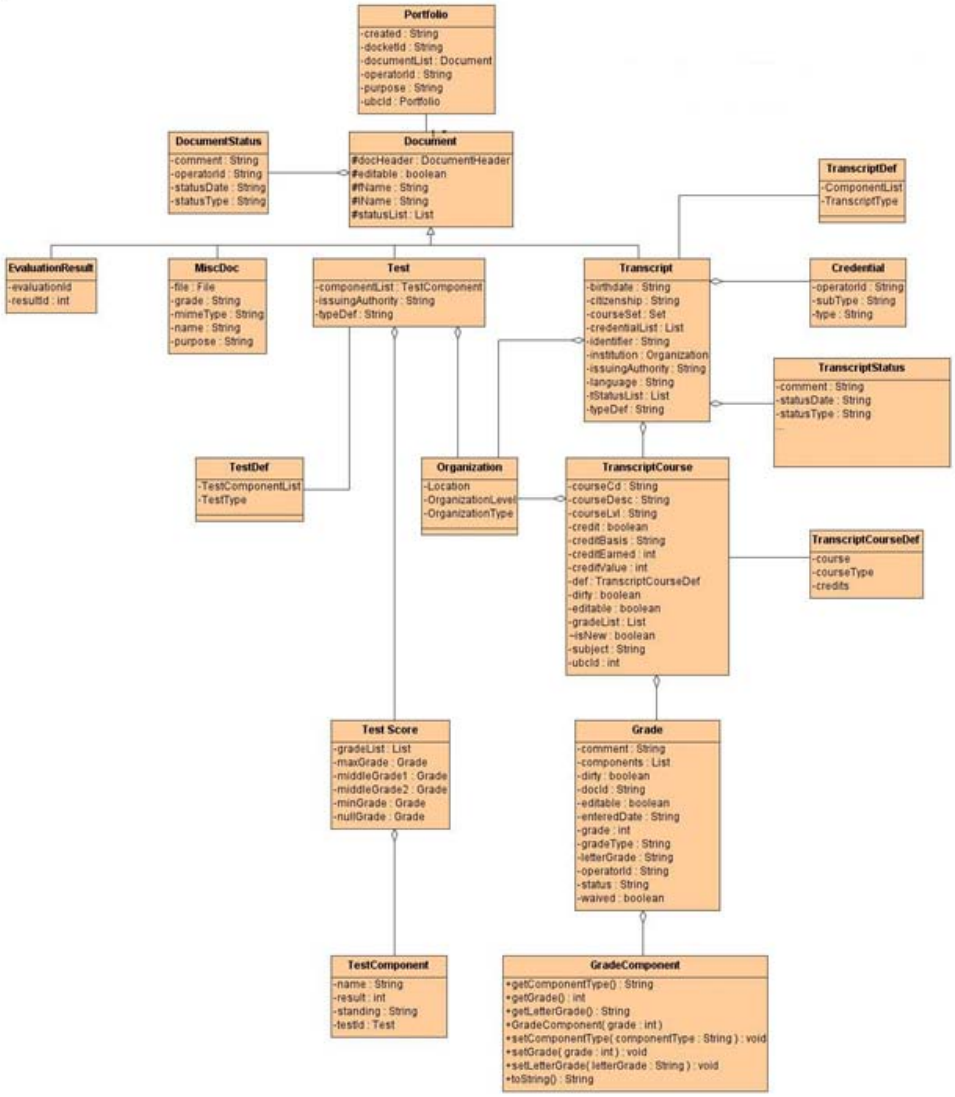
To summarize, messages and their arguments do not have a direct ontological interpretation, but express interaction. In turn, Sect. 6 proposed that interpretation should be expressed using association class attributes.

CASE STUDY

A case study was conducted to examine the feasibility of the proposed modeling rules in practical situations. The organization under study was a large North American university. The project under study was the provision of an opportunity for prospective students to assess their likelihood of admittance[3]. This project was chosen as the basis for the case study for two reasons. (1) The main stakeholders and informants of the analysis were still available for interviews. Their involvement with the project and the analysis was recent so that rich data could still be gathered. (2) The project team had used UML for an initial model of the organizational domain. UML class diagrams were used specifically for understanding the organizational domain. The project leader confirmed there was no intention to use them for later software design and all coding would be done independent of any generated UML model. It was hoped that additional insight could be gained by comparing the project team's UML model with that developed as part of this case study. When this case study was begun, the project was almost at the beginning of the implementation stage. Figure 3 shows the class diagram developed by the project team.

As part of the case study, an independent business analysis was undertaken by the first author in order to model the domain of student admissions and assessment. This served two purposes: (1) it tested the applicability of the proposed modeling rules and (2) produced an alternative model with ontological semantics, which could be compared to the original one created by the project team. Interviews were conducted with stakeholders and informants who contributed to the project. All interviews were conducted on-site using open-ended questions. The following interviews were conducted for purposes of domain analysis and model creation:

Figure 3. UML class diagram developed by project team



- Approx 1-hour interview with director, student systems, IT services
- Approx 1.5-hour interview with a high school student recruiter
- Approx 2-hour interview with an admissions officer
- Three approx 1-hour interviews with three first year university students
- Three approx 1 hour interviews with lead analyst of the project

In addition, access was provided to all project documentation, mainly requirements documents generated from a prior business process reengineering project. Moreover, frequent e-mail contact was maintained with the lead analyst of the project for clarification and discussion of details. For purposes of evaluating and comparing the independently generated model, more interviews were conducted:

- Approx. 2-hour interview with the project leader
- Approx. 2-hour interview with the lead developer

For preparation for these interviews, the entire set of independently created diagrams was provided two weeks prior to the interview with a request to carefully examine these for correctness, usefulness, usability and to compare these to the project's own UML model. The interviewees were made aware of these aims before the interviews commenced.

The process of analyzing the domain and modeling it according to the proposed ontological semantics and rules showed that all produced diagrams were valid UML models, and adhered to all UML syntactic rules. The models were neither trivial nor overly complex. Hence, use of the rules was found to be at least feasible in this practical setting. The independently generated model consisted of the following diagrams:

- 20 class diagrams showing 35 classes and 14 association classes,
- Eight sequence diagrams showing 37 messages, representing interactions that occur through changes to the attributes of the 14 association classes,
- Two state charts showing seven states and sub-states.

An excerpt of the class model is shown in Figure 5. In the model, application is not a thing (it is not represented as a class, but as an association class). Its attributes reflect mutual properties, the result of an interaction between the university and the applicant. Either the applicant or the university can modify these mutual properties, which would be further interaction between university and the applicant. Similarly, acknowledgement is not a thing (it is not represented as a class, but as an association class). Its attributes reflect mutual properties, the results of the application event/activity and can be changed by either the university or the applicant. Such changes are interactions. Note further that while the domain describes student admissions, there is no admission object. Instead, in the state chart in Figure 4, "accepted" is a state that the university can have with respect to a student. One may model acceptance as a state transition to this state, that is, a change in the university object.

The process of business analysis and modeling showed that at various stages in the process the rules and proposed semantics led the modeler to include information in the model that was not necessary for building software, but that was important for domain understanding.

With respect to action and interaction, the general absence of detailed state charts in the independent business re-analysis indicated mostly *qualitative* interactions (e.g. a student enrolling, a student being admitted, etc.). This might not be surprising, as non-technical, human organizational systems appear to generally involve more qualitative than quantitative change.

When quantitative change was modeled (e.g. as a transition between the states "Not Admissible," "Conditionally Admitted," and "Unconditionally Admitted" based on revisions to the required grades), application of the rules led to a fundamental insight into the domain. Instead of assigning states such as "on hold," "pending," "admitted," and so on to the student, the rules led us to assign such states to the university (Figure 4). The student's state cannot change without interaction, and changes to admission criteria by the university do not affect the student *per se*, but only the student's admissibility with respect to the university. Hence, it was concluded that these states were states of the university, defined using mutual properties of the university and the student. Consequently, the university possesses an independent sub-state machine for each student. This observation confirms the notion that in the real world it is the university that can change the state of the students (i.e., those aspects of state

Figure 4. Example state chart diagram from the case study

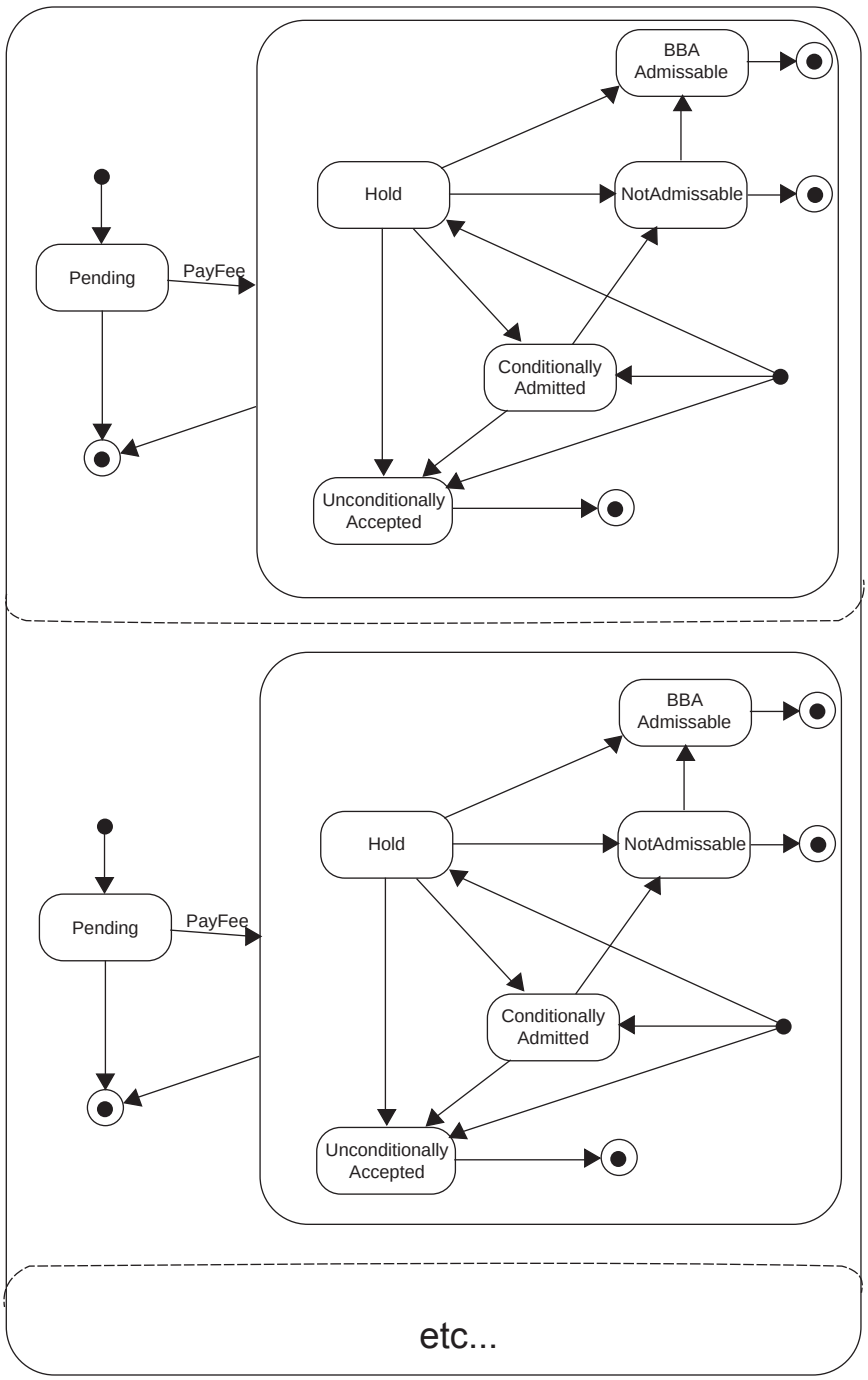


Figure 5. Excerpt of the case study class diagram

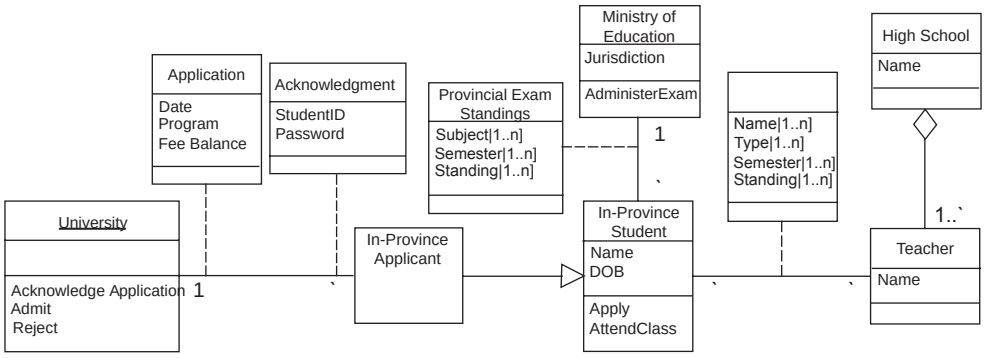
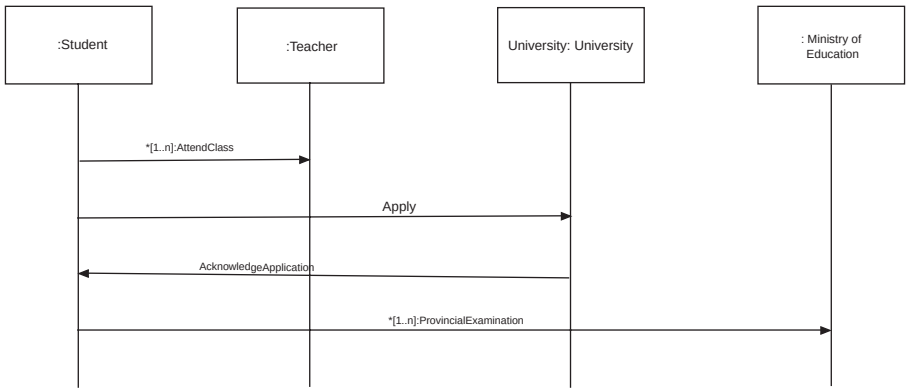


related to the university), and it is the university that holds the state information. Thus, modeling the admission domain with the view that admission information is part of the university state leads to a more realistic model. However, this may not be intuitively obvious to software designers or programmers.

The initial models created by the project team did not provide any operations. Attributes were assumed to be provided with accessor operations. Either approach hides the semantics of the changes inside any behavior implementations. Hence, this information might not be "visible" for the domain understanding and conceptual modeling process, and might be implicitly assumed by the software designer.

The newly developed models included operations for all object classes, developed based on the requirements to express qualitative and quantitative change. The former was derived from the different sub-classes that students can be in, the latter as expressed in state charts. In this way, the capabilities of an object of a given class become explicit and clear. Moreover, as these operations are related to external stimuli, modeled as messages in the sequence diagrams (e.g., Figure 6), the ordering of the changes expressed by methods can be deduced. For example (Figures 5, 6), it is clear that an In-Province Student (students refer to high-school, rather than university students in this domain) can become an applicant. The university can then process the application of the applicant and the Ministry of Education can administer exams for the In-Province Student. This information was lacking in the model developed by the project team. Explicating it in the concep-

Figure 6. Excerpt of the case study sequence diagram



tual model improved understanding and allowed critique and assessment of the correctness of the information about the application domain.

Subsequent discussion with two project team members, the project lead (LF) and the lead developer (CH) of the project, were undertaken to corroborate and confirm these observations. Both suggested that the newly developed models indeed included more information about the domain under study. Both team members commented on the fact that the original model contained many hidden and implicit assumptions:

We relied a lot on assumptions that were never written down in the model ... yours is more comprehensive. (CH - lead developer)

Ours [models] have all sorts of stuff around that is assumed but not modeled. (LF - project lead)

This may be in part due to the additional information included in the model. Note that this is contextual information, that is, information about aspects of the domain that would not be reflected in the design of the software. As such, this information would be useful in allowing team members and stakeholders to discover *why* the design for the information system is defined one way or another, even though the information does not itself constitute or directly affect the software design.

The second important purpose for a conceptual model besides the representation of a real world domain is the starting point for software design. The alternative model was seen as appropriate for this purpose:

I don't see any reason why you couldn't just take these [the models] and run with them. (CH)

During the discussion with the project lead, it also became clear that the use of UML without any guidelines was a substantial challenge in the project. Some analysts were aware of the subtle differences between possible interpretation and the difficulties associated with them:

It's normally difficult to model a course object, because it is a relationship ... What do you mean by a course? The curriculum, the interaction, the grade? (LF)

Another interesting finding is that the extensive use of sequence diagrams and modeling of interactions, which is a central aspect of the proposed ontological semantics and rules, was viewed as something that should be included more often in projects but is not done:

They don't get done as official project documents. When developers meet, two thirds of them will use in-official sequence diagrams ... That makes things much clearer. (CH)

This observation suggests that the interaction-centered perspective enforced by the proposed guidelines can make a positive contribution to understanding. Interactions are not officially documented, yet interaction diagrams appear as unofficial tools. This seems to indicate that explicit modeling of interactions, as prescribed by the proposed rules, can help with understanding of the model and the domain. This demonstrates the importance of interactions in analyzing a real-world domain.

When the modeling rules were revealed at the end of the case study, the project lead and lead developer agreed that modeling rules were necessary and helpful, both for guiding the modeling process and for ensuring model quality and consistency:

Such rules would have helped in our group. The rules would tell whether a model is good and can help answer some questions. They seemed like a lot of valid questions to ask. (CH)

Rules can force the modelers to think deeper about what they're modeling. (LF)

In summary, the case study supported the use of the proposed rules and confirmed their potential usefulness in understanding the domain and communicating that understanding through conceptual models.

Discussion

The objective of this work was to extend the use of object-oriented languages from software design to conceptual modeling of an application domain. This required that domain semantics be assigned to language constructs, which was done by defining mappings between language constructs and ontological concepts (Table 4). The article began by examining the central ontological concepts related to change and interaction and mapped them to object-oriented constructs. The ontological elements used include states, state transitions and lawful transformations. With this representation mapping in mind, object-oriented constructs such as sub-states, activity states and partitions were examined. We then re-examined ontological interaction and discussed the object-oriented concept of message passing.

Table 4 shows that most of the basic ontological concepts can be assigned an object-oriented equivalent. This mapping is either a one-to-one relation by definition or has been made so by our proposed modeling rules. This indicates that object-oriented languages can be used to model application domains.

Based on the proposed mappings, the article explored the consequences of transferring ontological assumptions to the language, resulting in a set of rules. These rules are applicable to object-oriented languages when they are used for conceptual modeling. However, they may not be applicable to, nor are they intended for, using object-oriented languages for software design. Yet, the rules do not contradict existing rules for using object constructs for software design.

These results extend well-known and widely used object-oriented languages into the domain of business analysis and conceptual modeling. The use of the same language for both domain modeling and software design can bridge the gap between system analysis and software design, often called "impedance mismatch" (Cilia et al., 2003; Kolp et al., 2002; Roe, 2003; Rozen & Shasha, 1989). Traditionally, the use of different languages required either a translation of the conceptual model to the software design model, or a relatively independent development of the software model based on the designer's understanding of the problem. Using the same language eliminates the translation step (Evermann & Wand, 2005a). Thus, it can eliminate a possible source of errors, inadvertent alterations, omissions, and so on. Figure 7 shows the traditional

Table 4. Summary of interpretations related to behavior and interaction

Ontological Concept	**Object-Oriented Construct**	**Remarks**
State	State	Connection with attributes of objects made.
State	Sub-state	
State	Action State	Action states are composite states.
Transition	Transition	
Transition	Operation	
Lawful Transformation	Method	
Interaction	Message	Not a substantial thing.

process. The domain is represented in a domain model, using a domain modeling language (1). This is then translated, a potentially error-prone step, to a software model in different language (2), which is then transformed to software (3).

Figure 8 shows software development without translating between modeling languages. The modeling language elements are interpreted with respect to the domain (1) and used to represent the domain using a common modeling language (2). Then, the semantics of the modeling language are assumed with respect to software (3) and the same model is interpreted as a software design model (4).

Domain analysts as well as software developers can use the same familiar language to communicate not only amongst themselves but also between the two groups, reducing the potential for misunderstandings and misinterpretation of diagrams.

Additionally, the use of the modeling rules leads to further benefits. Application of ontological modeling rules have been shown to reduce the variability in conceptual models (Hadar & Soffer, 2006). A reduction in the range of possible models of a domain allows easier and more effective stakeholder communication and can improve the consensus of stakeholders on how to describe the domain. It can also promote convergence of model interpretations, thus helping to ensure that stakeholders share the same problem and domain understanding.

CONCLUSION

The research results were tested on a case study that demonstrated the feasibility and applicability of the proposed semantics and modeling rules for medium size projects. The resulting models were found to be helpful and the modeling rules useful in the construction of the domain model.

Finally, we note that the results depend on the ontological model assumed. Thus, their validity can only be demonstrated by empirical methods. Such methods would include in particular, controlled experiments and realistic case studies. While experiments can test the usability of the rules and clarity of the resulting models (Evermann & Wand, 2006), case studies are required to examine the applicability and usefulness of the method.

ENDNOTES

1. The first author was with the School of Information Management, Victoria University of Wellington, Wellington, New Zealand for the duration of this research.
2. The terminology changed in UML 2.0. Here, operations are associated with behavior. Opaque behavior is a special class of behavior and represents what was called a method in UML 1.5.
3. Bunge's ontology is applicable to this domain comprising a university, high schools and other composite objects. According to Bunge (1977), certain things are composed of other things (composite things, pg. 114, Definition 3.4). Furthermore, if the parts of things interact, the composite thing is known as a system (Bunge, 1979, pg. 6, definition 1.1). Moreover, Bunge (1979) expounds a hierarchy of systems (ontological levels) that includes psychological and social/technical systems. For example, a university department is neither a simple (basic) thing, nor a mere composite, but a system with interacting ("connected") parts. The BWW ontology has been applied to a diverse range of domains, such as enterprise systems, workflows and business processes, etc., showing that it is applicable to organizational and social phenomena.

This work was previously published in Journal of Database Management, Vol. 20, Issue 1, edited by K. Siau, pp. 48-77, copyright 2009 by IGI Publishing (an imprint of IGI Global).

Chapter 2.2
An Ontology Based Representation of Software Design Patterns

Jens Dietrich
Massey University, New Zealand

Chris Elgar
SolNet Solutions Limited, New Zealand

ABSTRACT

This chapter introduces an approach to define Design patterns using semantic Web technologies. For this purpose, a vocabulary based on the Web ontology language OWL is developed. Design patterns can be defined as RDF documents instantiating this vocabulary, and can be published as resources on standard Web servers. This facilitates the use of patterns as knowledge artefacts shared by the software engineering community. The instantiation of patterns in programs is discussed, and the design of a tool is presented that can x-ray programs for pattern instances based on their formal definitions.

INTRODUCTION

Design patterns are artefacts used to share knowledge across particular communities. Software Design patterns (Gamma, Helm, Johnson, & Vlissides, 1995) describe structural and behavioural properties of software, and are used by the software engineering community in order to exchange knowledge about software design. Currently, this is done the old-fashioned way: patterns are published in books or on Web sites, and consumed by people reading and applying them. This includes recognising pattern instances in programs in order to comprehend the structure of complex programs, and using patterns as design blueprints in order to address a specific design problem.

The main limitation with this modus operandi is the lack of tool support—patterns have to be found, and good and appropriate patterns have to be selected manually. A more effective, tool supported way of processing patterns (in particular instantiation and recognition) requires a formal representation of the patterns that supports reasoning about patterns. There are some obvious con-

tenders of modeling frameworks and languages that could be used for this purpose. This includes first order predicate logic, higher order logic, and UML based modeling languages (either profiles or separate, MOF based modeling languages). In recent years, several approaches to Design pattern formalisation have been proposed based on these choices. While these representations allow us to reason about the internal structure of a pattern, there is limited support for reasoning about the patterns themselves, their metadata, and relationships to other patterns. Moreover, logic based and UML based approaches usually lead to monolithic, static models. While this has advantages (for instance, to ensure the consistency of the models) it does not support the sharing of patterns in an open environment like the Internet. Here, knowledge is distributed and inherently inconsistent, and additional means are needed to deal with inconsistency. This is one of the key issues addressed by the Semantic Web initiative endorsed by the W3C (Berners-Lee, Hendler, & Lassila, 2001). The Semantic Web is based on the idea of a distributed, open knowledge base where everybody can publish knowledge in the form of simple subject-predicate-object assertions. This leads necessarily to inconsistencies that must be resolved. The key to solving this problem is the prioritisation of knowledge based on metadata annotations—knowledge is selected based on the author, the time of creation, and other explicit and harvested metadata.

Another issue is whether it is realistic to hope that the software engineering community will adopt one particular model or vocabulary to represent patterns. It seems more likely that there will be multiple models, each supported by a particular community, standard body, or vendor group. Mappings defining transformations between instances of the respective models will have to be developed. In the case of formal logic, this is only possible with higher order constructs describing the relationship between different predicates, functions, and types. For UML based models, standards to transform instances of different meta models are only emerging now in the realm of model driven architecture (MDA), in particular QVT ("MOF QVT Final Adopted Specification," 2005). On the other hand, modern ontology languages like OWL have built-in support to express the relationship between different ontologies.

We claim that a modeling language suitable to publish Design patterns on the Web should meet the following requirements:

1. A formal semantics is needed in order to safeguard reasoning about the patterns.
2. Pattern definitions must be easy to process by tools. In particular, this is the case if an XML based serialization format is supported.
3. There must be facilities to describe the relationships with alternative models, languages, or pattern vocabularies.
4. The physical distribution of pattern definitions and the separation of schema and instances must be supported. The pattern definition language itself should be deployed as a network resource and single pattern definitions should reference this resource. In particular, it should be possible to validate the pattern definitions against such a central schema. This is similar to the validation of XML documents against their XML schema or DTD. Furthermore, patterns refining other patterns can also refer to them as network resources, and clients can easily resolve these references using standard network clients.

It appears that a pattern deifintion language based on the Web ontology language OWL (McGuinness & Harmelen, 2004) meets these requirements. Firstly, OWL has a formal semantics (Patel-Schneider, Hayes, & Horrocks, 2004) and built-in derivation rules which support safe reasoning about patterns. This can be used to infer additional knowledge from models or to check them for consistency. Secondly, OWL ontologies

(both schemas and instances) can be serialised as XML using the RDF/XML syntax, and a growing number of tools are available to facilitate the work with OWL knowledge bases, including editors like Protégé (Knublauch, Musen, & Rector, 2004), APIs like Jena ("Jena – A Semantic Web Framework for Java," 2006), documentation tools like OWLDoc ("OWLDoc," 2006) and reasoners such as Fact (Horrocks, 1999), Pellet (Sirin, Parsia, Grau, Kalyanpur, & Katz, 2006) and Racer (Haarslev & Moeller, 2001). Thirdly, OWL has built-in constructs that can be used to describe the relationship between different vocabularies. Fourthly, OWL has a simple yet powerful import facility (owl:imports[1]) that can be used to reference the assertions made in external knowledge bases. In particular, this feature can be used to link ontology instances with a central ontology schema.

For this reason we believe that OWL is a suitable language to formalise Design patterns. In this chapter, we will present an ontology that can be used to define patterns. We discuss how metadata can be used to reason about patterns, and sketch how tools can process these definitions. This leads to a discussion on Design pattern instances. The results presented here are mainly based on Dietrich and Elgar (2005a, 2005b).

BACKGROUND

The Semantic Web initiative aims at turning the Web currently focusing on human end users into a Web that also contains content that can be processed by machines (Berners-Lee et al., 2001). The basic infrastructure is provided by the resource description framework RDF (Klyne & Carroll, 2004)—a simple language that uses subject-predicate-object constructs to describe resources. This strongly resembles the structure of the Web for humans consisting of node-link-node triples with Web pages being the nodes and the hyper links connecting them being the edges.

Meaning is added to RDF by using an ontology language such as RDFS, DAML-OIL, or OWL. We focus on OWL as it is the most expressive of these languages, and has been standardised by the W3C. Using OWL, resources can be associated with resource types (classes), and predicates[2] can be defined for associating instances of certain classes. Furthermore, several constraints can be expressed restricting properties, and rules can be added to allow the assertion of new, additional properties. The formal semantics of OWL defines the precise meaning of these language constructs, and forms the sound base for OWL reasoners (Patel-Schneider et al., 2004). By describing how concepts are used in context, ontologies are defined—shared terminologies or "specifications of a conceptualization" (Gruber, 1993).

In Dietrich and Elgar (2005a), we have developed a terminology expressive enough to define basic Design patterns, and open enough to be extended whenever more expressiveness is required. This openness is important to define patterns that have a limited scope. Traditional pattern catalogues like the GangOf4 catalogue aim at programming language independent patterns, and their scope is object-oriented programming in general. However, it does make sense to publish patterns that refer to features not present in all languages, such as inner classes and annotations (Java) or class instance variables (Smalltalk). The scope of these patterns is a certain programming language, and they are shared within their respective communities. While the core ontology presented here does not directly support such PL specific patterns, it can be easily extended in various ways to do so.

Using OWL (or RDF for that matter) has another advantage: patterns are identified by uniform resource identifiers (URIs). These URIs are usually composed from the pattern name and a name space. This allows distinguishing between several flavours of one pattern all using the same name. A good example is Iterator. The definitions presented in Gamma et al. (1995) and

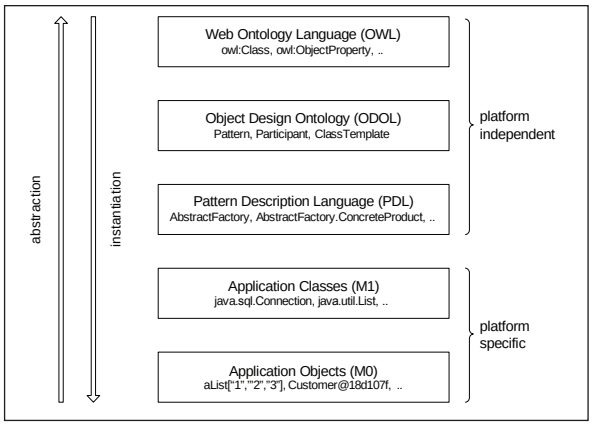
Grand (1998) differ—the GangOf4 definition has an additional first() method. The Iterator pattern used in Java is again different—there is an additional, optional remove() method. Adding a name space and referencing the pattern with the full URI immediately removes the ambiguity from the pattern definitions.

AN ONTOLOGY FOR SOFTWARE DESIGN PATTERNS

Metamodeling Architecture

The formal definition of Design patterns, their participants, and the properties of and relationships between the participants proposed here is based on an OWL ontology, that is, on a system of OWL classes, their properties, and relationships. These classes are instantiated in Design pattern definitions. Design patterns themselves do not contain classes, methods, and similar programming artefacts, but only placeholders or role names for such artefacts. In other words, Design pattern definitions contain typed variables that are instantiated by a particular pattern instance found in a concrete program. It has been pointed out by Eden (2002a) that for this reason UML class models are not suitable to represent Design patterns. The same applies to other M1 models—they contain concrete classes, not variables. In Dietrich and Elgar (2005a) we have proposed a meta model architecture to tackle this problem (Figure 1). The lower layers correspond to MOF M0 (application objects) and M1 (application classes, members, and associations). M1 artefacts instantiate pattern participants defined using the pattern description language (PDL). These are the variables found in pattern definitions like the AbstractFactory and the AbstractProduct in the AbstractFactory (Gamma et al., 1995) pattern. These variables are typed. The types are constraints restricting the kind of (M1) artefact that can instantiate these variables. These types are modeled in the object design ontology layer

Figure 1. Metamodeling architecture



(ODOL). In ODOL, the (OWL) ontology defined is the base for the pattern definitions. It contains classes such as ClassTemplate and MethodTemplate and their relationships, as well as the Pattern class representing patterns themselves. The meta model of ODOL is OWL– ODOL contains instances of OWL classes (for instance, owl:Class and owl:ObjectProperty).

The Ontology Schema

The ODOL ontology presented here is a revised version of the ontology presented in Dietrich and Elgar (2005a), adding pattern refinement and aligning it with the refactoring meta model proposed in Tichelaar, Ducasse, Demeyer, and Nierstrasz (2000). This adds significant expressiveness to the ontology, as it makes it possible to attribute relationships between participants such as Access, Association, and Invocation. Figure 2 does not show the full ontology, and in particular the data type properties (owl:DatatypeProperty) are omitted for space reasons. This includes the abstractness of class templates, access modifiers for member templates, cardinalities for associations, and similar properties. For the complete ontology, the reader is referred to "The ODOL OWL Ontology" (2006). The graph syntax used in Figure 2 and Figure 3 should not be confused with the RDF instantiation syntax. While the nodes do

Figure 2. The ODOL ontology: Class hierarchy

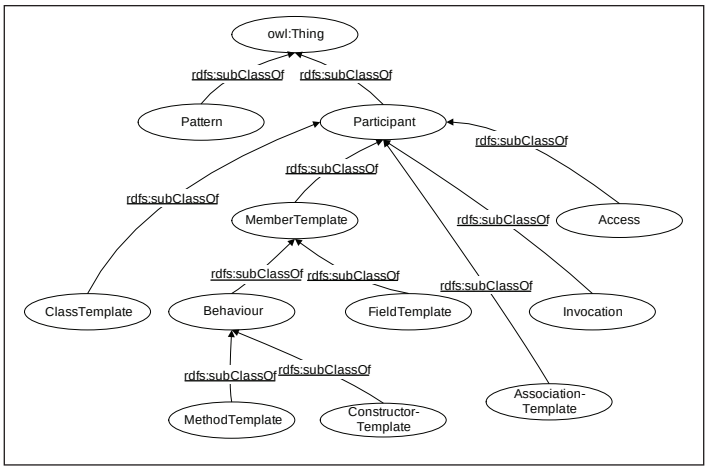


Figure 3. The ODOL ontology: Object properties

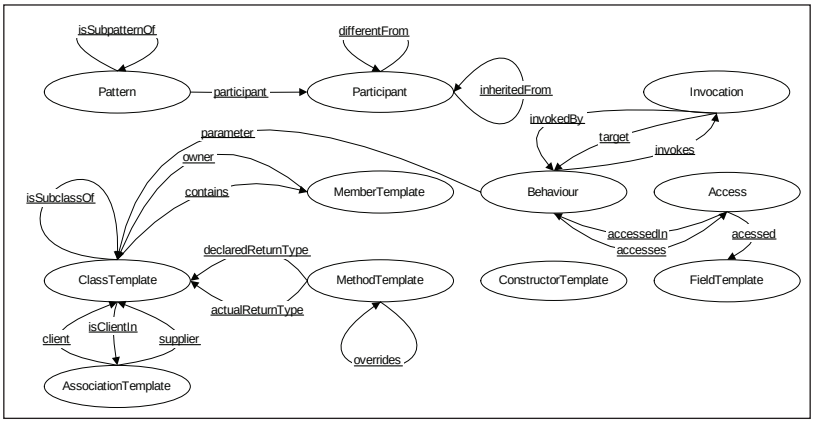

represent RDF resources (the OWL classes that are part of ODOL), the edges are object properties (owl:ObjectProperty) having the start node as the domain (rdfs:domain) and the end node as the range (rdfs:range). This is different from standard RDF graphs. We emphasise this difference by underlining the property names.

Built-In Rules

The model has a number of constraints describing its intended meaning. In particular, object properties are associated with OWL property types. For these types, the OWL semantics defines rules that can be used by reasoners to check the consistency of the model, and to infer additional assertions. This implies that pattern definitions do not have to include assertions that are redundant according to those rules. However, it is useful to have these redundant statements when processing pattern definitions, as this results in a better connected graph that is easier to process by applications. Table 1 shows some of the built-in rules.

In addition to these rules, the ontology contains references to *informal* definitions of some of the concepts defined. For instance, the (XML version of the) ontology contains the following references to Web sites intended for end users:

Table 1. ODOL rules (selection)

Property	Domain	Range	Rule(s)
isSubPatternOf	Pattern	Pattern	transitive
contains	ClassTemplate	MemberTemplate	inverseOf “owner”
owner	MemberTemplate	ClassTemplate	inverseOf “contains”, functional
associationClient	AssociationTemplate	ClassTemplate	functional, inverseOf “isClientIn”
associationSupplier	AssociationTemplate	ClassTemplate	functional
isClientIn	ClassTemplate	AssociationTemplate	inverseOf “associationClient”
isSubclassOf	ClassTemplate	ClassTemplate	transitive
overrides	MethodTemplate	MethodTemplate	transitive

```
<owl:Class rdf:ID=”Pattern”>
      <owl:sameAs
        rdf:resource=”http://en.wikipedia.org/wiki/Design_pattern_
        %28computer_science%29”/>
      <owl:sameAs
        rdf:resource=”http://hillside.net/patterns/definition.html”/>
</owl:Class>
```

Code Snippet 1: Informal definition of pattern in ODOL.

While the formal rules listed in Table 1 can be used directly by tools to process pattern definitions, these statements are intended for human end users like application programmers in order to help them to write correct applications consuming the patterns defined using this ontology. Using the terminology proposed by Uschold (2003), ODOL contains *formal* semantics intended for machine processing as well as *informal* semantics intended for human processing.

Defining Patterns

While the Design pattern ontology resembles the classical UML meta model, it contains some features that add additional expressiveness needed to represent Design patterns. For instance, the AbstractFactory pattern (Gamma et al., 1995) contains a ConcreteFactory method that overrides an AbstractFactory method and returns an instance of a ConcreteProduct class. The declared return type of the ConcreteFactory method instantiation equals the declared return type of the abstract method instantiation. Therefore, we must be able to distinguish between declared return type and the actual return type. In Code Snippet 2, the declared return type of the create method is the Connection class, while the actual return type is the ConnectionImpl class.

```
1. public Connection create () {
2.      return new ConnentionImpl () ;
3. }
```

Code Snippet 2: A concrete factory method.

To address this problem, the ontology has two object properties associating method templates with return types (class templates): declaredReturnType and actualReturnType. There is an implicit constraint relating these two properties that can be expressed as a rule:

$$\text{actualReturnType}(m,t_1) \;\&\; \text{declaredReturnType}(m,t_2) \Rightarrow \text{isSubclassOf}(t_1,t_2)$$

Currently, this kind of rule is not part of the

ontology. Languages like OWL do not support custom derivation rules, although this area is an active area of research with emerging standards such as RuleML (Boley, Tabet, & Wagner, 2001) and SWRL (Patel-Schneider et al., 2004). Therefore, the isSubclassOf property cannot be inferred and has to be added explicitly to the pattern definition, and it remains the responsibility of the client to check the constraint. On the instance level, this would usually be done by a compiler.

The definition of AbstractFactory (without data type properties) is depicted in Figure 4 and Figure 5. The types are defined in the central ontology deployed at a certain URL. This resource is explicitly imported using an owl:imports directive. This allows maintaining a central ontology that can be referenced by different patterns.

Figure 4. The AbstractFactory pattern (participants and their types)

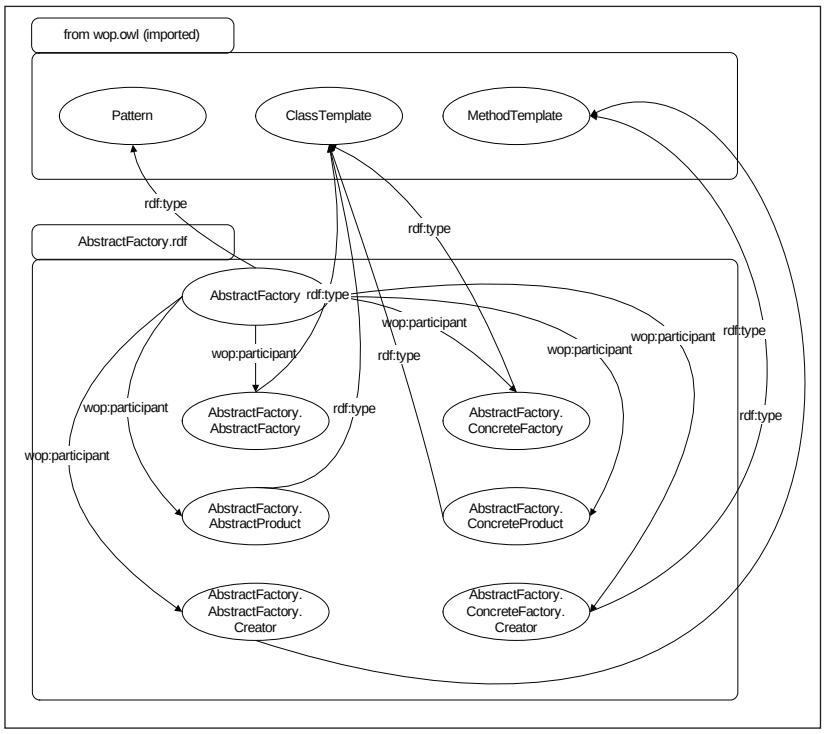

Figure 5. The AbstractFactory pattern (other object properties)

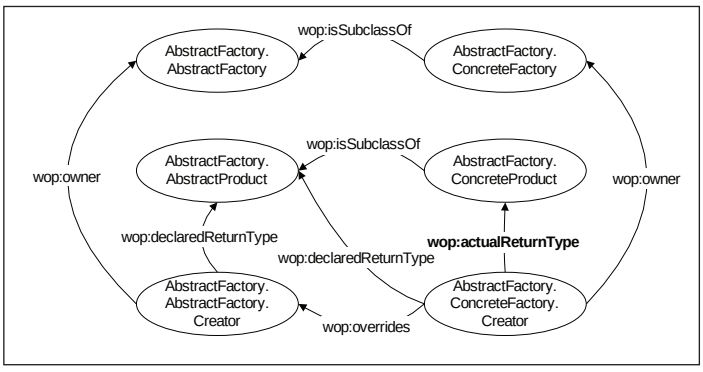


Pattern Refinement

Pattern refinement defines an inheritance relationship between patterns. Using refinement, patterns inherit participants from parent patterns, and add new participants or new relationships. The simplest form of refinement is a pattern definition that imports another pattern, references all of the participants using the wop:participant property, and adds new participants and properties.

In addition to this, ODOL contains additional constructs to support multiple inheritance and joins between participants inherited from different parents. The isSubPatternOf property associates a pattern with a parent pattern. This property is not functional, that is, multiple inheritance is explicitly permitted. The semantics of this property is that all participants and their properties of the parent pattern are appended to the definition of the importing pattern. Using a derivation rule, this can be expressed as follows:

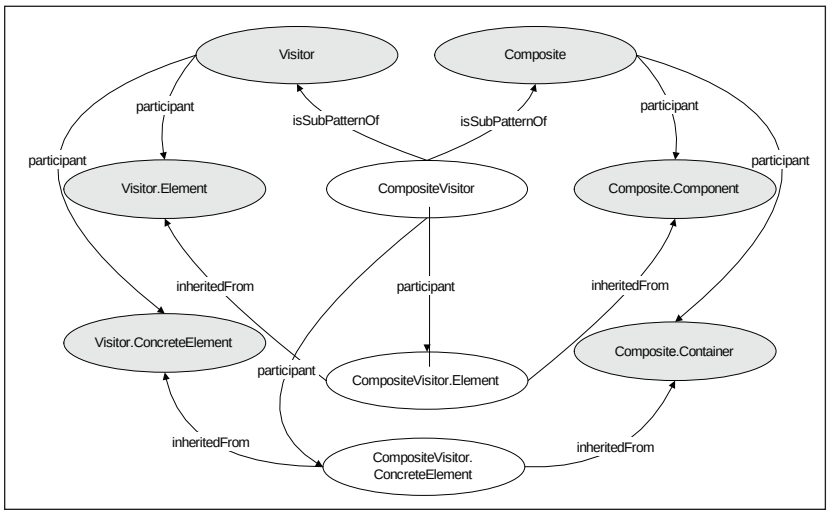
$$isSubPatternOf(pat_1,pat_2) \ \& \ participant(pat_2,part) \Rightarrow participant(pat_1,part)$$

The inheritedFrom relationship identifies participants with participants inherited from parents. The semantics is simple, the bindings for these participants must be the same. This property is also not functional, that is, a "local" participant can be associated with more than one imported/ inherited participant. This allows joining inherited participants, as depicted in Figure 6. In this example, the CompositeVisitor is a Visitor (Gamma et al., 1995) visiting a Composite (Gamma et al., 1995) structure. It refines both the Visitor and the CompositeVisitor pattern.

Multiple inheritance can lead to conflicts, for instance if participants with contradicting properties are defined. It is again part of the informal semantics of ODOL to require that inheritedFrom can only associate properties with no conflicting ODOL properties. That means that:

1. If two joined participants have an ODOL data type property, then the values of these participants must be the same.
2. The graph containing participants and ODOL object properties obtained by replacing the participants referenced using the inheritedFrom predicate by the referencing participants must be consistent.

Figure 6. Definition of CompositeVisitor using pattern refinement (imported participants are represented by the shapes with a darker colour)



An example for how condition 2 could be violated is the following situation: let R be a functional property in ODOL, and let R(a,b) and R(c,d) be statements in two pattern definitions P1 and P2 (written in relational syntax). If P is a sub pattern of both P1 and P2 with conditions joining a and c, but no condition joining b and d, the "functional" condition for R would be violated.

Note that both integrity conditions are explicitly referring to the ODOL vocabulary. Conflicts in other vocabularies might not be as critical. In particular, conflicts concerning metadata (such as dc:Description or dc:Creator) are acceptable.

Attaching Meta Information

Reasoning about patterns becomes important if patterns are published in an open, essentially uncontrolled and unmoderated environment like the Internet. In particular, this reasoning will facilitate the selection of trustworthy knowledge. There are no special constructs in ODOL to support metadata, instead standard vocabularies are used. In particular, the Dublin Core ("The Dublin Core Metadata Initiative," 2006) properties can be used to annotate the pattern instances in pattern definitions. Using these annotations, derivation rules can be used to select all GangOf4 patterns (using an assertion like "dc:Creator=GangOf4"). Often, additional predicates have to be used in these rules, either based on explicit meta information, or on harvested meta information such as:

1. **isSecure:** Has an HTTPS connection been used to download patterns?
2. **isKnownBy:** Is the pattern resource referenced by the Web sites of pattern communities such as hillside.net or on vendor Web sites like ibm.com.
3. **isWellknown:** Is the pattern definition known as well referenced by Google? That is, does the Google query link:<aPatternURL> return more than 42 results?

INSTANTIATING DESIGN PATTERNS

Pattern Instances

Defining the patterns in OWL/RDF enables us to deploy the pattern definitions on standard Web servers, where they can be found and accessed by applications and standard search engines. There are several use cases describing how to process Design patterns, the most important one being Design pattern recognition in programs. This enables users to X-Ray complex software packages in order to improve program comprehension. It may also be used to measure Design pattern density in software package in order to quantify design quality: the use of best practise Design patterns can be considered as desirable as it makes it easier for teams to communicate about design.

The Design pattern definitions can be easily translated into derivation rules in typed first order logic with the pattern itself as the predicate in the head of the respective rule, and the pattern participants as free variables. The precise definition is presented in Dietrich and Elgar (2005b), and we use the AbstractFactory pattern to explain the transformation. The pattern has the following participants: AbstractFactory (af), AbstractProduct (ap), ConcreteFactory (cf), ConcreteProduct (cp), AbstractFactory.Creator (afc), ConcreteFactory.Creator (cfc). These participants are associated with typed variables, and the types are the respective ODOL classes. The head of the rule is Abstract Factory(af,ap,cf,cp,afc,cfc). The prerequisites of the rule are:

1. isSubclassOf(cf, af)
2. isSubclassOf(cp, ap)
3. contains(af, afc)
4. contains(cf.cfc)
5. declaredReturnType(afc,ap)
6. declaredReturnType(cfc,ap)
7. actualReturnType(cfc, cp)
8. overrides(cfc, afc)
9. isAbstract(af,"abstract")

10. isAbstract(afc, ”abstract”)
11. isAbstract(ap,”abstract”)
12. ..

That is, object properties are translated into binary constraints associating participants with other participants (or more precisely, the respective variables), while data type properties are transformed into binary predicates associating participants with string literals. The typing imposes additional constraints that can be seen as unary predicates. In the AbstractFactory example, this would lead to additional prerequisites such as isClass(af), isMethod(afc), and so forth. Similar to the mechanisms proposed by other authors (Beyer, Noack, & Lewerentz, 2003; Eden, 2002a; Kraemer & Prechelt, 1996), Design pattern detection becomes a matter of instantiating the variables in these rules. The values binding the variables are artefacts from the program to be analysed. Artefacts include classes and their members, but also associations, method invocations, and field accesses. If Var(P) denotes the set of participants in a pattern P and A(Progr) the set of artefacts in a program Progr, then a pattern instance is a function instance:Var(P)→A(Progr).

Instantiation requires a universe of artefacts to be extracted from the analysed program, and a set of ground facts for the predicates used in the rules instantiated using these artefacts. Because the rules are structurally fairly simple (datalog without negation), the only challenge is to find the appropriate fact base. The universe itself must contain representations of the artefacts found in the program. These could either be names, instances of classes of the programming language representing artefacts (such as reflection frameworks), or instances of classes from separate object models describing the structure of programs. As far as the fact base is concerned, there are some fundamentally different approaches that can be used to instantiate predicates. This includes:

1. Using the reflective features of the programming language itself. Most modern PLs offer such a feature, and relationships such as membership, return type, and inheritance can be easily instantiated.
2. Source code analysis. Reflection based analysis is usually not suitable to instantiate associations and invocations. This often requires source code analysis. The respective concepts have been studied comprehensively in the realm of compiler technology. Source code is usually represented by abstract syntax trees (AST), and analysis is done using AST visitors. Using visitors, symbol tables are compiled to resolve the references between artefacts.
3. Naming pattern analysis. Often naming patterns do have meaning, and they can be used for program analysis as well. A good example for meaningful naming patterns is the java bean specification (“The JavaBeans Spec,” 2006).The use of certain prefixes for method names and parameter signatures indicates that there are certain properties of and relationships between objects. An example is the one to many relationship between event sources and event listeners. Tools such as GUI builders use these semantics.
4. Behavioural analysis. Based on the run and observe approach, behavioural analysis can detect relationships not accessible by any of the above methods. This includes the analysis of code that uses reflection, for instance the interpretation of strings as methods. Behavioural analysis requires that the program can be executed “completely,” that is, that each code branch is visited during code execution. In some cases, complete execution is provided by test suites, particularly if test-case driven methodologies like extreme programming (Beck, 1999) are used in conjunction with tools measuring test coverage. Technically, behavioural analysis can take advantage of

debugging APIs or newer approaches used to instrument code (for instance, aspect-oriented programming).

Client Architecture

The WebOf Patterns (WOP) project ("The WebOf-Patterns Project," 2006) is a client that consumes and produces pattern definitions based on ODOL. Technically, the client is an Eclipse plugin. It interprets the pattern definitions in Java, and features the following functionality: a *pattern scanner* with a built-in HTTP client that downloads patterns from a given URL, detects pattern instances in Eclipse Java projects and compiles JavaDoc style (HTML and XML) reports from the findings. The client also supports several pattern aggregations (see page 15). A *pattern browser* generates a graph from pattern definitions that can be navigated in a browser-like manner. A *pattern publishing wizard* allows users to select artefacts, their properties and relationships from projects, give those artefacts abstract role names, and generate the pattern definition as a RDF file. This file can then be deployed on a standard Web server.

The WOP client serves as a reference application for the ontology. It contains guidelines on how to consume the ontology based pattern definitions. This makes it part of the "formal semantics for human processing" (Uschold, 2003). This is similar to software specifications—many specs consist mainly of interfaces (UML, IDL, Java interfaces). The semantics of these interfaces is defined by documents, formal constraints (like OCL), and test suites. Often, a reference implementation is provided that can be considered as part of the semantics—software engineers are referred to the reference implementation if the other parts of the specification leave questions open.

The pattern scanner is the most important part of the WOP client, as it has to map the structures defined in the ontology to the structures found in the Java programming language. This is rather simple for some elements, as there is an obvious homomorphism (structure preserving mapping) between the ontology and the grammar of the programming language—classes have methods, methods have return types, and so forth. It is less obvious for participants that have no direct counterparts in Java, such as Association.

The WOP Client has the following structure:

- Participants are represented by Java classes in the nz.ac.massey.cs.wop package. Example: AssociationTemplate, ClassTemplate, Participant, Pattern.
- Artefacts instantiating the participants are represented by Java classes in the nz.ac.massey.cs.wop.reflect package. Example: Association, JClass, JMethod, and so forth.
- Object properties are represented by classes implementing the interface nz.ac.massey.cs.wop.BinaryConstraint<SOURCE,TARGET> in the nz.ac.massey.cs.wop.constraints package. Example: IS_SUBCLASS_OF, OVERRIDES.
- Data type properties are represented by subclasses of nz.ac.massey.cs.wop.UnaryConstraint<TYPE> in the nz.ac.massey.cs.wop.constraints package. Examples: IS_ABSTRACT_CLASS, IS_PUBLIC_MEMBER.

The type parameters of the generic constraint classes represent the types associated by the respective constraints. This must be consistent with the domain and the range types of the associated object property. The constraints contain methods defining the extension of the respective (unary or binary) predicate in the context of the program investigated. The Eclipse project analysed is represented by an instance of Workspace. This contains a reference to a class loader, the byte code location(s), the source code location(s), and entry points for behavioural analysis. In particular, the BinaryConstraint interface defines the following three methods (SOURCE and TARGET are the generic type parameters):

1. boolean check(SOURCE,TARGET,Workspace)
2. Iterator<SOURCE> getPossibleSourceInstances(Workspace,TARGET)
3. Iterator<TARGET> getPossibleTargetInstances(Workspace,SOURCE)

Code Snippet 3: Methods in BinaryConstraint defining the semantics of an object property in Java

These methods precisely define the semantics of the associated object property. The first method allows verifying whether two given instances instantiate the predicate. The other two methods return an iterator over possible instances if one instance is known. This supports the "navigation" of the predicates. There is no method that computes the entire extension of the predicate (i.e., an iterator over SOURCE-TARGET pairs). This is highly inefficient and can generally be avoided by choosing appropriate algorithms to resolve the constraints.

For instance, the IS_SUBCLASS_OF class implements BinaryConstraint as follows:

1. Both SOURCE and TARGET are JClass, JClass.
2. If instances of both source and target are given, reflection (isAssignableFrom in java.lang.Class) is used to check whether class 1 is a subclass of class 2.
3. If only the source is known, the reflection methods getSuperclass() and getInterfaces() are recursively called, the results are collected in a collection and an iterator over this collection is returned.
4. If only the target is known, all classes in the workspace are scanned to find all subclasses of the target, and the respective iterator is returned.

In general, classes implementing the interface nz.ac.massey.cs.wop.reflect.Analyser provide the structural information needed by the constraint classes. Analysers are organised as a chain, and if an analyser cannot provide the information requested the next analyser is called (ChainOfResponsibility pattern (Gamma et al., 1995)). The analysers currently implemented are based on reflection, (Eclipse) AST analysis, and naming pattern analysis.

The pattern scanner itself uses cost-based scheduling to arrange the constraint in an optimal order. It always attempts to solve "cheap" constraints (like those that can be verified using reflection) first, and arranges constraints so that at least one of the participants is already known. This is facilitated by having redundant constraints (the deductive closure according to the rules encoded in the ontology in Table 1), as this results in a better connected graph consisting of participants as nodes and binary constraints as edges. The ontology itself is accessed using the Jena ("Jena – A Semantic Web Framework for Java," 2006) framework that includes an OWL reasoner.

The constraint resolution process uses a simplified version of SLD (Robinson, 1965). The unification can be simplified as there are no complex terms in the pattern rule.

Validation

The question arises whether the formal pattern definitions and the tool processing them (the pattern scanner) capture the meaning of the respective pattern. This includes two aspects: firstly, correctness, that is, are all pattern instances detected *intended* instances? Secondly, completeness, that is, are all intended instances found by the scanner? In other terms, are there false positives (correctness) and are there false negatives (completeness)?

The WebOfPatterns client has been validated using test cases based on code that is part of two text books on patterns in Java (Grand, 1998; Stelting & Maassen, 2001). While this validation is successful in the sense that all test cases succeed, it has some obvious weaknesses. Firstly, the code examples used in these text books are (on purpose) very simple, and more complex language features such as inner classes and reflection, are avoided. The current version of the WebOfPatterns source

code analyser does not support inner classes, and therefore certain instances of predicates like actualReturnType and invokedBy are not detected. That is, the fact base built by the client is incomplete. Therefore, certain pattern instances are not found—there are false negatives. But as this is mainly due to limitations of the current implementation of the analysers, the problem should be solved as the client is improved. If behavioural analysis is used, the completeness of the fact base still depends on whether the analyser is able to cover the entire program. This would be the case for programs with unit test cases and 100% test coverage.

An interesting approach to validation would be the comparison of scan results with the results produced by other tools such as CrocoPat (Beyer, Noack, & Lewerentz, 2003) and Fujaba (Niere, Schafer, Wadsack, Wendehals, & Welsh, 2002).

The question whether there are false positives is more difficult to answer and requires the analysis of some scan results. This leads to the introduction of some new concepts related to pattern instantiation.

Normal and Aggregated Instances

The analysis of pattern instances found in non trivial programs reveals a number of "unintended instances." Most of them feature different participants instantiated by one artefact. For instance, consider the following code snippet:

```
1. public abstract class A {
2.     public abstract A copy ( ) ;
3. }
4. public class AImpl extends A {
5.     public A copy ( ) {
6.         A clone = new AImpl ( ) ;
7.         / / configure, set instance variables
8.         return clone;
9.         }
10. }
```

This program instantiates AbstractFactory in a trivial way: A is both the AbstractFactory (role) and the AbstractProduct, while AImpl is the ConcreteFactory and the ConcreteProduct. In this program, a cloneable structure is defined, with A representing the specification of the structure and AImpl being an implementor. The question arises whether there is an implicit constraint in AbstractFactory that requires that the factory and the product must be different. The ontology does contain the respective language feature, the wop:differentFrom property[3]. For some patterns, there is clearly a need for such a constraint. For example, in the Proxy (Gamma et al., 1995) pattern, the Proxy (wrapper) and the RealSubject (the wrapped class) must be different. For other patterns the situation is less clear. In this case we opt for not having such an explicit constraint. This leaves two options open: to use the refinement mechanism to add such an explicit constraint in a sub pattern, or make it a feature of the client to add the wop:differentFrom constraints on demand. Conceptually, we call instances of patterns where different participants are mapped to different artefacts *normal*. In other terms, normal pattern instances are injective.

The number of "good" instances found is surprisingly high. Often it is useful to identify some instances by abstracting from certain details. For instance, two AbstractFactory instances might be considered equal if all abstract participants are mapped to the same artefacts. Two instances of Bridge (Gamma et al., 1995) could be considered variants of the same instance if they have the same abstraction and the same implementor. In general, pattern aggregation is used to identify certain patterns. Instead of considering pattern instances as defined above, classes of instances modulo an equivalence relation ~. This relation meets the following three conditions:

1. **Reflexivity:** $\forall$ instance: instance ~ instance
2. **Symmetry:** $\forall$ $instance_1$,$instance_2$: $instance_1$ ~ $instance_2 \Rightarrow$ $instance_2$ ~ $instance_1$

Table 2. Scan results

Package	Time[d] (s)	Abstract-Factory	Adapter	Bridge	Composite	Proxy	Template-Method
Mandarax 3.4	35	166	91	0	3	2	495
MySQL ConnectorJ 3.1.12	134	56	289	28	0	0	0

3. **Transitivity:** $\forall$ $instance_1$,$instance_2$,$instance_3$: $instance_1$~ $instance_2$ & $instance_2$~ $instance_3$ $\Rightarrow$ $instance_1$~ $instance_3$

Such a relation can be defined as projection with respect to a subset of participants **S** that are part of a pattern as follows:

$instance_1 \sim_S instance_2$ iff $\forall p \in S: instance_1(p) = instance_2(p)$

There are a number of possible aggregations, each defining a separate view on the structure of the program investigated.

1. Identify instances if they map all marked participants to the same artefacts. This allows a default aggregation to be built into the ontology, making this aggregation part of the pattern itself. For this purpose, the ontology has a built-in data type property isAggregationPoint that allows tagging participants explicitly.
2. Identify instances if they map abstract participants to the same artefacts.
3. Identify instances if they map abstract classes to the same artefacts.
4. Identify instances mapping abstract class templates to the same classes, and method templates to methods sharing the same name and the same owner class. This allows the identification of instances containing overloaded methods.
5. No aggregation ("null aggregator").

Aggregation of instances is an alternative to using higher order logic constructs like Eden's higher dimension entities (Eden, 2002b) to describe patterns. By adding default aggregation support to the pattern definition itself but also allowing tools to override it by applying no or alternative aggregations we gain greater flexibility in supporting alternative views on the system design.

Limitations of our Approach and Future Trends

There are some known limitations with the approach presented here. ODOL is not expressive enough to describe constraints referencing instances (and not classes). An example of a pattern that uses this kind of constraint is Prototype (Gamma et al., 1995). The Prototype participant contains a clone() method. The semantics of this method is to provide a copy of the Prototype *object*. In Java style syntax, this can be written as follows: "prototype.clone()!=prototype". This cannot be expressed directly using the current version of ODOL. To address this problem, a data type property isClone is defined in ODOL. The semantics of this method is mainly informal, and the responsibility to interpret it correctly is delegated to applications. Obviously, there is a trade-off here between ontological reductionism (having a small number of modeling primitives with a clear semantics) on the one side, and how simple and convenient it is for software engineers to use the ontology on the other side. In the long term, the solution is to have more expressive vocabularies and to define more derived concepts by means of explicit rules.

There are entire families of patterns for which the ontology presented here is not appropriate.

Table 3. Pattern instance aggregation

Package/ Pattern	No Aggregation	Built-in Aggregation	Group by abstract participants	Group by abstract classes
Mandarax 3.4 / AbstractFactory	166	48	48	29
MySQL ConnectorJ 3.1.12 / AbstractFactory	56	46	46	16
MySQL ConnectorJ 3.1.12 / Bridge	28	1	8	1

Architectural patterns (Buschmann, Meunier, Rohnert, Sommerlad, Stal, Sommerlad, et al., 1996) use concepts such as tier and layer. On the other hand, code level patterns like lazy initialisation refer to concepts used in PL grammars like blocks and error handlers.

A very promising direction for further research is the adoption of the approach presented by Fowler (1999) and Opdyke (1992) for refactoring. A formal, ontology based refactoring language would enable software engineers to find solutions to design problems on the Web, and to perform them in the context of the programming language used. The design problems themselves can be described using an ontology similar to the one presented here as antipatterns. By means of additional derivation rules similarity between patterns can be defined, further increasing the chances of finding a solution to problems encountered.

The relationship between the platform independent ontology layer and the interpretation of these concepts in a particular programming language is an interesting area for further research. We have argued that a client is more than just an implementation. The client has to interpret the concepts found in the ontology correctly. This warrants a closer integration of ontology and client. In particular, for languages like Java where components can be deployed as Web resources,[5] RDF statements can be used to associate object properties and their correct interpretation in a context given by a programming language (Java) and a client application (WOP).

The pattern scanner presented here is far from being mature. Despite the gaps in the AST analyser mentioned, there are other issues related to scalability. The main benefit of having a scalable pattern scanner in the standard toolbox of software engineers (in the form of ANT tasks, or Eclipse plugins) is that this will enable researchers to gather vast amounts of empirical data about software design, and how this design evolves. This may lead to new research on pattern based metrics, and investigations into quantifying the correlation between patterns and software quality.

CONCLUSION

In this chapter, we have shown how techniques developed in the realm of the semantic Web can be used to formalise software Design patterns. We have elaborated an ontology based on the Web ontology language OWL and have shown how this fits into a meta modeling framework that extends the meta modeling architecture used by the OMG. Several aspects related to pattern instantiation discussed are not only relevant to our approach, but should be addressed whenever Design patterns are formalised. In particular, this concerns validation and pattern instance aggregation.

The semantic Web offers tremendous opportunities for the software engineering community. This community is most likely to adapt the semantic Web as it is already accustomed to share much of the knowledge it produces on the Web. It has pioneered the use of Wikis and Blogs, and

has found solutions for how to deal with inconsistencies in open environments. A good example is open source repositories like SourceForge using source control systems such as Subversion or CVS. Participating programmers produce inconsistencies that are resolved with merge and diff tools based on metadata (version tags, commit time, committer). Giving this community better tools to share their knowledge will significantly improve the way software engineering is done. It could eventually lead to an open eco system of patterns (and antipatterns, and refactoring, and ...) where Darwinian forces lead to the survival of the fittest.

Critical for the semantic Web to succeed in software engineering as well as in general is the availability of tools to manage the knowledge produced. Of particular importance is search engine support, for example, to be able to query Google for RDF resources containing instances of the ODOL ontology. Furthermore, modules that allow reasoning about knowledge based on customisable rules and mainly harvested metadata are needed.

Once the community accepts this approach, it is likely that domain specific ontologies will emerge serving the needs of particular communities. These communities are not necessarily organised around programming languages or vendors, but also application areas (desktop, server, embedded), industries (financial, e-commerce) or programming paradigms (Aspect-Oriented Programming). We will have to deal with a multidimensional space of ontologies. This poses new challenges for describing the relationships between these ontologies.

Chapter 2.3
Class Patterns and Templates in Software Design

Julio Sanchez
Minnesota State University, Mankato, USA

Maria P. Canton
South Central College, USA

ABSTRACT

This chapter describes the use of design patterns as reusable components in program design. The discussion includes the two core elements: the class diagram and examples implemented in code. The authors believe that although precanned patterns have been popular in the literature, it is the patterns that we personally create or adapt that are most useful. Only after gaining intimate familiarity with a particular class structure will we be able to use it in an application. In addition to the conventional treatment of class patterns, the discussion includes the notion of a class template. A template describes functionality and object relations within a single class, while patterns refer to structures of communicating and interacting classes. The class template fosters reusability by providing a guide in solving a specific implementation problem. The chapter includes several class templates that could be useful to the software developer.

DESIGN PATTERNS

Engineers and architects have reused design elements for many years (Alexander, Ishikawa, Silverstein, Jacobson, Fiksdahl-King, & Angel, 1977); however, the notion of reusing elements of software design dates back only to the early 1990s. The work of Anderson (1990), Coplien (1992), and Beck and Johnson (1994) set the background for the book *Design Patterns* by Gamma, Helm, Johnson, and Vlissides (1995), which many considered the first comprehensive work on the subject.

The main justification for reusing program design components is based on the fact that the design stage is one of the most laborious and time-consuming phases of program development. Design reuse is founded in the assumption that once a programmer or programming group has found a class or object structure that solves a particular design problem, this pattern can then be reused in other projects, with considerable savings in the design effort. Anyone who has participated in the development of a substantial

software project appreciates the advantages of reusing program design components.

The present-day approach to design reuse is based on a model of class associations and relationships called a class pattern or an object model. In this sense, a pattern is a solution to a design problem. Therefore, a programming problem is at the origin of every pattern. From this assumption we deduce that a pattern must offer a viable solution; it must represent a class structure that can be readily coded in the language of choice.

The fact that a programming problem is at the root of every design pattern, and the assumption that the solution offered by a particular pattern must be readily implementable in code, are the premises on which we base our approach to this topic. In the context of this chapter we see a design pattern as consisting of two core elements: a class diagram and a coded example or template, fully implemented in code. Every working programmer knows how to take a piece of existing code and reengineer it to solve the problem at hand. However, snippets of code that may or may not compile correctly are more a tease than a real aide.

Although we consider that design patterns are a reasonable and practical methodology, we must also add that it is the patterns that we ourselves create, refine, or adapt that are the most useful. It is difficult to believe that we can design and code a program based on someone else's class diagrams. Program design and coding is a task too elaborate and complicated to be done by imitation or by proxy. A programmer must gain intimate familiarity with a particular class and object structure before committing to its adoption in a project. These thoughts lead to the conclusion that it is more important to explain how we can develop our own design patterns than to offer an extensive catalog of someone's class diagrams, which can be difficult to understand, and even more difficult to apply.

CLASS TEMPLATES

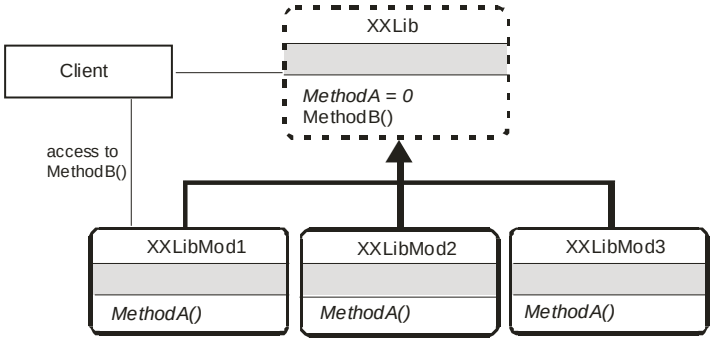
Occasionally, a programmer or program designer's need is not for a structure of communicating and interacting classes but for a description of the implementation of a specific functionality within a single class. In this case we can speak of a class template rather than of a pattern. The purpose of a class template is also to foster reusability by providing a specific guide for solving a particular implementation problem. In the following sections we include several class templates that could be useful to the practicing developer.

A Pattern is Born

We begin our discussion by following through the development of a design pattern, from the original problem, through a possible solution, to its implementation in code, and concluding in a general-purpose class diagram.

One of the most obvious and frequent uses of dynamic polymorphism is in the implementation of class libraries. The simplest usable architecture is by means of an abstract class and several modules in the form of derived classes that provide the specific implementations of the library's functionality. Client code accesses a polymorphic method in the base class and the corresponding implementation is selected according to the object referenced. But in the real world a library usually consists of more than one method. Since many languages allow mixing virtual and nonvirtual functions in an abstract class, it is possible to include nonvirtual methods along with virtual and pure virtual ones. The problem in this case is that abstract classes cannot be instantiated; therefore, client code cannot create an object through which it can access the nonvirtual methods in the base class. A possible but not very effective solution is to use one of the derived classes to access the nonvirtual methods in the base class. Figure 1 depicts this situation.

Figure 1. A class library implemented through dynamic polymorphism



The first problem of the class diagram in Figure 1 is that the client code accesses the nonvirtual MethodB() in the base class by means of a pointer to one of the derived classes. A second, and perhaps more important one, is that method selection must take place in the client's code. Both of these characteristics expose the class structure and add a substantial processing burden to the client.

There are several possible solutions to the first problem. We could make the base class a concrete class with MethodA() as a simple virtual function, with no real implementation. In this case MethodB() becomes immediately accessible. Another solution would be to create a new class to hold the nonvirtual methods originally in the base class and have this new class inherit abstractly. However, neither of these solutions addresses the most important problem, which is that client code must perform method selection. It is this characteristic of inheritance that breaks encapsulation.

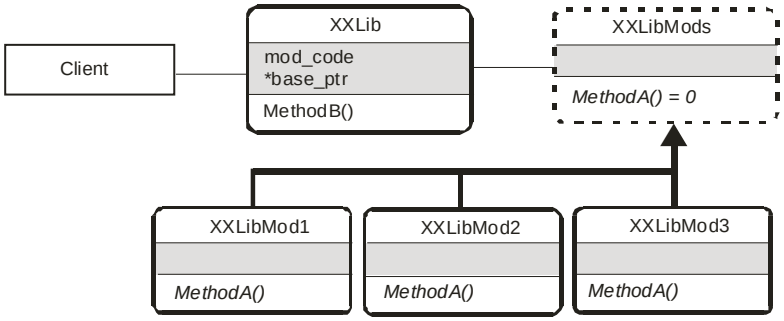
Encapsulation can be preserved by using object composition instead of inheritance. Also, combining object composition and inheritance achieves dynamic binding of polymorphic methods while preserving encapsulation. Figure 2 is a possible class diagram for implementing the library by means of object composition and inheritance.

Design of a VESA True Color Library

The design of a VESA true color graphics library can be based on combining object composition and class inheritance. The minimal functionality of this library can be stated as follows:

1. A way of setting the desired VESA true color mode.

Figure 2. An alternative implementation of the class library



2. A way of obtaining the current VESA mode as well as the vertical and horizontal resolution.
3. A way of drawing a screen pixel defined in terms of its x and y screen coordinates and its color attribute.
4. A way of reading the color attribute of a screen pixel located at given screen coordinates.

Figure 3 is a diagram of the library classes.

Observing the class diagram in Figure 3 we detect some features of the class structure:

1. The nonvirtual methods are located in the class named VesaTCLib.
2. VesaTCLib is a concrete class and can be instantiated by the client.
3. The mode-dependent, polymorphic methods for setting and reading pixels, named DrawPixel() and ReadPixel(), respectively, are located in an inheritance structure.
4. The methods named GetPixel() and SetPixel() in the class VesaTCLib provide access by means of a pointer to the polymorphic methods DrawPixel() and ReadPixel().

The result of this class design is that the implementation is now transparent to the client, as shown by the gray shaded background in Figure 3. The following program (Box 1) contains the schematic implementation of the class and inheritance structure in Figure 3.

The previous code sample, named SAMP-01.CPP, deserves a few additional comments. The constructor receives a coded signature that defines the VESA true color mode requested by the caller. A switch construct stores the VESA mode number, vertical and horizontal resolution, and the address of the library methods used in setting and reading a pixel in this mode. Therefore, the contingency code executes only once, when the object is created. Thereafter, each object of the class VesaTCLib is associated with a particular mode and keeps the address of the method to be used in its own pixel setting and reading operations. The methods GetPixel() and ReadPixel() of the class VesaTCLib are the client's interface to the pixel-level primitives in the library. The actual setting and reading of a screen pixel is performed as follows:

 return 0;
}
```

continued on following page

```
void VesaTCLib::SetPixel(int row, int col,
int atts) {
  base _ ptr->DrawPixel(row,  col,  attri-
bute);
};

void  VesaTCLib::GetPixel(int  row,  int
col) {
 base _ ptr->ReadPixel(row, col);
};
```

The processing in this case is done with a smaller processing overhead. The principal advantage of the new class design and implementation can be summarized as follows:

1. Contingency code to select the corresponding mode-dependant, pixel-level primitives is now located in the constructor; therefore, it executes only when the object is created.
2. Client code does not need to perform the mode selection operations, which have been transferred to the library classes.
3. Client code does not see or access the class inheritance structure since the pixel-level operations are handled transparently.

Developing the Pattern

In the previous sections we addressed a programming problem and found one possible solution that could be implemented in code. We also constructed a class diagram that reflects the relationships and associations of this solution in object-oriented terms. In order to make this solution easier to reuse we can eliminate all the case-specific elements from both the pattern and the coded example. Furthermore, the resulting abstraction can be given a name that provides an easy reference to the particular case.

In selecting a name for a design pattern we must carefully consider its purpose and applicability. Observe that the class structure for constructing the VESA true color library is probably applicable to many programming problems that are not related to computer graphics, or even to libraries. Its fundamental purpose is to provide an interface to an inheritance structure so that its operational details are hidden from client code. Since interface is too general a term, we could think of the word concealer in this context. For the lack of a better term we call this pattern a concealer, since its purpose is to conceal an inheritance structure so that its existence and operation are made transparent to the client. Figure 4 shows the concealer pattern in a more abstract form.

Unifying Dissimilar Interfaces

A simple but frequent design problem is to present a unified and friendly interface to a set of classes that perform different operations, for example, a set of classes that calculates the area of different geometrical figures, such as a parallelogram, a circle, a rectangle, and a square. The formula for the area of a parallelogram requires three parameters: the base, the side, and the included angle. The area of the circle and the square require a single parameter, in one case the radius and in the other one the side. The area of a rectangle requires two: the length and the width. Our task is to provide the client with a single interface to the calculation of the area of any one of these four geometrical figures. This class structure is known as a unifier pattern.

In the previous example the implementation could be based on the client passing four parameters. The first one is a signature code indicating the geometrical figure, the other three parameters hold the pertinent dimensional information. By convention, we agree that unnecessary parameters are set to NULL. The class diagram in Figure 5 represents one possible solution.

In the case of Figure 5 the method selection is based on an object of the corresponding class, therefore, it is a case of object composition. An alternative implementation could easily be based on pointers instead of object instances. Program

Figure 4. A Concealer pattern

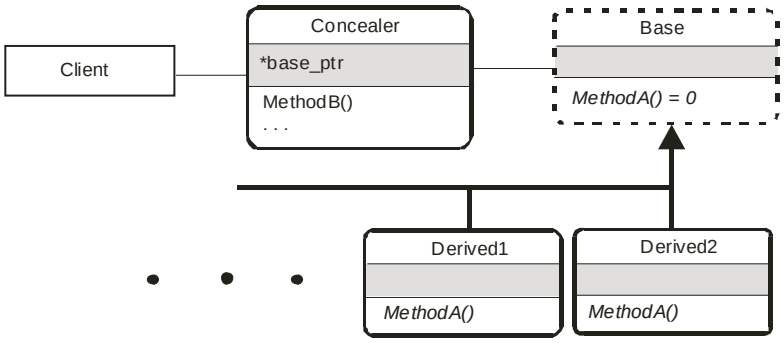

Figure 5. Implementing an interface class

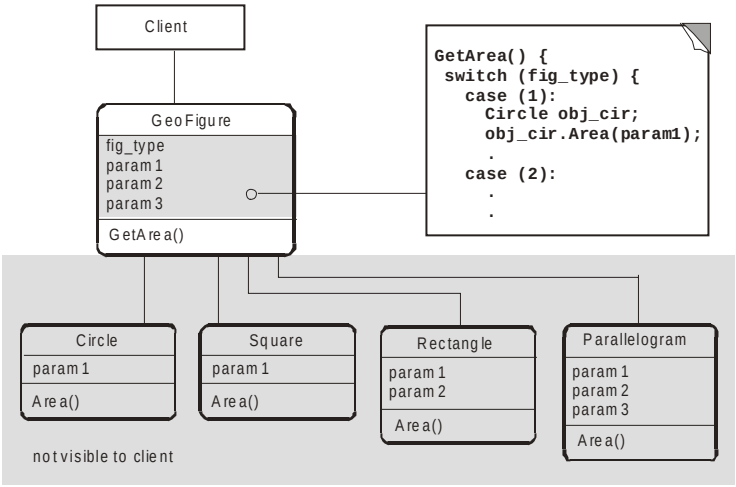

SAMP-02.CPP shows the necessary processing in the first case (Box 2).

Note that in program SAMP-02.CPP the objects are instantiated inside the switch construct in the GetArea() method. This ensures that only the necessary object is created in each iteration of GetArea(). Since the objects have local scope their lifetime expires when GetArea() returns. Therefore, only the necessary memory is used.

Unifier patterns have found frequent use in modeling object-oriented frameworks. InterViews 2.6 defined a similar construct for modeling interface elements such as buttons, scrollbars, and menus (Vlissides, 1988).

An Interface Pattern

By generalizing the class diagram in Figure 5 we can develop an interface pattern in which a class provides access to other classes that implement certain functionality. Figure 6 shows this generalization.

Aggregated Class Hierarchies

On occasions we may need to implement a set of classes related hierarchically. For example, a program can draw geometrical figures, such as circles, squares, and triangles, where each of the figures is contained in an invisible, rectangular

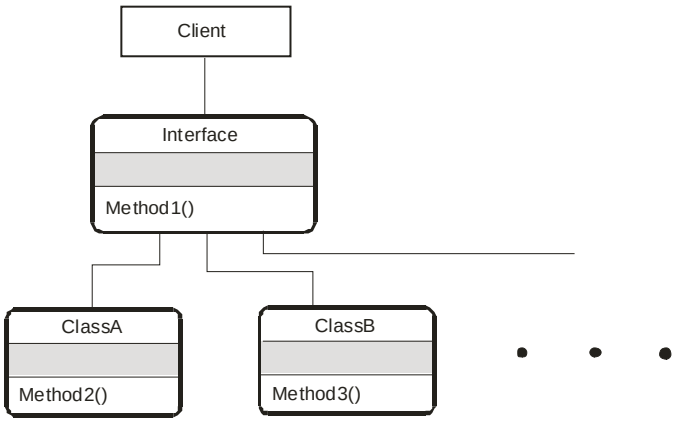
Figure 6. An interface pattern



frame. Also assume that in this case the figure and its containing frame are so related that the creating of a figure (i.e., a circle, rectangle, or triangle) mandates the creation of its container frame.

A library of figure-drawing primitives could be provided by means of four classes: three to create the circle, square, and triangle figures, and one to generate the containing frame. The client would create an object of the corresponding figure and then one of the frame. Alternatively, figure-drawing classes could be linked to the frame generation class so that for each figure a corresponding frame object would be automatically created. With this approach, the frame generation operation is transparent to the client and programming is simplified.

We can add complications to the preceding example without altering its validity. For instance, we can assume that each frame implies the creation of another element called a border, and that the border must be contained in still another one called a window. Therefore, the resulting hierarchy is a geometrical figure, contained in a frame, requiring a border, which, in turn, must exist inside a window. In this example the object structure is mandated by the problem description since all the classes in the hierarchy are obligatory.

A class hierarchy can be implemented in C++ by inheritance, because the creation of an object of a derived class forces the creation of one of its parent class. If the inheritance hierarchy consists of more than one class, then the constructor of the classes higher in the hierarchy are called in order of derivation. Destructors are called in reverse order. The program SAMP-03.CPP demonstrates constructors and destructors in an inheritance hierarchy (Box 3).

When program SAM12-03.CPP executes the following messages are displayed:

```
Constructing a BaseA object
Constructing a Derived1 object
Constructing a Derived2 object
Destroying a Derived2 object
Destroying a Derived1 object
Destroying a BaseA object
```

A Class Hierarchy by Object Composition

One way of solving the problem described at the beginning of this section is to use inheritance. For example, we could implement a class hierarchy in which Circle, Square, and Rectangle were derived from a base class called Figure. The Figure class could contain polymorphic methods for calculating and drawing the geometrical object, as well as methods for creating the frame, the border, and the window. In this case the client would have the responsibility of calling all of the required methods. This is an example of how inheritance often constraints programming and exposes the underlying class structure.

Although in some cases a solution based on class inheritance may be acceptable, it often happens that the hierarchy of super classes is related to a particular method of a derived class, or to several related methods, but not to all of them (Gamma et al., 1995). Consider the case of several types of geometrical figures, all of which must be part of a window, contain a border, and be enclosed in a frame as described previously. In this case the figure-drawing methods could be made part of an inheritance structure; however, the methods that produce the window, border, and frame need not be part of the inheritance construct since these elements are required for any of the geometrical figures. One possible solution is to implement a class structure in which some methods form part of an inheritance association while others are implemented by means of object composition. Figure 7 shows a possible class diagram for this case.

In Figure 7 there are two mechanisms collaborating within the class structure. An inheritance element provides polymorphic methods that can be selected at run time in the conventional manner. Simultaneously, another class hierarchy is

Box 3.

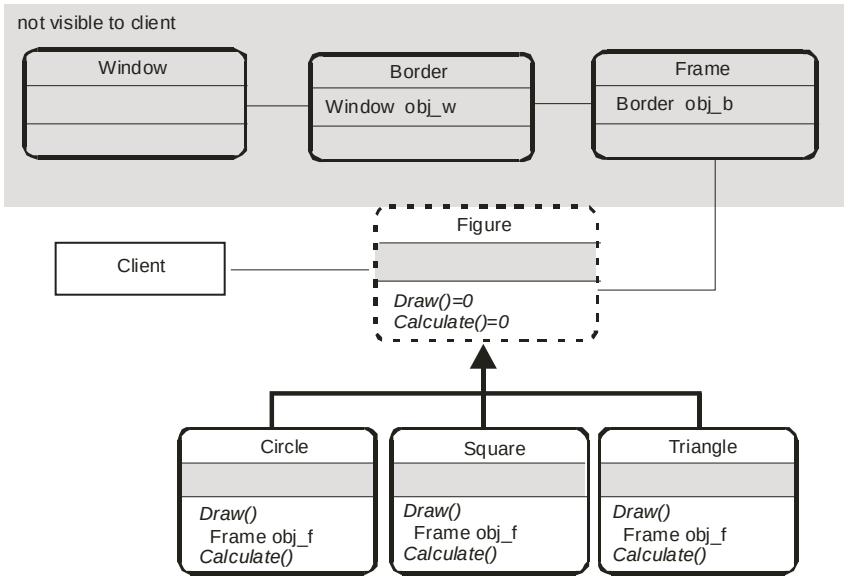
// in the hierarchy are automatically executed.

  Derived2 obj_d;
  return 0;
}
```

Figure 7. Class hierarchy by object composition



based on object composition. Note that the method Draw() of the classes Circle, Square, and Triangle, contains an object of the class Frame. Also note that the class Frame contains an object of Border, which contains an object of Window. Therefore, we can say that a circle, a square, and a triangle are a kind of figure and that all of them have a frame, a border, and a window. The program SAMP-04.CPP is an implementation of the class diagram in Figure 7 (Box 4).

Note in the program SAMP-04.CPP, as well as in Figure 7, that it is the method named Draw() in the concrete classes of the inheritance structure that instantiates the object of the class higher in the hierarchy, in this case the class named Frame. Once this object is referenced, the remainder of the hierarchy is produced automatically by means of the member object mechanism. The purpose of this construct is that the object hierarchy is generated when the method named Draw() ex-

ecutes, not when an object of the lower classes is instantiated. We can certify this operation when the program executes.

There may be cases in which we prefer that the hierarchy of super classes be instantiated at the time that the object of the lower class is created. In the example in Figure 7 this could be achieved by having a member object of the Frame class in the base class named Figure.

A Chain Reaction Pattern

In the class diagram of Figure 7 we note that when the lower classes (Circle, Square, and Triangle) instantiate an object of the class higher in the hierarchy, they start a chain reaction that produces objects of the entire hierarchy. We can abstract this operation by means of a class diagram that focuses exclusively on the chain reaction element, as is the case in Figure 8.

In Figure 8 we have implemented chaining by referencing the first chained object within a method of the Chainer class, and then by member objects of the chained classes. There are many other ways of implementing a chain reaction effect.

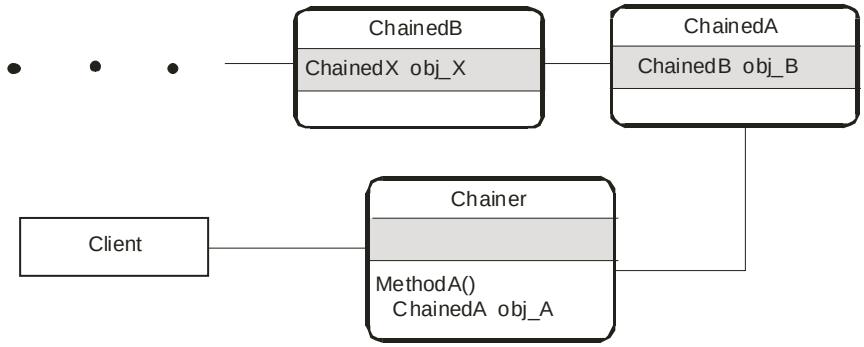
            // an object hierarchy
  return 0;
}
```

Figure 8. A chain reaction pattern



Object Chaining

A programming problem often encountered consists of determining which, if any, among a possible set of actions has taken place. For example, an error handling routine posts the corresponding messages and directs execution according to the value of an error code. A common way of performing the method selection is by contingency code that examines the error code and determines the corresponding action. In C++ this type of selection is usually based on a switch construct or on a series of nested if statements. Alternatively, we can use object composition to create a chain in which each object examines a code operand passed to it. If it corresponds to the one mapped to its own action, then the object performs the corresponding operation, if not, it passes along the request to the next object in a chain. The last object in the chain returns a special value if no valid handler is found.

One of the advantages of using an object chain is that it can be expanded simply by inserting new object handlers anywhere along its members. To expand a selection mechanism based on contingency code we usually have to modify the selecting method by recoding the switch or nested if statements.

An Object Chain Example

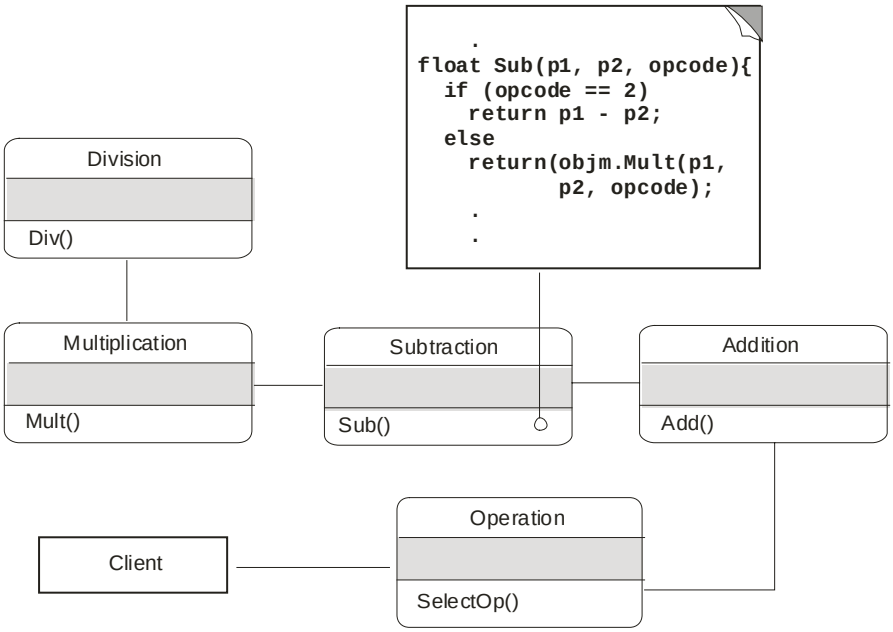
A slightly more complicated case is one in which the selected object must return a value back to the original caller. For example, we define a series of classes that perform arithmetic operations which take two operands. The classes are called Addition, Subtraction, Multiplication, and Division. An operation code is furnished as a third parameter to a class called Operation, containing a method called SelectOp() that calls the Add method in the first object in the chain. In this case the object is of the Addition class. Add() examines the opcode operand; if it corresponds to the add operation, add executes and returns the sum to the caller. If not, it passes the object to Subtract, which proceeds in a similar fashion. Figure 9 shows the class structure for this example.

The program SAMP-05.CPP shows the processing details for implementing an object chain (Box 5).

An Object Chain Pattern

We can generalize the example of an object chain in Figure 9 and abstract its basic components. In this case the fundamental characteristic of the class structure is a series of related methods, each one of which inspects a program condition that determines whether the method is to respond with a processing action or pass the request along to

Figure 9. Class diagram for an object chain



the next object in the chain. Figure 10 is a class diagram for an object chain pattern.

STRING HANDLING CLASS TEMPLATE

The solution of some program development problems is based on patterns of interacting classes and objects, while others simply require a description of the internal structure of a single class. In this case we speak of a class template. For example, programs that deal with strings or that perform substantial string manipulations could profit from a particular class design that is optimized for string handling.

String Operations

A string that is defined at run time is sometimes difficult to store as an array since its length may not be known beforehand. The C++ new and delete operators can be used to allocate memory in the free store area, but it is easier to implement a class that performs all string-handling operations consistently and efficiently, rather than to create and delete each string individually. Implementing a string-handling class is possible because the new and delete operators can be used from within member functions and pointers are valid class members.

String operations often require knowing the string's length. The strlen() function defined in the string.h header file returns this value. Alternatively, we can implement a string as an object that contains a pointer to a buffer that holds the string itself and a variable that represents its length. A parameterized constructor can take care of initializing the string object storage using the new operator as well as its length parameter. The contents of the string passed by the caller are then copied into its allocated storage. This operation determines that the two data members associated with each string object are stored independently, however, they remain associated to the object and can be readily accessed as a pair.

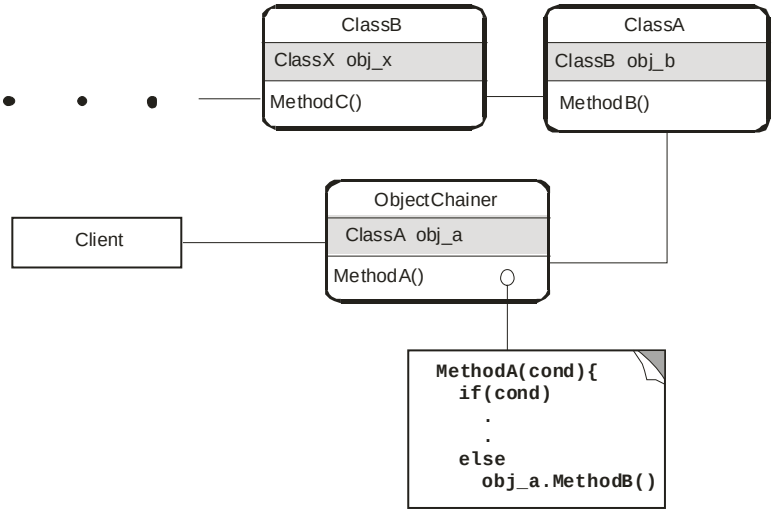
 cout << "Operation on obj_4: " << obj_4.SelectOp() << "\n";

 return 0;
}
```

Figure 10. Object chain pattern



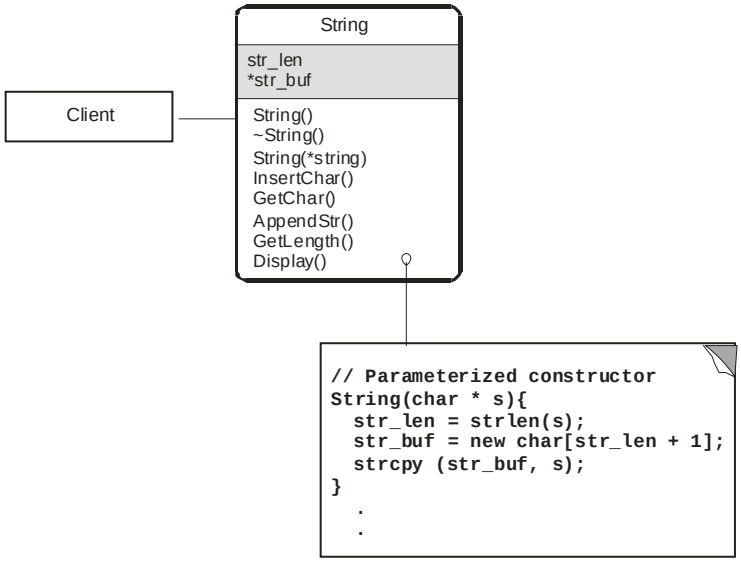
In addition to the parameterized constructor, the proposed class could have a default constructor that initializes both data members to zero whenever it is necessary. An explicit destructor method is also required in this case. The fact that the new operator is used to allocate space for the string buffer implies that the delete operator must be used to free the allocated memory. Other useful methods would be to get the length of the string and to insert a character in a string, to read a string character by specifying its index, and to append a new string to an existing one. Additional functionalities can be added by editing the class or by inheriting its methods. Figure 11 class diagram can serve as a template in this case.

The following program (Box 6) implements the string handling class template of Figure 11.

COMBINING FUNCTIONALITIES

In the implementation of libraries, toolkits, and application frameworks (Deutsch, 1989) we often come across a situation in which a given functionality is scattered among several classes. Rather than giving a client access to each one of these individual classes it is often a reasonable alternative to combine several methods into a single class which can then be presented and documented as standard interface.

Figure 11. String handler class template



A Mixer Pattern

One of the practical uses of multiple inheritance is in combining functionalities by creating a class that inherits from two or more classes. The inheriting class serves to mix and unify the methods of the participating base classes. The class in Figure 12 shows a pattern based on multiple inheritance into a mixer class.

The following code fragment shows how to implement multiple inheritance in the case of the mixer class in Figure 12:

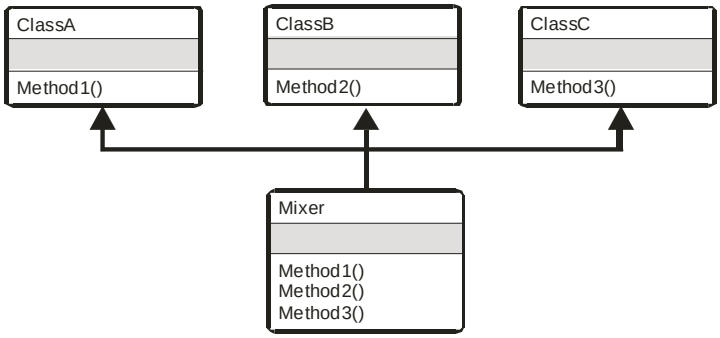
```
// Multiple inheritance
class Mixer : public ClassA, public ClassB,
public ClassC {
 // Implementation
};
```

When implementing multiple inheritance we must be careful to avoid situations which could lead to resolution conflicts; for example, inheriting a method that has the same name and interface in the parent classes, or inheriting multiple copies of the same method.

AN OBJECT-CLASSIFIER TEMPLATE

The objects in a class need not have identical signatures. A class can contain several parameterized constructors that create objects with different numbers or types of parameters. In this sense the constructors serve as object classifiers since each constructor executes according to the object's signature. The constructor can also store the object's type in a variable so that the object can be declassified during processing. For example, we wish to provide a class that calculates the area of various types of geometrical figures. Some figures such as the square require a single parameter, other figures such as the rectangle, have two parameters, and still others like the parallelogram have three parameters. If there is a parameterized constructor for each object signature, then the processing is automatically directed to the corresponding constructor, which can also preserve the object's type by storing an associated code. This action of the constructor is consistent with the notion of function overloading.

Figure 12. Mixer pattern for combining disperse functionalities



Processing routines can dereference the object type and proceed accordingly.

Implementing the Object Classifier

The following program (Box 7) shows the processing for implementing a class named GeoFigure with four constructors: a default constructor that zeroes all the variables, and three parameterized constructors, one for each object signature. The constructors of the GeoFigure class perform object classification as the objects are created.

Observe in the program SAMP-07.CPP that processing operations that are often the client's burden are now handled by the class. The classifier class encapsulates knowledge about each object type, which is encoded and preserved with its signature. Thereafter, client code need not classify objects into squares, rectangles, or parallelograms, since this information is held

Box 7.

```

 dim2 = y;
 fig _ type = 2;
}
// Constructor with three parameters
GeoFigure :: GeoFigure(float x, float y, float z){
 dim1 = x;
 dim2 = y;
 dim3 = z;
 fig _ type = 3;
}

float GeoFigure::Area() {
 switch (fig _ type) {
  case (0):
```

continued on following page

Box 7.

```
    return 0;
   case (1):
    return dim1 * dim1;
   case (2):
    return dim1 * dim2;
   case (3):
    return dim1 * (dim2 * sin(dim3));
   }
  return 0;
  }
//***************************
//     main()
//***************************
main() {
 GeoFigure fig0;       // Objects with different signatures
 GeoFigure fig1(12);
 GeoFigure fig2(12, 6);
 GeoFigure fig3(12, 6, 0.6);

// Calculating areas according to object signatures
 cout << "\nArea of fig1: " << fig1.Area();
 cout << "\nArea of fig2: " << fig2.Area();
 cout << "\nArea of fig3: " << fig3.Area();
 cout << "\nArea of fig0: " << fig0.Area() << "\n";

 return 0;
}
```

in the class and handled transparently by its methods. The objects created by the classifier class know not only their dimensions but also their geometrical type, which in turn defines the processing operations necessary for performing calculations such as the area.

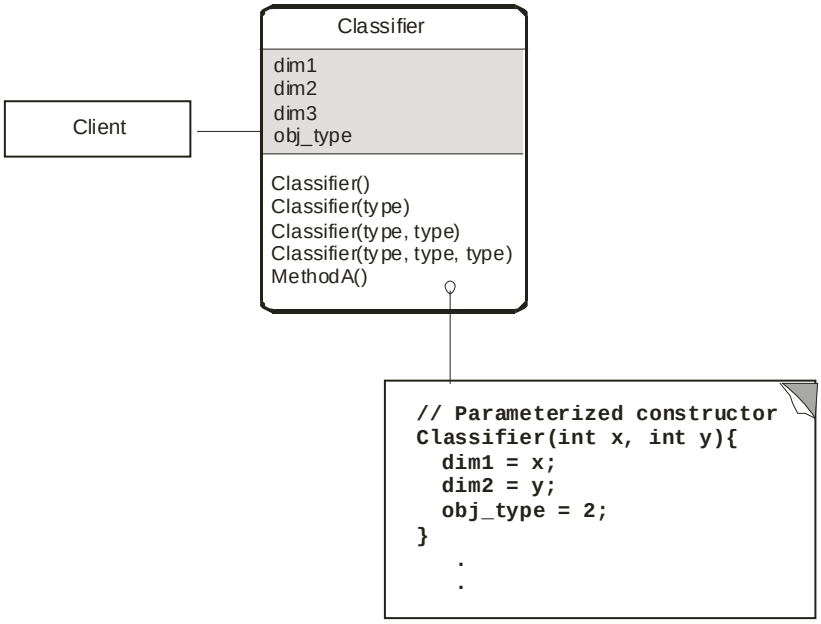
A classifier class is appropriate whenever there are objects with different signatures and their signatures determine the applicable processing operations or methods. Figure 13 is a generalized diagram for a classifier class; it can serve as a template for implementing this type of processing.

COMPOSING MIXED OBJECTS

Libraries, toolkits, and frameworks often provide two types of services to a client. A first level service performs the more elementary operations. A second-level service, called an aggregate or composite, allows combining several primitives to achieve a joint result. The pattern is referred to as a composite pattern. The composite is based on the notion of a Glyph, which is a class that encompasses all objects in

a document (Calder, 1990). Composite patterns are found in most object-oriented systems,

Figure 13. Object classifier class template



including the original View class of Smalltalk (Krasner & Pope, 1988). Also in financial applications, aggregation of assets in a portfolio have been modeled using a Composite class (Birrer & Eggenschwiler, 1993).

A Graphics Toolkit

For example, a drawing program provides primitives for drawing geometrical figures such as lines, rectangles, and ellipses, for displaying bitmaps, and for showing text messages. A second-level function (the composite) allows combining of the primitive elements into a single unit that is handled as an individual program component. In the context of graphics programming, the term "descriptor" is often used to represent a drawing primitive and the term "segment" to represent a composite that contains one or more primitives.

Often a toolkit designer gives access to both the primitive and composite functions. In other words, the programmer using the drawing toolkit mentioned in the preceding paragraph would be able to create drawings that contained any combination of primitive and composite objects using a single, uniform, interface. In this example it may be useful to think of a composite as a list of instructions that includes the methods of one or more primitives. Figure 14 shows an image that contains both primitive and composite objects. The composite objects consist of a rectangle, a bitmap, an ellipse, and a text message. The primitive objects are text, a rectangle, and an ellipse.

The class structure for the sample toolkit could consist of a class for every one of the primitive operations and a composite class for combining several primitives into a drawing segment. An abstract class at the top of the hierarchy can serve to define an interface. Figure 15 shows the class structure for the graphics toolkit.

Note in Figure15 that the abstract class Image provides a general interface to the toolkit. The class Segment contains the implementation of the segment-level operations, the methods CreateSegment(), DeleteSegment(), and DrawSegment(). The drawing primitives are the leaves of the tree

Figure 14. Primitive and composite objects in a graphics toolkit

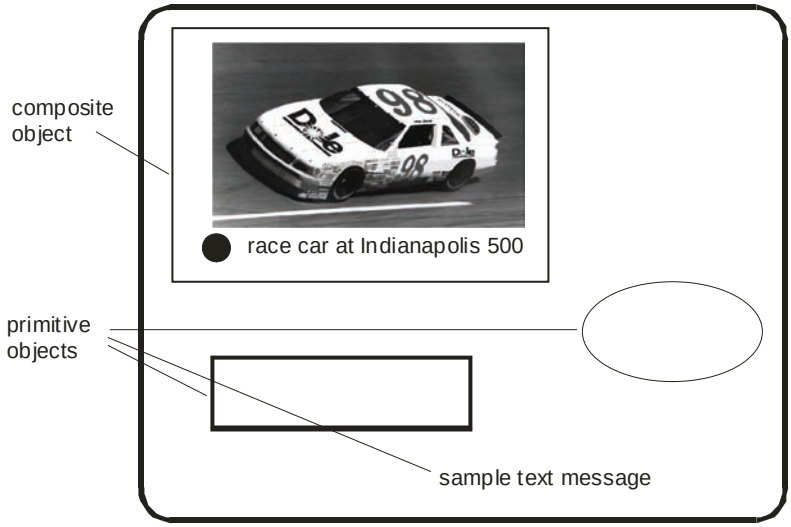


Figure 15. Tree structure for creating simple and composite objects

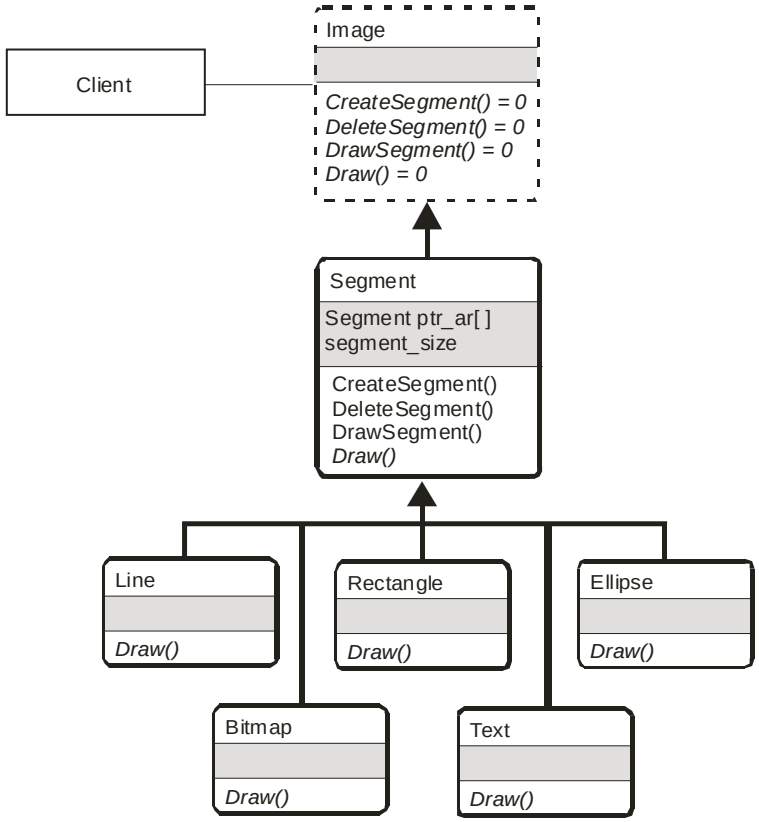

structure. Program SAMP-08.CPP (Box 8) is a partial implementation of the class diagram in Figure 15. Note that the classes Bitmap and Text were omitted in the sample code.

In the program SAMP-08.CPP the segment operation is based on an array of pointers. For this mechanism to work we need to implement run-time polymorphism since the composite (each instance of the Segment class) is created during program execution. In C++ run-time polymorphism can be achieved by inheritance and virtual functions. In this case the function Draw() is a pure virtual function in the abstract class Image, a virtual function in the class Segment, and is implemented in the leaf elements of the tree, which are the classes Line, Rectangle, and Ellipse. By making Draw() a simple virtual function we avoid making Segment into an abstract class. Therefore we can instantiate objects of Segment and still access the polymorphic methods in the leaf classes.

The actual code for implementing an array of pointers to objects has several interesting points. The array is defined in the private group of the Segment class, as follows:

```
Segment *ptr_ar[100];
```

This creates an array of pointers to the class Segment, and assigns up to 100 possible entries for each instantiation. The actual pointers are inserted in the array when the user selects one of the menu options offered during the execution of CreateSegment(). At this time a pointer to the Segment base class is reset to one of the derived classes, one of the Draw() methods at the leaves of the inheritance structure. The selected method is then placed in the pointer array named ptr_ar[]. For example, if the user selected the r (rectangle) menu option the following lines would instantiate and insert the pointer:

```
case ('r'):
    ptr_ss = &obj_rr; // Base pointer
set to derived object
  ptr_ar[n] = ptr_ss; // Pointer placed
in array
   n++; // Array index is bumped
   break;
```

Although it may appear that the same effect could be achieved by using a pointer to the method in the derived class, this is not the case. In this application a pointer to a derived class will be unstable and unreliable.

At the conclusion of the CreateSegment() method it is necessary to preserve with each object a count of the number of points that it contains. The seg_size variable is initialized to the number of pointers in the array in the statement:

```
seg_size = n;
```

At the conclusion of the CreateSegment() method, the array of pointers has been created and initialized for each object of the Segment class, and the number of pointers is preserved in the variable seg_size. Executing the segment is a matter of recovering each of the pointers in a loop and executing the corresponding methods in the conventional manner. The following loop shows the implementation:

```
for(int x = 0; x < seg_size; x++)
  ptr_ar[x]->Draw();
```

PATTERN FOR AN OBJECT FACTORY

By eliminating all the unnecessary elements in the class structure of Figure 15 we can construct a general class pattern for creating simple and composite objects. This version of the Composite class can be considered as a simple object factory which uses an array to store one or more pointers to objects. In addition, each object of the Composite class keeps count of the number of pointers

Box 8.

 Segment  obj_s;
 Line   obj_l;
 Rectangle obj_r;
 Ellipse  obj_e;

// Creating and drawing a segment
 cout << "\n\nCalling CreateSegment() method";
 obj_s.CreateSegment();
 obj_s.DrawSegment();
// Drawing individual objects
 obj_l.Draw();
 obj_r.Draw();
 obj_e.Draw();

 return 0;
}
```

in the array. This count is used in dereferencing the pointer array.

Alternatively, the pointer array can be implemented without keeping a pointer counter by inserting a NULL pointer to mark the end of the array. This NULL pointer then serves as a marker during dereferencing. In either case, the corresponding methods in the leaf classes are accessed by means of the pointers in the array. Method selection must be implemented by dynamic binding. In C++ the polymorphic method must be virtual in the composite class. The pattern is shown in Figure 16.

A Simplified Implementation

We can simplify the concept of primitive and composite objects, as well as their implementation in code, by allowing a composite that consists of a single primitive object. For example, if in Figure 15 we permit a segment that consists of a single primitive, then the client needs never to access the primitives directly. This makes the interface less complicated. In many cases this option should be examined at design time.

RECURSIVE COMPOSITION

In previous sections we considered the case of a composite class that contains simple or composite objects. We also looked at the alternative of a composite object that consists of a single primitive as a way of simplifying the interface. However, we have not yet considered the possibility of a composite object containing another composite (Gamma et al., 1995). Based on the class structure shown in Figure 15 we can construct an object diagram in which a Segment can contain another Segment as shown in Figure 17. Note that in this case we have preserved the distinction between primitives and composites.

Implementation Considerations

In the previous example recursive composition is based on a nested reference to the CreateSegment() method of the Segment class. However, recursion is often accompanied by a new set of problems; this case is no exception. The first consideration is to access the CreateSegment() method. Three possibilities are immediately evident:

Figure 16. Pattern for an object factory class

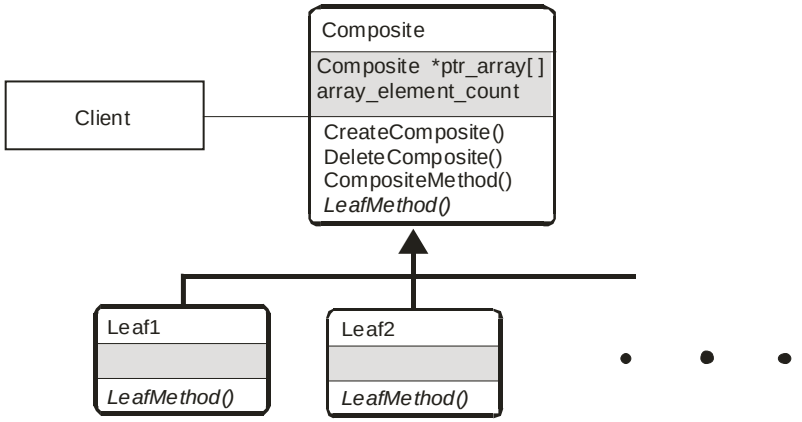

Figure 17. Object diagram for recursive composition

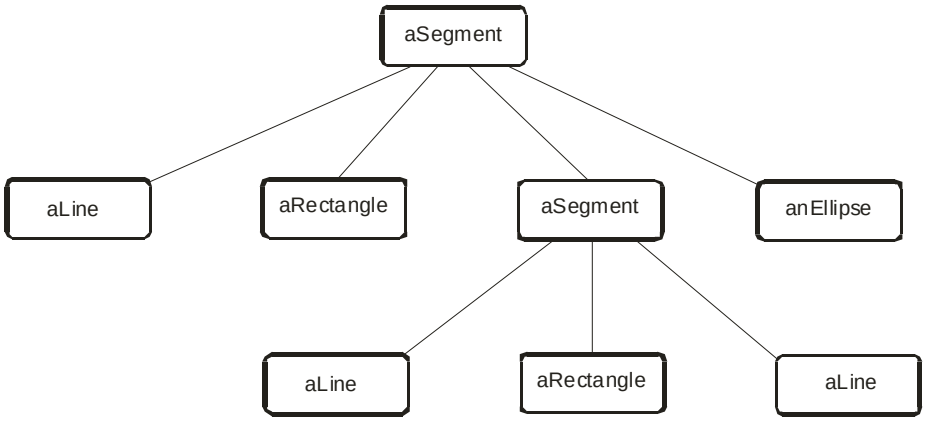

1. Since CreateSegment() is called from within the class, it can be referenced without instantiating a specific object.
2. We can access the CreateSegment() method by means of a this pointer. In fact, this is a different syntax but has the same result as the previous case. In both instances the current object is used.
3. We can create a new object and use it to access the CreateSegment() method.

Which method is suitable depends on the problem to be solved. Figure 18 shows a class diagram for recursively accessing the CreateSegment() method using the original object.

The program SAMP-09.CPP (Box 9) shows the implementation of the class diagram in Figure 18.

Several points in the code merit comment. In the first place notice that recursion occurs on the same object originally referenced at call time. This is accomplished by means of the C++ this pointer, in the following statement:

```
this->CreateSegment();
```

 Segment obj_ss;     // An object
 Segment *ptr_ss;     // Pointer to object
 Line   obj_ll;     // Object list
 Rectangle obj_rr;
 Ellipse obj_ee;

 if(instance == 0)
  n = 0;

  cout << "\n opening a segment...\n";
  cout << "Select primitive or end segment: "
  << "\n l = line"
  << "\n r = rectangle"
  << "\n e = ellipse"
  << "\n n = nested segment"
  << "\n x = end segment"
  << "\n SELECT: ";
 do {
  select = getche();
  switch(select) {
  case ('l'):
   ptr_ss = &obj_ll;     // Pointer to object initialized
   ptr_ar[n] = ptr_ss;    // and stored in array
   n++;
   break;
  case ('r'):
   ptr_ss = &obj_rr;
   ptr_ar[n] = ptr_ss;
   n++;
   break;
  case ('e'):
   ptr_ss = &obj_ee;
   ptr_ar[n] = ptr_ss;
   n++;
   break;
  case ('n'):
```

continued on following page

Box 9. continued

```
    cout << "\n   nested segment...";
    instance = 1;
    this->CreateSegment();
    cout << "\n   nested segment closed ...";
    cout << "\n SELECT: ";
    continue;

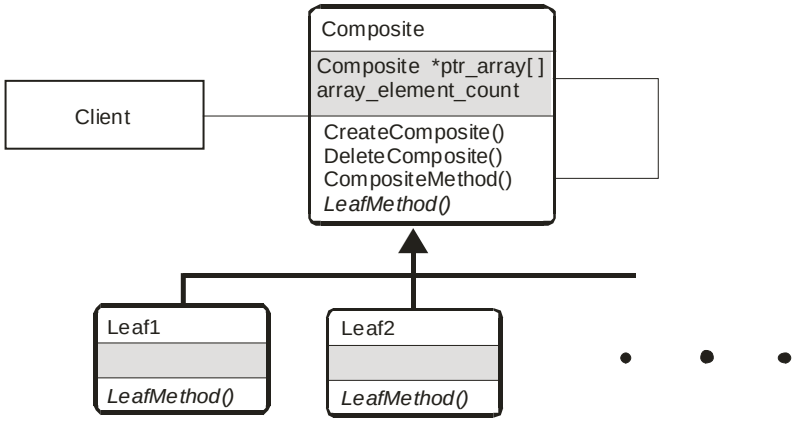
   case ('x'):
    break;
   default:
    cout << "\nInvalid selection - program terminated\n";
    exit(0);
  }
  }
  while( select != 'x');
   seg_size = n;
   cout << "\n closing a segment...";
   instance = 0;         // Reset instance control
}

void Segment::DrawSegment() {
 cout << "\n  displaying a segment...";
 for(int x = 0; x < seg_size; x++)
  ptr_ar[x]->Draw();
 cout << "\n  end of segment display ...";
 return;
}
//***************************
//     main()
//***************************
main() {
 Segment  obj_s;

// Creating and drawing a segment with possible nested
// segments
 cout << "\n\nCalling CreateSegment() method";
 obj_s.CreateSegment();
 obj_s.DrawSegment();

 return 0;
}
```

Figure 19. Pattern for recursive composition



The CreateSegment() method could have been accessed without the this pointer since it is allowed, within the same class, to access methods directly. When CreateSegment() is accessed recursively, all the local variables are automatically reinitialized. Since the program requires a count of the number of pointers in the pointer array, we made the iteration counter (variable n) a global variable and created a switch variable named instance. This variable is set to 1 when CreateSegment() is called recursively, determining that counter variable n is not cleared on entry to the method. The result is that n holds the number of pointers inserted in the pointer array, whether they were entered directly or recursively.

A Recursion Pattern

The pattern for recursive composition is similar to the one in Figure 16, except that in recursion there is an arrow pointing to the same composite class. This is shown in Figure 19.

CONCLUSION

Software design is one of the most laborious and time-consuming phases of program development. In object-oriented systems design reuse is based on classes and object structures that solve a particular design problem and on the assumption that these class structures can be applied to other similar problems. The most recent approach to design reuse is based on class associations and relationships called patterns or object models. In this sense a programming problem is at the origin of every pattern.

We have described the use of design patterns and template classes as reusable components in program design. The discussion has been complemented with class diagrams and examples implemented in code. The chapter introduces the notion of a class template as a structure that describes functionality and object relations within a single class, while patterns refer to structures of communicating and interacting classes.

KEY TERMS

Concealer Pattern: A class pattern designed to hide an inheritance structure so that its existence and operation becomes transparent to client code.

Chain Reaction Pattern: A class pattern that focuses on the property of classes that instantiate objects of other classes higher in the class hierarchy, thus starting a chain reaction in the production of objects.

Class Template: A structure of interactive objects that implements a particular functionality within a single class.

Design Pattern: A structure of interactive classes and communicating objects that provide a solution to a software design problem.

Interface Pattern: A pattern that provides access to other classes that implement a desired functionality.

Mixer Pattern: A class that inherits from two or more classes, thus providing a unified interface to the methods and objects in these classes.

Object Chaining: A chain of objects that successively examines an operand pass to them and makes some decision based on the result of this examination.

Object Classifier: A template for a class with constructors that create objects with different numbers and types of parameters.

Object Factory: A composite class that creates both simple and composite objects.

Unifier Pattern: A class pattern designed to present a unified and friendly interface to a set of classes that perform different operations.

Chapter 2.4
Motivation in Component-Based Software Development

G. Chroust
J. Kepler University Linz, Austria

INTRODUCTION

Information systems are designed for the people, by the people. The design of software systems with the help of software systems is another aspect of human-computer interfaces. New methods and their (non-)acceptance play an important role. Motivational factors of systems developers considerably influence the type and quality of the systems they develop (Arbaoui, Lonchamp & Montangero, 1999; Kumar & Bjoern-Andersen, 1990). To some extent, the quality of systems is a result of their developers' willingness to accept new and (supposedly) better technology (Jones, 1995). A typical example is component-based development methodology (Bachmann et al., 2000; Cheesman & Daniels, 2001). Despite considerable publication effort and public lip service, component-based software development (CBD) appears to be getting a slower start than anticipated and hoped for. One key reason stems from the psychological and motivational attitudes of software developers (Campell, 2001; Lynex & Layzell, 1997). We therefore analyze the attitudes that potentially hamper the adoption of the component-based software development approach. Maslow's Hierarchy of Need (Boeree, 1998; Maslow, 1943) is used for structuring the motives.

BACKGROUND

The Human Side of Software Engineering

Kunda and Brooks (1999) state that "software systems do not exist in isolation ... human, social and organizational considerations affect software processes and the introduction of software technology. The key to successful software development is still the individual software engineer" (Eason et al., 1974; Kraft, 1977; Weinberg, 1988). Different software engineers may account for a variance of productivity of up to 300% (Glass, 2001). On the other hand, any other single factor is not able to provide an improvement of more than 30%. The influence of an individual's motivation, ability, productivity, and creativity has the biggest influence by far on the quality of software development, irrespective of the level of technological or methodological support. Therefore, it is worthwhile investigating for what reasons many software engineers do not fullheartedly accept component-based methods (Lynex & Layzell, 1997).

Software development in general introduced a new type of engineers who show marked differences when compared to (classical) engineers (Badoo & Hall, 2001; Campell, 2001; Eason et al., 1974; Kraft, 1977; Kunda & Brooks, 1999; Lynex & Layzell, 1997). The phenomenon is not fully understood yet but seems to have to do with the peculiarities of software (Brooks, 1986), the type of processes and environments needed to develop software (Kraft, 1977), and especially to the proximity of software development to other mental processes (Balzert, 1996).

Maslow's Hierarchy of Needs

Maslow's theory (Boeree, 1998; Huitt, 2002; Maslow, 1943; McConnell, 2000) provides a practical classification of human needs by defining a five-level Hierarchy of Needs (Figure 1).

The five levels are as follows:

- Basic Physiological Needs (Survival): At this level, the individual is fighting for survival against an adverse environment, trying to avert hunger, thirst, cold, and inconvenient and detracting physical work environments.
- Security (Physical, Economic ...): On this level, the individual is concerned with the stability of his or her future and the safety of the environment. Worries include job security, loss of knowledge, loss of income, health, and so forth.
- Social Environment: This category includes the need to have friends, belong to a group, and to give and receive love.
- Recognition: Individuals strive to receive appropriate recognition and appreciation at work and to be recognized as having a valuable opinion.
- Self-Fulfillment: This level is considered the highest stage attainable in the development of a person, drawing satisfaction from the realization of one's own contribution to a goal and one's fullfillment of their full potential as a human being.

Reuse and Component-Based Software Development (CBD)

An old dream in software development is to avoid unnecessary duplication of work by consistently and systematically reusing existing artifacts. Reuse promises higher productivity, shorter time-to-market, and higher quality (Allen, 2001; Cheesman & Daniels, 2001). Initially, ready-made pieces of software were made available; these delivered a defined functionality in the form of a black box (i.e., without divulging the internal structure to the buyer/user). They were called COTS (commercials off the shelf) (Voas, 1998). Later, an improved and more restricted concept was employed: software components (Bachmann et al., 2000; Cheesman & Daniels, 2001; Woodman et al., 2001). Software components have to

Figure 1. Maslow's hierachy of needs

fulfill additional requirements, restrictions, and conventions beyond the properties of COTS. To a user of a software component, only its interfaces and functionality are known, together with the assurance that the component obeys a specific component model. This component model defines how the component can be integrated with other components, the conventions about the calling procedure, and so forth. The internal structure, code, procedures, and so forth are not divulged—it is a black box.

Systematic, institutionalized CBD needs a change in the attitude of software engineers, different work organization, and a different organization of the whole enterprise (Allen, 2001).

Component-Based Development and Software Engineers' Needs

The acceptance of a new technology often meets with strong opposition caused by psychological motives, which can be traced to Maslow's Hierarchy of Needs.

Basic Physiological Needs

This level does not have any strong relevance; software engineering is a desk-bound, safe, non-endangering activity. We have to recognize, however, that very often software engineers have to struggle with adverse infrastructure (floor space, noise, etc.) (deMarco, 1985).

Security

The desire for security is threatened by numerous factors. The fears can be categorized into four groups:

Losing the Job or Position

- Job Redundancy: CBD promises considerably higher productivity and less total effort as a result of removing the redundancy of reimplementing already existing functions. This carries the thread of making an individual redundant, especially since the development of components very often is outsourced to some distant organization (e.g., India).
- Implementing vs. Composing: deRemer (1976) stressed the difference between implementing a module/component (programming in the small) and building (composing) a system out of components (programming in the large). He emphasized the need for a different view and for new approaches and tools. Programming in the large needs a systems view, making much of long-learned patterns of work obsolete, even counter-productive.
- Changed Job Profile: The necessity of integrating existing components requires a different mindset than one implementing some program from scratch (Vitharana, 2003). Does the software engineer have the ability or qualifications to fulfill the new profile of an integrator?
- Loss of Knowledge and "Guru" Status: In traditional development, considerable domain know-how and low-level development know-how rests in the heads of seasoned developers having developed software for many years. The use of components encapsulates and hides both implementation details and domain know-how. In addition, system development methods change. Much of the accumulated experience and know-how previously valuable to the employing institution becomes irrelevant.
- De-Skilling: In addition, certain de-skilling takes place at the lower level of software development (Kraft, 1977). The need for increased skills with respect to performing high-level composition activities often is not recognized and appreciated by the individuals.

Loss of Low-Level Flexibility

- Pre-Conceived Expectations: Components often do not provide exactly what the original requirements specified. A developer then is challenged to find a compromise between the user requirements and the available components—a job profile dramatically different from developing bespoke software (Vitharana, 2003). Engineers also have to live with good enough quality (Bach, 1997; ISO/IEC, 2004), as provided by the components and often are not able to achieve best quality. This is often difficult to accept emotionally.
- Revision of Requirements: Mismatches between stated requirements and available components make it necessary to revise and adapt requirements (Vitharana, 2003). Requirements are no longer set in stone, in contrast to the assumptions of classical development methods (e.g., the waterfall model).
- Uncertainty About Functionality of Components: By definition, the internal structure of a component is not revealed (Bachmann et al., 2000). Consequently, the developer has to rely on the description and claims provided by the component provider (Crnkovic & Larsson, 2002; Vitharana, 2003).

Lack of Confidence

- Distrust in Component Quality: Quality problems experienced in the past have created a climate of distrust with respect to other developers' software products. This feeling of distrust becomes stronger with respect to components, because their internals are not disclosed (Heineman. 2000; Vitharana, 2003). This situation becomes worse for so-called software of unknown provenance (SOUP) (Schoitsch, 2003). The current interest in open source programs is an indicator of a movement in the opposite direction.
- Questions About Usability: Besides the issue of quality, problems with portability and interoperability of components, as often experienced with COTS, also reduce the confidence in using components (Vecellio & Thomas, 2001).
- Loss of Control of System: Engineers usually like to understand fully the behavior of the designed system (the why) and exercise control over the system's behavior (the how). In CBD, due to the black-box character of the components, understanding and control can be achieved only to a limited extent, leaving a vague feeling of uncertainty.

Effort for Reuse vs. New Development

- Uncertainty Concerning the Outcome of the Selection Process: Successful CBD depends to a considerable extent on the probability and effectiveness of finding a component with (more or less) predefined properties (Vitharana, 2003). Occasionally, this search will not be successful, causing a delay in the development schedule and some lost effort spent in the search.
- Effort Estimates: In general, software engineers underestimate the effort needed to build a system from scratch and overestimate the cost and effort of adapting a system. The reasons seem to be the initially necessary effort to achieve a certain familiarity with the whole system before making even small adaptations, the learning curve (Boehm & Basili, 2000), the difficulty, and often also the unwillingness of becoming familiar with somebody else's thoughts and concepts (not-invented-here syndrome).

Social Environment

- Reluctance to Utilize Outside Intellectual Property: Our society extends the notion

of ownership to immaterial products like ideas and intellectual achievements. They are protected by copyright, trademark, and patent legislation. Plagiarism is objected to and usually not sanctioned (Kock, 1999; Sonntag & Chroust, 2004). Reusing someone else's ideas is often deemed inappropriate.

- Immorality of Copying: In school, copying as a form of reuse and teamwork is usually discouraged. This might later cause some reluctance to actively share knowledge and to make use of someone else's achievements (Disterer, 2000).
- Adopting a New Technology: The adoption of a new technology seems to follow an exponential law (Jones, 1995). It starts with a few early adopters, and others follow primarily because of personal communication. The tendency of software developers to be introverts (Riemenschneider, Hardgrave, & Davis, 2002) might delay such a dissemination process.
- Change of Work Organization: CBD needs a different work organization (Allen, 2001; Chroust, 1996; Cusumano, 1991; Wasmund, 1995) resulting in rearranged areas of responsibility, power distribution, and status, potentially upsetting an established social climate and well-established conventions.

Recognition

A strong motivator for an individual is recognition by the relevant social or professional reference group, usually a peer group (Glass, 1983).

- Gluing vs. Doing: On the technical level, recognition usually is connected to a particular technical achievement. Gluing together existing components will achieve recognition only for spectacular new systems—and these are rare. Similarly, an original composer will gain recognition; whereas a person simply arranging music into potpourris usually goes unrecognized.
- Shift of Influence and Power: Successful CBD needs a change in organization (Allen, 2001; Kunda & Brooks, 1999), making persons gain or lose influence, power, and (job) prestige, a threat to the established pecking order.
- The CBD Water Carrier: Organizations heavily involved in CBD often separate the component development from component deployment (Cusumano, 1991). Component development to a large extent is based on making existing modules reusable "components as you go" and "components by opportunity" (Allen, 2001) and not on creating new ones from scratch "components in advance". Jobs in the reuse unit (similar to maintenance units) (Basili, 1990) might be considered to require less know-how and thus receive lower prestige, despite the fact that these jobs often require greater know-how and experience than designing components from scratch.
- Contempt for the Work of Others: The inherent individuality of software development, together with a multitude of different solutions to the same problem (i.e., there is always a better way), and the low quality of many software products have tempted many software developers into contempt for anyone else's methods and work (not-invented-here syndrome).
- Rewarding Searching Over Writing: As long as the amount of code produced (lines of code) is a major yard stick for both project size and programmer productivity searching, finding and incorporating a component will be less attractive than writing it anew.
- Accounting for Lost Search Effort: There is no guarantee that even after an extensive (and time-consuming) search an appropriate component can be found (Vitharana, 2003). In this case, management must accept these occasional losses so as not to discourage searching for components (Fichman & Kemerer, 2001).

Self-Fulfillment

- Not Invented Here: The ability to design wonderful systems is a strong motivator for software engineers. This feeling goes beyond recognition of peers—one knows it oneself. This makes it difficult for developers to accept other people's work (Campell, 2001; Disterer, 2000) in the form of components.
- No More Gold Plating: The feeling of self-fulfillment often cannot live with the knowledge that a system still should or must be improved, leading to endless effort in gold plating a system before delivery (or even thereafter). Externally acquired components cannot be modified (i.e., gold plated) because of the inaccessibility of their code.
- No Creative Challenge: Gluing together components provided by somebody else does not fulfill many engineers' attempt for novelty and, thus, is not considered to be a creative challenge. The highly creative process of finding the best-fitting component, restructuring the system, and perhaps modifying the requirements for using existing components often is not appreciated.
- No More Lone Artists: Software engineers aspire to become a Beethoven or a Michelangelo and not the directors of a museum arranging a high-class exhibition. Someone remarked that many system features are not needed by the users but are just a monument of their designer's intellectual capability. Assembling components utilizes only someone else's achievement.
- Lack of Freedom: The limited choice of available components, the limitations of a component model, the need to obey predefined interfaces, and so forth restrict the freedom of development and often are seen as a limit to creativity.

FUTURE TRENDS

The fact that the software industry needs a large step forward with respect to productivity, quality, and time-to-market will increase the reuse of software artifacts and, as a consequence, will encourage the use of component-based development methods. Understanding the basic state of emotion of software developers will support efforts to overcome developers' reluctance to accept this methodology by emphasizing challenges and opportunities provided by the new methods, re-evaluating the importance and visibility of certain tasks, changing job profiles, and changing the reward and recognition structure.

The consequence might be that software designers wholeheartedly accept component-based methodologies not only as an economic necessity but also as a means of achieving the status of a great designer, as postulated by Brooks (1986). In turn, this could lead to a new level of professionalism in software development and would allow component-based development methods to be utilized fully in the field of software engineering.

CONCLUSION

Soft factors like motivation and psychological aspects often play a strong role even in a technical, seemingly rational field like software engineering. We have discussed and identified key soft factors that often account for the slow uptake of component-based software development methods and relate them to the framework of Maslow's Hierarchy of Needs. The users of software components were the focus of this discussion. There are some indications that for providers of components, a different emotional situation exists (Chroust & Hoyer, 2004).

Recognition of the different levels of resistance and their psychological background will, among

other aspects, allow approaching the problems in a psychologically appropriate form. The need of the software industry to come to terms with its problems of quality, cost, and timeliness makes this a necessity.

KEY TERMS

Commercial Off the Shelf (COTS): Software products that an organization acquires from a third party with no access to the source code and for which there are multiple customers using identical copies of the component.

Component-Based Development (CBD): In contrast to classical development (waterfall-process and similar process models), CBD is concerned with the rapid assembly of systems from components (Bachmann et al., 2000) where:

- components and frameworks have certified properties; and
- these certified properties provide the basis for predicting the properties of systems built from components.

Component Model: A component model specifies the standards and conventions imposed on developers of components. This includes admissible ways of describing the functionality and other attributes of a component, admissible communication between components (protocols), and so forth.

Maslow's Hierarchy of Needs: Maslow's Hierarchy of Needs (Boeree, 1998; Maslow, 1943; McConnell, 2000) is used as a structuring means for the various factors. It defines five levels of need:

- self-fulfillment
- recognition
- social environment (community)
- basic physiological needs (survival)
- security (physical, economic ...)

In general, the needs of a lower level must be largely fulfilled before needs of a higher level arise.

Soft Factors: This concept comprises an ill-defined group of factors that are related to people, organizations, and environments like motivation, morale, organizational culture, power, politics, feelings, perceptions of environment, and so forth.

Software Component: A (software) component is (Bachmann et al., 2000):

- an opaque implementation of functionality
- subject to third-party composition
- in conformance with a component model

Software Engineering: (1) The application of a systematic, disciplined, quantifiable approach to development, operation, and maintenance of software; that is, the application of engineering to software and (2) the study of approaches as in (1) (Abran, Moore, Bourque, Dupuis & Tripp, 2004).

ABSTRACT

Understanding the context, structure, activities, and content of software development processes found in practice has been and remains a challenging problem. In the world of free/open source software development (F/OSSD), discovering and understanding what processes are used in particular projects is important in determining how they are similar to or different from those advocated by the software engineering community. Prior studies have revealed that development processes in F/OSSD projects are different in a number of ways. In this article, we describe how a variety of modeling perspectives and techniques are used to elicit, analyze, and validate software development processes found in F/OSSD projects, with examples drawn from studies of the software requirements process found in the NetBeans.org project.

INTRODUCTION

In the world of globally dispersed, free/open source software development (F/OSSD), discovering and understanding what processes are used in particular projects is important in determining how they are similar to or different from those advocated by the software engineering community. For

example, in our studies of software requirements engineering processes in F/OSSD projects across domains like Internet infrastructure, astrophysics, networked computer games, and software design systems (Scacchi, 2002, 2004, 2005), we generally find there are no explicit software requirements specifications or documents. However, we readily find numerous examples of sustained, successful, and apparently high-quality F/OSS systems being deployed on a worldwide basis. Thus, the process of software requirements engineering in F/OSSD projects must be different than the standard model of requirements elicitation, specification, modeling, analysis, communication, and management (Nuseibeh & Easterbrook, 2000). But if the process is different, how is it different, or more directly, how can we best observe and discover the context, structure, activities, and content software requirements processes in F/OSSD projects? This is the question addressed here.

Our approach to answering this question uses multimodal modeling of the observed processes, artifacts, and other evidence composed as an ethnographic hypermedia that provides a set of informal and formal models of the software development processes we observe, codify, and document. Why? First, our research question spans two realms of activity in software engineering, namely, software development and software process modeling. So we will need to address multiple perspectives or viewpoints, yet provide a traceable basis of evidence and analysis that supports model validation. Second, given there are already thousands of self-declared F/OSSD projects affiliated with OSS portals like SourceForge.net, Freshmeat.net, and Savannah.gnu.org, then our answer will be constrained and limited in scope to the particular F/OSSD projects examined. Producing a more generalized model of the F/OSS development process studied requires multiple, comparative project case studies, so our approach should be compatible with such a goal (Scacchi, 2002). Last, we want an approach to process modeling that is open to independent analysis, validation, communication, and evolution, yet be traceable to the source data materials that serve as evidence of the discovered process in the F/OSSD projects examined (cf. Kitchenham, Dyba, & Jorgensen, 2004).

Accordingly, to reveal how we use our proposed multimodal approach to model requirements processes in F/OSSD projects, we first review related research to provide the foundational basis for our approach. Second, we describe and provide examples of the modeling modes we use to elicit and analyze the processes under study. Last, we examine what each modeling mode is good for, and what kind of analysis and reasoning it supports.

RELATED RESEARCH AND APPROACH

There is growing recognition that software requirements engineering can effectively incorporate multiple viewpoints (Finkelstein, Gabbay, Hunter, & Nuseibeh, 1994; Leite & Freeman, 1991; Nuseibeh & Easterbrook, 2000) and ethnographic techniques (Nuseibeh & Easterbrook, 2000; Viller & Sommerville, 2000) for eliciting, analyzing, and validating functional and nonfunctional software system *product* requirements. However, it appears that many in the software engineering community treat the *process* of requirements engineering as transparent and prescriptive, though perhaps difficult to practice successfully. However, we do not know how large distributed F/OSSD projects perform their development processes (cf. Curtis, Krasner, & Iscoe, 1998).

Initial studies of requirements development across multiple types of F/OSSD projects (Scacchi, 2002, 2004) find that OSS product requirements are continuously emerging (Gans, Jarke, Kethers, & Lakemeyer, 2003; Gasser, Scacchi, Penne, & Sandusky, 2003; Truex, Baskerville, & Klein, 1999) and asserted after they have been implemented, rather than relatively stable and

elicited before being implemented. Similarly, these findings reveal requirements practice centers about reading and writing many types of communications and development artifacts as "informalisms" (Scacchi, 2002), as well as addressing new kinds of nonfunctional requirements like project community development, freedom of expression and choice, and ease of information space navigation. Elsewhere, there is widespread recognition that F/OSSD projects differ from their traditional software engineering counterparts in that F/OSSD projects do not in general operate under the constraints of budget, schedule, and project management constraints. In addition, OSS developers are also end users or administrators of the software products they develop, rather than conventionally separated as developers vs. users. Consequently, it appears that F/OSSD projects create different types of software requirements using a different kind of requirements engineering process, than compared to what the software engineering community has addressed. Thus, there is a fundamental need to discover and understand the process of requirements development in different types of F/OSSD projects.

We need an appropriate mix of concepts, techniques, and tools to discover and understand F/OSSD processes. We and others have found that process ethnographies must be empirically grounded, evidence-based, and subject to comparative, multiperspective analysis (Curtis et al., 1998; Finkelstein et al., 1994; Glaser & Strauss, 1967; Kitchenham et al., 2004; Nuseibeh & Easterbrook, 2000; Scacchi, 2002; Seaman, 1999). However, we also recognize that our effort to discover and understand F/OSSD processes should reveal the experience of software development newcomers who want to join and figure out how things get done in the project (Scacchi, 2005).

As participant observers in such a project, we find that it is common practice for newcomers to navigate and browse the project's Web site, development artifacts, and computer-mediated communication systems (e.g., discussion forums, online chat, project Wikis), as well as to download and try out the current software product release. Such traversal and engagement with multiple types of hyperlinked information provide a basis for making modest contributions (e.g., bug reports) before more substantial contributions (code patches, new modules) are offered, with the eventual possibility of proposing, changing, or sustaining the OSS system's architecture. These interactive experiences reflect a progressive validation of a participant's understanding of current F/OSSD process and product requirements (Bolchini & Paolini, 2004; Narayanan & Hegarty, 2002). Thus, we seek a process discovery and modeling scheme that elicits, analyzes, and validates multimode, hypertext descriptions of a F/OSSD project's requirements process. Furthermore, the process descriptions we construct should span informal through formal process models, and accommodate graphic, textual, and computationally enactable process media. Finally, our results should be in a form open to independent analysis, validation, extension, and redistribution by the project's participants.

MULTIMODE PROCESS MODELING, ANALYSIS, AND VALIDATION USING ETHNOGRAPHIC HYPERMEDIA

An ethnographic hypermedia (Dicks & Mason, 1998) is a hypertext that supports comparative, cross-linked analysis of multiple types of qualitative ethnographic data (cf. Seaman, 1999). They are a kind of semantic hypertext used in coding, modeling, documenting, and explaining patterns of social interaction data and analysis arising in contemporary anthropological, sociological, and distributed cognition studies. The media can include discourse records, indigenous texts, interview transcripts, graphic or photographic images, audio/video recordings, and other related information artifacts. Ideally, they also preserve

the form and some of the context in which the data appear, which is important for subsequent (re)analysis, documentation, explanation, presentation, and validation.

Ethnographic studies of software development processes within Web-based F/OSSD projects are the focus here. Ethnographic studies that observe and explain social action through online participant observation and data collection have come to be called "virtual ethnography" (Hine, 2000). Virtual ethnography techniques have been used to observe the work practices, compare the artifacts produced, and discover the processes of F/OSSD projects found on and across the Web (Elliott & Scacchi, 2003, 2005; Jensen & Scacchi, 2005a, b; Oza, Nistor, Hu, Jensen, & Scacchi, 2004; Scacchi, 2002, 2004, 2005). In particular, an important source of data that is examined in such studies of F/OSSD projects is the interrelated web of online documents and artifacts that embody and characterize the medium and continuously emerging outcomes of F/OSSD work. These documents and artifacts constitute a particular narrative/textual genre ecology (Spinuzzi & Zachry, 2000) that situate the work practices and characterize the problem solving media found within F/OSSD projects.

We have employed ethnographic hypermedia in our virtual ethnographic studies of F/OSSD projects. What does this mean, and what challenges or opportunities for requirements elicitation, analysis, and validation have emerged along the way? These questions are addressed below through examples drawn from a case study of the NetBeans.org OSSD project (Jensen & Scacchi, 2005a, b), which is one of the largest F/OSSD projects we have studied. The NetBeans.org project is a corporate sponsored OSSD project (Jensen & Scacchi, 2005a) focused on the development of an interactive development environment (IDE) for constructing application systems using Java enterprise beans technology. It is similar in size and scope to the Eclipse project founded by IBM, which is also developing a Java-based IDE.

As noted, the F/OSSD projects we study are found on the Web. Web sites for these projects consist of a network of hyperlinked documents or artifacts. Samples of sites we have studied include NetBeans.org, Mozilla.org, Apache.org, and GNUenterprise.org, among others (Elliott & Scacchi, 2003, 2004; Jensen & Scacchi, 2005a, b; Scacchi, 2002, 2004). A team of two to five researchers examines a project site (via browsing, searching, downloading, and cross-linking) over a period of 4-6 weeks initially, then periodically thereafter. The artifacts we examine include Web pages, e-mail discussion lists, bug reports, project to-do lists, source code files and directories, site maps, and more. These artifacts are an important part of the data we collect, examine, study, code, and analyze in order to identify F/OSSD work practices and development processes that arise in a given project.

We create a hypermedia of these artifacts in ways that allow us to locate the originating sources of data within the focal project's Web site. This allows us to maintain links to the source data materials that we observe as evidence of the process at hand, as well as to allow us to detect when these data sources have been updated or removed. (We also archive a local copy of all such data.) However, we create annotated and assembled artifacts that embed hyperlinks into these documents as part of our ethnographic hypermedia. As a result, multiple kinds of ethnographic records are created including annotated artifacts, rich hypermedia pictures, and ethnographic narratives. Juxtaposed about these records are other kinds of models including a process metamodel, attributed directed graph model, process domain ontology, and a formal, computationally enactable process model. Each is described next, and each is hyperlinked into an overall ethnographic hypermedia that provides cross-cutting evidence for the observed OSS requirements processes. This in turn provide us with an approach to mapping complex situations in various forms, which is consistent with recent

advances in grounded theory approaches to ethnographic study (Clarke 2003).

Annotated Artifacts

Annotated artifacts represent original software development artifacts like (publicly available) online chat transcripts that record the dialogue, discussions, and debate that emerge between OSS developers. These artifacts record basic design rationale in an online conversation form. The textual content of these artifacts can be tagged, analyzed, hyperlinked, and categorized manually or automatically (Rao, 2003). However, these conversational contents also reveal much about how OSS developers interact at a distance to articulate, debate, and refine the continuously emerging requirements for the software system they are developing. For example, Elliott and Scacchi (2003, 2005) provide conversational transcripts among developers engaged in a debate over what the most important properties of software development tools and components to use when building free software. They provide annotations that identify and bracket how ideological beliefs, social values, and community building norms constrain and ultimately determine the technical choices for what tools to use and what components to reuse when developing OSS. The following is an example of an excerpt of an online chat transcript found in a F/OSSD project where the developer (here identified anonymously as "ByronC") who is an outsider to the project lurking on the chat discussion and who advocates a strong belief for avoiding the use of nonfree software when developing F/OSS, as indicated by the (**boldface**) annotations we added.

<ByronC> Hello **(Outsider Critique-1**
<ByronC> Several images on the Web site seem to be made with nonfree Adobe software, I hope I'm wrong: it is quite shocking. Does anybody know more on the subject?
<ByronC> We should avoid using nonfree software at all costs, am I wrong? **(Extreme belief in free software (BIFS)-1)**
<ByronC> Anyone awake in here? **Outsider Critique-1)**

Basic ethnographic data like this draws our attention to look for practices within F/OSSD efforts to see if such beliefs do in fact constrain the choice of software tools used within F/OSSD processes.

Navigational Rich Pictures

Rich pictures (Monk & Howard, 1998) provide an informal graphical scheme for identifying and modeling stakeholders, their concerns and beliefs, objects and patterns of interaction. We extend this scheme to form navigational rich pictures constructed as a Web-compatible hypertext image map that denotes the overall context as the composition and relationships observed among the stakeholder roles, activities, tools, and document types (resources) found in a F/OSSD project. In the example figures that follow, we display the stakeholders/roles using human-like icons, their concerns or beliefs as clouds associated to the icons, and the objects and patterns or interaction as hyperlinked entities. Figure 1 displays such a rich picture constructed for NetBeans.org. Furthermore, associated with each hyperlinked entity is a *use case* (Cockburn, 2001) that we have constructed to denote an observable activity performed by an actor-role using a tool that consumes or produces a document/object type. An example use case is shown in Figure 2. Each other type of data also is hyperlinked to either a descriptive annotation or to a Web site/page where further information on the object type can be found.

Directed Resource Flow Graph

A directed resource flow graph denotes a recurring workflow pattern that has been discovered

Figure 1. A rich picture image map of the requirements and release process in the NetBeans.org F/OSSD project

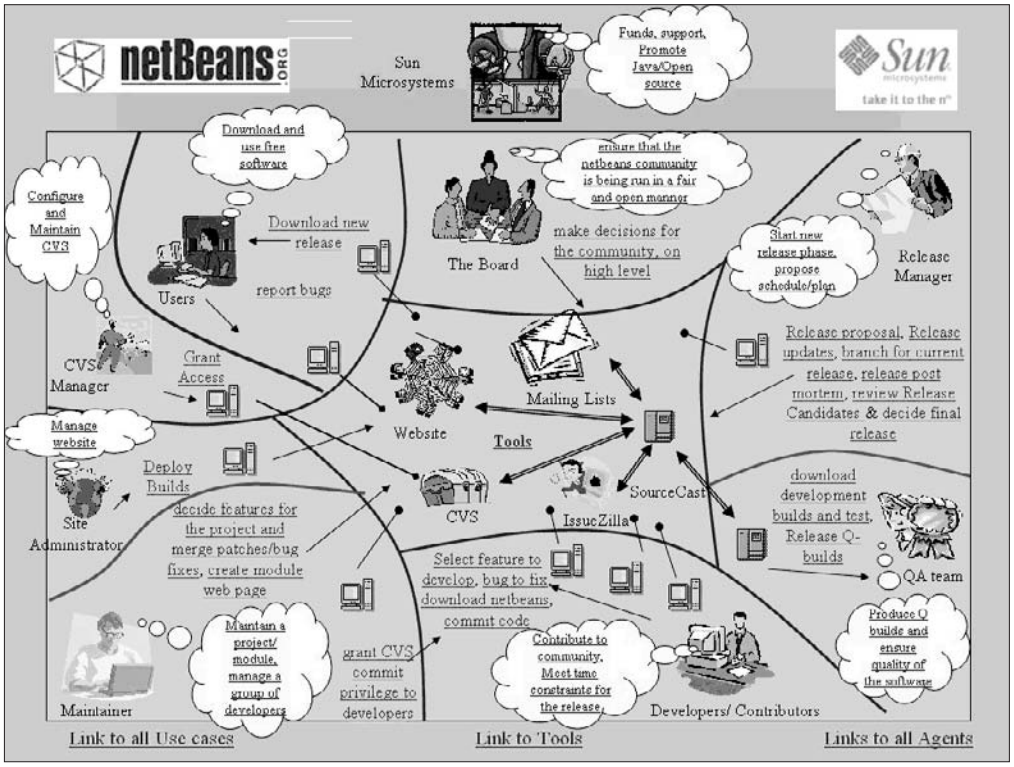

Figure 2. A hyperlink selection within a rich hypermedia presentation that reveals a corresponding use case

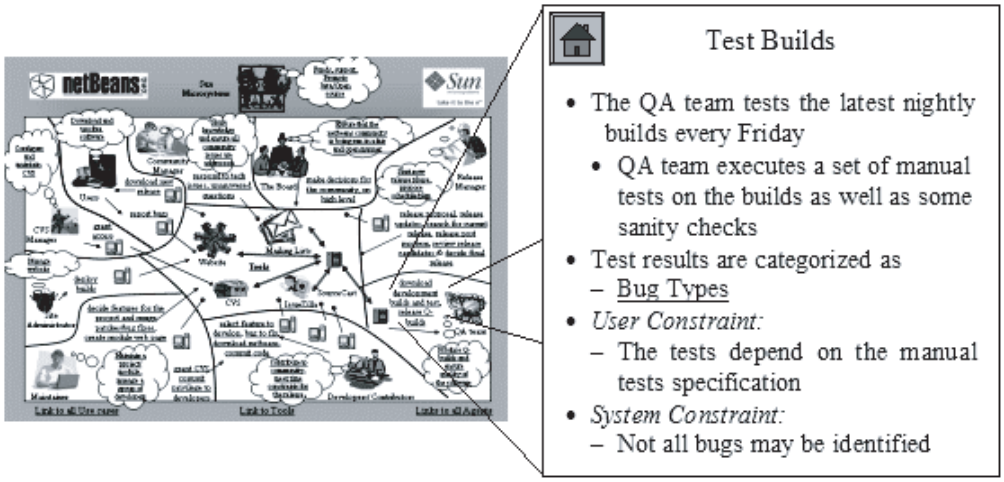
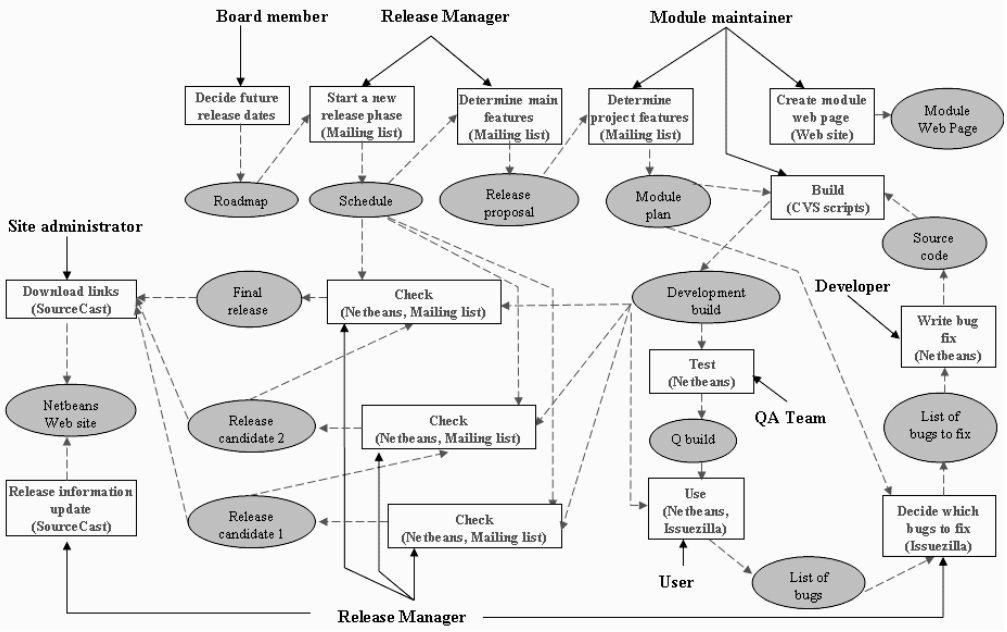


in an F/OSSD project. These workflows order the dependencies among the activities that actor-roles perform on a recurring basis to the objects/resources within their project work. These resources appear as or within Web pages on an F/OSSD project's Web site. For example, in the NetBeans.org project, we found that software product requirements are intertwined with software build and release management. Thus, the "requirements and release process" entails identifying and programming new/updated system functions or features in the course of compiling, integrating, testing, and progressively releasing a stable composition of source code files as an executable software build version for evaluation or use by other NetBeans.org developers (Elliott & Scacchi, 2003, 2005; Oza et al., 2004). An example flow graph for this appears in Figure 3. The code files, executable software, updated directories, and associated e-mail postings announcing the completion and posting the results of the testing are among the types of resources that are involved. Last, the rendering of the flow graph can serve as an *image map* to the online (i.e., on the NetBeans.org Web site) data sources from where they are observed.

Process Domain Ontology

A process ontology represents the underlying *process metamodel* (Mi & Scacchi, 1996; Noll & Scacchi, 2001) that defines the semantics and syntax of the process modeling constructs we use to model discovered processes. It provides the base object classes for constructing the requirements process (domain) taxonomies of the object classes for all of the resource and relation types found in the rich picture and directed resource flow graph.

Figure 3. An attributed directed graph of the resource flow for the NetBeans.org requirement and release process. Boxes denote tasks/actions, ellipses denote resources/objects, dashed lines denote resource flows, and solid lines and labels denote agent/stakeholder roles performing tasks that transform input resources into output resources.



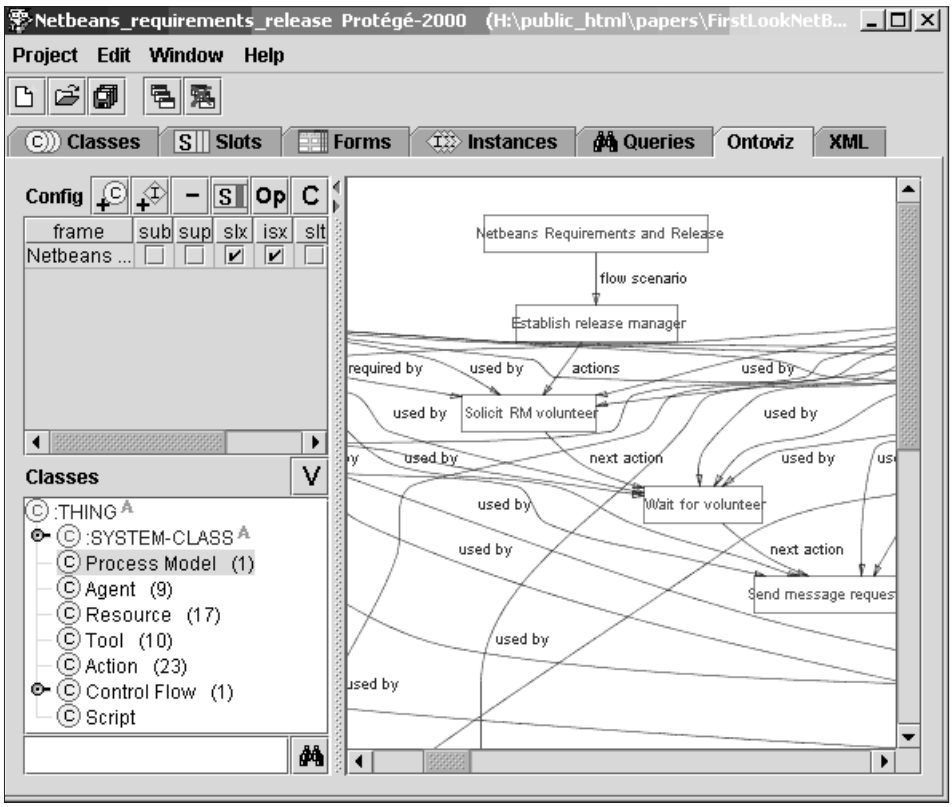
However, each discovered process is specific to an F/OSSD project, and knowledge about this domain is also needed to help contextualize the possible meanings of the processes being modeled. This means that a process domain entails objects, resources or relations that may or may not be have been previously observed and modeled, so that it may be necessary to extend to process modeling constructs to accommodate new types of objects, resources, and relations, as well as the attributes and (instance) values that characterize them, and attached methods that operationalize them.

We use an ontology modeling and editing tool, Protégé-2000 (Noy, Sintek, Decker, Crubezy, Fergerson, & Musen, 2001), to maintain and update our domain ontology for OSS requirements processes. Using Protégé-2000, we can also visualize the structure of dependencies and relations (Grinter, 2003) among the objects or resources in a semantic Web manner. An example view can be seen in Figure 4. Furthermore, we can create translators that can transform syntactic form of the modeling representations into XML forms or SQL schema definitions, which enables further process modeling and tool integration options (cf. Jensen & Scacchi, 2005b).

Formal Process Model and Its Enactment

A formal process model denotes a syntactically precise and semantically typed specification of the resource objects, flow dependencies, actor-roles, and associated tools that specifies an enactable

Figure 4. A view of the process domain ontology for the NetBeans.org software requirements and release process



(via interactive process-guided user navigation) hypertext representation we call an *organizational process hypertext* (Noll & Scacchi, 2001). This semantic hypertext, and its supporting run-time environment, enables the ability to walkthrough or simulate enactment of the modeled F/OSSD process as a process-guided, navigational traversal across a set of process linked Web pages. The semantic hypertext is automatically rendered through compilation of the process models that are output from the ontology editor in a process modeling language called PML (Noll & Scacchi, 2001). A PML-based model specification can be automatically checked for inconsistencies can be detected at compile-time or run-time. An example of an excerpt from such a model is shown in Figure 5. The compiled version of the PML produced a nonlinear sequence of process-linked Web pages, each one of which corresponds to one step in the modeled process. An example showing the result of enacting a process (action) step specified at the bottom of Figure 5 appears in Figure 6.

Constructing an Ethnographic Hypermedia Narrative for Process Validation

An ethnographic narrative denotes a final ethnographic hypermedia view. This is an analytical research narrative that is structured as a docu-

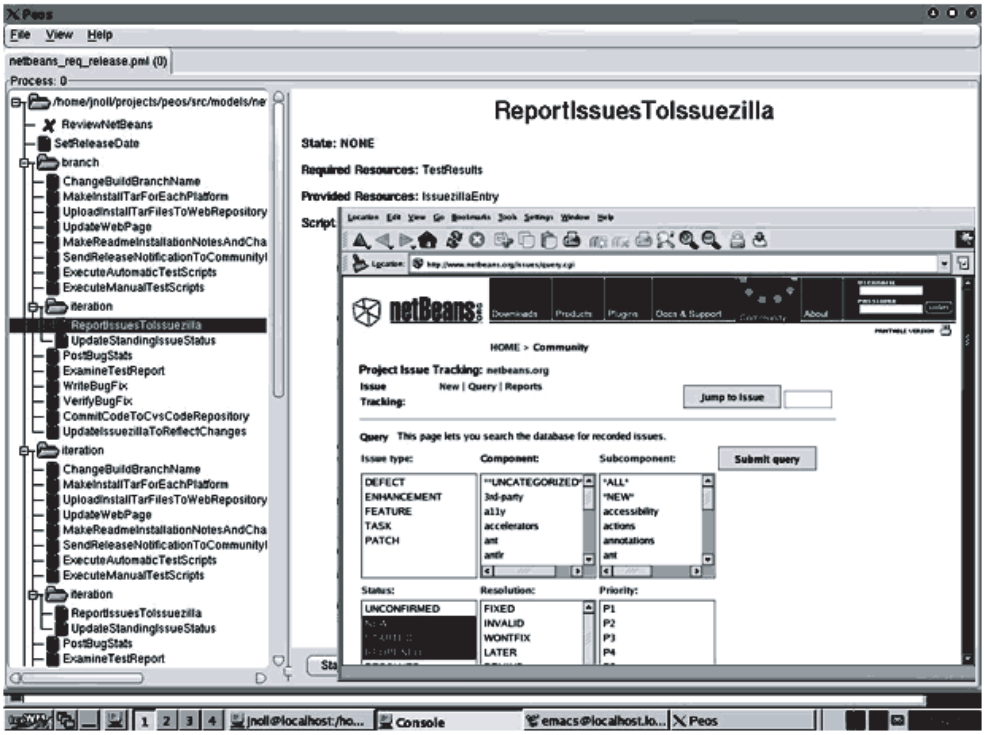
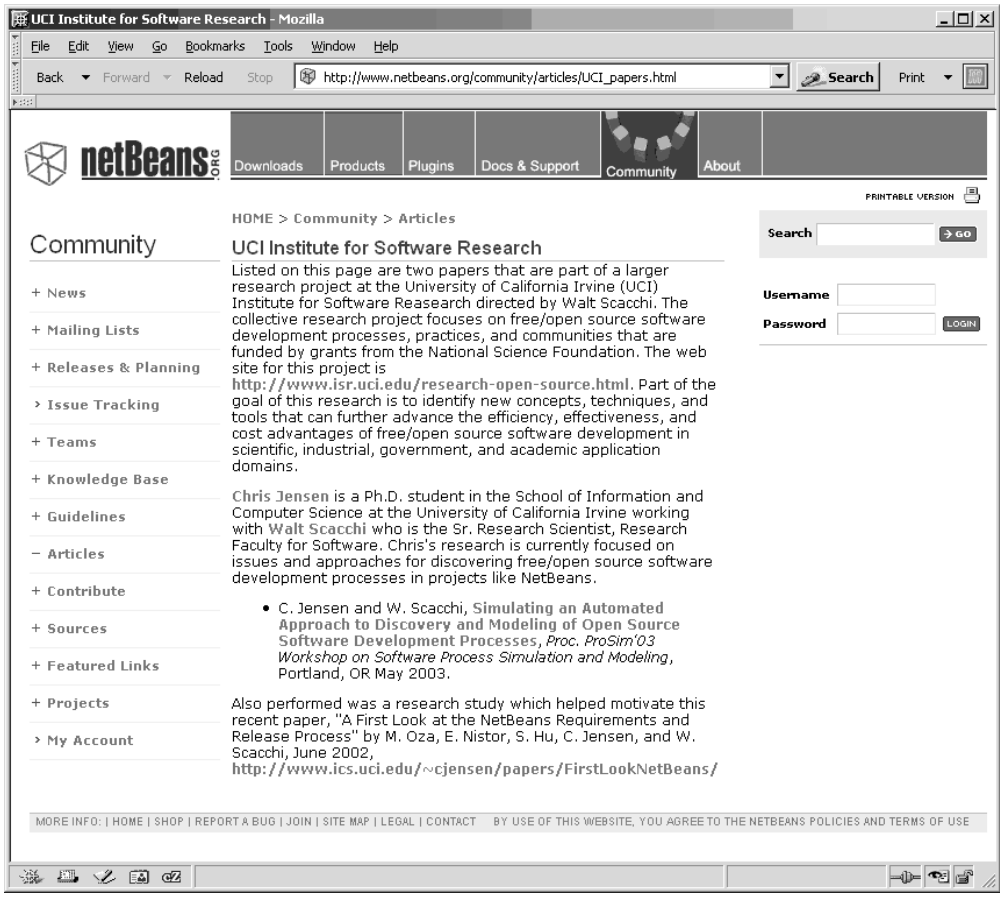
Figure 6. A screenshot displaying the result of the PML-based reenactment of one step ("Action Report issues to Issuezilla") in the NetBeans.org requirements and release process



ment that is (ideally) suitable for dissemination and publication in Web-based and printed forms. It is a composite model derived from selections of the preceding representations in the form of a narrative with embedded hyperlinked objects, and hyperlinks to related materials. It embodies and explains the work practices, development processes, resource types and relations, and overall project context as a narrative, hyperlinked ethnographic account that discovered at play within a given F/OSSD project, such as we documented for the NetBeans requirements and release process (Oza et al., 2004). In printed form, the narratives we have produced so far are somewhere between one-fourth to one-fifteenth the number of pages compared to the overall set of project-specific data (documents) at the first two levels of hyperlink connectivity; said differently, if the ethnographic report is 30 or so printed pages (i.e., suitable for journal publication), the underlying ethnographic hypermedia will correspond to a hypermedia equivalent to 120-450 printed pages.

The narrative is in a form intended for external review and validation by those not involved in the collection, modeling, and analysis activities, such as members of the project under study (NetBeans.org; see Figure 7). These external reviewers can read through the narrative during validation to see if there are gaps or inconsistencies, or to pose questions to the narrative's authors. When such shortfalls are detected or reported, then the task is to determine if the problem arises from either a gap in the modeling effort, or in its narrative rendering. Finally, the narrative and its hypermedia components are envisioned as open and living documents, so that feedback from the community may serve to keep them consistent with current practice, or to detect and report inconsistencies

Figure 7. Getting captured and analyzed process models out for validation and possible evolution by NetBeans.org project participants



that are in need of attention, update, or remediation, much like the software and artifacts found in the F/OSSD projects they describe.

DISCUSSION

We have learned a number of things based on applying and evaluating our approach to modeling development processes, such as those for software requirements, in different F/OSSD projects. First, no single mode of process description adequately subsumes the others, so there is no best process description scheme. Instead, different informal and formal descriptions respectively account for the shortcomings in the other, as do textual, graphic, and computationally enactable process representations. Second, incremental and progressive elicitation, analysis, and validation occur in the course of developing multimode requirements process models. Third, multimode process models are well-suited for discovery and understanding of complex software processes found in F/OSSD projects. However, it may not be a suitable approach for other software projects that do not organize, discuss, and perform software development activities in an online, persistent, open, free, and publicly accessible manner. Fourth,

multimode process modeling has the potential to be applicable to the discovery and modeling of software product requirements, although the motivation for investing such effort may not be clear or easily justified. Process discovery is a different kind of problem than product development, so different kinds of approaches are likely to be most effective.

Next, we observed that the software product requirements in F/OSSD projects are continually emerging and evolving. Thus, it seems likely that the requirements process in such projects is also continuous. Thus, supporting the evolution of multimode models of OSS requirements processes will require either automated techniques for process discovery and multimode update propagation techniques, or else the participation of the project community to treat these models as *open source software process models*, that can be continuously elicited, analyzed, and validated along with other F/OSSD project assets, as suggested in Figure 7, which are concepts we are currently investigating. However, it seems fair to note that ethnographic accounts are situated in time, and are not intended for evolution.

Last, each of the methods we used for modeling processes found in F/OSSD projects has been previously applied and shown to be useful by other researchers. Our effort brings these diverse approaches together in order to demonstrate and compare their individual and collective value. Thus, we find the multimode approach to modeling, analyzing, and validating F/OSSD processes provides a new threshold for research and practice that in turn give rise to new insights and findings that none of the individual approaches can realize on their own. Finally, we believe the multimode approach can be readily adopted, taught, and put into practices to support not only F/OSSD projects, but any software development project that is distributed and supported across the Web/Internet.

CONCLUSION

Ethnographic hypermedia are an important type of semantic hypertext that are well-suited to support the navigation, elicitation, modeling, analysis, and report writing found in ethnographic studies of F/OSSD processes. We have described our approach to developing and using ethnographic hypermedia to support the modeling, analysis, and validation of software development processes in F/OSSD projects like NetBeans.org, where multiple modes of informal to formal representations are involved. We find that this hypermedia is well-suited for supporting qualitative research methods that associated different type of project data, together with comparative analysis of process descriptions rendered in graphic, textual, and computationally enactable descriptions. We provided examples of the various kinds of hypertext-based process descriptions and linkages that we constructed in moving from abstract, informal representations of the data through a series of ever more formalized process models resulting from our studies.

Based on our efforts and results reported here, it appears that free/open source software development projects can benefit from the discovery, modeling, and validation of the development processes they practice, and that ethnographic hypermedia based representations of these processes provides an innovative scheme for capturing, representing, and evolving these representations in a manner that can be maintained and evolved in an open source way.

ACKNOWLEDGMENT

The research described in this report is supported by grants #0083075, #0205679, #0205724, and #0350754 from the U.S. National Science Foundation. No endorsement implied. Mark Ackerman at University of Michigan, Ann Arbor; Les Gasser at University of Illinois, Urbana-Champaign; and

others at ISR are collaborators on the research described in this article.

Chapter 2.6
Conceptual Model Driven Software Development (CMDSD) as a Catalyst Methodology for Building Sound Semantic Web Frameworks

ABSTRACT

This Chapter introduces Hyperservices as a unified application model for Semantic Web frameworks, and proposes Conceptual Model-Driven Software Development as a means of easy adoption to them. Hyperservices are based on agent societies, provided with structured information by the Semantic Web, and using Web services as a collaboration and communication interface. Afterwards, the WASP model is proposed as a framework for implementing Hyperservices, also adding personalization rules to modify the agents' perception as well as the HIVE Architecture as Semantic Information Server infrastructure within the WASP framework. For easier adoption of these new models, Conceptual Model-Driven Software Development is proposed. It separates the conceptual aspects from the technical details by automatically generating executable code from models while the implementation details are hidden to the end user, the service developer.

OVERVIEW

The Semantic Web and its effects are a mainstream catalyst for current Web development. Its influence is felt across many areas of research and business development: Agent systems, knowledge management frameworks, ontology definitions, and other areas are all refined by new ideas from Semantic Web research (and vice versa). Since many complex topics are now combined with the goal of building the "Next Generation Internet", it becomes more and more important to build sound and flexible frameworks to abstract the implementation details of the underlying technologies.

As underlying technologies are still in a state of flux as far as their implementation details are concerned, it seems to be very important to find a simple yet appropriate meta-model for the overall architecture which can be used to follow a kind of model-driven approach: Model the required system in a meta-level and then derive the actual implementation by transforming the model into executable code (or even directly executing the model). This approach allows both the early adoption of Semantic Web technologies and a continuing evolution of the implementation details.

Research shows that the underlying methodology for defining Semantic Web-oriented frameworks can be defined very well. This chapter will explain the main streams which will be integrated towards the Semantic Web and more importantly show, based on a thorough requirements analysis, how Semantic Web-oriented systems might be structured in a simple meta-model, allowing more detailed specification as research progresses. A new software development methodology, named Conceptual Model-Driven Software Development or CMDSD for short, which is currently under development in our research team, is used to provide a notion of the appropriate meta-models which will allow the early adoption of Semantic Web technologies in standard industrial projects.

The following steps in this chapter will lead to an early-stage meta-model which might be used to connect Semantic Web frameworks in an easy and non-intrusive way with standard projects:

- The main research streams and technologies making up the Semantic Web are identified. Their interrelations and resulting requirements for frameworks and systems are shown.
- An in-depth requirements analysis concerning the architecture of Semantic Web systems and the must-have features of such features provides the groundwork for the definition of the cornerstones of future Semantic Web systems. It will be shown that the basic cornerstones are limited in scope, thus making it possible to define a very simple high-level meta-model for a model-driven strategy.
- An approach to build multi-platform Semantic Web frameworks based on the core technologies of Agents, Ontologies, Web Services, and Personalization frameworks is explained. This approach is generic enough to encompass most currently-existing frameworks and lends itself towards the integration of emerging standards. A new type of service, a Hyperservice, is derived from integrating these core technologies into a new type of service infrastructure.
- An overview of Model-Driven Architecture (MDA) and Model-Driven Software Development (MDSD) will be given. It provides the infrastructure for our extension of CMDSD (Conceptual Model-Driven Software Development) which strives to close the gap between technology expertise and conceptual requirements by building meta-models focused on the conceptual task and defining a transformation path to build complex systems from simple meta-models.

EMERGING SEMANTIC WEB TECHNOLOGIES REVIEWED

First we will give an overview of existing Semantic Web research and describe the current underlying problems which need to be solved in the new future to let the Semantic Web become a living reality: The main task will be to narrow or close the gap between the reality of the Web (a disjoined and tangled mass of loosely-coupled information resources) and the vision for the Web: a tightly-integrated and openly-structured information network with machine-readable data that allows autonomous agencies to create new applications empowered by this wealth of information. Currently problems already start in the early stages of developing systems for the Semantic Web: Existing models and theories are relatively complex (compared to established Web standards like XML and HTML), frameworks still have a very dynamic state, and interfaces between frameworks are bound to change more often than not (if they exist at all at this point of time). We propose a framework to allow researchers and developers to choose the level of detail, the type of technologies, and the amount of computing power they want to utilize for their proposed solutions. We will use the building blocks of this framework as the grounding for a flexible yet very simple meta-model that ignores technical complexity and favors the easy integration of existing technologies. We focus for our framework on a flexible abstraction layer, pattern-oriented architecture, and open interfaces to build on the successful foundations of the Web: ease of use, flexibility, and almost unlimited expression power. Agents are the central paradigm for software development using this architecture.

The Evolution of the Web

The Semantic Web is pushed by the World Wide Web Consortium (W3C) as the foundation for a true information society (Berners-Lee, 1998; Berners-Lee, Hendler, & Lassila, 2001). The efforts of the W3C are supported by a wide range of multi-national research efforts combining theoretical and practical experiences from information technology.

Nonetheless progress is slow, and even if research would yield results at much greater speed, the results still need to be implemented. Current research hints at much more expressive and thus also more powerful means to represent data and information, but the price is added complexity required to build the representations. We therefore focus on trying to provide simple models which completely hide the underlying complexity of Semantic Web technologies. The World Wide Web was successful because people basically overnight were enabled to share information, with simple technology. This allowed for the enormous growth in information resources which we now face. We strive to reproduce this pattern to guarantee the further growth of the Web (Berners-Lee, 2000) by providing an early example for a simple meta-model (with ample extension points) at the end of this chapter.

The Web of Systems

The World Wide Web in its current form is the largest information system ever built by humans. At the same time, it probably is also one of the least structured information systems ever built. There are billions of Web pages (not counting other resources like images, videos, sounds, CGI interfaces to large databases, and more), and almost none of them are structured in a standardized way. The "Deep Web" is even larger (Bergman, n.d.). Most pages are built with HTML and coupled in a very loose manner; links lead into oblivion as often as they do not. Most existing links do not provide much semantic information (e.g., what is the meaning of a specific link except "someone thought that two information resources should be connected in some way"). Most information is presented in a way that allows humans to use

it, although access to this information usually is a problem because it becomes harder and harder to find the few tidbits of information in the existing mess of data. Studies by search engine companies show that current problems are to be found at a more basic level: Even the simple requirements of HTML are rarely correctly fulfilled and semantic information provision is not a topic high on the list of most interest groups present on the World Wide Web (Web Authoring Statistics, n.d.).

Thus we argue that we need to find ways to evolve from the current World Wide Web (a Web of Systems, so named because there are many individual systems that usually are only connected by the simplest means, namely hyperlinks) to something more.

It would be foolish and dangerous to try too much at once. At the same time, it would be as foolish and dangerous to create artificial boundaries and introduce building blocks that limit our power of expressiveness. Thus we propose to search for architectures and frameworks that support gradual evolution without limiting the final goal. We find practical examples that support the viability of this approach: Modular programming has spawned object-oriented programming to be able to control complexity with more natural concepts. For certain problem areas, agent-oriented systems have been discovered to be an immensely powerful and very natural concept for defining solutions (Ciancarini & Wooldridge, 2001). Now the industry momentum offers a huge chance to solve one of the basic problems of agent societies: Communication by Web services promises to do away with the artificial system boundaries currently inhibiting large-scale distributed autonomous agent systems. And finally, model-driven approaches (either MDA or MDSD) (Stahl & Völter, 2005) seem to be highly appropriate to serve as the glue between the evolving and varying technologies.

The Web of Services

Web Services currently are the preferred integration technology for business software companies. Web Services (Christensen, Curbera, Meredith, & Weerawarana, 2001; Gottschalk, Graham, Kreger, & Snell, 2002) in theory offer a standard means to communicate between disparate systems and applications with absolute disregard for programming languages, computer hardware, and system-specific communication protocols. Based on XML (eXtensible Mark-up Language) (Biskup & Marx Gómez, 2005), this new and exciting standard promises a new way of defining interfaces, without sticking to implementation details and basic technical questions. Together with HTTP (Hypertext Transfer Protocol) (Gourley & Totty, 2002) and SOAP (Simple Object Access Protocol) (Mitra, 2001) as protocols, we face an enormous opportunity to bring together previously-separated building blocks for the next generation Internet. XML is the unifying data representation standard that could be used to basically encode any kind of information. HTTP and SOAP are simple yet flexible protocols that allow a system-independent communication between heterogeneous systems. More generally, the basic notion of application-level protocols is very important to be able to conceptualize a working architecture for a true Web of Services. While it currently is very difficult to connect different Web-based systems, future interfaces could greatly benefit from these standards (e.g., when trying to combine a flight information system and a hotel booking system).

While theoretically already very strong in practice, many Web Services standards are not yet available. The specifications currently evolve at a much faster pace than the implementations, and many of the core technologies (e.g., distributed transactions and security) are still in a state of continuing change. These movements will stabilize eventually, but in the meantime the permanent flux of changes creates investment risks which

cause many commercial endeavors to use as little as possible of the new technologies. In turn, this causes specifications to be created with a certain lack of practical experience, which in turn shows in the quality of early specification versions and again hampers adoption.

If models can be provided that collect the basic ideas of the standard and completely hide the implementation details, companies could start today with integrating the existing standards. A model-driven approach seems to be the most appropriate way for this task: The conceptual tasks could be modeled on a meta-level by using a simple and abstracted modeling technology, and some kind of transformation engine would take these models and either directly execute them or transform them into executable code. In this way systems could be easily upgraded to new versions of specific Web Service technologies, as the meta-models will probably only change in minor ways or not at all.

A Web of Services thus could become a tangible possibility. This could be the next important step for Web technologies—because Web services possess many powerful features ideally suited for industrial use and commercial success stories. This also could build the momentum to ensure the wide-spread use of, in our point of view, a very important technology. Current developments support this theory; most new API versions and programming systems supply some sort of Web Services integration (from ancient languages like COBOL to the most recent developments like .NET).

The Web of Semantics

All afore-mentioned efforts target one underlying and ever present goal: the Semantic Web, an information network of machine-readable data that allows autonomous agencies to gather data, turn it into information, reason about it, and come to conclusions. This information network will be traversed by intelligent agents to fuel new and exciting services (Joy, 2000; McIlraith, Son, & Zeng, 2001; Metcalfe, 2000). Humans will never be able to fully utilize the mass of data collected in the World Wide Web; thus we need to find new ways to turn all the data into something more than a loosely connected set of HTML pages. The basic building blocks for the Semantic Web are made up by:

- **Semi-structured data:** XML has been accepted as the means of choice to represent platform-independent data in a semi-structured way that allows for an open-ended way of describing data (Bray, Paoli, Maler, Sperberg-McQueen, & Paoli, 2000). Based on plain text (but powered by Unicode), XML enriches pure data with metadata to allow machines to use the data more effectively and in ways not initially coded into the data format.
- **Machine-readable data:** The current proposal for this building block relies on XML as a means of expression and has been named RDF (Resource Description Framework) (Brickley & Guha, 2000; Lassila, 2000). It should be noted that RDF has various means of representation, but XML seems to be the most natural for the World Wide Web and the most widely used right now. RDF allows describing resources, properties of resources, and relations between resources. RDF can be extended to create more complicated languages and at the same time provides powerful foundations for reasoning (being based on first-order logic). Interestingly, RDF takes a very pragmatic approach to provide a viable solution for information representation: Right away, it allows for inconsistence, incorrectness, and incompleteness in the represented information and takes it as given that data can lead to situations where agents will not be able to come to a decisive or correct conclusion. This pragmatism adheres to the concepts

that established the current Web, ease of use with an allowance for mistakes.

- **Ontologies** as a means to describe the relations between objects and to define standard hierarchies as descriptions of "the world": A lot of research is concerned with the question of what should be in an ontology language in order to once more find the best way of combining computing and expression power with ease of use. Ontology languages like SHOE (Heflin, Hendler, & Luke, 1999), DAML (Hendler & McGuiness, 2000), and DAML+OIL (DAML+OIL, 2000) hint at the power of future metadata structures.

So far major concerns in the World Wide Web community were to standardize the encoding of data and information. Retrieval, automated reasoning about information, connection of services, and basically all other means of exploiting this information pool were only moderately successful. The Web spawned a variety of search engines and meta-search engines, but these, together with shop systems and Web directories, cover the efficient means of access to the World Wide Web for humans. There were some experiments with agents and agent societies (Brickley & Guha, 2000), but so far these attempts failed to become wide-spread successes due to the lack of a unified information infrastructure and lack of standardized interfaces; CGI (the Common Gateway Interface) is hardly sufficient to build even semi-complex applications in an abstract and elegant way. Other experiments (De Bruijn, Fensel, Keller, & Lara, 2005; Harper & Bechhofer, 2005) hint at different exciting possibilities to enhance the knowledge acquisition process for users, but still lack the unified foundation required to build a whole generation of such service enhancements. The need for such a foundation is proven by some extensive first-generation systems (Lin, Harding, & Teoh, 2005)), which show the basic building blocks that will be required again and again, and thus are the primary target for standardization attempts.

To cope with this situation we propose a new model of regarding future applications building on the foundations mentioned so far, a unit of abstraction we have named Hyperservices.

Proposing Hyperservices as a Unified Application Model

We believe that the next important step will be to find a unifying, language- and system-independent architecture that allows for a convergence in current research areas surrounding the Semantic Web. When we talk about Web-based applications, we mean "based on Web technologies". Web technologies have been widely accepted and have managed to bring together disparate system structures. While this goal in the first moment might be very ambitious, we will present a very simple (one might think trivial) way of allowing all these technologies to be integrated into current run-time environments. Ample extension points will be provided, and we refrain from requiring any specific implementation technologies.

Looking at the components currently available, a unified application model based on agent societies seems to be in reach: The Semantic Web allows us to reason about information by structuring information appropriately. This provides the basis for "intelligent" agents (with "intelligence" on a pragmatic hands-on level). Web services introduce the interface for collaboration among systems. Agents are the natural extension to achieve autonomous systems (Benjamins, 2003). Currently we face a multitude of ontology languages (Benjamins, Fensel, & Asunción, 1998) and many models and theories to map information to efficient data models and retrieval algorithms, but these means will only see wide-spread use if they become easy to communicate to future users (e.g., programmers), based on standard architectures and easy to integrate into existing systems. Integration still is one of the main problems faced by current computer science (from the business perspective), but the Web

can only remain successful if it manages to stay commercially interesting (whether by drawing enough people to it to supply Internet Providers with customers, or by introducing truly successful e-business models is not that important). Thus the integration of these new models into existing structures will be the most important task from a business point of view.

Topics under current discussion (e.g., agent societies and the Semantic Web) will not be able to replace classic information systems (e.g., tax accounting, enterprise resource planning, and logistics). But if built in the right way, they will be able to enrich classic systems by providing added value. They will open up a new venue of information systems, built around the necessity to decide between precision and speed. The sheer size of the Web and its constant flux will make it impossible to store nearly enough data in local systems to allow for efficient information systems (in the classic sense). Thus it seems much more likely that future information systems will be build around the idea of semi-autonomous agents wandering across the Web, collecting information, reasoning about it, and yielding results, either continuously or until specified resource limits (e.g., time, bandwidth, or a financial budget) have been exhausted (Hendler, 2001).

The WASP Model

We propose a unified framework that is founded on four building blocks which, in our point of view, will be absolute necessities to populate the future Web with more powerful applications:

- *W*eb Services as a means of providing a unified communication interfaces between applications and agencies (Christensen et al., 2001; Dale, 2002; UDDI, 2001);
- *A*gents as a natural and central means to represent typical tasks and solutions for a distributed and constantly changing information environment;
- *S*emantic Web technologies as a means to provide data and information in a consistent manner that allows retrieval and reasoning; and
- *P*ersonalization technologies to customize processes to the needs of the individual user, an absolute necessary concerning the current (and future) size of the World Wide Web, lest it becomes impossible to separate useless from useful information.

(The initials of these core technologies also provide the acronym for our framework: WASP)

Agents will be the central building block of this architecture, because they implement the actual business logic. Web Services are the natural means of communication and collaboration for agents working under the described model; the Semantic Web is the environment (world) for these agents, and the personalization rules basically can be used to make up or modify the beliefs of the agents. Thus the described components integrate very nicely and in a very natural manner into the underlying agent paradigm.

The WASP framework will account for a variety of necessities explained in the next sections. In contrast to existing major endeavors in this area (Finin, Labrou, & Mayfield, 1997; Object Management Group, n.d.; O'Brien & Nicol, 1998), we plan to provide an architecture that focuses on:

- proactive information agents that collect information and provide results by using inference mechanism to reason about the existing information;
- high-level technical support for the application developer (e.g., communication, distribution, data storage);
- tight integration of Web technologies (RDF, Web Services, DAML, SOAP, etc.);
- independence from specific kinds of implementations (e.g., no specific communication language will be enforced); and

- focus on agents relying on the Semantic Web as the dominant information source.

Thus the following central paradigms will be of greatest importance:

Open Interfaces

Since it is impossible to enforce one true operating system, one true programming language, or one true CPU architecture for the network underlying the World Wide Web, it is of paramount importance to provide a powerful means of communication between the interacting agencies. SOAP and HTTP (as the underlying protocols), together with Web Services (as a means of interface specification), seem to be natural choices. The framework will provide a layer of abstraction to be able to disconnect from these particular technologies, should, for example, other protocols become more important.

Service Agencies

Agents seem to be a very natural way for describing typical scenarios of Web usage. They are the machine representation of human beings who right now have to do most of the work manually. Thus the WASP framework will provide means to define a variety of agents: mobile, autonomous, reactive, and so forth. To enhance the usefulness of the framework, it is set up to allow agents to be self-describing, thus automatically turning agents into services that can be used by others and integrated via standard interfaces. This allows for wide-spread service dissemination and easy integration with other systems.

It will be especially important to integrate current agent research into this framework layer; efforts like DAML (DARPA Agent Mark-up Language) allow for powerful modeling means to devise agents and agencies.

Data and Information Gathering

The framework must provide for means to accumulate data, compare it, and reason about it. Data might be persistent (to allow for agents with increasing reasoning power) or transient (to model short-effect tasks), and data should be interchangeable between different agents. It must be possible to integrate ontologies to allow for a solidified view of the "world" (in regards to the agent or agents).

Personalization Integration

It must be easy to integrate personalization technologies. At the most basic level, it should be possible to specify user preferences and dislikes, and to integrate them in the reasoning and retrieval process to improve the quality of the returned information.

The HIVE: Semantic Web Brokering Simplified for WASP Agents

Web servers have been the technical foundation for the success of the World Wide Web. Applications servers have been a successful model in abstracting from the everyday chores of building complex applications and thus form the basis for modern large-scale business applications. Thus it seems natural to evolve to Semantic Information Servers that provide a corresponding environment for Semantic Web agents specialized on utilizing the Semantic Web resources to provide information services to the end user.

Application servers offer persistence, transactions, distributed processing, and scalability if the software complies with a predefined component model (e.g., Java 2 Enterprise Edition / J2EE). This allows developers to focus on the actual task at hand, for example, implementing the business logic for a complex transaction portal. In our view, a similar model is required for Semantic Web applications based on agent societies. Different layers of abstractions will allow concentrating on

functional requirements and help to abstract from the details of the implementation. In the same way that a J2EE application server takes away the details of persistence from the developer, a Semantic Information Server can abstract from the details of, for example, storing semantic information, retrieving it, and reasoning about it. This holds true for other areas as well (e.g., information recovery from the Web, resource management for agents, and communication between members of local and remote agencies). Within the WASP framework, we intend to call the Semantic Information Servers a HIVE (not an acronym but rather a play of words continuing the WASP idea).

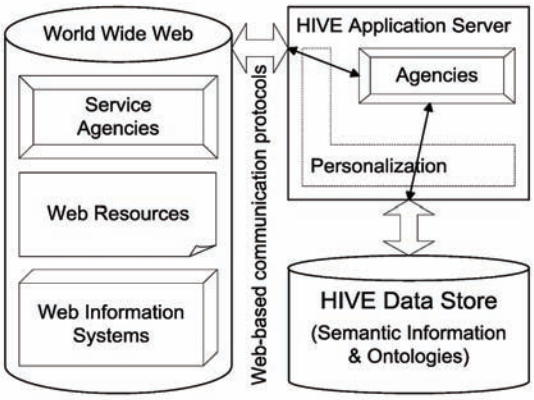
These ideas result in the infrastructure diagram in Figure 1.

Important Semantic Web Research Areas

In this section we intend to describe a few of the more important current research topics needing to be solved to further the development of Semantic Web services:

- Ontology integration and translation is a major problem for interconnecting distributed services and systems (Gruber, 1993; Heflin & Hendler, 2000; Heflin et al., 1999): How can differing ontologies for related topics be mapped on each other?
- Web Service orchestration, interoperation, and transaction handling needs to be standardized (UDDI, 2001; Web Services Choreography Requirements, 2003; Web Services Transaction, 2002).
- Standards to allow for personalization need to find wide acceptance (PICS, n.d.; Stahl & Völter, 2005; for discussions on currently-available, yet still rarely-used standards).

Figure 1. HIVE architecture



Remaining Challenges

Besides the technical questions which currently enjoy most attention, a multitude of additional topics needs to be investigated before distributed agent systems and the Semantic Web become truly viable. A few of them are:

- **Modeling challenges:** In which way can Semantic Web systems be modeled so that a broad user base will be able to understand and utilize these technologies? We make an early attempt to answer this question in the last major part of this chapter.
- **Cost challenges:** Who is going to pay for the resources being used in distributed agent networks? It is safe to assume that such agent services will be a lot more cost-intensive than the "simple Web information platforms of today" (e.g., Web servers).
- **Pricing challenges:** Already now there is a tendency to commercialize high-quality services. How will future information systems be rated in terms of usage fees if the component services of some complex service (e.g., the logistics service, the currency conversion service, and the mapping service for a complex online order service) each incur fees, but the user of the complex service might not necessarily add to the income of the complex service provider (e.g., because

the user decides against buying something after getting the shipment information)?
- **Business challenges:** What are viable business models for Semantic Web agencies and services?
- **Quality challenges:** How will services be able to guarantee a certain level of quality if they rely on the data collected in the Semantic Web, an information storage that will be as inaccurate as the currently-available World Wide Web (mostly because everyone will be able to put up whatever he or she deems correct and appropriate)?
- **Trust challenges:** How can I be sure that not only the quality of results gained by Semantic Web analysis is sufficient for me but also correct at all?
- **Workflow challenges:** How can complex workflows (like booking a complete holiday trip) be orchestrated when dynamic service directories, user preferences, potentially faulty information, and other factors need to be considered?
- **Performance challenges:** How must services be constructed to be able to retrieve useful data in a timely manner from the Semantic Web, a Web that is infinitely more complex to search compared to current search engines and technologies due to the far more involved complexity created by allowing inferences, conclusions, and reasoning about information?
- **Security challenges:** How can personal and private information be protected from prying eyes? What new security challenges arise from the architectural decisions made for the WASP framework?
- **Legal challenges:** Who will be held responsible for incorrect, imprecise, or faulty information derived from or modified by Semantic Web content?
- **Architectural challenges:** What are the best-of-breed software infrastructures/ application architectures to allow for a rapid dissemination of the technologies involved? How can user and developer acceptance be increased?

REQUIREMENTS ANALYSIS CONCERNING SEMANTIC WEB ARCHITECTURES

As explained in our example Semantic Web architecture, different technology layers usually will be found in a Semantic Web-based system. In this section, we will continue the example by analyzing the essential requirements to be fulfilled both by our similar architectures in order to be Semantic Web-ready. We will start at the bottom-most layer (the database tier) and work upwards from there. Differences compared to standard enterprise architectures will be explained in the individual sections.

Requirements for the HIVE Data Store

The HIVE Data Store will store and evaluate data gained by analyzing Semantic Web resources. To provide a useful and extensible model, the following functional and technical requirements must be taken into account:

- The HIVE Data Store should be independent from the specific type of storage (DBMS, RDF store, flat file, some kind of network service). Thus it will be possible to choose the best type of storage for a given situation. Additionally this is a basic requirement to be able to exchange data store implementations as technology and research continue to evolve.
- The HIVE Data Store must not assume that data is correct, complete, or unambiguous. The Internet by design is a place where data is provided in a spontaneous and improvised manner. Thus the Data Store must be able

to cope with such data. This is also a major difference from classical enterprise systems, where usually the utmost care is taken to insert only verified, correct, and unambiguous data into databases.

- The HIVE Data Store must provide inference support. The true value of the Semantic Web can be used only by analyzing the gathered data and drawing conclusions. Thus inference support is paramount. Nonetheless there must not be any assumptions about the specific inference approaches being used, again to allow flexibility and configurability.
- The HIVE Data Store must be able to access data from a variety of sources. This is absolutely necessary due to the size and varied nature of the underlying information sources. The Internet itself is just too large to be kept on one server or a whole farm of servers; while in most cases an application will not need to access all the information available on the whole of the Internet, for some of the more exciting Semantic Web applications it will be a necessity to be at least potentially able to access all available information.
- The HIVE Data Store must be able to integrate ontologies into its repository. Ontologies are the basic mechanism to define the meaning of concepts modeled in, for example, RDF structures. An important add-on functionality will be the ability to compare ontologies and map them onto each other to be able to integrate differing ontologies designed for the same problem area.
- The HIVE Data Store must include a facility to manage the credibility of sensitive information. Mission-critical data must only be accepted from sources that are able to authenticate themselves and prove their credibility (e.g., with certificates or similar mechanisms).
- The HIVE Data Store should be able to organize itself physically, to manage its resources, and to restructure information based on dynamic changes of the environment. This is an optional but highly recommended functionality, as it is to be expected that the Data Store of a widely-used system will grow with leaps and bounds. To remain efficient and to conserve resources, the Data Store itself has to take responsibility for this.
- The HIVE Data Store must explicitly consider data retention periods, along with models and algorithms for purging; otherwise, the data cached there will rapidly become stale and will overload the database.
- The HIVE Data Store must provide a management facility so that external users can examine the state of the server, the data, and the rules accumulated in the store. Additionally, typical functionality must be provided to configure the data sources and control resource allocation of the store. It should be noted that the management facility might have a very different outlook depending on the underlying storage mechanism being used for the specific server.

To be able to incorporate these widely varying requirements, an abstraction layer will be required through which all HIVE Data Store access operations will be routed. This will add functionality as required (e.g., by defining a HIVE Data Store proxy that collects requests, runs through a caching layer to increase performance, and then delegates unanswered requests to the actual physical or distributed Data Store).

Requirements for the HIVE Agent Server

The HIVE Application Server is responsible for running the various agents that implement the business logic side of the framework and access

all other components to achieve their goals. The following functional and technical requirements need to be taken into account:

- The HIVE Agent Server must provide a runtime environment for varying agents that share a common interface, as defined by the WASP framework. There must be support for both mobile and static agents to allow for a wide range of application scenarios.
- The HIVE Agent Server must provide a security layer that controls resource access for all agents operating on the server. This is an absolute necessity for servers incorporating mobile agents and allowing mobile agents to migrate from one server to another.
- The HIVE Agent Server must provide access to the HIVE Data Store in an abstracted and generalized manner. Agents must not be required to know about the details of data storage or inference.
- The HIVE Agent Server must provide access to the "outside world" so that the sensors of the agents involved can operate. The HIVE Agent Server may modify perceived data based on personalization and security rules.
- The HIVE Agent Server must allow for communication using a variety of agent communication languages (ACLs) to be able to integrate a variety of agent systems. This probably will include the necessity to provide translation services between different agent communication languages in order to allow communication between agents of different breeds.
- The HIVE Agent Server must provide a management facility so that external users can examine the state of the server and the agents running on it. The management facility must include all kinds of standard management functionality to allocate resources, control permission, direct agents and so on.
- The WASP Agent Interface must be structured so that existing agent frameworks can be easily integrated into the system while there also must be enough room to develop new concepts and architectures. Additionally, the interface must be extensible, so that incremental extensions may be made both forward and backward compatibly, allowing upgrades to clients or servers in either order.

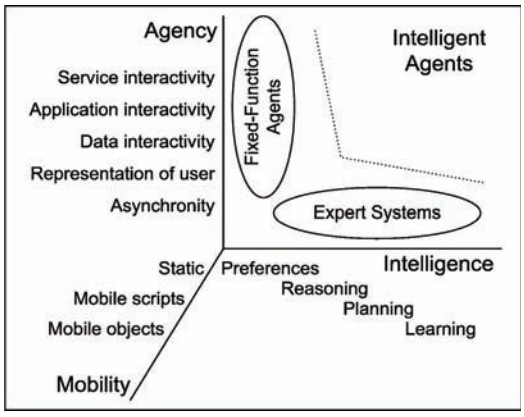
Interestingly, the requirements concerning the actual agents are very small; when examining, for example, the proposed scope of software agents in Gilbert, Aparicio, Atkinson, Brady, Ciccarino, Grosof, et al. (1995), the only functional requirements that must be provided by the HIVE Agent Server is mobility. Everything related to the intelligence aspects of agents can be modeled in the HIVE Data Store and the agent implementation. All other aspects are determined by the actual agent implementation.

Requirements for the HIVE Personalization Layer

The HIVE Personalization layer modifies both the perceived external environment (e.g., the Internet and other servers) and the perceived internal environment (especially the information gathered in the HIVE Data Stores). To provide a meaningful level of personalization, the following functionalities are of utmost importance:

- The HIVE Personalization Layer must provide permission-based personalization so that the perceived environment adjusts based upon the permissions of each individual agent. Permissions will have to be modeled on per-server-, per-agent- and per-user- base in order to be fully effective.
- The HIVE Personalization Layer must be able to handle agent-specific inference rules

Figure 2. Scope of intelligent agents (Adapted from Gilbert, et al., 1995)



in order to modify and control the inference process based on agent preferences.

- The HIVE Personalization Layer must be able to handle user-specific inference rules in order to modify and control the inference process based on agent preferences.

REQUIREMENTS FOR THE HIVE COMMUNICATION LAYER

The HIVE Communication Layer connects the HIVE Agents with external systems (e.g., the Internet, other servers, and so on).

The argumentation in the sections above shows that the HIVE Communication Layer also should serve another important purpose: The various components of the WASP Framework need to be connected in a system-independent and flexible way; by using the HIVE Communication Layer not only for inter-system but also for intra-system communication, several powerful synergy effects can be utilized:

- Communication uses but one protocol layer. This makes it much simpler to distribute agents, objects, and servers since no separate protocols are required for communication and information exchange. The implementation of the HIVE server itself is simplified, too.
- Intra-system services (e.g., resource management, process supervision, and more) can, if wanted, be modeled as agents to use the infrastructure provided by the WASP framework to implement the WASP framework itself. This is analogous to database systems that store database meta-information in their own database structures or compilers used to compile themselves, and serve as a good proof of concept for the simplicity and validity of the architecture, once implemented.
- The communication layer must integrate mechanisms to transparently handle both scalability of the system as a whole and to increase the fault tolerance when concerned with individual requests.

To be able to fulfill these expectations, a number of functional requirements must be considered:

- The HIVE Communication Layer must be implemented with a system-independent protocol and communication API. It must be possible to exchange atomic and complex information objects. Web Services and the associated communication protocols (e.g., SOAP) will serve nicely as a basis for the HIVE Communication Layer.
- The HIVE Communication Layer must be able to communicate with external systems through a standard protocol. Otherwise communication would be too limited for a reasonable system trying to support Semantic Web applications.
- The HIVE Communication Layer must provide some means to execute a lookup for external services and resources. Services like UDDI (Heflin & Hendler, 2000) and maybe also LDAP are typical candidates to be integrated. Although this might seem like a rather minor and trivial point at first

(especially given the fact that more or less established technologies like LDAP and UDDI already exist), it must be stressed that the integration of a powerful lookup service for other services and resources is of major importance, especially so when considering the stress on "fault tolerance" and "scalability".

Scalability is rather easy to achieve in some respects if a lookup mechanism exists: Requests for services, on one hand, can be dispatched to service endpoints based on a variety of load-balancing strategies and algorithms; only imagination limits the possible scenarios ranging from simple round-robin algorithms to elaborate agent-based schemes where agents monitor the CPU load on connected systems and use that information to control the dispatching of further incoming requests. Hardware-based load-balancing mechanisms can also be easily integrated as the endpoint of a service, and can represent a façade for a server cluster with a hardware load balancer handling the incoming requests. Naturally these techniques can also be combined.

To be able to effectively handle faults, several approaches can be implemented; the important concern is whether service faults on the actual service level (e.g., complete service failures due to unavailable servers, etc.) or on the logical level (e.g., service errors, etc.) are examined. The communication layer can easily enhance the fault tolerance of a Hyperservice-based system on the service level: A simple protocol handler extension can be integrated in order to allow the resubmission of service requests if a service endpoint fails to respond. This behavior can be enhanced by integrating a regular availability check into the service/resource registry to be able to filter out or deactivate temporarily-unavailable endpoints and thus reduce the overall network load. Errors on the logical level cannot be handled in a transparent level in the HIVE communication layer without extensive semantic descriptions of the services themselves. Since the idea of the HIVE architecture is to provide a simple and extensible architecture. For now, no logic fault handling at all will be integrated into the communication layer. Future research will have to show whether such extensions can be integrated in a simple yet effective manner.

Finally it is important to note that, as the internal HIVE services also can and should make use of the service and resource registries, the HIVE system itself transparently benefits from the integration of the features concerning fault handling and scalability as described above.

- The HIVE Communication Layer must be system- and programming language-independent. Again, Web Services and the associated protocols nicely fit this requirement.
- The HIVE Communication Layer must use standardized protocols to be able to connect to as many systems as possible.

Common Requirements

Finally there are some common requirements that are shared by all frameworks like, for example, compositionality, reusability and extensibility, that must be taken into account. Of special importance for the WASP framework is language independence (even if the reference implementation might use a specific language like Java or C#), in order to be able to connect as many systems as possible. Since these requirements are not unique or special to the presented topic, we will not elaborate them any further within the bounds of this chapter.

The Requirements Analysis in Review

In order to make the Semantic Web as accessible as possible, a highly-abstracted framework with open interfaces and simple overall concepts is

very important, especially since the underlying technologies mentioned above individually already require a high level of expertise to be able to use them effectively. We have shown that such an infrastructure framework is defined by a manageable amount of requirements, and that available standards (ready or just evolving) already cover a lot of ground. The next challenge is to provide a means of integration that is simple yet powerful and extensible at the same time. This will be the focus of the rest of this chapter.

MODEL-DRIVEN SOFTWARE DEVELOPMENT FOR THE SEMANTIC WEB

In this final section, we will try to give an answer on how to increase the acceptance of Semantic Web technologies by leveraging recent developments in the area of model-driven software development (MDSD). So far we have talked about how to simplify the development of Semantic Web-based systems, and this is the classical perspective of most approaches available today.

Now we would like to concentrate on a new way of approaching software development. Model-Driven Architecture (MDA) and Model-Driven Software Development (MDSD) both strive to simplify software development by automatically generating executable code from models (Stahl & Völter, 2005). These approaches seem to be well-suited for Semantic Web development considering the implied semantic definitions of models, agents, and ontologies, for example, provided by DAML. Nonetheless, one inherent weakness is left unconsidered by these approaches: Both MDA and MDSD require a sound understanding of the underlying technological and theoretical foundations, combined with a good amount of experience about how to model systems in the best way. This does not really help in transferring the conceptual knowledge that software customers possess into software systems as the developers still concentrate on building sound technological models and keep all the minute details under control.

We thus propose the next step in model-driven technologies, which we have named "Conceptual Model-Driven Software Development (CMDSD)".

The Notion of Conceptual Model-Driven Software Development (CMDSD)

The basic idea of our methodology of Conceptual Model-Driven Software Development (CMDSD) is to model systems through intuitive models on the conceptual level. These models must not be based on one global theory (like MDA with the Meta-Object Facility (MOF)), but rather utilize the most pragmatic theoretical foundation possible for the problem at hand. Additionally, the model should abstract as much as possible from the technological details of the system and focus on the conceptual facets which are possible. Models are aggregated into more complex models while great care is taken to provide a simple transformation from the individual model to the run-time system representation of the model. This allows software developers and architects to work together with customers and concentrate on the business side of the system; a simple and effective transformation from business problem to system representation is assumed. Existing design patterns support this notion.

Of greatest importance is the way in which CMDSD-based models are made available to the conceptual experts at hand: We require that models use a language (in the formal meaning) that comes as close as possible to the tools and ways used by the target audience to express their concepts. Thus the way of modeling will differ between areas of expertise. While this might feel like a disadvantage at first because software engineers will have to learn many differing modeling languages, we regard this as an advantage for a simple reason: The rules for transforming/execut-

ing these models need only be understood by a very small number of persons, namely those persons who build the actual transformers or interpreters. In contrast the user base for the concepts modeled typically will be very large in comparison. Thus it seems more reasonable to build models which are intuitive for the end user base and not the (intermediate) developers. Additionally it benefits the developers by forcing them to concentrate on the conceptual aspects of development and to hide the technical details.

One might argue that this is just a step back to the "model wars" in the years from 1990 to 2000 before the advent of UML. We argue that UML and similar OMG approaches did not really solve those problems as far as the actual specification of conceptual tasks goes. UML provides very effective models in order to specify technical details, but those technical details, most of the time, are of no interest at all to the conceptual experts who require a solution for their non-technical problems. The gap between available means to specify technical aspects and the lack of means to formally specify the purely conceptual parts of a problem leads to a high number of failing software projects (failing software projects are those that fail to meet their goals in time, money, or quality).

Current studies concerning success and failure of software projects seem to prove this point (Standish Group, n.d.): More than 75% of all failed software projects failed due to problems with requirements analysis and errors in the resulting specifications. We thus argue that more problem-oriented models are a must-have in order to facilitate the communication between technical and non-technical experts which work together on a complex project.

Additionally, our CMDSD methodology requires Rapid Prototyping (Reilly, 1996) as a means to be easily able to verify specifications.

Using CMDSD to Build Semantic Web Servers

How does all this help with Semantic Web development? Many of the underlying technologies for the Semantic Web are highly complicated and very involved. Rare is the architect or developer who understands agent technologies, Web service specifications (in their ever-growing numbers), and the details of building efficient application servers all at once. If architects and developers trained in more than one of these topics are already rare, how can we then assume that the end users for Semantic Web technologies (e.g., the people building Websites today) will be able to grasp the varying concepts and details of implementation?

As explained in the sections above, one of the research directions currently being actively investigated is the research in semantically-rich descriptions for Web services. Now imagine a development system that can understand existing semantic descriptions of services, load them, and generate definition and aggregation interfaces for such services. Suddenly developers and customers can work together in a semantically-rich environment to model the business side of systems and, by using a framework like the WASP framework, can mostly ignore the technological side as the underlying framework handles configuration and assembly.

While we still need to work on the actual implementation of a server that can handle arbitrary agent frameworks and expose them as Web Services, a specialized server for one type of agent system is within reach. Additionally, many projects will be able to be handled today by using but one technology, as the integration of differing agent systems requires quite a bit of research in the future. The next section will show how such a system can be integrated into existing application and Web servers with CMDSD methods.

A CMDSD-Based Approach for Agent and Service Integration

First of all, we specify the most important requirements that must be fulfilled in order to make it simple to use Semantic Web technologies. Please note that these definitions are flexible and based on our point of view; different focuses will yield different definitions. We intend to base our initial CMDSD-based model on the following requirements:

1. The model must be formulated in such a way that current Web developers will feel immediately comfortable using its syntax.
2. The model must hide the complexities of both the underlying technology and the integration questions popping up as soon as actual integration into an application or Web server comes to mind.
3. The model must allow for flexible data structures to both be sent to the agents and be received from the agents.
4. It must be possible to modify the data in both directions.
5. Standards should be used to implement the model transformation/executions.

To fulfill these requirements, we make the following decisions:

1. The model will be formulated in "an XML-like syntax similar to HTML" (see below). This will allow current Web developers to easily grasp the concepts. As a side effect, the model definitions for now will be included in the definitions for HTML pages. The special tags defined to describe WASP models will be shown below.
2. The model for now will only fulfill the most basic requirements of a basic IO system. Complex logic will be hidden in the underlying agents and processes. The model is thus only concerned with retrieving data from some source and sending (other) data to a sink (which provides the results as a response).
3. Technically we will assume that some kind of extension of the underlying server that analyzes the HTML code before it is sent to the client, extracts the WASP-specific definitions, processes them, and re-integrates the results of those definitions. Possible technical solutions could be Apache Plug-Ins (Bloom, 2002), Java Servlet Filters or Java Servlets (Bell, Loton, Allamaraju, Dalton, Brown, Harbourne-Thomas, et al., 2002) or ISAPI extensions for the Microsoft Internet Information Server (Genusa, Addison, & Clark, 1999).
4. XML will be used to represent data (Bray et al., 2000).
5. Simple transformations will be handled by XSL transformations (Cagle, Cornig, & Diamond, 2001). Complex data transformations will require specialized agents or Web services.
6. Services and agents will be represented by URNs (Uniform Resource Names) (URI Planning Interest Group, n.d.) in the models. The interpretation of those models will, for now, be server-specific, although future systems should strive to standardize URNs in the same way as XML namespaces.

Based on these requirements and definitions, we now will provide a simple example for a Hyperservice call. Note that in the HTML snippet in Figure 3, all WASP- (and model-) specific elements use the "wasp:" namespace.

The interpretation of the given code snippet is intuitive if you are even slightly versed in HTML; and now about the meaning of XSLT:

- The tag "<wasp:hyper service="urn:wasp:service:GetStockQuotes">" defines a hyperservice call. The service itself is identified by the given URN. The specifics of connecting

Figure 3.

```
…
<table width="100%">
<wasp:transform xslt="/xslt/
CreateRowsFromStockQuotes.xslt">
  <wasp:hyper service="urn:wasp:service:GetStockQuotes">
    <wasp:parameter name="verbosity" value="detailed"/>
    <wasp:parameter uses="stockMarketLocation"/>
  </wasp:hyper>
</wasp:transform>
</table>
…
```

to the service are completely hidden from the user (e.g., the Web page author) and must be configured in the server environment. A definition of the interface of that service also exists separately and is fulfilled implicitly by the next two lines of code (see below).

- Two parameters are defined:
  - The parameter "verbosity" is set to the value "detailed" which (intuitively) means that a detailed list of stock quotes is requested.
  - The parameter "stockMarketLocation" is defined dynamically (as indicated by the attribute "uses" instead of "value" as in the previous example); "uses" implies that the parameter value is taken from the request parameters. This allows defining parameters dynamically by, for example, building dynamic URLs or submitting parameters with a form.
- The result of the service request is transformed using XSLT as defined in the enclosing tag "<wasp:transform xslt="/xslt/CreateRowsFromStockQuotes.xslt">". This special tag applies an XSL transformation to the body of the tag (which in turn is produced by dynamically executing the service call explained above). Again an implicit knowledge about the result structure is assumed. Given a meaningful XSL transformation, the stock quote list (in XML format) will be transformed into a user-friendly and nicely formatted HTML representation of the data.

In order to allow for more complex structures, we will allow extended parameter definitions so that the results of calls can be, in turn, reused as parameters for other calls. Assuming the existence of a service to transform stock quote lists from XML format to HTML, we could rewrite the code above in the way Figure 4 shows.

In this revised example, the parameter named "list" is derived by calling the above-mentioned stock quote service and using the result of that service as the input for the second service. In a certain way, we pipe inputs and outputs in a comparable way to UNIX shell commands. The true power of these rather simple models becomes obvious when chaining several services (Figure 5).

In this example, three input parameters are processed: For a given user ("userID"), a destination ("destination"), and an indicated price limit ("maxPrice"), first the list of preferred airports is determined by calling one service, and then the available flights are searched by calling a second service, and combining both dynamic parameters and results from user interaction. In this way complex scenarios can be based on a very simple model.

Figure 4.

```
…
<table width="100%">
<wasp:hyper
service="urn:wasp:service:CreateRowsFromStockQuotes">
  <wasp:parameter name="list">
    <wasp:hyper service="urn:wasp:service:GetStockQuotes">
      <wasp:parameter name="verbosity" value="detailed"/>
      <wasp:parameter uses="stockMarketLocation"/>
    </wasp:hyper>
  </wasp:parameter>
</wasp:hyper>
</table>
…
```

Figure 5.

```
…
<table width="100%">
<wasp:hyper service="urn:wasp:service:FindFlights">
  <wasp:parameter name="airportList">
    <wasp:hyper
service="urn:wasp:service:FindPreferredAirports">
      <wasp:parameter uses="userID"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter name="benefits">
    <wasp:hyper
service="urn:wasp:service:FindPersonalBenefits">
      <wasp:parameter uses="userID"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter uses="destination"/>
  <wasp:parameter uses="maxPrice"/>
</wasp:hyper>
</table>
…
```

Also the level of abstraction is very high: Assume, for example, that all XML data structures are connected to an ontology. If service A requires input conforming to ontology o_A and receives its input from a service B which in turn is only able to produce results conforming to ontology o_B the runtime environment can (transparently for the model builder!) search for a transformation rule $o_A \rightarrow o_B$ and apply it, all this without requiring any in-depth knowledge of the "end user" (the HTML modeler/designer). Additionally, it will be possible to optimize the system by changing the configuration and not the model; the interpreter for the model will automatically take into account the new settings. Finally a change of technologies also is transparent for the "end user" (e.g., the page designer) as the special tags introduced above are independent of the implementation.

The final aspect of flexibility to be introduced within the context of this chapter is a way to an

actual service lookup. To allow for this, we now also allow the service URN to be provided dynamically (Figure 6).

Another simple extension of the model focuses on the "hyperlinked" nature of the Web: By not only accepting special URNs but generic URIs, it easily becomes possible to link separate systems into a more complex system. The following example illustrates this by using external URIs for some services from the previous example (Figure 7).

Again most of the underlying complexity is moved to the run-time environment which has to determine the actual service descriptions, match it against the expected interfaces, call the remote service with an appropriate protocol, accept the results, and so forth. Even details like session-based authentication might be handled transparently for the page designer by the underlying framework.

The formal semantics of the model are beyond the scope of this chapter but should be intuitive enough to derive for the interested reader.

Implementing the Proposed CMDSD Model

The most basic component required to implement the model proposed in the previous sections is the actual tag parser component. If, for example, a J2EE application server were used as the run-time environment, it would be a natural fit to implement the special WASP tags as a Tag Library (Brown, 2003) because tag libraries integrate in a very natural way into the run-time environment. The more complicated components concern the actual integration of services and agents. A way

Figure 6.

```
…
<table width="100%">
<wasp:hyper>
  <wasp:parameter name="service">
    <wasp:hyper service="urn:wasp:service:ServiceLookup">
      <wasp:parameter name="serviceName"
value="FindFlights"/>
      <wasp:parameter name="typeSpecialization"
value="lastMinute"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter name="airportList">
    <wasp:hyper
service="urn:wasp:service:FindPreferredAirports">
      <wasp:parameter uses="userID"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter name="benefits">
    <wasp:hyper
service="urn:wasp:service:FindPersonalBenefits">
      <wasp:parameter uses="userID"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter uses="destination"/>
  <wasp:parameter uses="maxPrice"/>
</wasp:hyper>
</table>
…
```

Figure 7.

```
…

<wasp:hyper>
  <wasp:parameter name="service">
    <wasp:hyper service="http://www.quinscape.de/services/
ServiceLookup">
      <wasp:parameter name="serviceName"
value="FindFlights"/>
      <wasp:parameter name="typeSpecialization"
value="lastMinute"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter name="airportList">
    <wasp:hyper service="https://www.foo.bar/
FindPreferredAirports">
      <wasp:parameter uses="userID"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter name="benefits">
    <wasp:hyper
service="urn:wasp:service:FindPersonalBenefits">
      <wasp:parameter uses="userID"/>
    </wasp:hyper>
  </wasp:parameter>
  <wasp:parameter uses="destination"/>
  <wasp:parameter uses="maxPrice"/>
</wasp:hyper>
</table>
…
```

needs to be found to describe service descriptions from agent specifications/implementations. An efficient system needs to be implemented to allow for ontology comparisons and transformations. Finally, a performance analysis of the implementation is a necessity in order to estimate how well the implementation scales under real-world conditions. Current research projects work on answering these questions.

SUMMARY AND CONCLUSION

In this chapter, we have shown how viable Semantic Web Frameworks can be developed with currently-existing technologies. We have underlined the importance of providing ways to allow for an easy adoption of Semantic Web technologies lest all efforts are moot due to not being accepted by the public. We have defined our notion of Hyperservices and presented the WASP architecture which facilitates the creation of extendable Semantic Web systems. We have analyzed the requirements for general Semantic Web frameworks and used the results thus gained in order to describe a conceptual model for our WASP framework. In order to facilitate these endeavors we have described our "Conceptual Model-Driven Software Development (CMDSD)" approach and given examples to illustrate how easy a model for accessing Hyperservices can be defined.

By providing such a foundation, we have disconnected undergoing research in the Semantic

Web area from the need to start making these technologies available for a wider audience.

BACKGROUND INFORMATION

This chapter is based on published and well-accepted papers by the authors as well as their continuing research in the areas of Semantic Web, Agent Systems, and Conceptual Model-Driven Software Development, among them Biskup, Marx Gómez, and Rautenstrauch (2005), Biskup and Marx Gómez (2004a, 2004b), and Biskup and Marx Gómez (2005).

Chapter 2.7
Formal Modeling and Specification of Design Patterns Using RTPA

Yingxu Wang
University of Calgary, Canada

Jian Huang
University of Calgary, Canada

ABSTRACT

Software patterns are recognized as an ideal documentation of expert knowledge in software design and development. However, its formal model and semantics have not been generalized and matured. The traditional UML specifications and related formalization efforts cannot capture the essence of generic patterns precisely, understandably, and essentially. A generic mathematical model of patterns is presented in this article using real-time process algebra (RTPA). The formal model of patterns are more readable and highly generic, which can be used as the meta model to denote any design patterns deductively, and can be translated into code in programming languages by supporting tools. This work reveals that a pattern is a highly complicated and dynamic structure for software design encapsulation, because of its complex and flexible internal associations between multiple abstract classes and instantiations. The generic model of patterns is not only applicable to existing patterns' description and comprehension, but also useful for future patterns' identification and formalization.

INTRODUCTION

Design patterns are a powerful tool for capturing software design notions and best practices, which provide common solutions to core problems in software development. Design patterns are a promising technique that extends reusability of software from code to design notions. A representative work of design patterns is initiated by

Gamma and his colleagues in *Design Patterns: Elements of Reusable Object-Oriented Software* in 1994 (Gamma, Helm, Johnson, & Vlissides, 1995). Design patterns may speed up the development process by providing tested and proven development paradigms. Reusing design patterns helps to prevent subtle issues in large-scale software development and improves code readability for architects and programmers. Design patterns can contribute to the definition, design, and documentation of class libraries and frameworks, offering elegant and reusable solutions to design problems, and consequently increasing productivity and development quality (Gamma et al., 1995; Wang, 2007a). Each design pattern lets some aspects of the system structure vary independently of other aspects, thereby making the system more robust to a particular kind of change.

Design patterns are used to be modeled and specified in natural language narratives, object-oriented programming languages, and UML diagrams. The traditional means are either inherently ambiguous or inadequate (Lano, Goldsack, & Bicarregui, 1996; Vu & Wang, 2004; Wang & Huang, 2005). The major problems in current methodologies for pattern specification are identified as follows:

- **The lack of a unified and generic architecture of patterns as a multilayered complex entity with a set of abstract and concrete classes and their interrelations:** Patterns have been classified in three categories known as the *creational*, *structural*, and *behavioral* patterns (Gamma et al., 1995). However, the theories for the nature of patterns and their generic architecture are yet to be sought.
- **The lack of abstraction:** Almost all patterns are described as a specific and concrete case in natural language, UML diagrams, or some formal notations. However, no generic mathematical model of patterns is rigorously established, which may form a deductive basis for deriving concrete and application-specific patterns.
- **The lack of uniqueness:** In the conventional pattern framework, there are different patterns that may be implemented by similar code; Reversely, the same pattern may be implemented in various ways.
- **The use of unstructured semantic means to denote highly complicated design knowledge in patterns:** The informal descriptions of patterns puzzle users and cause substantial confusions. Even the creators of patterns demonstrate inconsistent over the semantics of certain patterns.

The authors perceive that the above fundamental problems can be alleviated by introducing formal semantics for design patterns and their generic mathematical models (Wang, 2002, 2003, 2006a-c, 2007a-c). This approach allows for unambiguous specifications, enables reasoning about the relationships between abstract and concrete patterns, and promotes a coherent framework for the rapidly growing body of software patterns in software engineering (Beck, Coplien, Crocker, & Dominick, 1996; Bosch, 1996; Wang, 2002, 2006a, 2007a). This article presents a generic model of design patterns and a formal specification method for design patterns using Real-Time Process Algebra (RTPA) (Wang, 2002, 2003, 2007a). The approach proposed in this article aimed at the following objectives:

- **It is generic:** The same pattern model can be adopted to specify any existing and future pattern, particularly user defined patterns. To some extent, the general pattern model is the pattern of patterns.
- **It is formalized:** The mathematical semantics and formal notation system are based on RTPA (Wang, 2002, 2003, 2007a).
- **It is expressive:** Only 34 notations are used to denote class association relationship and specify patterns from three facets known

as the architecture, static behaviors, and dynamic behaviors of patterns.

- **It is structured:** Patterns are described from high-level to detailed-level via stepwise refinement using a coherent set of notations.

In this article, existing pattern specification techniques are reviewed in the following section. The RTPA methodology for pattern specification is introduced. A generic model of design patterns is rigorously modeled. Based on the mathematical semantics and general model, case studies on deriving specific pattern specifications are presented using three well known patterns such as the State, Strategy, and the MasterSlave patterns.

APPROACHES TO SOFTWARE PATTERN DESCRIPTION

A number of pattern modeling methodologies have been proposed, such as the layout object model (Bosch, 1996), the constraint diagrams (Lauder & Kent, 1998), the *language for pattern uniform specification* (Eden, Gil, Hirshfield & Yehudai, 2005), *meta-models* (Pagel & Winter, 1996; Sunye, Guennee, & Jezequel, 2000), *object calculus* (Lano et al., 1996), *pattern visualization techniques* (Lauder et al., 1998), and the *design pattern modeling language* (Mapelsden, Hosking, & Grundy et al., 1992). This section briefly reviews three major pattern specification methods and comparatively analyzes their strengths and weaknesses.

The Layout Object Model

The layout object model (LayOM) (Bosch, 1996) is an extension of object-oriented languages containing components that are not supported by the conventional object models such as layers, categories, and states. It supports the representation of design patterns in object-oriented programming languages.

In LayOM, layers are used to encapsulate objects and intercept messages that are sent to and by the objects. The layers are organized into classes and each layered class represents a concept, such as a relation with another object or a design pattern. A *state* in LayOM is a dimension of the abstract object state that is an externally visible abstraction of the internal, concrete state of objects. A *category* is defined as a client category that describes the discriminating characteristics of a subset of possible clients. *Relations* in LayOM are denoted by structural, behavioral, and application-domain relations.

For example, the *adapter* design pattern can be described in LayOM, as shown in Figure 1, which converts the interface of a class into another interface that is expected by its clients. The adapter layer can be used to class adaptation by defining a new adapter class consisting only of two layers.

In LayOM, a one-to-one mapping between the design and implementation of a pattern is provided. Another advantage of it is that there is no requirement for defining a method for every method that needs to be adapted. However, a

Figure 1. The adapter pattern described in LayOM (Bosch, 1996)

```
class Adapter
layers
adapt: Adapter (accept mess1 as newMessA,
accept mess2 and mess3 as newMessB);
inh: Inherit (Adaptee);
end;
```

disadvantage of the adapter technique is that the arguments of the message will be passed as is, which is not flexible to cover semantic analyses. Another drawback is the implementation overhead, because messages sent to or from an object need to pass all the defined layers.

The Constraint Diagrams

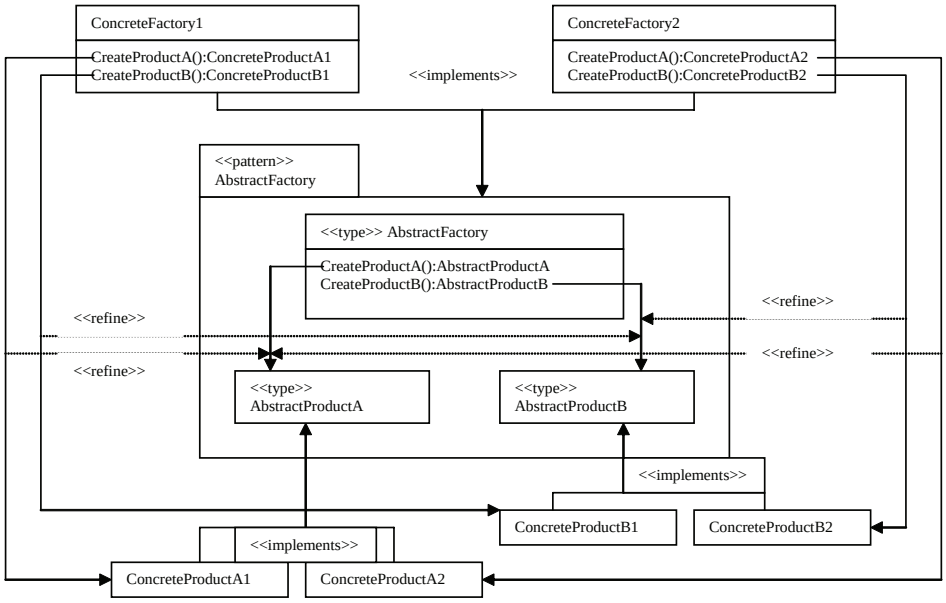
The *constraint diagram* (CD) (Lauder & Kent, 1998) denotes a pattern by three separate models known as the role, type, and class. A *role* model in CD is the most abstract and depicts layer that describes the essential spirit of a pattern without specific details. A *type* model in CD refines to the role model with abstract states and operation interfaces forming a domain-specific refinement of the pattern. A *class* in CD model implements the type model, thus deploying the underlying pattern in terms of concrete classes.

An *abstract factory pattern* deployed as a constraint model is shown in Figure 2. The core of the pattern is represented as a role mode, further refined by a type model, and implemented by a class model. However, a graphical model is not enough for a precise and unambiguous specification. There is still a need to describe additional constraints about the objects in the model. Otherwise, ambiguities cannot be avoided in the model (OMG, 1997).

LePUS: Language for Patterns Uniform Specification

Language for patterns uniform specification (LePUS) is a declarative language based on logic introduced in 1997 (Eden et al., 2005). It models class relationships and semantics, and facilitates reasoning with higher order sets. LePUS permits concise description of complex software artifacts. In LePUS, a program is represented primarily as a set of ground entities and relationships among them. Various interactions and associations that occur between participants of design patterns are abstracted classes and functions. A uniform set of classes of a dimension *d* is denoted by the class of dimension *d*+1. Total relations are functions that describe the relations between two sets of entities. Bijective and regular correlations between sets of functions, classes, and hierarchies may also be

Figure 2. The constrain diagram of an abstract factory pattern (Lauder & Kent, 1998)



modeled. A specification of the *strategy* pattern in LePUS is shown in Figure 3.

The advantage of LePUS is its higher order logic means. However, it is difficult to directly map a LePUS specification of patterns into executable programs. In addition, patterns specified in LePUS are application specific rather than generic.

Other Approaches

Meta-models for design pattern instantiations and validations are proposed in Pagel and Winter (1996) and Sunye et al. (2000) without supporting for code generation. In Florijn, Meijers, and Wionsen (1997), the *fragment-based technique* allows the representation and composition of design patterns. A design pattern proof techniques is proposed in Lano et al. (1996) using the *object calculus* as a semantic framework. The *design pattern modeling language* (DPML) is proposed in Mapelsden et al. (1992) as a visual language for modeling patterns and their instances.

A common weakness of the methods proposed so far is that they concentrate only on specific pattern descriptions. The essence of pattern structures and the generic pattern theory are overlooked. Therefore, there is still a need to seek a more powerful means and methodology that help users to utilize pattern theories and models freely in pattern-based system design.

THE RTPA METHODOLOGY FOR PATTERN MODELING AND SPECIFICATION

In the preceding section, it can be seen that existing methods for pattern specifications were inadequate and inefficient in generic pattern specifications. This section adopts RTPA to formally specify design patterns, which is a set of new mathematical notations for formally describing system architectures, static and dynamic behaviors (Wang, 2002, 2006b).

RTPA is a mathematic-based software engineering notation system and a formal method for addressing problems in software system specification, refinement, and implementation. RTPA provides an expressive means for the formal and explicit description of software patterns in order to enhance the readability of pattern architecture, semantics, and behaviors. In RTPA, a software system is perceived and described mathematically as a set of coherent processes. RTPA encompasses 17 meta processes and 17 algebraic process combination rules known as the process relations. Detailed description of RTPA may be referred to Wang (2002, 2003, 2007a).

\end{array}
$$

The Generic Model of Classes in RTPA

A unified notion of classes can be formally described by RTPA as given in "Wang (2007a)." The fundamental types of classes are the Abstract Classes (ACs) and the Concrete Classes (CCs). The former is a class that serves as a general and conceptual model to be inherited but not be instantiated. The latter is an ordinary class derived from an AC that can be instantiated.

A generic AC specified in RTPA is shown in Figure 4. The architecture part is used to specify the architectural attributes of the abstract class, which include internal variables shared by the hierarchy of classes. The static behavior part of an AC is used to define the method signatures of the AC class, where detailed implementation will be left to be done in derived concrete classes. It is noteworthy that an AC has no dynamic behavior in the specification because ACs cannot be instantiated.

Similarly, a generic CC can be formally specified in RTPA, as shown in Figure 5. The CC implements the dynamic behaviors that can be instantiated and executed in a derived object. Possible events that drive a method in a CC can be classified into message, time, and interrupt. More formal treatment of classes and their relational operations may be referred to RTPA (Wang, 2002, 2003, 2007a) and concept algebra (Wang, 2006a, 2007c).

$$

The Generic Model of Patterns in RTPA

A pattern is a highly reusable and coherent set of complex classes that are encapsulated to provide certain functions. According to "Gamma et al. (1995)," patterns can be classified into the *creational*, *structural*, and *behavioral* ones. Using RTPA notations and methodology, a pattern is denoted by three parallel components known as the *architecture*, *static*, and *dynamic* behaviors, as shown in Figure 6. The architecture of a pattern specifies how many classes and components are used to compose the pattern and what relationships are among those components. The static behaviors of a pattern define what kinds of components are used to compose this pattern and what rules all components should abide. The dynamic behaviors of a pattern describe how those components interact and collaborate to realize functionality at run-time.

In Figure 6, the *architecture* of the generic pattern can be refined by a set of component logic models (CLMs), which describes the structures of a class, particularly its attributes (Wang, 2002). The *static behaviors* of the generic pattern are refined by a set of processes that are corresponding to each of the methods within the class. The process behaviors are denoted by RTPA meta-processes

}

and their combinations using process relations for manipulating internal attributes or interacting with external components of the generic pattern. The *dynamic behaviors* of the generic pattern are refined by event-driven processes deployed by the system.

The generic pattern model may be treated as a super metapattern in object-oriented system design and programming, which models any specific software pattern at four levels known as the *interface*, *implementation*, *instantiations*, and *associations*. According to the generic model of patterns, the features of patterns lie in the hierarchical architectures as described by PatternST.ArchitectureST, as shown in Figure 6. It is noteworthy that a class is usually modeled as a two-level structure with only the class *interface* and *implementations* in literature (Taibi, & Ngo, 2003; Vu & Wang, 2004). However, the four-level hierarchical model introduced here reveals the nature of how classes may be used to form complex patterns via *instantiations* and *associations*.

The *interface* of a pattern, PatternST.ArchitectureST.InterfaceST, isolates users of the pattern from its internal implementation. Users may only access the pattern via its interface. This mechanism enables the implementation of the pattern independent of its users. Whenever the internal implementation needs to be changed, it is transparent to the users of the pattern as long as the interface keeps the same (Wang & Huang, 2005). The interface of a pattern specifies the communication protocol among pattern components. Although instances could extend their behaviors beside those interface defined in this part their communication should abide those definition. The interface is the only access point of a component inside a pattern.

Because a pattern is a highly reusable construct of a software entity, the *implementation* of a pattern, PatternST.ArchitectureST.ImplementationST, is kept at a generic abstract class until the pattern is invoked by a specific application or instantiation. In other words, because a pattern is a generic model of reusable functions, specific behaviors in an execution instance are dependent on run-time information provided by users of the pattern.

The forth component in the generic pattern hierarchy is the internal *associations*, which is used to model the interrelationships among other three-level abstractions of classes and interfaces within the pattern. The *associations* of the pattern define relationships among all components in the

pattern. Component collaborations are the soul of patterns that capture component collaborations. The flexibility, reusability, and differences of patterns are embodied by the associations (Wang & Huang, 2005). A comprehensive set of pattern association rules may be referred to Concept Algebra (Wang, 2006b, 2007c).

The generic model of patterns or the meta pattern model describes software patterns in a coherent, concise, and unambiguous way. External relationship among patterns could be deduced by this formula as well, when a super pattern is considered beyond all the component patterns. The method developed in this section helps readers avoid the drawbacks of conventional patterns, in order to develop more efficient, reusable, flexible, and predicable software systems.

CASE STUDIES ON FORMAL SPECIFICATIONS OF PATTERNS IN RTPA

This section applies the RTPA pattern specification methodology in three case studies. The *State* and *Strategy* patterns are used to demonstrate that differences between these two patterns can be clearly distinguished by RTPA specifications, while other methods rendering vague message to users. The *MasterSlave* pattern (Buschmann, 1995) is used to demonstrate the expressive power of RTPA specifications. All cases studies show that not only conventional design patterns, but also newly discovered patterns can be precisely specified by RTPA.

Formal Specification of the State Pattern

The *State* pattern allows an object to alter its behavior when its internal state changes. The structure of this pattern proposed in Gamma et al. (1995) is shown in Figure 7.

A formal model of the state pattern can be derived on the basis of the generic pattern model developed in Figure 6. Corresponding to Figure 7, the RTPA specification of the *State* pattern is given in Figure 8.

Formal Specification of the Strategy Pattern

The *Strategy* pattern defines a family of algorithms, encapsulates them in a coherent structure, and makes them interchangeable (Gamma et al., 1995). This pattern lets the algorithm vary independently from clients that use it. The structure of the Strategy pattern is shown in Figure 9.

A formal model of the Strategy pattern can be derived on the basis of the generic pattern model developed in Figure 6. Corresponding to Figure 9, the RTPA specification of the strategy pattern is shown in Figure 10.

Contrasting the State and Strategy patterns in UML, it is noteworthy that both patterns share almost identical structures. In other words, UML

class diagrams, as shown in Figures 7 and 9, may not be able to discriminate the differences between these two patterns. This results in the main confusions, ambiguities, and difficulties in pattern comprehension and applications using UML-based methodologies.

However, the specifications in RTPA, as shown in Figures 8 and 10, can clearly capture the differences in the sections of class associations by

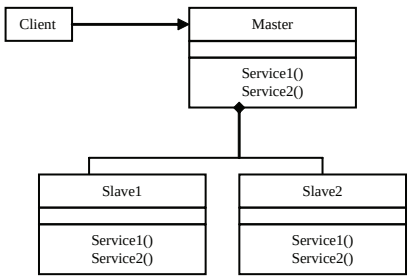
different composition approaches. The RTPA models show that in the former, all concrete state classes are instantiated by concrete classes simultaneously, where the concrete state objects have the same lifecycle as those of the concrete context objects; while in the latter, only one concrete strategy object alive within any point of time in the concrete context object lifecycle. This is the essential difference between those two patterns, which cannot be expressed explicitly by UML syntaxes and semantics.

Formal Specification of the MasterSlave Pattern

It is observed that traditional methods for pattern modeling are focused on existing and specific patterns proposed in "Gamma et al. (1995)." However, most practical patterns in software engineering are user-defined rather than pre-specified. Therefore, a generic pattern model is needed to support users to deductively model new patterns in practice.

A system pattern, *MasterSlave* (Buschmann, 1995) as shown in Figure 11, is presented in this subsection in order to demonstrate the application of the generic pattern model and the expressive power of RTPA for modeling patterns. The *MasterSlave* pattern handles the computation of replicated services of a software system to achieve fault tolerance and robustness. Replication of services and the delegation of the same task to several independent slave servers is a common strategy to handle fault-tolerant requirements in safety-critical software systems.

Figure 11. The UML structure of the MasterSlave pattern



The *MasterSlave* pattern consists of two kinds of components: the master and the slaves. Clients of the pattern interact with the master component directly. However, the master component does not implement services by itself. It delegates the services to a number of slave components, where at least two identical slave components exist in the system with the same set of functionality. The slave components are completely independent of each other, and they may use different strategies for providing the designated service. The master component delegates a requested service to all slave components and chooses one of the most suitable responses as the result for the client.

A formal model of the MasterSlave pattern can be derived on the basis of the generic pattern model developed in Figure 6. Corresponding to Figure 11, the RTPA specification of the MasterSlave pattern is given in Figure 12. The derived pattern precisely describes the architecture and associations between member classes of the *MasterSlave* pattern. Several strategies may be available for the master component to select results provided by the slaves, such as the result first returned, the majority result returned by all slaves, or the average result of all slaves.

CONCLUSION

This article has reviewed existing pattern specification methods and problems yet to be solved. A generic mathematical model of patterns has been presented using Real-Time Process Algebra (RTPA). Based on it any design patterns, either system-specified or user-defined, can be derived. With the RTPA support tool, a pattern specified in RTPA can be automatically translated into code in programming languages (Tan, Wang, & Ngolah, 2006).

```

This work has revealed that a software pattern is a highly reusable design encapsulation that encompasses complex and flexible internal associations between a coherent set of abstract classes and instantiations. The generic model of patterns has provided a pattern of patterns. It is not only applicable to existing patterns' modeling and comprehension, but also useful for future patterns' identification and formalization.

ACKNOWLEDGMENT

The authors would like to acknowledge the Natural Science and Engineering Council of Canada (NSERC) for its partial support to this work. We would like to thank the anonymous reviewers for their valuable comments and suggestions.

Chapter 2.8
Building an LMS with Ubiquitous Software

Michael Rees
Bond University, Australia

Charles Herring
G-Netech Pty Ltd, Australia

ABSTRACT

Teaching institutions around the world are using large, unwieldy, and expensive learning management system (LMS) packages that are beginning to have profound effects on their whole organizations. Such LMS packages in turn go to great lengths to interoperate with the desktop information productivity software that almost all institutions use, Microsoft Office System. Since a very large part of the instructional content is generated in Office, it seems sensible to investigate whether straightforward extensions of the Office System could become an LMS in their own right. This chapter describes research and development that integrated Microsoft Office System, SharePoint Windows Services, and SharePoint Portal server (SPS) as the heart of an off-the-shelf LMS. Already designed to work closely with Office, SPS features are compared against the list of features expected of an ideal LMS. Where gaps in the LMS features were discovered in SPS, a number of small extensions of standard Office applications were proposed to fill these gaps and create a credible LMS. These Microsoft tools and custom extensions were put to use in teaching and administration during a 2-semester (8-month) trial at Bond University. The SPS installation was hosted in partnership with G-Netech Pty Ltd. This Bond University/G-Netech SharePoint Alliance project (BUGSA or SharePoint Alliance) was able to call upon combined research, development, and teaching expertise provided by the partners. The outcomes of the short trial support the concept of the Office System as a viable LMS.

INTRODUCTION

When one surveys the choice of learning management system (LMS) software, one finds a very lop-sided situation. What were the two leading examples of a LMS deployed across the higher edu-

cation institutions of the world, WebCT (WebCT, 2006) and Blackboard (Blackboard Academic Suite, 2006), have now merged into one company although for the time being the two products are still differentiated. Together these products account for 70-80% of the total market. Significant in the context of this chapter is that with a decade of development both products are available in enterprise versions comprising collections of major components, which include content management systems, portals, and communication tools. Such all-encompassing feature sets inevitably lead to high costs and significant training needs.

Despite such dominance, there is a long tail of alternative software for the primary LMS function. At the tail's end are the local in-house systems that each institution has developed with their own technical and teaching staff. Of late, there has been a significant effort by a group of 80 institutions worldwide to work together on producing a common learning environment called Sakai (2006). The Sakai Project uses an interesting variant of the open source development model called the community source model, which involves some financial inputs. What remains are open source systems with their growing group of users and several less significant commercial LMS packages that typically target the smaller institutions.

From their own product descriptions, the supplier companies extol the fact that an integrated LMS is an enterprise level system. Such systems by implication therefore require very significant support in terms of technical design, administration, and staff training in addition to content design and creation teams for the support of the teaching staff. It is not surprising that the founder of the WebCT LMS, Goldberg (2004), in his keynote presentation at AusWeb 2004 indicated that, in his experience for many institutions the LMS, has become the most important information system on a university campus after the payroll system! By implication, however, this entails a large cost in software acquisition, technical support, ongoing maintenance, and integration with other institutional information systems.

It is the authors' contention that an important avenue of LMS development has largely been ignored, that of adapting existing off-the-shelf content management and interactive communication systems intended for use by organisations in general across all industry and government sectors. One major example of this class of systems is the Microsoft SharePoint technologies (2006) aimed at generic Web portal and information repository use. As will be described in detail in this chapter, a very great advantage of SharePoint is its tight integration with the ubiquitous Microsoft Office applications. These are the main information content creation tools used by educators across the world and are licensed by very many institutions.

In the pages that follow, a case is made for adopting SharePoint as the foundation of an LMS. Examples and case studies show how this can be achieved. Some new developments that are happening now, and planned changes to Microsoft Office over the next months, are discussed. This shows that future trends will lend credence to the use of off-the-shelf software to compete with the highly specific and less flexible LMS packages currently in use. Leveraging existing software in this way helps in reducing software acquisition costs and training needs.

BACKGROUND

The authors have worked together for a number of years in a research centre environment where software development of new leading-edge solutions was the norm. Often these software packages were built from scratch unnecessarily, and the authors soon became proponents of the intelligent deployment of straightforward off-the-shelf software that can often be extended to provide support for new solutions. This comment applies to apparently mundane applications such

as Microsoft Word, Excel, and PowerPoint. These applications can often be tailored for significant specific needs by writing embedded extensions in Visual Basic for Applications that manipulate the inherent document object models.

During their years of research collaboration, the authors have also been using and gaining experience with the often-ignored Microsoft Office System SharePoint technology (Microsoft SharePoint, 2006). Various research and development projects used SharePoint for a wide range of different purposes (Herring & Rees, 2001). The uses range from innovative collaboration environments based solely on the Windows desktop and Windows Explorer (Herring, Rees, Loch, & Rhodes, 1998) to distributed software engineering support (Herring et al., 2001) and research into military command and control systems (Barros, Herring, Hildebrandt, & Rees, 2000) as a replacement for a very complex, purpose-built collaboration system.

In October 2003, the release of Microsoft Office System 2003 significantly enhanced the SharePoint technology. The existing portal server became SharePoint Portal server 2003 (SPS) and a significant reduction in licence costs made this software more accessible. SPS is designed so that it can scale across a large enterprise. At the same time, the underlying server technology has the capability to be effective for situations where only tens of users are involved. SPS needs Windows Server 2003 as the operating system together with the SQL Server 2000 database.

The underlying heart of SPS uses a free software enhancement for Windows Server 2003 and the IIS Web server called Windows SharePoint Services (WSS) that provides an extensive set of features to provide highly interactive collaborative Web sites. An added bonus allows WSS to be used stand-alone without SPS and may even utilise the free Microsoft SQL Server Desktop Environment (MSDE) for effective, small-scale deployments. As will be discussed in detail in a later section WSS Web sites provide substantial overlap with the requirements of an LMS as defined below.

From the authors' experience, it appears that SharePoint is viewed as a tool only suitable for the corporate environment where teams are engaged in typical commercial activities such as production, sales, and marketing. The authors attempt to show that SharePoint technologies are much more flexible than that, and can find a role as the foundation of an LMS system. This is particularly true of the primary role of delivering educational materials in an effective manner for teaching and learning.

With the imminent launch of Office System 2003, the Brisbane office of Microsoft Australia launched the *Spotlight on Office 2003* software competition to showcase powerful new uses of the software. The authors teamed up with G-Netech Pty Ltd to enter the "Education Services" software into the competition. The Education Services system consisted of a managed Sharepoint Portal Server and custom applications developed by G-Netech Pty Ltd staff with some Bond University student involvement. This university developed subject-specific Windows Sharepoint Services sites and used them as part of the trial. Deployed during May through September 2003, just prior to the Office System 2003 launch in October that year, Education Services was selected as one of three finalists in the competition, and also won a prestigious Asia-Pacific Solution Developer Award.

Following on the education services case study Bond University approached G-Netech to initiate a further trial of SharePoint with participants from several faculties at the university. This became the SharePoint Alliance (SPA) case study that lasted for two semesters, a period of 8 months at Bond where there are three full 14-week semesters in each calendar year. The SPA case study added further experiences and examples to the authors' expertise and lends additional credence to the SharePoint LMS role.

Over recent months, Microsoft has begun to realize that SharePoint can even play other supporting roles with enterprise LMS systems such as Blackboard. The discussion concludes with comments on these plans and the type of resources that are likely to emerge. In addition, the next major version of SharePoint will play an even more important central role in the new Office 2007 System expected early in that year. Some early indications of the additional benefits are presented.

This article first compares the features that SharePoint technologies provide out of the box with the features of an LMS and shows the significant overlap. Next, the basis of the SharePoint Alliance (SPA) Trial conducted at Bond University is discussed. One of the authors taught a sample university subject using SPA and the experiences and outcomes are described in some detail. The paper ends with a discussion of the SPA Trial results with suggestions for improvements if the approach is adopted.

LEARNING MANAGEMENT SYSTEM CHARACTERISTICS

Bond University is Australia's first private university established in 1989. Bond has about 3,000 students across four broadly defined faculties and prides itself on high quality, small-class teaching. Any adoption of an LMS is intended to act as an out-of-class supplement to the face-to-face teaching that all students receive in class. Even in this supporting role, the list of characteristics that must be present in an LMS turns out to be the same as for distance learning except that the emphases on different LMS components are different.

At Bond, only a very small number of subjects are offered in a distance-learning mode. To date mainly static Web sites are used to support classes in a somewhat ad hoc manner. The LMS is intended to replace this teaching support with a consistent, interactive collection of educational materials accessible online in 24x7 mode. Indeed at this time of writing Bond is starting the implementation of BlackBoard as the campus-wide LMS. However, there are positive signs that the early SharePoint experiences described here will carry forward into a joint use of BlackBoard. This is described further in the Future Trends section below.

Establishing a succinct set of characteristics that a LMS should possess is not straightforward when taking into consideration the wide range of teaching styles. Kennedy (2005), in surveying students' reaction to the open source Moodle (2006), gives a compact set of features outlined in Table 1 split across three broad support categories: tools for communication, students and course contents. The lists are comprehensive but are biased towards technical descriptions such as drop box and wiki, for example.

Table 1. Kennedy's learning management system features

1. Communication Tools	**2. Student Tools**	**3. Course Tools**
1.1 E-mail	2.1 My notes	3.1 Staff information
1.2 Student list	2.2 Student drop box	3.2 Assessment
1.3 Discussion board	2.3 Change your information	3.3 External links
1.4 Virtual classroom	2.4 Student calendar	3.4 Announcements
1.5 Student pages	2.5 Student manual	3.5 Course map
1.6 Group homepages	2.6 Student homepage	3.6 Study material
	2.7 Wiki	3.7 Search

When Bond University began the process to choose an LMS a conventional Web-based teaching and learning working group was established (one of the authors was a member). The chapter authors put forward the education services enhancement to SharePoint before this group as a contender for the LMS. As part of this process group members were asked to draw up an ideal list of LMS features. Table 2 shows the feature list drawn up by the authors augmented with comments indicating whether WSS and/or SPS can support each feature. This second table incorporates the three tool sets from Table 1 into a single list.

It is interesting to contrast this list to one given in Wikipedia (Virtual Learning Environment, 2006), only discovered after Table 2 was first drawn up. Note that virtual learning environment (VLE) is the preferred term (changed recently from Managed Learning Environment) but with a note of several other equivalent terms, LMS is one of them. Only feature 9, assessment support, is missing from the SharePoint capabilities and to a lesser extent feature 8, full support of class lists. However, it is recognized that assessment support and centralized grade books play significant roles in teaching and learning. Class list management too is one of the larger administrative tasks for teaching staff, and any support of this activity is to be welcomed.

SharePoint ALLIANCE TRIAL

A small steering group of staff formed the Bond University-G-Netech SharePoint Alliance (SPA) trial to take place over two teaching semesters (semesters 2 and 3) between May and December

Table 2. Learning management system feature list

	Feature	WSS Support	SPS Support
1	Structured access to and search of repository of learning materials with upload capability	Full support via document libraries per class	Institution-wide repositories
2	Cross-site searching for learning object names and content	Full support per class site	Institution-wide search
3	Fine-grained secure access based on user roles (staff, tutor, student, class representative, and so on) down to individuals	Full support	Full support
4	Subject events (schedules) for class times, assessment deadlines, reminders, and so on	Full support per class	Some support; extension required
5	Notices: announcements, news, task lists, surveys	Full support per class	Full support across institution
6	Discussion groups: inter-class communications, frequently asked questions	Full support	Full support at institution level
7	Notifications of Web site changes: additions, modifications, deletions	Full support via e-mail alerts	Full support at institution level
8	Class lists and group membership (tutorial, workshop, presentation)	Some support via users and contacts lists	Full support via active directory
9	Assessment submission and marks reporting	Very limited support	Simple workflow for document submission only
10	Template based creation of subject Web sites and Web site components	Full support	Full support
11	Real-time class communication; instant messaging, audio, and video	Some support via MS instant messenger integration	As per WSS

2004 (Bond University operates three full teaching semesters each year so that a 6-semester university Bachelors degree can be completed in two calendar years). With staff and equipment resources not being available from within Bond University itself it was decided to outsource the hosting of the SPA trial to a local IT company, G-Netech Pty Ltd. Four faculties, business, law, humanities and information technology, contributed equally to the very modest costs of the SPA trial.

Eventually staff in business, information technology, and humanities used SPA for teaching or coordinating student work. During the trial period, the university was being audited by the Australian Universities Quality Audit organization and some material pertinent to this administrative task was also entered into the SPA portal. A number of staff used additional SPA sites for planning and preparation of information content of various kinds.

Bond University contracted with G-Netech Pty Ltd to provide a managed server at a cost of USD 750/month to host the SharePoint Portal. The server used was a standard Dell dual-processor, one gigabyte RAM, 73-gigabyte RAID disk system as typically used for hosting. Setup and installation of all required software took less than one man day of labour. Microsoft provides universities with heavily discounted prices that make this enterprise level system extremely attractive to deploy. At the time of the SPA trial, the annual cost for an SPS license was about USD 3,750. From a systems administration perspective, once the portal is initially set up, the administration of the information structure and content creation can be delegated to a group of end users. Using the role-based security of SharePoint the senior user group can in turn delegate further, thus spreading the administrative load and providing administrative control at the appropriate positions within the information and teaching hierarchy.

A sample portal home page is shown in Figure 1. This demonstrates some of the top-level features available to all users. A single sign-on for each user assigns roles that control the visibility of content and dictate access permissions. Major portal content areas are shown across the heading section and are easily customised. Depending on the roles assigned to them, users can perform a defined set of actions, or possibly none of the actions, listed in the left column. Figure 1 shows the actions available to an administrator. The main content in the central column shows the modules known as Web parts selected by the page author. In this case, the enterprise-wide news service is displayed together with the events Web part. News items can be targeted at specific individual or sets of roles so that list of news items each user sees is highly customised.

Two other major features appear at the top right of Figure 1. The enterprise search feature allows a number of search scopes to be defined ranging from portal areas, the whole portal, and specified external sources that are constantly indexed by the portal search mechanism. The second feature is "My Site," which is an individual, editable Web site that can be allocated to each user including all students. This Web site makes available a comprehensive set of portal Web parts for each user. A sample My Site is shown in shown in Figure 2.

The My Site user is given a powerful individual Web site that can be used to collect a wide variety of information related to the portal such as links, news items, tasks, and e-mail from an exchange server, and public and private documents. Different collections of information can be made available in the public and private views of the Web site. New pages, each containing several Web parts, can be added to the site and cross linked. Searching is also possible across the user's own My Site. At a single stroke, the My Site features satisfy the student tools section of Table 1.

Using the spotlight on office work mentioned above the first author was able to build subject Web sites very quickly for the SPA trial. A screenshot of the home page of the sample site is shown in Figure 3. Note that by default all WSS sites are

Figure 1. SharePoint portal home page

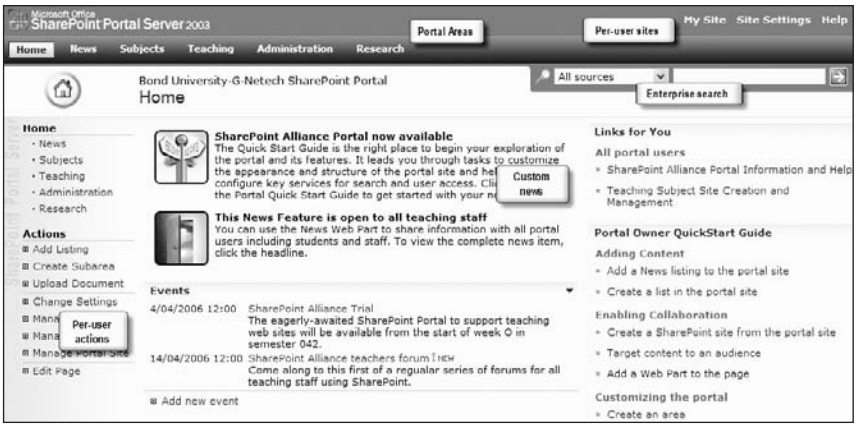

Figure 2. Sample My Site

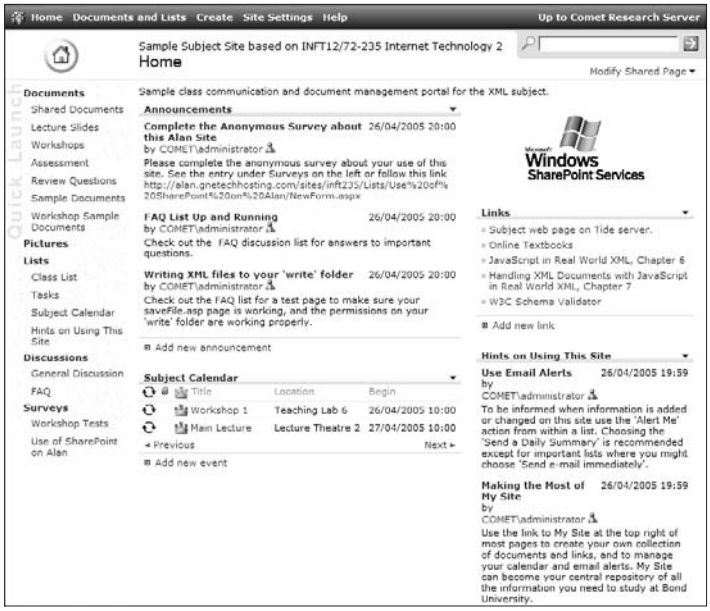
split into three columns. Other layouts such as the more typical two columns are possible.

Several of the important LMS features from Table 2 are shown in Figure 3. On the left appears the main content navigation showing document libraries (repositories) for various types of subject study materials, subject calendar, outstanding tasks, class list, discussion forums, and surveys. The main page content appears in the central column, which shows the important announcements with automatic expiry dates and the upcoming events in the subject calendar–vital information for the students. On the right is shown a series of useful hyperlinks to both internal and external teaching resources and some hints. The search box in the top right is standard on all pages in a WSS site. Searching for keywords in titles and document contents plays a vital role in improving the user experience of any LMS.

Thus, the portal and Web site contents in Figure 1, Figure 2, and Figure 3 exhibit all the LMS features of Table 2 except for nine. The instant messaging requirement of feature 11 relies on the use of Windows Messenger or MSN Messenger symbols appear to the right of user names the user can click to contact that user with Windows or MSN Messenger.

Nevertheless it can be seen that the SharePoint technologies otherwise provide the bulk of the features one would expect to find in a full-featured

Figure 3. Sample Windows SharePoint services site for a subject



LMS. It was on this basis that some staff at Bond decided to instigate a trial of SharePoint with a view to determine its suitability primarily for teaching delivery, but also for the related teaching preparation and administration processes.

WEB SITE AND PORTAL COMPONENTS

According to the Wikipedia definition, "portlets are reusable Web components that display relevant information to portal users." SPS supports the portlet concept but refers to them as "Web parts." SPS and WSS are delivered with a standard set of about 20 useful Web parts such as documents and links lists, calendars, announcements, tasks, discussion boards, surveys, and so on. Every new list that a Web site owner creates becomes a new Web part. Once created the Web parts can be arranged in columns making up a page by simple dragging and dropping into position.

Web part glue facilities are also incorporated so that Web parts can be linked together with the output of one Web part being input to another. Simple glue can be applied without programming. More powerful Web parts can be coded to work with the Web part object model available to the standard application program development tools such as Visual Studio.

The two SharePoint technologies acting together provide the dual architecture that is typical of enterprise portal software that is used to implement an LMS:

- The outer or community level where institutional information is located plus an information set potentially customized for each individual user.
- The inner Web sites where educators locate information and interact with tools specific to a teaching class, educational activity such as content preparation and planning, or administrative processes.

In the case of Blackboard, for example, these functions are embodied in two separate major modules that are almost separate products in their own

right. In the case of SharePoint, the community level is a single product, SharePoint Portal server 2003, and the inner Web sites sit above the IIS Web server and constitute an additional software layer for which is a standard component of the Windows operating system.

SharePoint Portal server provides a number of important features at the university community level controlled by an administrator with portal responsibilities:

- The overall portal information structure is made visible via institutional areas and regions, and a single sign-on gives access according to each user's role.
- Each page at the top portal level varies dynamically according to individual user role so users see a view personalized for them.
- Users are provided with their own Web site called "My Site"; users can copy and link to resources and learning objects and create and upload their own Web part content.
- Cross-portal news and announcements targeted at particular user audiences defined by the institution.
- Information islands located in individual Web sites are aggregated to provide a cross-portal search with users only able to access information specific to their role.

One of the authors acted as the portal administrator for the SPA trial, but with less than 200 portal users the news feature was used only a little, and searching was allowed across the whole portal content. Other features such as single sign-on, My Site and portal user roles were exercised much more fully.

As previously mentioned software developers can build custom Web parts to provide virtually any functionality both in terms of integration within the SharePoint system or to interface to external systems. An example customized Web part was developed by one of the authors to permit a consolidated event calendar view for each user. The motivation for this was to give students the ability to see all of their lectures, labs, and any other appointments on a single event list in one view within their My Site pages. This demonstrated the flexibility of extending the system to provide new learning management specific features.

Another example of extending the Office System was the development of an "Office research pane" within Word that provided the ability for a user to query the Bond University Library catalogue directly. Figure 4 shows how a query to the library information system appears within the Word research pane. Students can easily follow the hyperlinks associated with the library resources and insert references into their Word documents with one click.

One of the new applications in the Office System suite is InfoPath. InfoPath is an XML-based "smart" forms creation and deployment application. InfoPath is integrated with SharePoint form libraries into which the form templates are placed.

Figure 4. Bond University Library catalogue search in the word research pane

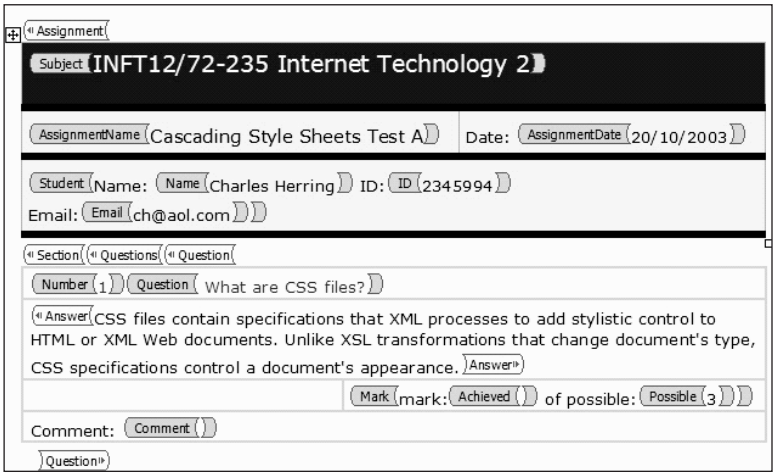
Clicking on an InfoPath form opens a Web page in which the user can enter the data required by the form. A submit button uploads the form contents to the Form library. From here, users can view and manipulate data originating from InfoPath forms. An InfoPath assessment and submission form was developed to demonstrate this capability and to allow students to submit details of an assignment and attach the assessment document set to the form.

Finally, a Word "smart document" was developed that showed how it is possible to build, submit, and mark assessments. The assessment is created as a Word document with specially marked smart sections where students enter their answers. On completion, the students upload their documents to an assessment document library, a drop box. There the assessor opens these smart documents in Word. Figure 5 shows the document opened in Word with the smart tags displayed, normally these tags would be hidden during actual assessment. The smart code assists the marker by reading correct answers from a database and displaying them in a form in the Word task pane (not shown) with fields for the assessor to allocate marks for each answer section and enter comments. A submit button merges the marks and comments into the students' original documents which are placed in another document library from where the students can download them. This solution required a specific test (on Cascading Style Sheets) to be created with correct answers and marks allocation. Custom code was then added to create the task pane functionality. As a result of this experience the authors realise that a wizard approach is needed to make such assessments generic. However, it is pleasing to see how little code is required.

Of course, the survey Web part built into WSS can be used very easily to build quizzes and online tests. The surveys can be exposed at the correct times and each student limited to one attempt. Once completed the collected survey responses (quiz answers) can be hidden from other students (or exposed if need be). However, there is no built-in assessment process. The assessor must view each response and allocate marks manually. Nevertheless, the survey Web part does contain a useful graphical summary of responses that can be used to assess student opinion in an automatic way.

From the initial analysis and from experience it is clear that SPS and WSS are weak in terms of support for class assessment. A set of specific assessment Web parts need to be written to march the features of other LMS packages. However, the

Figure 5. Assessment document in word using smart tags



two extensions described above help to fill the gap in SharePoint assessment support.

SAMPLE SUBJECT ON SPA

At Bond, where the primary teaching delivery is face-to-face in small classes, the need for high-cost multimedia-based interactive educational material is substantially reduced. The instructors provide the teaching interaction, do the demonstrations, act the roles, encourage student group activity, and so on. Of course study materials and external electronic resources still need to be available on the subject Web site.

The first author created four subject Web sites during the trial, two in each semester. The features used were substantially those shown in Table 2:

- Document libraries for subject description, lecture slides, lecture notes, tutorial and workshop handouts, assessment sheets, marks, data files, and all other documents used in the subject. Students mostly receive printed copies of these materials
- Lists for class members, class calendar, and upcoming tasks
- Several additional Web part pages that contain additional subject content.
- At least two discussion groups, the unmoderated general discussion group and a moderated FAQ group for more formal queries
- A number of surveys to elicit student opinion and for simple supervised online test submission
- Hyperlink lists to internal and external educational resources

For instructors, document library and list creation is as simple as clicking on the "create" link at the top of the subject home page and selecting from the list of options that includes a custom list creation mechanism. Each document library and list is a new Web part and can be placed in any Web part page. Document libraries also become Web folders so that Windows Explorer can be used to drag and drop documents between folders on the instructor's local machine and the subject sites. All Office applications can open and save directly to Web folders, while most Windows applications exhibit this behaviour as well. Little or no staff training is needed as this is a simple extension of the normal document management activities on any Windows machine.

Creating announcements, new class events, tasks, links, and other list contents is a simple matter of filling in a form for each item. Microsoft Excel is fully integrated with SharePoint and can be used to download or upload any list. Teaching and learning content creation could not be simpler.

Of course, many of the same benefits apply to student access to the teaching Web sites. Their ability to change lists and document libraries on the subject site is appropriately restricted, but on their own My Site they have access to much the same functionality. In common with most of the popular LMS software no student training is needed apart from the occasional demonstration in class to overcome the usual initial reticence to alter information on a Web site.

In the opinion of the instructor, probably the most useful feature of SharePoint is the e-mail alert capability. For any list or document library, the user can nominate to be informed by e-mail of changes in content. The e-mail can be sent immediately, or most usefully, in a daily or weekly summary consolidated from all nominated lists. Hyperlinks in the e-mail take the user directly to the list items in question so that the new information can be viewed directly without having to navigate from the home page of the site. The benefits to students, too, should be obvious, and in several surveys students nominated this feature as the most beneficial. However, despite constant urgings not all students by any means expended the effort (only 3 clicks per list) to switch on e-mail alerts. In fact, the surveys show that only

just over 50% of the students used e-mail alerts during the subject.

The end of semester surveys yielded detailed results that show strong student support for SharePoint as a beneficial learning tool. Only a few representative samples are presented here. From a class of 19 students there were 15 responses to the online survey. One important question asked students to give an indication of how often they accessed SPA and Figure 6 shows the distribution. Assuming a 5-day studying week the results indicate the site was accessed 1-2 times each day.

Again, from a survey students were asked to rate from 1 (low) to 10 (high) how well SPA supported various class activities, the results were: communicating with the lecturer 7.9, communicating with classmates 6.7, during practical assignments 7.7 and overall 6.8. Staff-student communication came top with a somewhat surprising practical assignment support a close second. This latter result is probably due to the general discussion group where students often help each other (usually in the early hours of the morning just before an assignment deadline), and a FAQ discussion group where the instructor answers questions about problems with the practical assignments.

When asked about the good features of the SharePoint sites the top three, in order, were e-mail alerts, document libraries, and class calendar. The three least useful features in order were My Site, Web page layout, and login problems. It was disappointing to see the apparently very useful My Site not being used to any great extent. A possible explanation is the short time limit of the SPA trial, and the students knowing that the My Site information they gathered was only likely to be temporary. In addition the mechanism for downloading their carefully gathered site content at the end of the subject was not spelt out in detail by the instructor. This is a lesson that all instructors using LMS packages that offer individual student sites will do well to remember.

The login problems stemmed from the need to allocate students additional user accounts for the SPA trial—our technical services group were not able to allow the on-campus authentication system to be accessed from the external G-Netech hosting site. The problems with the Web site layout are more puzzling since the site templates have been carefully designed. A possible explanation is that once a document in a library or an additional Web part page is opened the connection with the Web site can be lost unless the content creator is careful and consistent.

The built-in SharePoint page access log analysis can be a useful educational tool for the instructor. A part of the access log for a subject Web site over the semester is shown in Figure 7. A student with a very low access count compared to other students might need some additional help, especially one with a negligible value in the

Figure 6. Distribution of site accesses per week

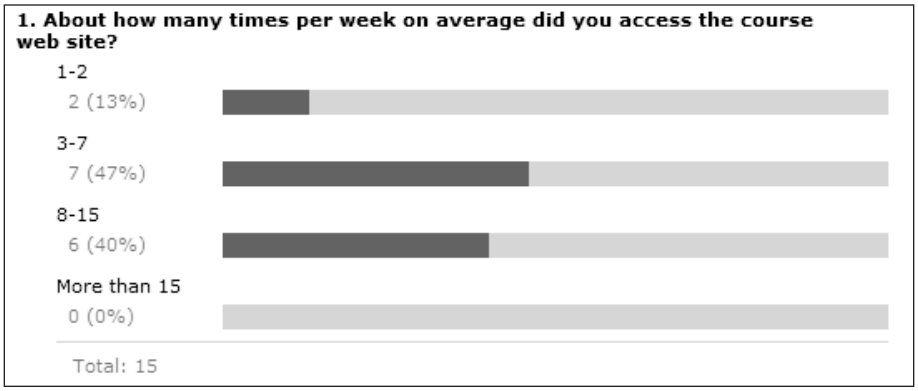


Figure 7. Subject Web site page access log

User	Total Hits	Recent Month
gnetech\jostensj	355	84
gnetech\jwatson	123	2
gnetech\jwinberg	223	73
gnetech\kkha	482	402
gnetech\mdavidse	976	383
gnetech\mrees	1038	341
gnetech\omisje	423	140
gnetech\wlee	557	257

last month of the subject! With Bond semesters consisting of 70 weekdays and taking the average value of 500 page accesses over the semester gives a figure of seven page accesses per day. If the student figures shown in Figure 6 are accurate this means between 3 and 7 pages are viewed on each visit to the subject site.

Note that the instructor in this example, mrees, has the highest access count, which is to be expected. A detailed statistical analysis has not been performed but a simple inspection of eventual overall grades against site access counts shows the students with the highest grades always have very high page access counts.

Probably the primary use of the log data is to determine which pages are the most popular so that the most valuable resources can be identified. Other interesting data gathered shows the students' choice of operating system and Web browser on their own machines. Being information technology students, the range of different browsers is wider than normal. Fortunately, another major benefit of SharePoint is its ability to work with all popular browsers.

FUTURE TRENDS

The usefulness of SharePoint technologies to support LMS features is likely to lead to increased deployments in higher education institutions. The cost of the SharePoint Portal server and SQL Server is likely to be an obstacle for smaller installations in the first instance. A more likely scenario is the use of Windows SharePoint Services to begin a small-scale LMS deployment where no SPS or SQL Server licences are needed. A typical example of such a situation is the University of Vermont Business School (2006). Here WSS was used successfully by both staff and students as part of a much larger trial of a collection of Microsoft software including Office.

In October 2005, Blackboard and Microsoft (2005) issued a press statement indicating that they had started a project to link up the Blackboard Community Portal with SharePoint Portal server. Very soon after this announcement came the news that the Blackboard Learning for Microsoft .NET (2005) had been released which would indicate that the SharePoint/Blackboard integration when running on Windows would be made more straightforward.

The integration work is still progressing and looks likely to join the Web parts model in SharePoint with the Blackboard building block architecture. An obvious mechanism to use is the Web services for Remote Portlets protocol proposed by the OASIS Technical Committee (OASIS WSRP, 2006). The first author eagerly awaits the outcomes of this project as it will be an intelligent marriage of SharePoint and Blackboard, and will allow the author's expertise to

be leveraged into the future. Bond University eventually decided to implement Blackboard 7.0 from May 2006.

Probably the most exciting development will be the introduction of a major new design for SharePoint in the forthcoming release of Office 2007 due in early 2007. Not only will SharePoint become the heart of the Office System with even tighter Office integration, it will be partnered by the new Groove Server, which will bring full-featured shared workspaces to Office users. The many additions will make SharePoint even more attractive as an LMS, blogs, RSS feeds, and wiki pages being just a few of the examples.

CONCLUSION

Over the SPA trial, six coordinating teaching staff created nine teaching sites that were used throughout one full semester. About 15 other staff members, administrative and teaching, were allocated SPA accounts, and they experimented with SharePoint for short periods. Apart from student teaching, SPA was used for course planning and preparing educational content as well as some administrative tasks such as the quality audit.

The majority of the teaching staff reported their satisfaction with SharePoint although they were not able to carry out student surveys. It should be remembered that the use of SharePoint as an LMS reported here is very specifically as a supplement to face-to-face teaching, which is the main delivery paradigm. At Bond SharePoint was trialled against existing static Web sites. SharePoint proved to be more collaborative, interactive, and easy to populate with content. To this extent, the SPA trial was successful.

Surprisingly considering the corporate origins of SharePoint the administrative experiment with the quality audit was not a success. The intention was to present documents about the audit on a Web site, and then to survey all staff to determine that they had accessed the documents. The need to allocate new accounts for up to 400 staff was not a barrier. Despite the ease of creating the survey itself, the inability to incorporate the survey Web part into another page satisfactorily was the eventual stumbling block. Web part features became the limiting factor.

There is considerably less doubt of the usefulness of SharePoint as a collaborative intranet for designing courses by teams of teaching staff (Dain, 2003). SharePoint is also valuable for forging a community of practice and expertise as described in McFerrin, Tewson, and Wallis (2003). Such a collaborative environment encourages the sharing of ideas and exemplars.

It should not be forgotten that the major defect in SharePoint as regards its use as an LMS lies in the lack of a centralized grade book and compelling features for online testing, the submission of assessment and marking. The authors did show that a relatively small development effort is needed to start to add customized assessment features using InfoPath forms and Word smart documents. Further development of more powerful assessment Web parts would further improve SharePoint's standing as a complete LMS.

ACKNOWLEDGMENT

The authors would like to thank the other members of the SPA Management Group, Jay Forder (law) and Peter Stewart (vice-chancellors office), for their help and support during the trial period. Thanks are also due to the deans of the faculties of business, humanities, law and information technology for funding the trial. Robert Bannerman of Microsoft initiated the Spotlight on Office competition and was very supportive of our effort. Significant programming support for the Bond University Research Pane was provided by Ole Rynning, a Bond Masters student in information technology, and the authors are appreciative of his work.

Chapter 2.9
Development of Machine Learning Software for High Frequency Trading in Financial Markets

Andrei Hryshko
University of Queensland, Australia

Tom Downs
University of Queensland, Australia

ABSTRACT

Foreign exchange trading has emerged in recent times as a significant activity in many countries. As with most forms of trading, the activity is influenced by many random parameters, so that the creation of a system that effectively emulates the trading process will be very helpful. This chapter presents a novel trading system using Machine Learning methods of Genetic Algorithms and Reinforcement Learning. The system emulates trader behavior on the Foreign Exchange market and finds the most profitable trading strategy.

INTRODUCTION

In spite of many years of debate between economists and financiers, the question of whether financial markets are predictable remains open. Numerous tests with financial data have been conducted by researchers but these have tended to support both sides of the issue. In our view, the best evidence of predictability of financial markets would be the development of a strategy or an algorithm which is capable of consistently gaining a profit from the financial market. In this chapter we demonstrate that machine learning techniques are capable of performing this task.

The use of machine learning and optimization methods in finance has become a fairly common practice amongst financiers and researchers. With the continuous deregulation and increasing volatility of financial markets, competition in the financial industry is getting stronger and new techniques are being developed to provide efficient trading for financial institutions and the public.

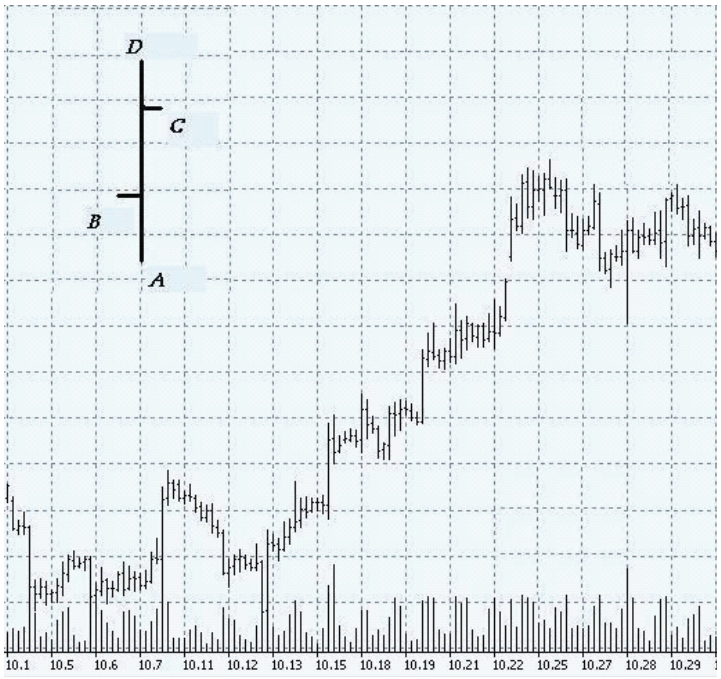
At the present time, millions of people trade in financial markets and even more wish to become involved. The main problems they face are how to trade and how to develop a profitable strategy. Usually it takes several years to become a successful trader and sometimes success remains elusive.

Trading usually takes place through a broker who provides software for the trader to buy and sell assets on a financial market. This software provides information to the trader such as current and past share prices, exchange rate, market indicators, etc. Based on this data, a trader can decide when to sell and when to buy a particular stock or currency. Choosing these actions in order to maximize profit is a difficult task, not just for beginners, but also for experienced traders. The market is constantly changing so that different rules and concepts apply in different situations. It is not uncommon that a trader's strategy that works well at a given time performs poorly two hours later. Hence the trader has to determine the times at which a strategy should be changed and to identify the changes that should be made. Another problem for the trader is that different strategies are successful for different financial markets. Thus, a strategy should be tailored to a particular situation in a particular market.

To deal with these problems, the issue of market information analysis needs to be addressed, not only theoretically but also practically. In this chapter, we describe our investigations into this issue and how they can be used to develop a software system capable of operating in the manner of a human trader.

Some related studies have previously been carried out, but the question of how to combine

Figure 1. EUR/USD prices and volumes for October, 2004



theoretical investigations with practical trading requires further attention. Existing methods (at least those in the open literature) are examined and are considered not capable of generating significant profits and therefore cannot be applied to online trading.

THE FOREIGN EXCHANGE MARKET

The Foreign Exchange (FX) Market is an interbank market that was created in 1971 when international trade began using floating rather than fixed exchange rates. The FX Market was an integration of deregulated domestic stock markets in leading countries. Since the time of its creation, currency rates have been determined based on supply and demand with regard to each currency (Carew & Slatyer, 1989). Figure 1 displays a sequence of four-hour prices and volumes for the Euro/US dollar market during October 2004.

Each element of the upper curve has the structure shown at the upper left of the figure. In this structure, points A and D indicate the lowest and highest rates achieved in a four-hour period, and points B and C indicate the opening and closing prices, respectively, for the four-hour period. The histogram-like plot along the bottom of the figure indicates the volume of transactions over each four-hour period.

It is our view that the FX market is a good basis for testing the efficiency of the prediction system because:

1. Historical data on exchange rates of currencies is readily available.
2. The FX market is easily accessible. It is open to individual investors and doesn't require large deposits.
3. The FX market provides freedom to open and close positions of any size at any time at the current market rate.
4. The FX market is open 24 hours a day, five days a week. This means that at each moment of time every time zone (London, New York, Tokyo, Hong Kong, Sydney) has dealers who can quote prices for currencies.
5. A trader can define a period of time for his position on the FX market. This means that his position is kept open until that time has elapsed.

STATISTICAL APPROACH TO TECHNICAL ANALYSIS

There are two basic approaches to market analysis: fundamental analysis and technical analysis.

Fundamental analysis focuses on the economic forces of supply and demand and determines whether prices move higher, lower or stay almost the same. It examines all relevant factors affecting the price in order to determine the intrinsic value of the market. Intrinsic value means worth based on the law of supply and demand. Technical analysis is the practice of trying to forecast market prices by examining trading patterns and comparing the shape of current charts to those from the past.

Both of these approaches to market forecasting try to solve the same problem, that is, to determine in what direction prices will move. The difference between fundamental and technical analyses is that the first one explores the causes of movements on the market and the second one explores the effect of these movements.

Fundamental analysis is generally concerned with longer-term trends than technical analysis. So given that most traders on the FX market are intra-day traders they use just technical analysis and do not take into consideration the fundamental method. The main instrument employed by technical analysts is the set of available indicators, which helps traders to discover trends, reversals of trends and other fluctuations.

An indicator makes use of a set of mathematical formulae that may, for instance, be derived from past prices or from other market data such as trade volumes. Different indicators play different roles in the analysis. Some indicators work better when the market has a strong trend, and some when the market is neutral. The Machine Learning system described here makes use of ten commonly used indicators.

The simplest indicator we use is the Moving Average (MA) that shows the average value of prices during a defined period of time. The *n*-day MA is calculated using the simple formula:

$$MA = \frac{P_1 + ... + P_n}{n}$$

where P_i is the price *i*-1 days previously.
