DISORDERS OF HEMOGLOBIN

Genetics, Pathophysiology, and Clinical Management

SECOND EDITION

This book is a completely revised new edition of the definitive reference on disorders of hemoglobin. Authored by world-renowned experts, the book focuses on basic science aspects and clinical features of hemoglobinopathies, covering diagnosis, treatment, and future applications of current research. While the second edition continues to address the important molecular, cellular, and genetic components, coverage of clinical issues has been significantly expanded, and there is more practical emphasis on diagnosis and management throughout.

The book opens with a review of the scientific underpinnings. Pathophysiology of common hemoglobin disorders is discussed next in an entirely new section devoted to vascular biology, the erythrocyte membrane, nitric oxide biology, and hemolysis. Four sections deal with α and β thalassemia, sickle cell disease, and related conditions, followed by special topics. The second edition concludes with current and developing approaches to treatment, incorporating new agents for iron chelation, methods to induce fetal hemoglobin production, novel treatment approaches, stem cell transplantation, and progress in gene therapy.

Martin H. Steinberg is Professor of Medicine, Pediatrics, Pathology and Laboratory Medicine at Boston University School of Medicine and Director of the Center of Excellence in Sickle Cell Disease at Boston Medical Center. He received his BA from Cornell University and an MD from Tufts University School of Medicine. Dr. Steinberg is a diplomat of the American Board of Internal Medicine in the subspecialty of Hematology, a Fellow of the American Association for the Advancement of Science and a member of the American Society for Clinical Investigation and Association of American Physicians.

Dr. Steinberg's research and clinical interests are focused on disorders of the red blood cell with a special emphasis on sickle cell disease and inherited disorders of hemoglobin. His current work focuses on genotype-phenotype relationships in sickle cell disease and thalassemia, and how multiple genes influence the phenotype of disease. Dr. Steinberg has published nearly 300 articles in his areas of interest and has edited three textbooks that focus on the basic science and clinical aspects of sickle cell disease and other disorders of the hemoglobin molecule.

He has served as a scientific consultant for the American Heart Association, FDA, NIH, NSF, Doris Duke Charitable Foundation, US-Israel Binational Science Foundation, Wellcome Trust, Telethon2002, ISERM, Accreditation Council for Graduate Medical Education, and the Department of Veterans Affairs, and served on the editorial boards of the *American Journal of Hematology*, *American Journal of the Medical Sciences*, *BMC Medical Genetics*, *Haematologica*, *Journal of Laboratory and Clinical Medicine* and *Hemoglobin*.

Bernard G. Forget is a distinguished physician scientist in Hematology, nationally and internationally recognized for research accomplishments in the field of Molecular Hematology pertaining to the molecular biology of gene expression in blood cells and the molecular basis of hereditary disorders of the red blood cell, including hemoglobinopathies. He is the co-author with Dr. H. F. Bunn of a highly respected textbook entitled *Hemoglobin: Molecular, Genetic and Clinical Aspects*, (WB Saunders Co., Philadelphia, 1986). He is the senior author of a large number of scientific publications in the field of Molecular Hematology and red blood cell disorders, published in leading journals He has also co-authored a number of chapters on thalassemia and other red blood cell disorders in various leading hematology textbooks.

Douglas R. Higgs qualified in medicine at King's College Hospital Medical School in 1974 and trained as a haematologist. He joined the MRC Molecular Haematology Unit (Oxford) in 1977 and is currently Professor of Molecular Haematology at the University of Oxford and Director of the MRC Molecular Haematology Unit. The current interests of the Unit are (i) to understand the processes of lineage commitment in haemopoiesis with particular emphasis on erythropoiesis (ii) to understand how the globin genes are activated and regulated during normal erythropoiesis (iii) to study the human genetic diseases affecting these processes. The main interest of his own laboratory has been to understand how the human alpha globin genes are regulated from their natural chromosomal environment in the telomeric region of 16p13.3. Recently the group has characterised the terminal 2 Mb of chromosome 16 and concentrated on understanding how gene expression is influenced by epigenetic modifications of this region (e.g. chromatin structure, histone acetylation, methylation, timing of replication, nuclear positioning) and the proteins that mediate these processes.

David J. Weatherall is currently Regius Professor of Medicine Emeritus, University of Oxford and Chancellor, Keele University, Keele, UK. His major research contributions have been in the elucidation of the clinical, biochemical and molecular characteristics of the thalassaemias and their related disorders, the population genetics of these conditions, and the application of this information to the development of programmes for the prevention and management of these diseases in the developing countries.

List of Contributors

Foreword

H. Franklin Bunn, MD
Professor of Medicine
Division of Hematology
Brigham and Women's Hospital
Harvard Medical School
Boston, MA

Preface

Martin H. Steinberg, MD

Bernard G. Forget, MD

Douglas R. Higgs, MD, FRS

Sir David J. Weatherall, MD, FRS

Introduction

Sir David J. Weatherall, MD, FRS
Emeritus Professor of Medicine (University of Oxford)
Weatherall Institute of Molecular Medicine
University of Oxford
John Radcliffe Hospital
Headington, Oxford, UK

SECTION ONE. The Molecular, Cellular, and Genetic Basis of Hemoglobin Disorders

Douglas R. Higgs, MD, FRS
Professor of Molecular Haematology and Director of the MRC Molecular Haematology Unit (University of Oxford)
MRC Molecular Haematology Unit
Weatherall Institute of Molecular Medicine
University of Oxford
John Radcliffe Hospital
Headington, Oxford, UK

Bernard G. Forget, MD
Professor of Medicine and Genetics
Director, Hematology Training Program
Section of Hematology
Department of Medicine
Yale University School of Medicine
New Haven, CT

Chapter 1: A Developmental Approach to Hematopoiesis

Elaine Dzierzak, PhD
Professor of Developmental Biology
Erasmus Stem Cell Institute
Erasmus Medical Center
Rotterdam, The Netherlands

Chapter 2: Erythropoiesis

Sjaak Philipsen, PhD
Professor of Genomics of Cell Differentiation
Department of Cell Biology
Erasmus University Medical Center
Rotterdam, The Netherlands

William G. Wood, PhD
Professor of Haematology
MRC Molecular Haematology Unit
Weatherall Institute of Molecular Medicine
University of Oxford
John Radcliffe Hospital
Headington, Oxford, UK

Chapter 3: The Normal Structure and Regulation of Human Globin Gene Clusters

Bernard G. Forget, MD.

Ross C. Hardison, PhD
T. Ming Chu Professor of Biochemistry and Molecular Biology
The Pennsylvania State University
University Park, PA

Chapter 4: Nuclear Factors That Regulate Erythropoiesis

Gerd A. Blobel, MD, PhD
Professor of Pediatrics
Division of Hematology
The Children's Hospital of Philadelphia
University of Pennsylvania School of Medicine
Philadelphia, PA

Mitchell J. Weiss, MD, PhD
Associate Professor of Pediatrics
Division of Hematology
The Children's Hospital of Philadelphia
University of Pennsylvania School of Medicine
Philadelphia, PA

Chapter 5: Molecular and Cellular Basis of Hemoglobin Switching

George Stamatoyannopoulos, MD, Dr Sci
Professor of Medicine and Genome Sciences
Director, Markey Molecular Medicine Center
University of Washington School of Medicine
Seattle, WA

Patrick A. Navas, PhD
Research Assistant Professor
Division of Medical Genetics
Department of Medicine
University of Washington School of Medicine
Seattle, WA

Qiliang Li, PhD
Research Professor of Medicine
Division of Medical Genetics
Department of Medicine
University of Washington School of Medicine
Seattle, WA

Chapter 6: Structure and Function of Hemoglobin and Its Dysfunction in Sickle Cell Disease

Daniel B. Kim-Shapiro, PhD
Professor of Physics
Department of Physics
Wake Forest University
Olin Physical Laboratory
Winston Salem, NC

Chapter 7: Hemoglobins of the Embryo, Fetus, and Adult

Martin H. Steinberg, MD
Professor of Medicine
Pediatrics, Pathology and Laboratory Medicine
Boston University School of Medicine
Boston, MA

Ronald L. Nagel, MD
New York, NY

SECTION TWO. Pathophysiology of Hemoglobin and Its Disorders

Martin H. Steinberg, MD

Chapter 8: Rheology and Vascular Pathobiology in Sickle Cell Disease and Thalassemia

Dhananjay K. Kaul, PhD
Professor of Medicine
Division of Hematology
Albert Einstein College of Medicine
Bronx, NY

Chapter 9: The Erythrocyte Membrane

Patrick G. Gallagher, MD
Professor of Pediatrics
Section of Perinatal Medicine
Yale University School of Medicine
New Haven, CT

Clinton H. Joiner, MD, PhD
Professor of Pediatrics
Children's Hospital Medical Center
Cincinnati, OH

Chapter 10: The Biology of Vascular Nitric Oxide

Jane A. Leopold, MD
Associate Professor of Medicine
Cardiovascular Medicine Division
Department of Medicine
Brigham and Women's Hospital
Boston, MA

Joseph Loscalzo, MD, PhD
Hersey Professor of the Theory and Practice of Medicine
Chairman, Department of Medicine
Brigham and Women's Hospital
Boston, MA

Chapter 11: Mechanisms and Clinical Complications of Hemolysis in Sickle Cell Disease and Thalassemia

Gregory J. Kato, MD
Director, Sickle Cell Vascular Disease Unit
Vascular Therapeutic Section
Vascular Medicine Branch
National Institutes of Health
Bethesda, MD

Mark T. Gladwin, MD
Professor of Medicine
Division Chief, Pulmonary, Allergy, and Critical Care Medicine
University of Pittsburgh Medical Center
Director, Hemostasis and Vascular Biology Research Institute
University of Pittsburgh
Pittsburgh, PA

Chapter 12: Animal Models of Hemoglobinopathies and Thalassemia

Mary Fabry, PhD
Professor of Medicine
Division of Hematology
Albert Einstein College of Medicine
Bronx, NY

SECTION THREE. α Thalassemia

Douglas R. Higgs, MD, FRS

Chapter 13: The Molecular Basis of α Thalassemia

Douglas R. Higgs, MD, FRS

Chapter 14: The Pathophysiology and Clinical Features of α Thalassemia

Douglas R. Higgs, MD, FRS

Chapter 15: Unusual Types of α Thalassemia

Douglas R. Higgs, MD, FRS.

Veronica J. Buckle, MD
MRC Senior Scientist
MRC Molecular Haematology Unit
Weatherall Institute of Molecular Medicine
University of Oxford
John Radcliffe Hospital
Headington, Oxford, UK

Richard Gibbons, MD
University Lecturer and Honorary
Consultant Clinical Geneticist
Weatherall Institute of Molecular Medicine
University of Oxford
John Radcliffe Hospital
Headington, Oxford, UK

David Steensma, MD
Associate Professor of Medicine and Oncology
Consultant, Division of Hematology
Mayo Clinic
Rochester, MN

SECTION FOUR. The β Thalassemias

Bernard G. Forget, MD

Chapter 16: The Molecular Basis of β Thalassemia, δβ Thalassemia, and Hereditary Persistence of Fetal Hemoglobin

Swee Lay Thein, MD
Professor of Molecular Haematology
Head, Division of Gene and Cell Based Therapy
King's College London School of Medicine and King's College Hospital
London, UK

William G. Wood, PhD

Chapter 17: Clinical Aspects of β Thalassemia and Related Disorders

Nancy F. Olivieri, MD
Senior Scientist
Division of Clinical Investigation and Human Physiology
University Health Network
Toronto General Hospital
Toronto, ON, Canada

Sir David J. Weatherall, MD, FRS

Chapter 18: Hemoglobin E Disorders

Suthat Fucharoen, MD
Director, Thalassemia Research Center
Institute of Science and Technology for Research and Development
Mahidol University
Salaya Campus
Puttamonthon, Nakornpathom, Thailand

Sir David J. Weatherall, MD, FRS

SECTION FIVE. Sickle Cell Disease

Martin H. Steinberg, MD

Chapter 19: Clinical and Pathophysiological Aspects of Sickle Cell Anemia

Martin H. Steinberg, MD.

Kwaku Ohene-Frempong, MD
Professor of Pediatrics
Hematology
The Children's Hospital of Philadelphia
Philadelphia, PA

Matthew M. Heeney, MD
Instructor in Pediatrics
Harvard Medical School
Boston, MA

Chapter 20: Sickle Cell Pain: Biology, Etiology, and Treatment

Samir K. Ballas, MD
Professor of Medicine and Pediatrics
Thomas Jefferson University
Philadelphia, PA

James R. Eckman, MD
Professor of Medicine
Comprehensive Sickle Cell Center
Emory University School of Medicine
Atlanta, GA

Chapter 21: Hemoglobin SC Disease and Hemoglobin C Disorders

Martin H. Steinberg, MD

Ronald L. Nagel, MD

Chapter 22: Sickle Cell Trait

Martin H. Steinberg, MD

Chapter 23: Other Sickle Hemoglobinopathies

Martin H. Steinberg, MD

SECTION SIX. Other Clinically Important Disorders of Hemoglobin

Martin H. Steinberg, MD

Chapter 24: Unstable Hemoglobins, Hemoglobins with Altered Oxygen Affinity, Hemoglobin M, and Other Variants of Clinical and Biological Interest

Martin H. Steinberg, MD

Ronald L. Nagel, MD

Chapter 25: Dyshemoglobinemias

Neeraj Agarwal, MD
Assistant Professor, Oncology Division
University of Utah, School of Medicine
Salt Lake City, UT

Ronald L. Nagel, MD

Josef T. Prchal, MD
Professor of Medicine
Internal Medicine
Hematology Division
University of Utah
Salt Lake City, UT

SECTION SEVEN. Special Topics in Hemoglobinopathies

Martin H. Steinberg, MD

Chapter 26: Population Genetics and Global Health Burden

Sir David J. Weatherall, MD, FRS

Thomas N. Williams, PhD
Wellcome Trust Senior Clinical Fellow
Kenya Medical Research Institute/Wellcome Trust Programme
Centre for Geographic Medical Research
Kilifi District Hospital
Kilifi, Kenya

Chapter 27: Genetic Modulation of Sickle Cell Disease and Thalassemia

Martin H. Steinberg, MD

Ronald L. Nagel, MD

Chapter 28: Laboratory Methods for Diagnosis and Evaluation of Hemoglobin Disorders

Mary Fabry, PhD

John M. Old, MD
Consultant Clinical Scientist
National Haemoglobinopathy Reference Laboratory
Oxford Haemophilia Centre
Churchill Hospital
Oxford, UK

SECTION EIGHT. New Approaches to the Treatment of Hemoglobinopathies and Thalassemia

Martin H. Steinberg, MD

Chapter 29: Transfusion and Iron Chelation Therapy in Thalassemia and Sickle Cell Disease

Janet L. Kwiatkowski, MD
Assistant Professor of Pediatrics
Division of Hematology
The Children's Hospital of Philadelphia
Philadelphia, PA

John B. Porter, MA, MD, FRCP, FRCPath
Professor of Haematology
Department of Haematology
University College London
London, UK

Chapter 30: Induction of Fetal Hemoglobin in the Treatment of Sickle Cell Disease and β Thalassemia

Yogen Saunthararajah, MD
Associate Professor
Cleveland Clinic/University of Illinois at Chicago
Twissing Cancer Institute
Cleveland, OH

George F. Atweh, MD
Koch Professor of Medicine
Director, Division of Hematology/Oncology
Director, Barrett Cancer Center
University of Cincinnati College of Medicine
Cincinnati, OH

Chapter 31: Novel Approaches to Treatment

Kirkwood A. Pritchard Jr., PhD
Professor of Pediatric Surgery
Medical College of Wisconsin
Milwaukee, WI

Alicia Rivera, PhD
Instructor of Pediatrics
Harvard Medical School
Boston, MA

Cheryl Hillery, MD
Blood Center of Wisconsin
Associate Professor
Pediatrics and Medicine
Medical College of Wisconsin
Milwaukee, WI

Carlo Brugnara, MD
Professor of Pathology
Harvard Medical School
Children's Hospital
Boston, MA

Chapter 32: Stem Cell Transplantation

Emanuele Angelucci, MD
Associate Professor
Head, Hematology Department and BMT Centre
Armando Businco Cancer Centre
Cagliari, Italy

Mark Walters, MD
Director, Blood and Marrow Transplantation Program
Children's Hospital Oakland Research Institute
Oakland, CA

Chapter 33: Prospects for Gene Therapy of Sickle Cell Disease and Thalassemia

Derek A. Persons, MD
Assistant Member
Department of Hematology
Division of Experimental Hematology
St. Jude Children's Research Hospital
Memphis, TN

Brian P. Sorrentino, MD
Member
Department of Hematology
Director, Division of Experimental Hematology
St. Jude Children's Research Hospital
Memphis, TN

Arthur W. Nienhuis, MD
Member
Department of Hematology
Division of Experimental Hematology
St. Jude Children's Research Hospital
Memphis, TN

Foreword

H. Franklin Bunn

The study of hemoglobin continues to be a rewarding endeavor. Cumulative progress since the turn of the last century has laid cornerstones in protein chemistry and molecular genetics and has provided a wealth of insight into the pathogenesis of some of the world's most prevalent and devastating disorders. The first edition of *Disorders of Hemoglobin*, published 8 years ago, was a comprehensive compilation and analysis of the basic science of hemoglobin and its application to the thalassemias, sickle cell disease, and other globin mutants that spawn a wide range of clinical phenotypes. This second edition now presents an updated overview of all aspects of the hemoglobin story as well as a detailed account of the impressive advances that have been made in biochemistry, genetics, and clinical investigation.

Hemoglobin boasts a proud history. By the end of the nineteenth century, it was well established that hemoglobin was a composite of protein and heme that could reversibly bind oxygen and that this substance was found in almost all living creatures. Entry into the twentieth century marked the dawn of quantitative physiology, biochemistry, and the application of the scientific method to medicine. All three of these developing disciplines owe their early impetus to hemoglobin and the lessons learned from this remarkable molecule. Physiologists from Scandinavia (Bohr and Krogh) and England (Barcroft, the Haldanes, and Roughton) made accurate equilibrium and kinetic measurements of oxygen–hemoglobin binding as a function of pH and thereby provided a mechanistic understanding of the reciprocal transport of oxygen from lung to tissues and of acid waste from tissues to lung. These early contributions set the stage for an appreciation of how the homeostasis of the organism depends on the orderly integration of its organ systems.

The fledgling science of biochemistry was given a jump start by the studies of Adair and Svedberg, which established that hemoglobin is a uniform protein with a large but narrowly defined molecular weight and was therefore, like sodium chloride and glucose, a bona fide molecule. Hemoglobin and its cousin myoglobin were the first proteins whose structures were solved at high resolution by X-ray crystallography by Perutz and Kendrew, respectively, thereby, providing an opportunity for detailed exploration of structure–function relationships. Hemoglobin was the first multisubunit protein to be understood at the molecular level and therefore was the model system used by Monod, Changeux, and Wyman for establishing the principles of allostery, which dictate the regulation of a broad range of enzymes, receptors, transcription factors, and so on.

The linkage of specific diseases to abnormalities of specific molecules began with Pauling's demonstration in 1949 that patients with sickle cells have hemoglobin with an altered surface charge. Within 8 years, Ingram demonstrated that sickle hemoglobin differs from normal hemoglobin only by a substitution of valine for glutamic acid in the sixth residue of the β-globin subunit. This was the first example of how an abnormal gene can change the structure of a protein and, therefore, verified in a most satisfying way the Beadle–Tatum one gene–one enzyme hypothesis.

During the last quarter of the twentieth century, with the development of recombinant DNA technology and genomics, hemoglobin again became *primus inter pares* among biological molecules. Indeed, the human globin genes were among the first to be molecularly cloned and sequenced. This soon led to the identification of a wide range of globin gene mutants responsible for the α and β thalassemias. Understanding the mechanisms by which these genotypes impair globin biosynthesis provided insight into the diverse clinical manifestations encountered in patients with different types of thalassemia. In addition, the evolving knowledge of human globin genes enabled the development of molecular techniques for antenatal diagnosis and polymorphism-based population studies, both of which were then applied to many other disorders.

To date, more than 1,000 hemoglobin variants have been discovered and characterized. Study of these variants, so amply documented in this book, established the principle of how a mutant genotype alters the function of the protein it encodes, which in turn can lead to a distinct clinical phenotype. This linkage is at the heart of how molecular genetics impacts our understanding of pathophysiological mechanisms.

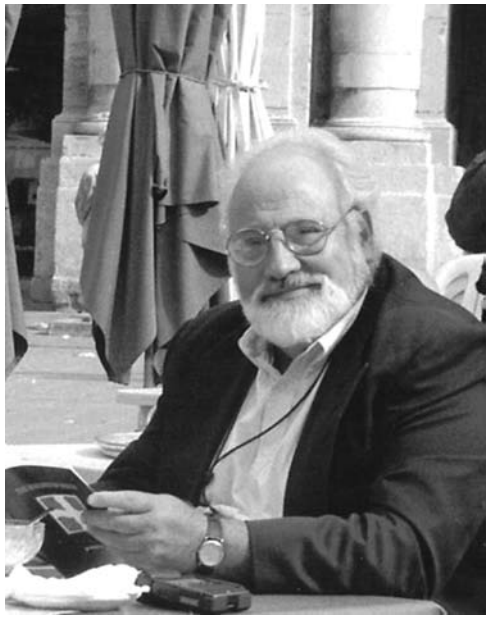
Thus, hemoglobin held center stage in the biomedical discoveries of the twentieth century, and, in the new millenium, there is no indication that the pace has slackened. This book begins with authoritative and up-to-date coverage of all aspects of hemoglobin, beginning with overviews of erythropoiesis, globin gene regulation, and structure–function relationships. Subsequent sections of the book are devoted to in-depth coverage of the thalassemias, sickle cell disease, and other hemoglobinopathies. A recurrent theme is how understanding pathophysiology at the molecular

level has informed the design and development of novel, rationally based therapy.

This second edition incorporates a number of advances that have been made in the past 8 years. Chapter 4 describes the important insights that have accrued from the discovery of α-hemoglobin stabilizing protein (AHSP), the chaparone that protects the α-hemoglobin subunit during assembly of the tetramer. Chapters 6, 10, and 11 include new information on nitric oxide and its controversial roles in allosteric modulation of hemoglobin function and in the pathophysiology of sickle cell disease and other types of hemolytic anemia. Chapter 27 presents recent information on the contribution of genetic polymorphisms to the clinical phenotypes of sickle cell disease and thalassemia. The last 4 chapters cover the development of oral iron chelators as well as bolder therapeutic strategies, including impressive progress in globin gene therapy.

The creative energy that continues to bear down on all aspects of hemoglobin research is well represented by the impressive list of basic and clinical investigators who have contributed to this book. As in any field at the cutting edge of science, controversies enrich the scientific dialogue among hemoglobinologists. In carefully reading chapters on closely related topics, the thoughtful reader will adopt a policy of caveat emptor, appreciating that strongly held opinions need to be vetted by both experimentation and alternative hypotheses. This proviso notwithstanding, *Disorders of Hemoglobin* offers authoritative and comprehensive coverage of one of the most exciting and fruitful areas at the interface of bioscience and clinical medicine.

Preface



Eight years have passed since this monograph first appeared, and the advances in basic, translational, and clinical research during this interval justify a new edition. To conserve space and avoid duplicating our first edition, we review very briefly historical aspects, summarize established older information, and focus on the progress of the past 8 years. Although some older references are retained, we have tried to focus on the literature since 2001. In expanding our coverage of clinical issues, we also have decreased the length of the book by considering together pathophysiological features common to many hemoglobin disorders such as vasculopathy, erythrocyte membrane damage, and mechanisms of hemolysis. More than half of the contributors to this volume are either new authors or previous authors addressing different topics; David Weatherall has joined the editorial team.

Hemoglobin has been an interest of basic and translational scientists, clinicians, and clinical diagnostic laboratories. So, we continue to address the molecular, cellular, genetic, diagnostic, and clinical aspects of hemoglobin disorders. When applicable, we provide practical recommendations for diagnosis and treatment. The first section of the book again focuses on molecular, cellular, and genetic aspects of hemoglobin and includes discussions of developmental hematopoiesis, erythropoiesis, globin genes and their regulation, minor normal hemoglobins, and an update on new structural and functional features of normal and variant hemoglobins. Pathophysiology of hemoglobin disorders follows, with new chapters on vascular biology, the erythrocyte membrane, the biology of nitric oxide, mechanisms of hemolysis, and how animal models of disease provide new pathophysiological insights. Four sections deal with diagnosis, complications, and treatment of α thalassemia, β thalassemia, and related conditions, including hemoglobin E diseases, sickle cell disease, and less common genetic and acquired hemoglobin disorders. This is followed by special topics such as population genetics and the health burden of hemoglobin disorders, the genetic modulation of sickle cell disease and thalassemia, and developments in laboratory detection, including antenatal diagnosis. Finally, current and developing approaches to treatment, incorporating new agents for iron chelation, methods to induce fetal hemoglobin production, novel treatment approaches such as antioxidants, antiinflammatory agents, enhancement of nitric oxide effects, and agents that modulate membrane cation and water transport are discussed, concluding with the use of stem cell transplantation and progress in gene therapy.

Ronald L. Nagel (pictured), a coeditor of the first edition, has retired as Irving D. Karpas Professor of Medicine, Physiology and Biophysics and Head of the Division of Hematology at Albert Einstein College of Medicine. Although no longer a coeditor of this monograph, his influence in the field is felt in most chapters. His contributions to the structure, function, pathophysiology, and genetics of hemoglobin disorders are vast and time tested. The editors, and the field of hematology, will miss his scientific insight and originality.

The Editors

Introduction

David J. Weatherall

A few years ago, an eminent British professor of medicine, while reviewing a new edition of a well-known textbook of medicine, suggested that works of this type were becoming valueless because they were already out of date by the time they were published. His derogatory comments went further: Having taken the trouble to weigh the book, he suggested that volumes of this type would suffer the same fate as dinosaurs and become extinct by collapsing under their excessive weight. Even allowing for this bizarre and completely erroneous view of the biological fate of the dinosaurs, does this argument carry any weight beyond its metaphorical context?

Undoubtedly, there is feeling rife among medical publishers that the day of the major monograph in the biological sciences may be coming to an end. They argue that there is so much information online that the need for works of this type is becoming increasingly limited. Is this really the case? Although it is impossible to deny that the long gestation of monographs of this type may lead to the omission of the occasional "breakthrough" in a field, it seems very important that in any rapidly moving area of the biomedical sciences there is a regular and broad critical review of where it has got to and how it has been modified by recent advances. Not uncommonly in medical research and practice, today's breakthrough is tomorrow's breakdown.

Is the hemoglobin field moving rapidly? This was another question that had to be considered by the editors of this new edition. As judged by the amount of space given to disorders of the red cell in current journals, the volume of work in this field seems to have declined considerably over recent years. A visitor from outer space, browsing through the journals, might be excused for wondering how Homo sapiens transfers oxygen to their tissues. Hence, it might have been perceived that there is insufficient material to warrant this new edition.

A broader review of the field over recent years suggests, however, that this is not the case. There undoubtedly have been major advances in our understanding of the regulation of hematopoiesis, some of which have important implications for a better understanding of the pathophysiology of the hemoglobin disorders that may, in the longer term, lead to more definitive approaches to their management. Furthermore, there have also been dramatic developments in many areas of genome technology that have direct application to the many unanswered questions of the hemoglobin field, not in the least the reasons for the remarkable phenotypic variation of its diseases. Of even greater importance, there has been a genuine increase in the appreciation of the major public health burden that these diseases are likely to cause in the future. This is particularly relevant to the poorer countries of the world in which the epidemiological transition following improvements in nutrition and basic public health is resulting in a reduction in neonatal and childhood mortality; many babies with severe hemoglobin disorders who would previously have died in early life are now surviving to present for diagnosis and management.

It is only in the last few years that these public health issues have been recognized by the major international health agencies. In 2002, the World Health Organization (WHO) published a report, *Genomics and World Health*, in which the hemoglobin disorders were described as a prime example of how the new technology of molecular genetics can be applied for the benefit of poorer countries. At the 118th session of the WHO Executive Board, held in 2006, the sickle cell disorders and thalassemias were formally recognized as major health burdens that required immediate action. In 2007, it was decided to include the hemoglobin disorders in the Global Burden of Disease Program, an international study conducted under the auspices of several universities, the WHO, the Bill and Melinda Gates Foundation, the World Bank, and others that attempts to define the relative global burden posed by each of the major diseases. Previous versions of this work have undoubtedly had a major influence on developing healthcare policies by governments and international healthcare agencies.

Clearly, this new edition is appearing at the same time as a major drive to define the most appropriate ways of controlling and managing the hemoglobin disorders, particularly in the developing countries, and to determine the most cost-effective and efficient ways of approaching this problem. We hope, therefore, that this updated distillation of knowledge about the scientific, clinical, and epidemiological aspects of this field will be of value to scientists and clinicians, not only to those in wealthier countries but particularly to those who are attempting to cope with these diseases with limited resources in the developing countries of the world.

There is also an important message for our younger readers. There are still some extraordinarily exciting areas of this field to be pursued, not in the least a better understanding of the reasons for the remarkable clinical

diversity of all the hemoglobin disorders; a better appreciation of their pathophysiology at the molecular level with respect to novel approaches for their more definitive management; and an understanding of the long-neglected role of the environment in their clinical diversity, the cellular mechanisms whereby protection against malaria has resulted in their extremely high frequency, how current knowledge of their diagnosis and control may be applied in the poorer countries of the world, and many other stimulating questions. Currently, the hemoglobin field offers challenges ranging from basic cell and molecular biology through clinical research at the bedside to epidemiology, public health, and the social sciences.

Finally, we thank Cambridge University Press and particularly Beth Barry and more recently Larry Fox for continued support of this project. We are also extremely grateful to the authors from many parts of the world who have willingly given their time to writing parts of this new edition, and for the personal help that we have received from Liz Rose, during its preparation. It is particularly gratifying to be able to report that the marriages of the four editors have survived another edition.

SECTION ONE

THE MOLECULAR, CELLULAR, AND GENETIC BASIS OF HEMOGLOBIN DISORDERS

Douglas R. Higgs and Bernard G. Forget

Over the past 30 years we have become familiar with the way in which different types of hemoglobin are expressed at different stages of development. In the human embryo the main hemoglobins include Hb Portland ($\zeta_2\gamma_2$), Hb Gower I ($\zeta_2\varepsilon_2$), and Gower II ($\alpha_2\varepsilon_2$). In the fetus, HbF ($\alpha_2\gamma_2$) predominates and in the adult, HbA ($\alpha_2\beta_2$) makes up the majority of hemoglobin in red cells. These simple facts belie the complexity of the cellular and molecular processes that bring about these beautifully coordinated changes in the patterns of globin gene expression throughout development.

To understand these phenomena we have to consider the individual components including 1) the origins of erythroid cells in development, 2) the processes by which erythroid cells differentiate to mature red cells at each developmental stage, and 3) the molecular events that produce the patterns of gene expression we observe.

Two different types of erythroid cells are observed during development. The first erythroid cells to be seen in the developing embryo are located in the blood islands of the yolk sac. These primitive erythroid cells are morphologically different from the definitive erythroid cells made in the fetal liver and bone marrow and contain predominantly embryonic hemoglobins. Somewhat later during embryonic development, definitive erythroid and other hematopoietic cells originate from multipotent cells identified in a part of the embryo that lies near the dorsal aorta, in the region close to where the kidneys first develop: the so-called aorta-gonads-mesonephros (AGM) region. It is thought that the cells that are destined to provide fetal- (liver) and adult- (bone marrow) derived red cells originate from AGM cells, although the ultimate origin of hematopoietic stem cells is still a matter of controversy. In the first trimester of pregnancy, fetal erythroid cells derived predominantly from hematopoiesis in the liver contain mainly HbF with small amounts of embryonic hemoglobin. There are no circumstances in which expression of embryonic globins persists at high levels or becomes substantially reactivated in fetal or adult life, although low levels of ζ-globin chains are present in the most severe form of α thalassemia. Until approximately the time of birth, fetal cells continue to make predominantly HbF but switch to making HbA between 30 and 40 weeks postconception. In contrast to the situation in embryonic cells, there are many conditions in which HbF synthesis persists or becomes reactivated in adult red cells. The simplest explanation for all of these observations is that the switch from embryonic to fetal–adult patterns of hemoglobin synthesis involves the replacement of embryonic cells (with one program of expression) by definitive cells (with a different program of expression). In contrast, the switch from fetal to adult hemoglobin expression takes place in definitive cells so this represents a true change in the molecular program within a single lineage of erythroid progenitor cells.

At present we do not know when during development the embryonic and fetal programs are established in the differentiating hematopoietic cells. Furthermore we do not fully understand by what mechanisms the programs of globin gene expression are initiated or maintained. Perhaps the greatest progress toward such an understanding has been to identify key regulatory molecules, including transcription factors, cofactors, and chromatin-associated proteins that play important roles in specifying the formation of erythroid cells from multipotent hematopoietic stem cells. Of greatest importance in this area has been the characterization of the tissue-restricted zinc finger proteins (GATA-1 and GATA-2), their cofactors (FOG-1 and FOG-2), the b-Zip family of proteins (NF-E2, Nrf1, Nrf2, Nrf3, Bach1 and Bach2), and the erythroid Krüppel-like factors (EKLF and FKLF). Experiments in which GATA-1, GATA-2, and FOG-1 have been inactivated in the mouse genome show that these proteins play a major role in establishing the erythroid lineage and allowing differentiation to mature red cells.

A major focus of interest over the past 20 years has been to understand how these developmental programs are played out on the α- and β-globin gene clusters. We now know that in most mammals in each cluster the globin genes are arranged along the chromosome in the order in which the genes are expressed in development: the α-like globin gene cluster on chromosome 16 (ζ-α_2-α_1-) and the β-like globin gene cluster on chromosome 11 (ε-$^{G}\gamma$-$^{A}\gamma$-δ-β-), suggesting that gene order may be important in unfolding this program. Expression of each cluster is dependent on remote regulatory elements, originally identified as DNase I hypersensitive sites in the chromatin of nucleated erythroid cells. In the α-globin gene cluster there is a single regulatory element (RE or HS -40) that lies 40 kb upstream of the gene complex, and in the β-globin gene cluster there are five major hypersensitive sites, collectively referred to as the β-globin locus control region (β-LCR) lying 5–20 kb upstream of the locus. Again, many details remain unknown but it appears that the ζ and ε genes are switched on in embryonic cells and are largely

off in definitive cells in which they cannot be substantially reactivated. With regard to the switch from γ- to β-globin gene expression during fetal development and neonatal life, the situation is complex. There is strong evidence for autonomous silencing of the γ genes, in a manner analogous to that of the ε gene, but it also appears that there may exist some degree of competition between the γ- and β-globin genes that is modified by the transcriptional milieu, which can change dramatically during this time of development, with the balance tipped toward γ-globin gene expression in fetal life and β-globin gene expression in adult life. The balance between γ- and β-globin gene expression may be altered in vivo (in hereditary persistence of fetal hemoglobin and other hemoglobinopathies) as well as in various experimental systems. Changes in the repertoire or amounts of transcription factors may influence the switch from γ- to β-globin gene expression. For example, without EKLF the β-globin genes cannot be fully activated during development. Alternatively, alterations in the arrangement of the β-LCR and the γ- and β-like genes with respect to each other may alter the pattern of switching. The precise molecular mechanisms underlying these changes are still poorly understood but it seems unlikely that changes in the patterns of globin gene expression are only brought about through changes in the repertoire of *trans*-acting factors present in embryonic, fetal, and adult red cells, as originally proposed; however, they may be influenced by other epigenetic changes in the chromosome (e.g., chromatin structure and modification, replication timing, and methylation).

Despite our continuing interest and frustrated attempts to fathom how the entire globin clusters are regulated, we do know a lot about the structure and function of individual genes. The globin genes have provided the paradigm for understanding the general arrangement of mammalian genes including their promoters, exons, introns, and processing signals. Furthermore, the mechanisms by which these genes are transcribed into pre-RNA, processed into mature RNA, and translated into protein are now understood in detail. This brings us back in a full circle to where modern molecular biology started by establishing the structure and function of the proteins that are expressed by globin genes. Hemoglobin was one of the first proteins whose amino acid sequence and crystal structure were solved, which in turn led to a complete understanding of how it captures, transports, and releases oxygen. Given the very large number of natural mutants of hemoglobin that have now been identified it also provides an unsurpassed example of how mutations can give rise to "molecular diseases," the best example still being sickle cell disease.

Even with this apparent depth of knowledge, there are still surprises. We know from theory and experiment that erythrocytes containing embryonic hemoglobins and fetal hemoglobins have a higher affinity for oxygen than those containing adult hemoglobin. Traditionally we have surmised that this enables the developing fetus to acquire oxygen more efficiently from the maternal circulation, a seemingly important consideration. We have known for many years, however, that the babies of mothers whose blood contains mainly fetal (high-affinity) hemoglobin are entirely normal. Similarly, thanks to experimental work in model systems, we know that mice, which by design only make embryonic hemoglobin throughout fetal and adult life, survive normally and thrive as adults. Presumably the complex system of hemoglobin switching that keeps investigators so busy has been molded in very subtle ways by natural selection. So why do we pursue this subject with such enthusiasm? There are two main reasons. The first is that the globin system still provides the most thoroughly studied and comprehensively understood example of mammalian gene expression we have. If there are undiscovered general principles governing the regulation of mammalian genes, then analysis of globin gene expression is likely to elucidate them. The second is that understanding how these genes are controlled offers the best hope of developing strategies to ameliorate or cure the many thousands of severely affected patients who inherit defects in the structure or production of the α- and β-like globin chains that make up embryonic, fetal, and adult hemoglobins.

The following seven chapters trace the genesis of hemoglobin, from the earliest appearance of erythroid cells during development, through the nuclear factors that govern its synthesis, the evolution of globin genes, their organization and switching, to the production of hemoglobin and its functions in the erythrocyte.

A Developmental Approach to Hematopoiesis

Elaine Dzierzak

INTRODUCTION AND GENERAL CONSIDERATIONS

During mammalian development, the first morphologically recognizable blood cells in the conceptus are those of the erythroid lineage. The early production of erythroid lineage cells in the yolk sac is required for the development of the vertebrate embryo. These blood cells are short-lived, however. In contrast, long-term adult hematopoiesis results from a complex cell lineage differentiation hierarchy that produces at least eight functionally distinct lineages of differentiated blood cells. The founder cells for this hierarchy are the hematopoietic stem cells (HSCs), which undergo progressive differentiation, proliferation, and restriction in lineage potential. The adult blood system is constantly replenished throughout adult life from rare HSCs harbored in the bone marrow. The field of "developmental hematopoiesis" investigates how this complex adult system is generated in the conceptus. Current research interests in this field include 1) the embryonic origins, cell lineage relationships, and functions of the cells within the multiple embryonic hematopoietic compartments; 2) the changing developmental microenvironments that support hematopoietic (stem) cell growth; and 3) the molecular programming of the hematopoietic system during ontogeny. This chapter will focus on our current knowledge concerning the embryonic beginnings of the adult hematopoietic system. Insights emerging from such a developmental approach should lead to novel molecular and cellular manipulations that could aid in the ex vivo generation and/or expansion of HSCs and progenitors for clinical use in transplantations for leukemias or blood-related genetic disease.

ONTOGENY OF THE HEMATOPOIETIC SYSTEM

Developmental studies provide insight into the initiation, growth, and function of cells in the wide variety of adult tissues. The cellular interactions and molecular programs governing tissue development are conserved throughout evolution, as revealed in a variety of animal models ranging from invertebrates to mammalian vertebrates. Similarly, conserved developmental principles also govern the generation of the hematopoietic system. Our current knowledge of the embryonic origins of the adult hematopoietic system has been gained from the study of nonmammalian vertebrate embryos such as frogs and birds[1,2] and the widely used mammalian vertebrate model, the mouse.[3] These cumulative results have provided wide support for multiple de novo hematopoietic specification events, at least three independent embryonic origins of hematopoiesis, and for the colonization theory of hematopoiesis. The variety of in vivo and in vitro hematopoietic assays and the ease of genetic manipulation of mice have significantly expanded our molecular knowledge of mammalian blood development. Studies of human embryonic hematopoiesis are further facilitated through xenotransplantation studies of human cells into mice[4] and induced hematopoietic differentiation of embryonic stem cells (ESCs) (mouse and human).[5,6] Thus, a more dynamic view of human embryonic hematopoiesis has been realized.

Initiation and Appearance of Hematopoietic Cells

Mesoderm

The hematopoietic system is one of the earliest tissues to develop during ontogeny. It is derived from the mesodermal germ layer of the conceptus, and in the human this embryonic stage is referred to as the "mesoblastic" period.[7] The mesoderm forms through an inductive interaction between the ectodermal and endodermal germ layers during the midblastula stage (Fig. 1.1A). Much of our knowledge of mesoderm induction comes from studies of amphibian embryos in which the manipulation, grafting, and culture of embryos are facilitated by their large size and development outside the mother. Nieuwkoop[8] was the first to demonstrate that culture of the amphibian midblastula stage animal cap (ectoderm) alone leads to the production of epidermis, whereas coculture of the animal cap with the vegetal pole (endoderm) leads to the generation of mesodermal structures such as muscle, notochord, heart, pronephros, and blood (Fig. 1.1B). Cell lineage mapping studies show that mesodermal cells are formed from the presumptive ectoderm that receives signals from the underlying vegetal component and presumptive endoderm.[9,10] Recent studies suggest that the earliest hematopoietic mesoderm is derived from a specialized mesendodermal layer of cells.[11,12] Animal cap assays have identified mesoderm-inducing factors including transforming growth factor–β_1 (TGFβ_1) family members BMP-4, activin, and Vg1, and members of the fibroblast growth factor (FGF) family.[11–13] The production (by endodermal cells) of these factors and their graded distribution suggest that they act as morphogens. Together with the

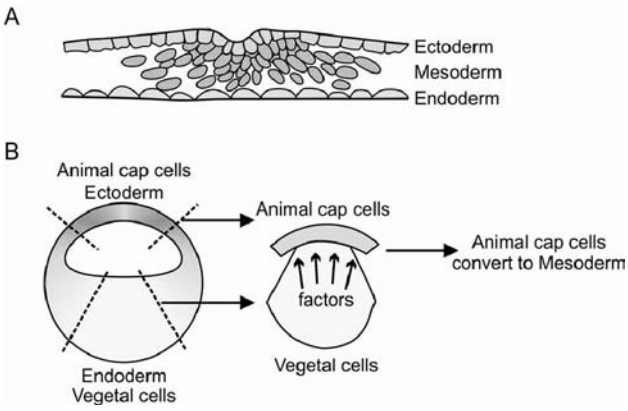

Figure 1.1. Schematic diagram of germ layer development in vertebrate embryos. **(A)** Mesoderm arises from an inductive interaction between ectoderm and endoderm. **(B)** Experimental scheme in Xenopus embryos that shows that mesodermal cells arise from the ectoderm (animal cap cells) under the inductive influence of the endodermal vegetal fragment.[10] (See color plate 1.1.)

extensive rearrangements of cell movement during gastrulation, different lineages of mesoderm are formed: dorsal, paraxial, lateral, and ventral. Numerous secreted factors (as well as transcription factors and adhesion molecules) play roles in this patterning of mesoderm.[12,14]

Similarly, mesoderm induction is the first step leading to the specification of hematopoietic cells in the mammalian conceptus. Mesoderm induction occurs in the primitive streak of the mouse conceptus beginning at embryonic day (E) 6.5/7.0. Single-cell marking of the presumptive mesoderm in the mouse epiblast showed that the first mesoderm emerging from the posterior primitive streak contributes to extraembryonic hematopoietic tissue, that is, yolk sac and allantois[15] (Fig. 1.2A). Mesodermal derivatives within the rostral embryo body arise from epiblast cells that ingress through the anterior primitive streak. Thereafter, cells that give rise to lateral blood-forming mesoderm of the anterior trunk (Fig. 1.2B) transit through the primitive streak. Mesoderm emigrating from more caudal regions of the streak forms the mesoderm of the remaining trunk regions.[16] Interestingly, the entire epiblast of the early- and midstreak stage mouse embryo contains hemogenic potential, but that potential is later restricted to the trunk and posterior region of the embryo.[17] Thus, induction of prospective hematopoietic mesoderm is conserved between vertebrate species.[16]

Extraembryonic Hematopoiesis: Yolk Sac

Yolk sac blood islands containing primitive erythrocytes are detectable in the mouse conceptus at E7.5[18] and in the human conceptus at approximately 16–20 days of gestation.[19] Mesodermal cells migrate to this extraembryonic site and come in close contact with the endoderm. As shown in avian embryos, interaction with the endoderm is required for the initiation of hematopoiesis.[20] Several endodermally produced developmental factors and morphogens in the chick[21] and the Indian hedgehog factor produced by the endoderm in mouse embryo cultures[22,23] play inductive roles in patterning hematopoietic mesoderm.

The close temporal and spatial appearance of hematopoietic and endothelial cells in the yolk sac has led to speculation of a common mesoderm precursor cell for these two lineages, the hemangioblast.[24,25] Indeed, the shared expression of markers such as Flk-1 (KDR), SCL, and CD34 by hematopoietic cells and endothelial cells and the complete lack of endothelial and hematopoietic cells in Flk-1-deficient embryos support the existence of hemangioblasts in the mammalian conceptus.[26–28]

ESC hematopoietic differentiation cultures have facilitated the isolation and characterization of hemangioblasts. Stepwise differentiation of ESCs toward the mesodermal lineage and thereafter to hematopoietic and endothelial lineages closely parallels such development in the yolk sac.[29] Under controlled culture conditions, ESCs differentiate to form cells expressing Brachyury, a well-known mesodermal marker. Brachyury expression in mouse ESCs is upregulated following exposure to mesodermal inducing factors such as FGF, TGF-β_1, and BMP-4. Shortly thereafter these cells express Flk-1 and have potential to differentiate to angioblasts and SCL^+CD34^+ blast colony–forming cells (BLCFC)[30] The ESC-derived BLCFCs are considered to be hemangioblasts. This cell type has also been identified in the early mouse embryo. At E7.5 $Brachyury^+$ cells become $Flk1^+$. When put in culture, these cells (and a small fraction of the $Brachyury^+Flk1^-$ cells) exhibit the functional properties of BLCFC.[31] Additional studies have

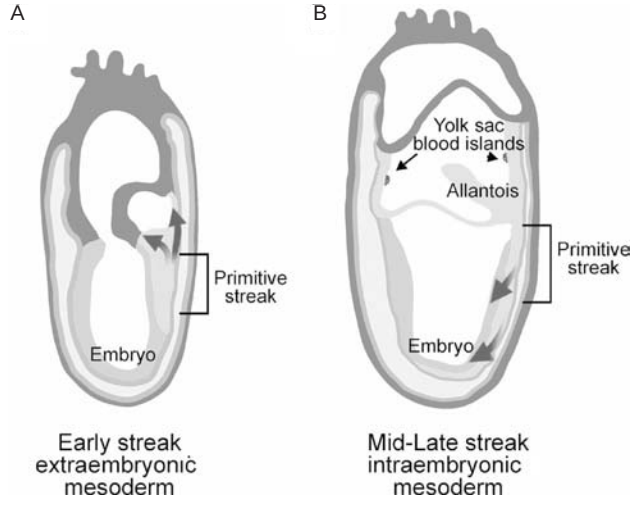

Figure 1.2. Mesodermal migration during mouse embryogenesis. **(A)** Schematic diagram of a mouse conceptus at the early primitive streak stage. Emerging from the posterior primitive streak are waves of yolk sac mesoderm migrating to form this extraembryonic tissues. Slightly later, this mesoderm also forms the allantois. Hemangioblasts are found in the posterior primitive streak. **(B)** Schematic diagram of a mouse conceptus at the mid–late primitive streak stage. Mesoderm emerging from the anterior primitive streak forms the paraxial and lateral mesoderm of the trunk region of the embryo (mesoderm for the prospective PAS/AGM region). At this stage the allantois is visible, as are the first primitive erythroid cells in the yolk sac blood islands. (Drawings adapted from ref. 3.) (See color plate 1.2.)

established that subsequent SCL expression can be used to isolate the hemangioblast from angioblasts.[26] Surprisingly, hemangioblasts in vivo are localized not in yolk sac but in the posterior primitive streak[31] (Fig. 1.2A). As they migrate to the yolk sac they become committed endothelial and hematopoietic progenitors and several of these cells contribute to the formation of each blood island.[32] Studies with human ESCs and other animal models further demonstrate the existence of hemangioblasts in the earliest stages of mesoderm and blood development, and there are some suggestions that hemangioblasts may persist in postnatal stages.[26]

Extraembryonic Hematopoiesis: Chorion, Allantois, and Placenta

The placenta has long been recognized as a site where hematopoietic cells are harbored and circulate; however, it is only recently that this tissue was shown to possess hemogenic properties.[33,34] Placenta organogenesis is initiated through the fusion of the chorionic membrane with the allantois, both derived from the extraembryonic mesoderm. The growth of this highly vascularized extraembryonic tissue is a cooperative effort between fetus and mother, allowing nutrients to be delivered to the fetus and wastes exported to the mother.

The hemogenic properties of the allantois were initially studied in avian embryos. The avian allantois, before it becomes vascularized, contains clusters of hematopoietic cells resembling blood islands[35] and, upon grafting, forms adult blood and endothelium.[36] In contrast, initial grafting studies of the mouse allantois did not reveal erythroid lineage contribution in vivo, although a small population of erythroid cells was found in cultured tissues.[37] Recently, both the mouse allantois and chorion have been shown to possess intrinsic hematopoietic potential that is not dependent on chorioallantoic fusion.[33,34] Mouse allantois and chorion tissues contain multilineage hematopoietic potential as shown by colony–forming unit-culture (CFU-C) assays. They express the Runx1 transcription factor, a molecule required for hematopoietic induction. The rudiments of the prospective placenta are hemogenic before the vascular continuity between the allantois and yolk sac is established, and thus are thought to generate de novo hematopoietic cells. In addition, soon after the formation of the placenta, potent hematopoietic progenitor and stem cell activity can be found at high frequency in this tissue.[38–40] It remains to be determined what percentages of these hematopoietic cells are de novo generated in the placenta and whether placental cells contribute long term to the adult hematopoietic system.

Intraembryonic Hematopoiesis: Paraaortic Splanchnopleura/Aorta-Gonad-Mesonephros

In the mid-1970s, amphibian and avian embryo culture and grafting approaches were used extensively to study

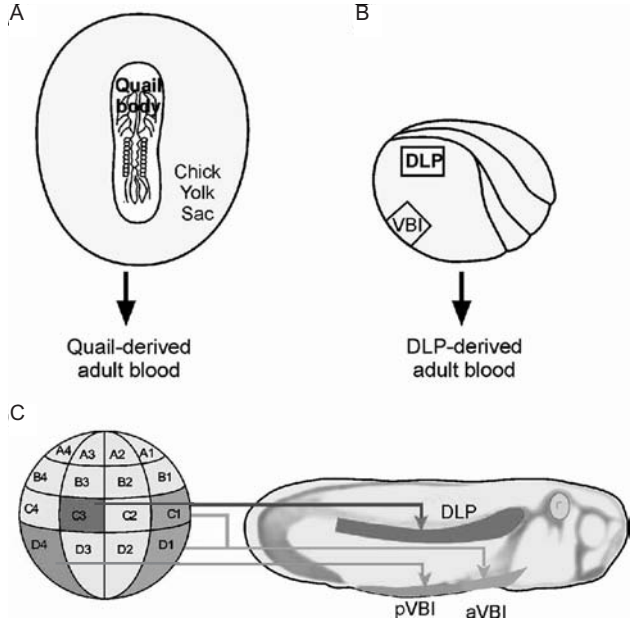

Figure 1.3. Nonmammalian vertebrate embryo–grafting experiments used for determining the origin of the adult hematopoietic system. **(A)** A schematic diagram of the avian embryo grafting strategy in which quail embryo bodies were grafted onto chick yolk sacs at the precirculation stage of development. **(B)** A schematic diagram of the amphibian embryo grafting strategy in which genetically marked dorsal lateral plate (DLP) or ventral blood island (VBI) regions were transplanted onto unmarked Xenopus or Rana embryos. **(C)** Genetic marking experiment in 32 blastomere Xenopus embryo (left). Marking of the C3 blastomere, D4 blastomere, and C1 and D1 blastomeres allowed the tracing of progeny cells to the DLP, pVBi, and aVBI, respectively, at the larval stage (right). (Drawings adapted from ref. 3.) (See color plate 1.3.)

cell fate, morphogenesis, and organogenesis. In the avian species, grafts between quail and chick embryos or between different strains of chicks were used to create chimeras in which the embryonic origins of adult blood cells were determined.[1,41] Donor-specific nucleolar or immunohistochemical markers determined whether the differentiated adult blood cells were derived from the graft or the recipient. For example, yolk sac chimeras were constructed by grafting a quail embryo body onto the extraembryonic area of a chick blastodisk (Fig. 1.3A). The combined results of many such experiments[41–44] led to the following conclusions: 1) the first emergence of hematopoietic cells is extraembryonic, in the yolk sac; 2) slightly later, hematopoietic cells emerge both extraembryonically and intraembryonically; and 3) intraembryonically derived hematopoietic cells are permanent contributors to the adult hematopoietic system. Most extraembryonically derived hematopoietic cells become extinct. Furthermore, multipotential hematopoietic progenitors as assayed in in vitro clonal cultures are associated with the dorsal aorta of avian embryos.[45] The close association of hematopoietic cell clusters and endothelial cells on the ventral aspect of the dorsal aorta[41] led to the hypothesis that hematopoietic cells are derived from endothelial cells. Indeed, when chick aortic endothelial cells are labeled in situ with lipophilic dye during prehematopoietic stages,[46,47] labeled intraaortic hematopoietic clusters are found 1 day later, thus

demonstrating a precursor–progeny relationship between endothelial cells and hematopoietic clusters.[2]

Similarly, chimeric embryo studies in amphibians have demonstrated independent intraembryonic and extraembryonic mesodermally derived sites of hematopoiesis.[48–50] Using DNA content as a marker, chimeric frog embryos were generated by reciprocal grafting of the ventral blood island (VBI) region (a region analogous to avian and mammalian yolk sac) and the dorsal lateral plate (DLP) (a region analogous to the avian intraembryonic region containing the dorsal aorta) from diploid and triploid embryos (Fig. 1.3B). Again, the ventral mesodermal yolk sac analog produces the first hematopoietic cells, and slightly later, the dorsal mesodermal intrabody compartment generates adult hematopoietic cells. Unlike birds, some ventrally derived hematopoietic cells persist to adult stages and appear to contribute to red and white blood cell populations.[48,49] The specific localization of intrabody hematopoiesis has been found to be associated with the dorsal aorta and pronephros, with the most abundant hematopoiesis in the pronephros.[51] Indeed, lineage-tracing experiments in which individual blastomeres in the 32-cell stage embryo are marked show that the blastomeres contributing to the formation of the VBIs (anterior and posterior) are distinct from each other and from the blastomere that contributes to the formation of the DLP[52] (Fig. 1.3C). Moreover, in early embryos the prospective hematopoietic cells in the VBI (primitive) and DLP (adult) can be reprogrammed to an adult or primitive hematopoietic fate. The programs become fixed at a later time point and are thought to become restricted through regulatory interactions from the local environment.[53] Thus, there are three distinct origins of prospective hematopoietic cells in Xenopus that are influenced by the local microenvironment. Similarly, in the early-stage mammalian embryo, there are at least three distinct mesodermal tissue origins of hematopoietic cells, the yolk sac, intraembryonic aorta-gonad-mesonephros (AGM) region, and the chorioallantoic placenta (and possibly the vitelline and umbilical vessels) (Fig. 1.4A). The AGM region de novo produces the first adult type HSCs[54–55] (reviewed in Dzierzak[56]). This intraembryonic region contains a single central aorta surrounded by the differentiated urogenital tissue (Fig. 1.4B). At early developmental stages, the AGM is identified as the paraaortic splanchnopleura (PAS)[57]) and consists of the paired dorsal aortae and the surrounding mesenchyme adjacent to the gut endoderm.

The establishment of the vascular connection between the mouse embryo body and the extraembryonic sites at E8.25[37] precludes the identification of extra-versus intraembryonically derived hematopoietic cells. Potent hematopoietic progenitors CFU-spleen (S)[58] B lymphoid,[59] and multipotent (erythroid-myeloid-lymphoid) hematopoietic progenitors[60] have been found in the E9 PAS/AGM region. At slightly later stages of mouse embryogenesis (E10), adult-type HSCs are autonomously generated in the AGM region[54,55] and more specifically the dorsal aorta.[61]

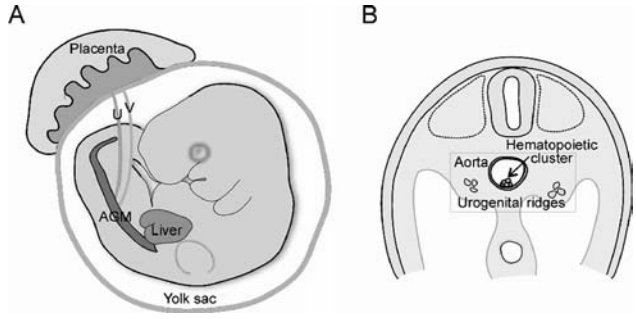

Figure 1.4. Sites of hematopoietic activity in the midgestation mouse conceptus. **(A)** A whole E10.5 mouse conceptus is shown. The placenta, AGM, yolk sac, and the vitelline (V) and umbilical (U) vessels harbor and/or generate hematopoietic cells at this time. **(B)** Transverse section through the AGM region of an E10.5 mouse embryo is shown. The dorsal aorta is located in the midline, with the neural tube on the dorsal and gut on the ventral side. The urogenital ridges laterally flank the aorta. Hematopoietic cell clusters are found in the lumen of the dorsal aorta as they emerge from the ventral hemogenic endothelium. (See color plate 1.4.)

As reported in a wide range of species,[41,52,62,63] hematopoietic foci appear as clusters adhering tightly along the ventral wall of the dorsal aorta (Fig. 1.4B). Cell surface markers, such as CD34 and CD31,[63,64] are shared between the hematopoietic cell clusters and endothelial cells. Both cell types also express the Runx1 (AML1, CBFα2) transcription factor,[65] which is required for definitive hematopoiesis[66,67] and the Sca-1 marker used for sorting adult HSCs.[68] Thus, the PAS/AGM region plays an important role as an early and potent intraembryonic site of hematopoiesis. Hemogenic potential is localized to a subset of endothelial cells lining the wall of the dorsal aorta. Interestingly, the other major vasculature (umbilical and vitelline vessels) of the mouse embryo also contain hematopoietic clusters and it is thought that potent hematopoietic cells emerge from hemogenic endothelium in the midgestation vasculature.

Secondary Hematopoietic Territories: Liver and Bone Marrow

In mammalian species, the liver serves as a temporary hematopoietic territory during fetal stages of development. The colonization theory of hematopoiesis first suggested that the hematopoietic cells generated within the extraembryonic yolk sac migrate and colonize the fetal liver and then later move to the bone marrow where they contribute to adult hematopoiesis.[69] Now included in the colonization theory of the fetal liver are the potent hematopoietic cells generated in the PAS/AGM and allantois/chorion/placenta (Fig. 1.5). Abundant evidence from coculture experiments and quantitative temporal and spatial analyses of hematopoietic progenitors/stem cells supports the currently accepted dogma that fetal liver does not de novo generate hematopoietic cells but instead is seeded with cells from these generating tissues.[3] Moreover, the demonstration that mouse embryos with a deficiency of β_1-integrin contain normal yolk sac hematopoiesis but lack fetal liver hematopoiesis provides the first genetic

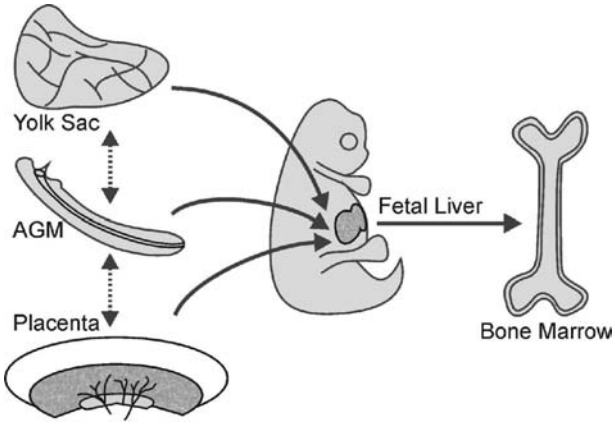

Figure 1.5. Sites of hematopoiesis and possible migration and colonization events during mouse embryonic development. It is generally accepted that migration to the fetal liver and adult bone marrow occurs, as indicated by the solid arrows. Cell migration between the embryonic tissues (yolk sac, AGM, and placenta) generating different types of hematopoietic cells is as yet undetermined (dotted arrows).

evidence that adhesion/homing molecules play a role in the colonization process.[70,71] In addition to providing a niche for harboring hematopoietic cells, the fetal liver expands and differentiates the newly emigrated cells, particularly directing differentiation toward the erythroid lineage.[72] Colonization with hematopoietic progenitors begins at late E9[73,74] and HSCs appear at E11 in the mouse fetal liver.[56,75] The liver remains a hematopoietic niche until birth when the hematopoietic cells again migrate and colonize the newly established trabecular spaces in the long bones, the so-called bone marrow. In the human fetal liver, CD34+ hematopoietic progenitors appear at 30 days of gestation and hematopoiesis continues in this tissue only until 20 weeks of gestation. At week 10, the bone trabeculae are being established and marrow hematopoiesis commences 1 week later.[19]

The Embryonic Hematopoietic Hierarchy

The complex lineage relationships of the cells within the adult mammalian hematopoietic hierarchy are well known and are based on results of in vivo and in vitro differentiation assays of bone marrow cells[76] (see Table 1.1 for assay descriptions). These assays measure the maturational progression of cells at the base and branch points of the hematopoietic system all the way through to the terminally differentiated cells of all the distinct blood lineages. The stem cells and progenitors measured by in vitro hematopoietic assays such as CFU-C, fetal thymic organ culture, stromal cocultures, CAFC and LT-CIC, and in vivo transplantation approaches for CFU-S and short-term and long-term repopulating HSCs have led to a placement of these cells within the "textbook" depiction of the hierarchy for adult hematopoiesis. Molecules expressed by distinct hematopoietic lineages and undifferentiated hematopoietic progenitor and stem cells have been instrumental

Table 1.1. Assays to detect hematopoietic cells in the mouse cconceptus

Cell type	Hematopoietic assay	Method	Lineage	Reference
Erythroid–myeloid progenitor	CFU-C	In vitro culture for 5–14 d in semisolid medium with growth factors	Erythrocytes, macrophages, granulocytes, mast	77
Erythroid–myeloid progenitor	CFU-S	In vivo transplantation into lethally irradiated adult recipients leading to macroscopic spleen colony formation at 8–16 d	Erythrocytes, macrophages, granulocytes	58
T-lymphoid progenitor	Fetal thymic organ culture/OP9-delta coculture	In vitro culture with T-depleted thymus for 9–21 d or coculture with delta producing stromal line	T lymphoid	60, 94
B-lymphoid progenitor	Stromal coculture	In vitro 14-d coculture with IL-7 and stromal cells	B lymphoid	60, 95
Multipotent progenitor	Single-cell multipotential assay	A two-step in vitro culture. Tissue explants/cells cultured on S17 or OP9 cells followed by CFU-C and B/T lymphoid assay or in vivo transplantation to immunodeficient adults	Erythroid, myeloid, B and T lymphoid	60
Neonatal repopulating HSC	Neonatal liver transplantation	In vivo transplantation directly in the liver of 1-day-old hematopoietic ablated recipients. Yields long-term, multilineage repopulation	All hematopoietic lineages	111
Adult repopulating HSC	Adult transplantation	In vivo transplantation into lethally irradiated adult recipients. Yields long-term, high-level, multilineage repopulation	All hematopoietic lineages	55, 75, 123

in assigning direct precursor–progeny relationships and prospectively isolating the cells within the adult hierarchy.

The adult hierarchy begins with the HSC and proceeds unidirectionally, with restrictive events occurring throughout hematopoietic differentiation to produce all the differentiated cells in the hematopoietic system. Although these events are represented by discrete cells in the hierarchy, it is most likely that there is a continuum of cells between these landmarks. Indeed, use of the Flt3 receptor tyrosine kinase surface marker along with many other well-studied markers has redefined the early branch points of the adult hierarchy and the subsets of cells committing to myeloid and lymphoid lineages.[77] With the description of further markers to identify additional intermediate cell subsets, it may be possible to determine all the molecular events needed for the differentiation of entire adult hematopoietic system and the transit time necessary for differentiation to the next subset.

Until recently, little was known about the embryonic hematopoietic hierarchy.[3] Although the adult hematopoietic system is usually in a state of equilibrium, the hematopoietic system of the embryo is vastly different: It must de novo generate the entire hematopoietic system, generate these cells within a short span of time in several mesodermally derived microenvironments (yolk sac, amnion/chorion/placenta, and PAS/AGM), and promote the sequential migration, colonization, and maintenance of hematopoietic cells in yet other microenvironments (liver, circulation, other) before they are finally localized in the bone marrow of the adult (Fig. 1.5). Additionally, different subsets of hematopoietic cells exist in the embryo, possess unique functions, and are not long-lived. Thus, to model the embryonic hematopoietic hierarchy cell origins, precursor–progeny relationships and lifespans of the hematopoietic cells throughout ontogeny must be established. A description of the types of terminally differentiated cells, committed progenitors, immature progenitors, and HSCs existing within the mouse conceptus, and in some cases the human conceptus, is provided here.

Erythropoiesis

Histological sectioning reveals that cells of the erythroid lineage are the earliest differentiated hematopoietic cells in the human and mouse conceptus. Primitive erythroblasts are observed in the yolk sac blood islands of the human at E16–20,[78] and mouse at E7.0/7.5.[18,79,80] In human embryos, up to 100% of all nucleated blood cells at 4–8 weeks of gestation are erythropoietic. These cells are found in the chorial and umbilical vessels, liver sinusoids, and other intraembryonic blood vessels. A switch to enucleated definitive erythropoietic cells occurs at 7–10 weeks of gestation in the blood, and slightly earlier in the fetal liver[78] (Fig. 1.6). Similarly, in the mouse, nucleated primitive erythropoietic cells predominate in the yolk sac and fetal liver until a switch

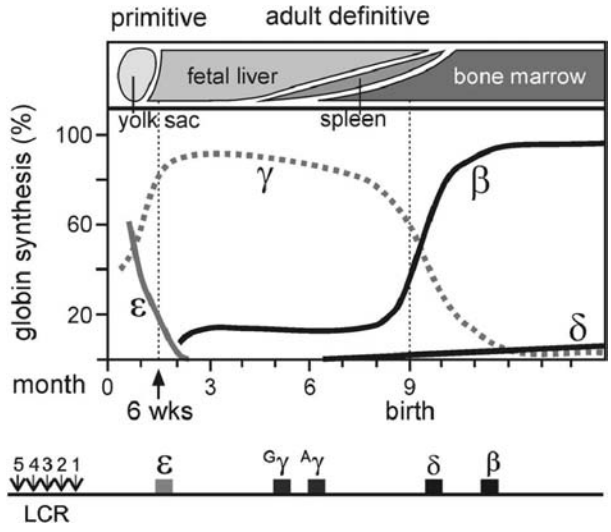

Figure 1.6. Developmental expression of the human globin genes. Sites of primitive and definitive hematopoiesis throughout development are shown. Sequential waves of ε (epsilon), γ (gamma), and β (beta) globin synthesis begin with ε-globin expression in the first month of human development, followed by γ-globin expression in the fetal stage, to just after birth when β-globin becomes the predominant hemoglobin type in definitive erythroid cells. The chromosomal organization of the genes of the human β-globin locus is in a linear arrangement that correlates with developmental expression. The arrows indicate the DNase1 hypersensitive sites of the LCR (locus control region), which is a region important for globin gene regulation.

from primitive to definitive cell types occurs between E10 and E12.[81,82]

In both species, the switch from primitive to definitive erythropoiesis is characterized by changes in the expression of the developmentally regulated fetal and adult globin genes (reviewed in refs. 83, 84 [Fig. 1.6]). Individual erythroid progenitors from ESC differentiation cultures can give rise to both fetal and adult erythroid cells[85] and single fetal liver cells can switch from a fetal to adult globin gene expression program.[86] The general populations of mature erythroid cells, however, are derived from developmentally separate stem cell populations in the embryo.[80,87] Moreover, the receptor tyrosine c-kit appears to be required for fetal liver hematopoiesis but not yolk sac erythropoiesis,[88] suggesting the origins of primitive and definitive erythroid cells from distinct and differentially regulated hematopoietic progenitor/stem cell populations. Additional molecular differences in primitive and definitive erythropoietic programs, particularly in the requirements for erythropoietic growth factors such as erythropoietin and transcription factors (GATA-1 and EKLF) are well documented.[89]

Myelopoiesis

The first cells of the monocyte–macrophage lineage appear in human conceptuses at 4–5 weeks in gestation.[78] Monocytes are routinely represented in human embryos at approximately a 1%–4% frequency in nucleated blood

populations after 11 weeks of gestation. Interestingly, macrophages can be found in early human blood smears only until approximately 14 weeks of gestation. This is consistent with findings in the mouse that two separate lineages of macrophages are thought to develop in ontogeny: primitive macrophages and the monocytic lineage of macrophages.[90] In the mouse, primitive macrophages (which begin to appear at E9 in the yolk sac) are thought to arise from a local precursor and not a monocytic progenitor. These primitive macrophages proliferate and colonize other embryonic tissues. In contrast, adult macrophages do not circulate through the blood. These cells of the monocytic lineage begin to appear in the fetal liver and yolk sac at E10. Thus, the ontogeny of the monocyte–macrophage is different in the early embryo compared with its later developmental stages and it has been suggested that adult macrophages are the progeny of monocytic precursors from the AGM.[91]

Lymphopoiesis

The production of lymphoid cells begins in the human at 7–10 weeks of gestation.[78] Small lymphocytes are found in the blood: 0.2% of nucleated cells at weeks 9–10 and 14% after 14 weeks. Large lymphocytes represent 3%–5% of nucleated blood cells after 11 weeks of gestation. No lymphoid cells are found in the yolk sac, although the presence of lymphoid progenitors has not been examined. Lymphopoiesis begins in the human fetal liver, thymus, gut-associated lymphoid tissue, and lymph plexuses at approximately 7 weeks of gestation, whereas the bone lymphocytes are found only at week 12.

Extensive analyses on the development of lymphoid progenitors have been performed in the mouse. Although no functional lymphocytes are found in the mouse conceptus at early gestational stages, cells with lymphoid potential are present. E8.5 yolk sac contains T lymphoid potential when cultured in depleted fetal thymic explants.[92,93] B lymphoid potential is found in the embryo body (E9.5) and subsequently the yolk sac (E10) of the mouse conceptus by coculturing such cells in the presence of stromal cells.[94] Dissection of the PAS/AGM region has revealed the presence of an AA4.1-positive progenitor for the B1a lineage of B cells as early as E8.5.[59,60] A two-step culture system with E7.5 mouse embryo tissues has demonstrated multipotential lymphoid progenitors in the intraembryonic PAS but not in the yolk sac. Only beginning at E8.5 does the yolk sac acquire such multipotential lymphoid activity,[57] suggesting that PAS-generated multipotential lymphoid progenitors may migrate to the yolk sac after E8.5 when the intra- and extraembryonic circulation is connected. Alternatively, the yolk sac may be capable of producing such progenitors de novo but 1 day later than the PAS. At E10, multipotent B-lymphoid progenitors are found in the circulation, reach a maximum number at E12, and are undetectable in the blood at E14.[95] B-cell precursors are detected in the fetal liver at E14 and in the embryonic marrow at E15.

Interestingly, adult mouse bone marrow and fetal liver HSC–enriched populations exhibit different T- and B-lymphoid lineage potentials. In the T-lymphoid lineage, fetal liver but not bone marrow HSCs produce Vγ3 and Vγ4 T-cell receptor–positive subsets.[96] Such T cells can also be cultured from yolk sac after E8.5.[93,96] Similarly in the B-lymphoid lineage, the B1a subset of cells is produced by fetal liver,[97] yolk sac,[98] and PAS,[59] but not by adult bone marrow. It is interesting to propose that the distinct B1a–B cell subset, as well as Vγ3–4 T-cell subsets, may be the product of a special subset of developmentally regulated progenitors or HSCs in the PAS of the early embryo. It is not known whether such lymphoid subsets and progenitors exist in human embryos.

Erythroid–Myeloid Progenitors: CFU-C

The early presence of hematopoietic progenitors within the developing mouse yolk sac was established using in vitro culture approaches developed initially for measuring the hematopoietic potential of adult mammalian bone marrow. The culture of yolk sac cells in semisolid medium in the presence of colony-stimulating factors revealed the presence of erythroid and granulocyte–macrophage progenitors beginning at E7.[69,99] Burst-forming unit-E (BFU-E) and CFU-Mix are also found in the yolk sac at E8,[99] and mast cell precursors are found at E9.5.[100] At E8.25, following the first wave of primitive erythropoiesis and before the circulation is established, myeloid progenitors are detected in the yolk sac.[101] After the circulation is established myeloid progenitors are also found in the trunk region.[89] Tissue explant culture prior to CFU-C assay reveals that both the E8 yolk sac and E8 PAS contains cells with potential to become myeloid progenitors.[57] Similar cultures of precirculation allantoides[34] also revealed cells with myeloid potential. By E9 the placenta contains an abundance of myeloid progenitors.[38] Analyses of two mutant mice, *Cdh5*$^{-/-}$ and *Ncx1*$^{-/-}$, have provided strong in vivo evidence for the de novo production of definitive myeloid progenitors in the yolk sac. In *Cdh5*$^{-/-}$ conceptuses there is no vascular connection, whereas in *Ncx1*$^{-/-}$ conceptuses the vitelline vessels are intact but there is no heartbeat to promote the circulation between the yolk sac and embryo body. Similar numbers of myeloid progenitors were found in the E9.5 *Cdh5*$^{-/-}$ yolk sac compared with wild-type conceptuses, although macrophage and mixed colony–forming progenitors were decreased in number.[102,103] In *Ncx1*$^{-/-}$ conceptuses, the numbers of myeloid progenitors of all types in the yolk sac were found to be equivalent to the cumulative number of progenitors in the *Ncx1*$^{+/+}$ conceptuses in all anatomical sites.[103] No progenitors were found in the *Ncx1*$^{-/-}$ PAS, suggesting that the yolk sac normally generates all of these progenitors and

distributes them to the PAS and liver. Alternatively, Ncx1-deficient conceptuses, which lack hemodynamic stress, do not produce the proper signals to induce myeloid progenitor formation in the PAS.[104] Thus, several types of definitive myeloid progenitors are generated de novo in the yolk sac and also in the chorioallantoic placenta and PAS/AGM.

In the human, yolk sac hematopoiesis covers the period from midweek 3 in gestation to week 8. BFU-Es have been found at early stages in the yolk sac but begin to decrease in frequency at week 5, when the fetal liver BFU-E frequency increases,[105] thus suggesting a colonization of the fetal liver by yolk sac progenitors. Along with erythroid progenitors, the yolk sac and embryo body have been found to contain clonogenic myeloid progenitors and erythroid–myeloid multipotent progenitors at 25–50 days into human gestation.[106,107] At the 4- to 5-week stage of gestation, a discrete population of several hundred cells bearing the cell surface phenotype of immature hematopoietic cells ($CD45^+$, $CD34^+$, $CD31^+$, and $CD38^-$) are found adhering to the ventral endothelium of the dorsal aorta.[63,107] These clusters are similar to those described in the chick and mouse. Interestingly, when these cell clusters are cocultured with bone marrow stromal cells and assayed in methylcellulose for CFU-Cs, they yield many progenitors and large multilineage hematopoietic colonies.[63]

Erythroid–Myeloid Progenitors: CFU-S

To determine whether the more immature hematopoietic progenitor compartment of the adult hierarchy is present early during embryonic development, in vivo transplantation analyses for CFU-S have been performed in irradiated mice. CFU-S are immature erythroid–myeloid progenitors that yield macroscopic colonies on the spleens of lethally irradiated mice 9–14 days following transplantation.[108,109] Beginning at E9, statistically significant numbers of CFU-S are found both in the yolk sac and PAS/AGM.[58,69] It is difficult to determine from which tissue these in vivo progenitors originate because the vascular connection between the yolk sac and embryo body is made at E8.5. The absolute numbers of CFU-S from the developing mouse embryo up to late E10 reveal that the AGM region contains more CFU-S than the yolk sac.[54,58] When an organ culture step is used before in vivo transplantation of yolk sac or AGM, the numbers of AGM CFU-S increase substantially, whereas only a slight increase in yolk sac CFU-S numbers is observed.[54] Thus, the AGM region is the more potent generator of CFU-S. CFU-S are localized to both the aorta subregion and urogenital subregion of the AGM and are also found in the vitelline and umbilical arteries.[109]

Erythroid-Myeloid-Lymphoid Multipotential Progenitors

Within the mouse embryo, these in vitro progenitors are found at E7.5 within the intrabody PAS/AGM region by a two-step culture system, 1 full day earlier than in the yolk sac.[57] Results of temporal studies suggest that preliver intrabody hematopoiesis is more complex and potent than extraembryonic yolk sac blood formation, and such PAS-generated multipotent progenitors may seed the yolk sac after the circulation is established at E8.5. The multipotential progenitors in the E8–9 PAS have also been tested in vivo for CFU-S and adult repopulating HSC activity. In vivo, these cells do not repopulate lethally irradiated adult recipient mice short term or long term after transplantation; however, they do contribute to long-term, low-level hematopoiesis following transplantation into immunocompromised adult recipients. These results suggest that they are not fully competent adult HSCs but could be candidates pre–stem cell population. Similarly, the human AGM but not the yolk sac contains multipotent progenitors beginning at day 24 in gestation. They express CD34, and $CD34^+$ hematopoietic cell clusters begin to appear on the ventral wall of the dorsal aorta at day 27. These multipotent cells could be HSCs or precursors of such cells.[19,28,110]

Neonatal Repopulating Hematopoietic Stem Cells

A more potent in vivo repopulating multilineage hematopoietic cell has been described through the use of another transplantation assay. Neonatal mice from pregnant dams treated with busulfan (for myeloablation to enhance engraftment) were injected (directly into the liver at the time of birth) with yolk sac or PAS/AGM cells. When E9 $CD34^+c\text{-}kit^+$ cells from E9 yolk sac and E9 PAS/AGM were transplanted in this manner, both were capable of multilineage engraftment and secondary engraftment into adult lethally irradiated recipient mice.[111] Neither of these sorted populations could repopulate primary adult lethally irradiated recipients nor engraft the hematopoietic system of the primary neonatal recipient to 100%. Because the yolk sac contains more neonatal repopulating cells than the PAS/AGM, these investigators suggest that the yolk sac may be the generating source. Previous studies have suggested that the early-stage yolk sac cells can indeed lead to long-term hematopoiesis when transferred into embryonic recipients, either transplacentally or into the yolk sac cavity.[112,113] These studies showed donor yolk sac–derived cells in the erythroid and lymphoid lineages, respectively, of fully developed adults. Thus, neonatal/fetal repopulating cells are long-lived multilineage progenitors that have the potential to become competent adult-type HSCs when exposed to the appropriate microenvironment.

Hematopoietic Stem Cells

At the base of the adult hematopoietic hierarchy are HSCs. They are defined by their ability to high-level, multilineage, long-term repopulate irradiated adult mouse recipients. The presence of differentiated hematopoietic cells

and many restricted, multipotent and in vivo immature hematopoietic progenitors in the PAS/AGM region, yolk sac, and chorioallantoic placenta of the mouse conceptus leads to the prediction (within the context of the adult hematopoietic hierarchy) that HSCs should be present from the onset of embryonic hematopoiesis at E7.0/7.5. In mouse embryos, however, the first adult repopulating HSCs are found only beginning at E10 in the AGM region[55] and at E11 in the yolk sac[55,69,70] and placenta.[39,40] Organ explant culture before in vivo transplantation has revealed that the AGM region is the first tissue to generate autonomously HSCs.[54] The yolk sac and placenta may subsequently be seeded by AGM-generated HSCs, or alternatively, these tissues may be capable of de novo generating their own HSCs.

Direct Precursors to the Hematopoietic Lineages

Primitive erythroid cells arise from hemangioblasts, whereas the "definitive" classes of hematopoietic progenitor stem cells are thought to arise through different precursors, the so-called "hemogenic endothelium." Discrete subsets of vascular endothelial cells in the conceptus exhibit hemogenic potential.[25] Cross-species immunohistochemical studies have shown hematopoietic clusters tightly adherent to the ventral endothelium of the dorsal aorta and that of the umbilical and umbilical arteries[2] (Fig. 1.4B). The first appearance of hematopoietic clusters is in parallel to the appearance of the first definitive HSCs that can be detected. In the chick embryo, metabolic lineage tracing (AcLDL-DiI) or retroviral labeling of endothelial cells prior to hematopoietic cell appearance has confirmed the endothelial–hematopoietic lineage relationship of aortic hematopoietic clusters.[46,47] Similar marking attempts in ex utero cultured E10 mouse embryos show AcLDL-DiI$^+$ definitive erythroid cells in the circulation 12 hours after intracardiac injection and marking of aortic endothelium.[114] The phenotypic profile and spatial localization of HSCs in the AGM are also supportive of hemogenic endothelium as the direct precursor to definitive hematopoietic cells. All AGM HSCs are CD45$^+$, Ly-6A (Sca-1) GFP$^+$, c-kit$^+$CD34$^+$, Runx1$^+$, SCL$^+$, and Gata2$^+$.[68,115–119] These markers (with the exception of CD45) are also expressed by some or all endothelial cells in the ventral aspect of the dorsal aorta at E10/11. Most or all AGM HSCs express cell surface vascular endothelial cadherin,[117,120] which is typically thought of as an endothelial marker. Interestingly, not all the cells in the hematopoietic clusters express the same hematopoietic markers: Only some cells express CD41$^+$[121] or the *Ly-6A GFP* transgene,[122] indicating that some cells in the clusters take on the HSC fate whereas others are fated to be progenitors. Studies in the mouse conceptus have identified hematopoietic clusters on both the ventral and dorsal aspects of the dorsal aorta.[123] Functional studies indicate that definitive hematopoietic progenitors reside on both aspects of the aorta, but only the ventral aspect contains fully potent HSCs.[123] Thus, there appear to be subsets of hemogenic endothelium.

In contrast, some studies suggest that HSCs are derived from mesenchyme located directly underneath endothelial cells in the ventral aspect of the dorsal aorta, or in discrete patches ventral–lateral to the dorsal aorta (subaortic patches). In Runx1-haploinsufficient AGMs, HSCs are present within the Runx1-expressing mesenchymal cells underlying the ventral aspect of the dorsal aorta (as defined by the phenotype CD45$^-$, CD31$^-$, and vascular endothelial cadherin$^-$). AGM cells similarly sorted from wild-type embryos did not contain HSCs,[117] suggesting that HSCs are normally localized in the aortic endothelium. When cells from the subaortic patches (CD45$^-$ckit$^+$AA4.1$^+$) are transplanted into immunodeficient adult recipients, some long-term repopulating activity was found but the level of engraftment was low, ranging from 0.4% to 1.9%.[124] These cells are not as potent as the Runx1$^+$ or Ly-6A (Sca-1) GFP$^+$ aortic endothelial/cluster HSCs that provide up to 100% engraftment of irradiated adult recipients.[68,117] The hematopoietic cells localized in the subaortic patches may be precursors to the fully potent HSCs found in the aortic endothelial hematopoietic clusters or may represent differentiated progeny of hemogenic endothelium that have ingressed (as in the chick embryo) into this site. Together, these mouse data strongly indicate that the direct precursors of HSCs are predominantly hemogenic endothelial cells. In addition, the vascular endothelium of the human embryo has blood-forming potential.[125]

A Model of the Embryonic Hematopoietic Hierarchy

The appearance of terminally differentiated primitive erythrocytes in the mouse conceptus 3 days before the appearance of adult-type HSCs is the antithesis of the adult hematopoietic hierarchy. In the conceptus, the stepwise progressive appearance of distinct cells with increasingly complex hematopoietic potential supports a model in which the embryonic hematopoietic system is not a single-lineage differentiation hierarchy but is instead many hierarchies. It is a continuum of hematopoietic fate determining events occurring within distinct subsets of presumptive hemogenic mesoderm that specify a variety of temporally and spatially separate precursor cells – hemangioblasts and hemogenic endothelium (Fig. 1.7). Dependent on developmental time and position within the extra- and intraembryonic tissues (yolk sac, placenta, and AGM), cells emerge with different hematopoietic potentials. Thus, the embryonic hematopoietic hierarchy is modeled on the appearance of functionally different cells without indications for lineage relationships. Although it is clear that "hemangioblasts" and hemogenic endothelium play roles, further results are necessary to determine whether the wide range of hematopoietic activities in the conceptus are achieved directly through hematopoietic fate

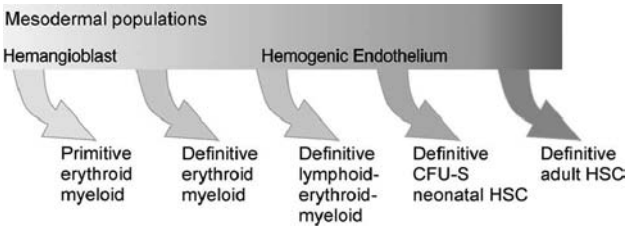

Figure 1.7. The early embryonic/developmental hematopoietic hierarchy is unlike that of the adult. The temporal appearance of hematopoietic cells in the mouse conceptus suggests that many of these cells do not arise from an HSC but instead they arise directly from mesodermal populations that go through a hemangioblast and/or hemogenic endothelial intermediate. Thereafter, hematopoietic fate is acquired and hematopoietic cells are generated. The sequential appearance of primitive erythroid–myeloid cells, followed by increasingly more complex definitive hematopoietic cells and finally the appearance of definitive HSCs is contrary to adult hematopoietic differentiation hierarchy with the expected precursor–progeny relationships. Instead, the hematopoietic system in the embryo is generated at least five independent times in different mesodermal populations.

determination events in a variety of nonhematopoietic precursors (hemangioblasts and different subsets of hemogenic endothelium) or through the acquisition of more complex hematopoietic activities imposed by the microenvironment after hematopoietic fate determination of a small cohort of similarly active cells. In the human conceptus, the sequential appearance of differentiated and more complex hematopoietic progenitors is consistent with what has been observed in the mouse conceptus.[106,107] Moreover, the distribution of these hematopoietic cells occurs similarly in the yolk sac, AGM, liver, spleen, and bone marrow (the hematopoietic activity of the placenta is predicted but is as yet uncertain (Fig. 1.8).

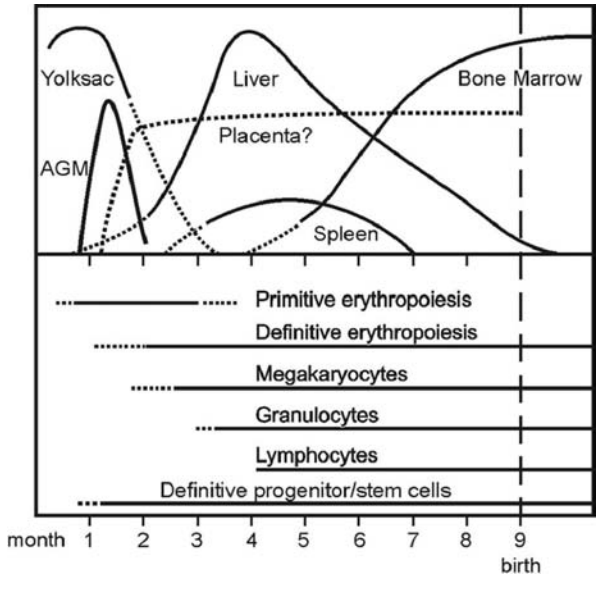

Figure 1.8. The sites of hematopoietic activity and the temporal appearance of the distinct hematopoietic lineages in the human embryo. There is a general correspondence of the hematopoietic sites and the temporal appearance of hematopoietic cells between the human and the mouse embryo. (Figure adapted from ref. 196.)

Hematopoietic Colonization and Migration During Development

Until 1965 it was thought that the hematopoietic populations found in adult vertebrates were intrinsically generated in tissues such as the liver, spleen, bone marrow, thymus, and bursa of Fabricius (only found in avian species). A paradigm shift occurred when it was shown that hematopoietic cells generated in earlier embryonic tissues colonized these secondary hematopoietic tissues. The generating sources of the hematopoietic cells are likely to be one or more of these tissues: the yolk sac, PAS/AGM, and chorioallantoic placenta. In this section a summary of the findings demonstrating the migration of hematopoietic cells during development is provided.

Avian

The results of experiments by Moore and Owen,[126] in which parabiosed chick embryos were examined, suggested that the thymus, spleen, bursa of Fabricius, and bone marrow were colonized by blood-borne cells. Definitive proof that the hematopoietic cells in adult tissues are extrinsically derived comes from the quail–chick and chick–chick embryo grafting experiments. Initial experiments focused on the colonization of the grafted thymus and spleen rudiments with embryonic hematopoietic precursors.[41,44] Each tissue rudiment provided the stroma or microenvironment for the seeding and differentiation of extrinsic precursors. Interestingly, it was found that several short periodic waves of lymphoid precursors enter the thymus, whereas a single long wave of precursors enter and colonize the bursa.[127] These studies showed that the tissue rudiments exhibited limited times of receptivity for emigrating hematopoietic cells and suggested the emergence of progenitors at several discrete developmental times.

Similarly, the ontogeny of the multilineage hematopoietic system was examined in embryo grafting experiments in which yolk sac chimeras were made (reviewed in ref. 1 and references therein) (Fig. 1.3A). The sites of de novo hematopoietic cell emergence were determined to be the yolk sac and the intraembryonic region containing the dorsal aorta. Only very briefly in early stages of embryogenesis do yolk sac–born erythrocytes predominate in the blood. Subsequently, intrabody-born erythrocytes rapidly predominate and red cells from the yolk sac disappear completely by the hatching stage. At least two generations of hemoglobin-producing cells were observed: the first from yolk sac–derived cells and the second from yolk sac– and intrabody-derived cells. During embryonic stages a small number of intrabody-derived cells can be found in the yolk sac and likewise, a small number of yolk sac–derived macrophage-like (microglial) cells can be found intraembryonically in the eye and in the brain. These cellular exchanges are thought to occur through the circulation of small populations or subsets of hematopoietic cells that

may serve a specialized, short-lived function. In the adult, the originating source of adult blood was confirmed to be the intrabody region. When the prevascularized quail allantoic bud was grafted in the coelom of a chick host, cells of both the hematopoietic and endothelial lineages were found in the bone marrow of the host.[36] Thus, the bone marrow is seeded by hematopoietic and endothelial precursors that arise in situ in the allantois. Hence, the allantois- as well as the paraaortic-derived cells of the avian embryo migrate and seed the adult blood system.

Amphibians

Waves of colonization are also observed in the amphibian model system. Embryo grafting experiments show that the larval liver is colonized by intrabody-derived hematopoietic cells.[128] The liver is thought to be seeded by intrabody cells that migrate through the interstitium because intrabody cells are not found in the circulation. Interstitial migration of cells is an efficient means of cell distribution within the amphibian embryo body and has been found to occur even before the completion of the vascular network.[50] Support for interstitial migration has been provided recently in the zebrafish. $CD41^{+}$ hematopoietic cells in the interstitium enter the circulation by intravasation via the posterior cardinal veins.[129] In later stages of amphibian development, near the time of metamorphosis, intrabody-derived hematopoietic clones fluctuate in their contribution to the liver and some ventral blood island–derived clones are detected[128,130] but do not become the predominant cell type.

Mammals

In contrast to the ease of in vitro culture and manipulation of amphibian and avian embryos for the analysis of hematopoietic cell migration and colonization, the in utero inaccessibility of the mouse conceptus necessitates the use of other approaches for these studies. Some of the first experiments probing hematopoietic migration and colonization involved culturing whole E7 mouse embryo bodies in the presence or absence of the yolk sac.[69] After 2 days, tissues were dissected and analyzed for granulocyte–macrophage colony formation. Only embryo bodies that retained their yolk sac were able to give rise to hematopoietic cells, suggesting that the yolk sac is the only embryonic site producing hematopoietic cells that colonize the liver rudiment. This experiment, as well as those examining the kinetics of CFC production in the yolk sac and fetal liver, suggests a dependence of early fetal hepatic hematopoiesis on an influx of exogenous yolk sac–derived cells.[69,80,99] Other researchers have demonstrated that at late E9 fetal liver is populated by yolk sac–derived erythroid cells when these tissues are cultured adjacent to each other.[131] Recently, studies in mouse conceptuses deficient for *Cdh5* and *Ncx1* genes suggest migration of yolk sac–derived myeloid progenitors to the embryo body.[102,103] In the absence of a vascular connection or heartbeat to promote the circulation, myeloid progenitors of all types were found in the yolk sac but not the embryo body. This suggests that the yolk sac normally generates all of these myeloid progenitors and distributes them to the PAS/AGM and liver. It is possible, however, that the PAS/AGM requires the normal stimulus of hemodynamic stress present in the wild-type conditions to generate these progenitors. Moreover, these experiments are limited to analysis of only very early tissues, and thus cannot take into account the multiple waves of hematopoietic cell generation and migration seen in the nonvertebrate species, particularly those that give rise to the adult hematopoietic system.

Spatial and temporal quantitative analyses for CFU-C, CFU-S, and HSCs in the mouse conceptus provide strong support for migration of AGM, yolk sac, and placental-derived cells to the fetal liver.[39,54,58,75] Data on B lymphopoiesis in the mouse conceptus suggest migration of these cells to the fetal liver through the circulation.[95] The spleen and thymus are seeded either directly from the generating tissues or from the fetal liver.[132,133] As found in avian embryos, the early classes of mouse hematopoietic cells (those defined by hematopoietic activity less potent than an HSC's and with limited life span) may provide maturation signals to the rudiments of the secondary hematopoietic territories in the mouse to promote their growth and receptivity for the later generated HSCs.[134,135]

There is convincing evidence that integrins play an important role in the embryo in the colonization of secondary hematopoietic territories. Mouse embryos lacking β_1-integrin die during preimplantation stages of gestation.[70] Chimeric embryos with β_1-integrin$^{-/-}$ ESCs were generated to examine its role during later stages of hematopoietic ontogeny.[71] Although the yolk sac was found to contain normal numbers of hematopoietic cells derived from the β_1-integrin$^{-/-}$ ESCs, the fetal liver did not contain any β_1-integrin–deficient hematopoietic cells. The clonogenic potential of the yolk sac hematopoietic cells was normal, and such cells were found in the circulation of embryos until E15. These results strongly suggest that β_1-integrin is required for the successful migration of hematopoietic cells to the fetal liver. Additionally, and in accordance with a role for β_1-integrin in adult hematopoietic cell migration, no β_1-integrin–deficient hematopoietic cells were found in the thymus, bone marrow, or blood of adult chimeric mice.

To trace the lineage of cells in the mouse conceptus that give rise to the permanent hematopoietic system in the adult, molecular marking using the Cre-lox recombination system[136] has been attempted. This in vivo marking technology is based on the expression of a marker transgene (*Rosa 26* locus inserted fluorescent or enzymatic gene) that is activated through the excision of a stop sequence positioned between two lox recombination sites. Cre recombinase performs the recombination event in specific cells depending on transcriptional regulatory elements

driving its expression and the activity of Cre recombinase (Cre-ERT), which can be controlled in a temporal manner by administration of tamoxifen. Thus, hematopoietic cells can be marked within a specific window of developmental time and the progeny of these marked cells can be followed through later fetal and adult stages. When the SCL (expressed in endothelial cells and definitive HSCs[118]) and Runx1 (expressed in all definitive hematopoietic cells, hemogenic endothelium, and some mesenchymal cells[117]) regulatory elements were used to direct Cre-ERT expression and early and midgestation mouse conceptuses were exposed to tamoxifen, approximately 10% of the bone marrow cells in the adult expressed the marker.[137,138] These results indicate that the progeny of SCL- and Runx1-expressing cells in the mouse conceptus migrate to the adult bone marrow and contribute to adult hematopoiesis. Thus, the progeny of hematopoietic cells generated in the embryo (tissue origin as yet unknown) migrate to the bone marrow where they reside and contribute to hematopoiesis through adult life.

Molecular Aspects of Embryonic (Primitive) and Adult (Definitive) Hematopoiesis

Molecular interactions regulate the generation of the hematopoietic system. Some of these interactions include developmental signaling pathways, transcription factors, and chromatin remodeling factors. Induction events are orchestrated by the signaling pathways that "turn on or off" transcription factors that regulate the expression of specific panels of genes (genetic programs) associated with hematopoietic fate and function. Moreover, the genetic programs are controlled by a limited number of epigenetic regulators (chromatin modifiers) that confer a "cell-specific molecular memory" and thus maintain the hematopoietic fate of the cell. The microenvironments in the mouse conceptus where hematopoietic cells are generated (yolk sac, PAS/AGM, and chorioallantoic placenta) differ from each other and from the secondary hematopoietic territories (fetal liver and adult bone marrow) that promote maintenance, self-renewal, and/or differentiation of hematopoietic progenitor and stem cells. Thus, beginning with the cell extrinsic influences of morphogens and factors emanating from the surrounding cellular environment, developmental signaling pathways are triggered and activate distinct but overlapping genetic (and epigenetic) programs to direct hematopoietic development in the mouse conceptus.

Our understanding of the molecular programming of the hematopoietic system throughout ontogeny has been profoundly influenced by the use of gene-targeting technologies in mouse ESCs.[139] The ability to generate mice with mutations in any chosen gene has resulted in the identification of numerous signaling pathways, transcription factors and epigenetic regulators that are critical for the development of the hematopoietic system. The most striking hematopoietic defects found are genetic mutations that affect both primitive and definitive hematopoiesis and mutations that profoundly affect definitive but not primitive hematopoiesis. Because the deletion of some hematopoietic genes results in anemia and early embryonic lethality, study of the affects of such genes at the later developmental stages is facilitated by chimeric mouse generation with homozygous mutant ESCs and also conditional gene targeting strategies.

Functional differences in the cells that make up the primitive (embryonic) and definitive (adult) hematopoietic systems predicted differences in molecular programming through development. Prime examples include the developmental regulation of the globin genes (α and β)[83] in primitive and definitive erythroid cells and the T- and B-cell receptor genes (Vγ3-Vγ4 and B1a, respectively) in fetal lymphoid cells.[96,97] These programs are regulated at the level of the HSC and thus suggest distinct developmental subsets of HSCs (dependent on the stem cell source and/or local microenvironment). Genes involved in hematopoietic specification also may be developmentally regulated in mesodermal cells as they emerge from the primitive streak and move to the extraembryonic yolk sac (ventral mesoderm) and intraembryonic PAS/AGM (lateral mesoderm). Thus, the genetic programs leading to hematopoietic specification overlap to a large degree but also possess unique features related to hematopoietic potential, function, site, and life span.

This section and Table 1.2 summarize some of the signaling pathways, transcription factors, and epigenetic factors that most affect the development of the embryonic and adult hematopoietic systems.

Signaling Pathways

Hematopoietic specification occurs shortly following the onset of mesoderm formation. The effects of various factors of the TGFβ_1 superfamily and FGF family of genes in mesoderm and blood formation[13,140] have been revealed in the Xenopus embryo model. The TGFβ_1 superfamily member, BMP-4, acts as a ventralizing molecule within the mesoderm (the region known to form hematopoietic cells). BMP-4 also induces the expression of *Mix.1*, a gene that has been shown to induce hematopoiesis in the Xenopus animal cap assay.[53,141] Interestingly, the three blood compartments (aVBI, pVBI, and DLP) are specified from mesoderm that encounters different concentrations of BMP-4[142] and the timing of expression of pivotal hematopoietic transcription factors (SCL, LMO2, and Runx1) is controlled by FGF.[143]

Similar to the interactions between endoderm and prospective hematopoietic mesoderm in Xenopus, such interactions are also necessary for hemogenic induction in the chick embryo. Blood island generation occurs only when the mesothelial and endoderm germ layers are cultured together – when cultured separately no primitive erythroblasts form.[20,21,144] Somitic mesoderm, which normally only contributes to endothelium in the dorsal aspect of

Table 1.2. Molecules involved in early mouse hematopoietic development

Class	Gene	Phenotype	Reference
Developmental growth factor/signaling pathway	TGFβ_1	Lethal at E9.5–11.5, defects in hematopoiesis and vascular network formation	149
	BMP-4	Lethal at gastrula stage, no mesodermal differentiation. Later embryonic lethal, decreased yolk sac (YS) mesoderm formation and decreased erythropoiesis. Expressed in cells underlying aortic hematopoietic clusters	122, 148, 152
	Flk-1/VEGF	Lethal at E8.5–9.5, defective in YS blood island and vessel formation, severe decrease in YS progenitor cell number and no definitive hematopoiesis	27, 154, 155
	Notch1	Conceptuses die at E10, almost normal numbers of YS primitive erythroid and erythroid–myeloid progenitors, but no AGM hematopoiesis or HSCs. Notch1 and Delta-like 4, and Jagged 1 and 2 expressed in aortic endothelium	157, 158
	c-kit/SF	Severe mutants lethal at E16, deficiencies in hematopoietic cells, CFU-S, primordial germ cells and melanocytes	88, 161, 162
Transcription factor	SCL	Lethal at E9.5, deficient in primitive and definitive hematopoiesis and defective in angiogenesis	165, 169
	GATA-2	Lethal at E10.5, severe FL anemia. Relatively normal YS hematopoiesis but decreased CFU-C. No AGM HSCs or aortic clusters	115, 116, 178
	Runx1	Lethal at E12, complete absence of definitive progenitors and HSCs and aortic clusters. Primitive hematopoiesis relatively normal	65, 66, 67, 117, 181
Epigenetic factor	Mel-18,	Enhanced HSC self-renewal	190
	Mph1/Rae28	Embryonic lethal due to insufficient hematopoiesis	191
	Bmi-1	Self-renewal defect in FL HSCs	192
	Mll	Complete lack of definitive hematopoiesis in the conceptus and early embryonic lethality	195

the dorsal aorta and not to the ventral endothelium or hematopoietic clusters, can be reprogrammed to assume the latter fates following transient exposure to endoderm prior to grafting.[21] Several signaling molecules, including vascular endothelial growth factor (VEGF), basic (b)FGF, and TGFβ_1 could substitute for this endodermal signal[21] and the overexpression of BMP-4 has been found to influence mesodermal subtype formation.[145] Thus, graded expression patterns of factors specify unique subsets of mesoderm including the presumptive hematopoietic mesoderm.[14]

Studies in the mouse conceptus also show that contact with visceral endoderm is necessary for primitive hematopoiesis in yolk sac explants. Exposure of prospective neurectoderm to endoderm or heparin–acrylic beads soaked in Indian Hedgehog (Ihh) could respecify this normally nonhematopoietic tissue to hematopoietic fate.[22,23] Ihh is normally produced by the visceral endoderm, and this expression pattern, together with the explant data, suggests that Ihh signaling is essential for primitive erythropoiesis. Ihh signaling is essential for hematopoiesis in the zebra fish equivalent of the AGM and is at the beginning of a signaling cascade for blood cell formation in the dorsal aorta that includes the downstream effectors VEGF, Notch, GATA-2, and Runx1.[146] Although deletion of Ihh or its receptor Smoothened (Smo) in mice does not eliminate primitive erythropoiesis in the yolk sac, it does profoundly affect yolk sac vascularization[147] and may also affect the AGM region.

In the mouse VEGF/Flk-1, FGF, and TGFβ_1 (and family members) are generally thought of as ventralizing factors. ESC differentiation cultures and gene-targeting studies reveal a role for the VEGF/Flk-1 and TGFβ_1 signaling axes in vasculogenesis and hematopoiesis.[27,148] In the TGFβ_1 homozygous null condition, perinatal lethality occurs in 50% of the embryos between E9.5 and E11.5.[149] The initial differentiation of endothelial cells from mesoderm occurs, but there is no organization of these cells into a vascular network. Defects in yolk sac vasculogenesis and hematopoiesis appear to be responsible for embryonic death, although the severity of the endothelial and hematopoietic cell defects do not always correlate. TGFβ_1 signaling in the hematopoietic system suggests complex effects (indirect and/or redundant), because it is a member

of the large TGFβ_1 superfamily that interacts through an array of receptors and intracellular Smad proteins.[150]

Another TGFβ_1 family member, BMP-4, plays a role in early stages of mouse hematopoiesis. It induces the in vitro hematopoietic differentiation of ESCs.[151] Gene targeting supports a role for BMP-4 in specification of hematopoietic mesoderm. Mouse embryos deficient for BMP-4 usually die at the time of gastrulation with little or no mesodermal differentiation.[148] The few BMP-4–deficient embryos that do survive to slightly later ontogenic stages show profound decreases in mesoderm formation and erythropoiesis in the yolk sac, indicating a strict requirement for BMP-4 in the formation of the ventral-most mesoderm. BMP-4 can influence hematopoietic cell formation from the presumptive anterior head fold, normally a nonhematopoietic portion of the mouse epiblast.[17] When added to AGM explant cultures, BMP-4 increases the number of HSCs.[122] Interestingly, BMP-4 is localized in the mesenchyme underlying aortic clusters in the mouse[122] and human[152] embryo and thus appears to be an important effector in hematopoietic specification and growth. It controls the expression of some pivotal hematopoietic transcription factors such as SCL and GATA-1 (reviewed in ref. 153).

Mouse embryos deficient in the VEGF/Flk-1 signaling axis exhibit more severe and consistent defects than TGFβ_1-deficient embryos. All Flk-1–deficient embryos die between E8.5 and E9.5.[27] They are defective in the production of yolk sac blood islands and vessel formation, and the numbers of hematopoietic progenitors are dramatically reduced. A *LacZ* marker gene inserted in the *Flk-1* gene allowed tracking of endothelial and hematopoietic cell formation in embryos. Those embryos lacking functional Flk-1 expressed the *LacZ* marker appropriately in the developing mesoderm. However, these expressing cells accumulated in the amnion instead of the areas of blood island formation, suggesting the requirement for Flk-1 as early as the formation and/or migration of the yolk sac mesodermal cells. The gene for VEGF, the ligand of Flk-1, has also been mutated. The generation of chimeric embryos with VEGF $^{+/-}$ ESCs results in embryonic lethality at E11, defective vasculogenesis, and a substantially reduced number of yolk sac red blood cells.[154,155] VEGF can direct the in vitro differentiation of ESCs to both endothelial and hematopoietic lineages.[156] Flk-1 is expressed by presumptive hemangioblasts, as shown by ESC studies and analyses of early-stage mouse conceptuses in the posterior region of the primitive streak.[30,31,156]

Although gene targeting of all these signaling molecules results in defects in both primitive and definitive hematopoiesis, Notch1 signaling in the mouse conceptus has been found to be selectively important for AGM (adult definitive) but not yolk sac (primitive) hematopoiesis. Notch1-deficient mouse conceptuses die at E10 and contain almost normal numbers of yolk sac primitive erythroid and erythroid–myeloid progenitors, but have no AGM hematopoiesis or HSCs.[157] Notch1, Notch4, and their ligands Delta-like 4, Jagged 1, and Jagged 2 are expressed in endothelial cells lining the dorsal aorta.[158] Mutations that affect Notch signaling in zebra fish eliminate Runx1 expression and hematopoietic cluster formation in the AGM.[146,159] Overexpression of Runx1 in Notch signaling mutants in both zebrafish and mice restores AGM hematopoiesis.[159,160] Thus, Notch1 appears to be a unique and pivotal factor in the onset of AGM definitive hematopoiesis.

c-kit is a receptor tyrosine kinase closely related to Flk-1. Many natural mutations for c-kit, and its ligand, steel factor (SF), have been found in mice. W and Sl strains of mice, respectively, mutant for these genes,[161,162] exhibit deficiencies in hematopoiesis, primordial germ cells, and melanocytes. The most severe mutations result in embryonic lethality beginning at E16. Yolk sac primitive erythropoiesis is not affected, but definitive CFU-S progenitors and mast cells are absent. SF has been shown to act as a proliferative[88,163] or antiapoptotic[164] agent in hematopoietic progenitors and CFU-S. Thus, c-kit/SF signaling is required for normal definitive hematopoiesis and may play a role in clonogenicity of early hematopoietic progenitors or, as in primordial germ cells and melanocytes, play a role in definitive hematopoietic progenitor migration.

Transcription Factors

The SCL transcription factor (basic helix-loop-helix family) is known to play a pivotal role in the production of all hematopoietic cells in the embryo as shown by gene targeting in the mouse.[165–169] SCL$^{-/-}$ mouse conceptuses die at E9.0 of a complete absence of blood formation. Unlike TGFβ_1 and Flk-1, SCL is not required for all endothelial cell and vascular formation; yolk sac capillaries are initiated. Vitelline vessel formation, however, is blocked and subsequent angiogenesis in the yolk sac is defective. A transgenic rescue of the hematopoietic defects in SCL$^{-/-}$ embryos confirms that SCL is necessary for embryonic angiogenesis.[169] Interestingly, ectopic injection of RNA encoding the SCL hematopoietic transcription factor specifies normally nonhematopoietic pronephric mesoderm to become hematopoietic.[170] The graded expression of this hematopoietic transcription factor may initiate the normal spatial borders of hematopoiesis in the different mesodermally derived regions of the embryo. Differentiation studies using SCL$^{-/-}$ ESCs indicate that this factor is essential for hematopoietic differentiation and vascular remodeling, playing a role in the hematopoietic commitment of the hemangioblast.[171] Similarly gene-targeted deletion of the *LMO2* gene results in a phenotype identical to that of SCL$^{-/-}$ embryos.[172,173] It has been found that the LMO2 protein heterodimerizes with the SCL protein forming a transcriptional regulatory complex.[174,175]

GATA-2 is a member of GATA (DNA-binding motif) transcription factor family of genes. The GATA factors are highly conserved among all vertebrate species. Along with GATA-1 and GATA-3, studies in mammalian cell lines have

shown that GATA-2 plays a role in transcriptional regulation within the hematopoietic system.[176,177] Specifically, GATA-2 is thought to act in HSCs and progenitors, due to its specific expression pattern. Mice lacking the transcription factor GATA-2 suffer from slightly reduced primitive erythropoiesis and a complete lack of other committed progenitors and HSCs and die at E10.5.[178] GATA-2 is expressed in the aortic endothelium[116] and is thought to affect the expansion of the hemogenic population emerging from these cells.[115] Interestingly, GATA-2 haploinsufficiency profoundly decreases the number of AGM HSCs, but yolk sac HSCs are only slightly affected. The tissue differences suggest a developmental timing component in the requirement of HSCs for GATA-2, different tissue-specific interacting partners for GATA-2, and/or different downstream targets. Nonetheless, GATA-2 is strictly required for adult (definitive) hematopoiesis and is expendable for embryonic (primitive) erythropoiesis. GATA-2 is thought to work together with SCL and the Ets transcription factor Fli-1 in recursive gene regulatory circuit in early mouse hematopoietic development.[179,180]

The *CBF* transcription factor genes are the most frequent targets of chromosomal rearrangements in human leukemias and were thus suggested to function in the hematopoietic system. Runx1 (also called CBFα2 and AML-1) and $CBF\beta_1$ form a heterodimeric factor that interacts through Runx1 DNA-binding domain to bind the core enhancer motif present in a number of hematopoietic-specific genes. Targeted mutagenesis revealed that *Runx1* and $CBF\beta_1$ genes[66,67,181] are required for definitive but not primitive hematopoiesis – embryos present with a complete lack of definitive hematopoietic progenitors and HSCs, fetal liver anemia, and embryonic lethality occurring after E11.5.[66,67,182] Yolk sac vessels and primitive erythropoiesis appear normal in these embryos. *Runx1* appears to act at the level of proliferation, generation, or maintenance of definitive hematopoietic progenitor and/or stem cells. Insertion of a *LacZ* maker gene into the *Runx1* locus[65] shows Runx1 expression ventrally in the mesenchyme, endothelium, and hematopoietic clusters of the dorsal aorta,[65,117] confirming a role in the establishment of the first adult-type HSCs.

Haploinsufficiency of *Runx1* leads to an early increase in AGM HSCs when these are directly isolated from the embryo and transplanted into irradiated adult mice.[65,117,182,183] When hematopoietic tissues of $Runx1^{+/-}$ conceptuses are first cultured as explants and then transplanted, they display interesting differential responses to *Runx1* haploinsufficiency. HSCs were profoundly decreased in AGM explants but were increased in both yolk sac and placenta, suggesting that different regulatory networks, downstream targets, interacting molecules, or altered developmental timing are operative in these tissues.[183] The Ets family transcription factor, PU.1, which is required for definitive hematopoiesis, is a critical downstream target of Runx1.[184] Also, studies have shown that the hematopoietic cytokine gene *IL-3* is a target of Runx1 and that IL-3 affects AGM HSC numbers.[183] As a pivotal factor in HSC ontogeny, transcriptional regulation of Runx1 requires the recruitment of a SCL/LMO2/Ldb-1 complex to its intronic enhancer sequence. This enhancer targets all definitive HSCs in the mouse embryo, suggesting that it integrates the other major hematopoietic transcriptional networks to initiate HSC generation.[179]

Thus, an understanding of how the master regulators are controlled and fine-tuned with respect to their levels in different hematopoietic subpopulations and sites will provide insight into the genetic network that governs hematopoietic emergence in the conceptus. By analogy to the ESC program,[185] it may be possible to establish hematopoietic identity in nonhematopoietic cells with just a small set of factors (Runx1, GATA, Ets, and SCL).

Epigenetic Factors

Lineage-specific gene expression programs are not only controlled at the level of transcription factor recruitment, but are coordinated and maintained in an active or repressed state of expression through the involvement of chromatin modifiers.[186] Cellular memory enables cells to maintain a specific lineage fate over many cell divisions and involves epigenetic modifications that include DNA methylation and histone acetylation. Groups of proteins called the polycomb group (PcG) and trithorax group (trxG) proteins, recruit histone deacetylases and methyltransferases and are well conserved in evolution in many different species. PcG proteins are transcriptional repressors and trxG proteins are transcriptional activators during development. These proteins associate with chromatin at specific loci but their core proteins do not bind DNA. The importance of PcG protein in development was recognized through their role in maintaining a silent state of *Hox* gene expression.[187] *Hox* genes are known to be important in the hematopoietic system. When *Hox* genes are overexpressed in HSCs, they proliferate extensively, increasing their pool size.[188] Although PcG proteins are involved in many loci in a variety of stem cells, most studies investigating the role of PcG and trxG proteins in HSCs focus on fetal liver and adult bone marrow–derived HSCs.

The PcG protein Ezh2 is found in a complex with histone deacetylases. Ezh2, together with Eed protein, also binds DNA methyltransferases.[187] These complexes are thought to be involved in the initiation of gene repression and act functionally to preserve HSC quality and prevent HSC exhaustion after trauma.[189] Several other PcG proteins affecting HSC self-renewal are thought to maintain gene repression. These include Mel-18, Mph1/Rae28, and Bmi-1.[190–192] Homozygous deficiency of Mel-18 leads to enhanced HSC self-renewal; Mph1/Rae28 deficiency is embryonic lethal due to insufficient hematopoiesis during development; and Bmi1-deficient fetal liver HSCs are impaired in self-renewal.

An example of a trxG protein involved in hematopoiesis is the *Mll* gene. MLL1 is a histone methyltransferase.[193,194] It is misexpressed following chromosomal translocation in acute leukemias. Moreover, gene targeting of *Mll1* in the mouse results in a complete lack of definitive hematopoiesis in the conceptus and early embryonic lethality.[195] Thus, the control of HSC self-renewal by PcG and trxG proteins supports a role for epigenetic modifications in the homeostasis of the hematopoietic system as it is initiated in the mouse conceptus, and such mechanisms most likely play a role in the initiation and maintenance of some leukemias.

IMPLICATIONS OF EMBRYONIC HEMATOPOIESIS FOR POTENTIAL CLINICAL APPLICATION IN HUMAN BLOOD-RELATED THERAPIES

Significant progress continues to be made in the field of developmental hematopoiesis. The previous dogma concerning the origins of the adult mammalian hematopoietic system in the yolk sac has given way to a new understanding of multiple and independent sites of hematopoietic generation in the early- and midgestation conceptus. The initiation of the first multipotential hematopoietic progenitors and adult-type HSCs is now known to occur in the intraembryonic PAS/AGM. The placenta has been shown to be a potent generator of hematopoietic cells, and perhaps other yet untested embryonic tissues may also possess hematopoietic potential. The molecular programming within the variety of hematopoietic cells and embryonic compartments begins to reveal differences in developmental levels and timing of expression of pivotal hematopoietic transcription factors and the heritable genetic program that defines specific hematopoietic fate. The in vitro production of hematopoietic cells from factor-directed ESC differentiation cultures is improving due to knowledge obtained from results of molecular and cellular studies on the normal in vivo embryonic development of hematopoietic cells. Together with the long-anticipated direct precursor to hematopoietic cells, the hemangioblast, the rapid acceptance of hemogenic endothelium as the predominant precursor to definitive adult hematopoietic cells suggests a new strategy for hematopoietic cell production – one that would involve the isolation, expansion, and induction of hemogenic endothelium, perhaps from adult vasculature, to establish HSC fate. Through further knowledge of the cells and molecules that lead to the normal generation of the adult hematopoietic system, we can continue to improve medical strategies for the treatment of blood-related genetic diseases and leukemia.

Erythropoiesis

Sjaak Philipsen and William G. Wood

INTRODUCTION

Erythropoiesis involves the production of mature enucleated erythrocytes from committed erythroid progenitor cells, which in turn are derived from multilineage progenitors and ultimately from the hematopoietic stem cell (HSC). In human the mature erythrocytes turn over at a rate of approximately 1% per day and it can be estimated that maintaining the red blood cell count in an adult requires approximately 2.4×10^6 new erythrocytes to be produced each second. It is not surprising, therefore, that the regulation of erythropoiesis is a complex, multifaceted process that has to cope with not only maintaining the steady state but also with providing reserves to cope rapidly with increased demand as a result of physiological or pathological demands. In this chapter we will consider the developmental origins of red cell production, their differentiation from HSCs as well as production of the hormone erythropoietin. We will examine how erythropoietin responds to tissue hypoxia and exerts its effect through cell surface receptors on erythroid cells to trigger a number of cell signaling cascades to maintain, through critical transcription factors, the survival, proliferation, and maturation of the erythron.

ERYTHROPOIESIS DURING DEVELOPMENT

The first erythrocytes appearing during vertebrate development are known as primitive erythrocytes. These cells are produced by a transient first wave of hematopoiesis, which is almost entirely dedicated to the production of primitive red cells. Primitive erythropoiesis has been studied in evolutionary distant vertebrates, in particular in fish, amphibians, birds, and mammals. Despite the considerable anatomical differences between the developing embryos of these phyla, primitive erythropoiesis appears to be a remarkably conserved process allowing observations made in lower vertebrates to be extrapolated – with care – to mammals. The establishment of blood circulation is important to provide oxygen and nutrients to the developing embryo. Primitive erythrocytes are relatively large cells characterized by the expression of embryonic globins. In mammals, these are the only erythroid cells that retain their nucleus when they enter the circulation. Definitive hematopoiesis gives rise to all hematopoietic lineages and replenishes the hematopoietic compartment throughout the lifespan of the organism. In fish, amphibians, and birds the definitive erythrocytes remain nucleated. Mammalian definitive erythrocytes expel their nucleus before they enter the circulation. Definitive erythrocytes are smaller than primitive erythrocytes and express fetal/adult globins. We will now describe the main features of erythropoiesis in fish (zebrafish, *Danio rerio*), amphibians (African clawed frog, *Xenopus laevis*), birds (chicken, *Gallus gallus*) and mammals (mouse, *Mus musculus*, and human, *Homo sapiens*).

ZEBRAFISH (*Danio rerio*)

The zebrafish has become a popular model organism to study early vertebrate development in particular. Large numbers of fertilized eggs can be obtained easily. The eggs are transparent and development of the embryos can therefore be monitored without any interference. Development proceeds rapidly: from the fertilized egg to hatched fry takes only 72 hours. Large collections of mutants are available that have been generated through forward genetic screens, using insertional, radiation-induced and *N*-ethyl-*N*-nitrosourea–mediated mutagenesis.[1] Effective "knockdown" of specific proteins can be achieved by injecting antisense-modified oligonucleotides, known as morpholinos, into fertilized eggs.[2] The morpholinos are designed to bind to the translation initiation site or a splice junction of a particular RNA molecule, thereby preventing the synthesis of protein. With the zebrafish genome sequence at hand, one can thus perform a very quick functional analysis of any protein of interest. To distinguish the morpholino-injected fish from genetic mutants, they are called "morphants".[3] Complementary proteins can be overexpressed through the injection of RNA synthesized in vitro. Finally, fish transmitting transgenes through the germline can be obtained by injection of linearized plasmids, albeit with low efficiency.[4] Nevertheless, useful reporter strains have been generated in this way, for instance lines expressing green fluorescent protein in the endothelial cells of the vasculature[5] and in erythroid cells.[6,7] Such transgenic reporter fish provide easy visualization of mutants and morphants in which erythroid development is disturbed. From the forward genetic screens, approximately 25 complementation groups affecting blood formation have been identified.[10] These groups fall into categories ranging from defective HSC generation (e.g., the *cloche* mutant affecting an as yet unidentified gene[11]), arrested erythroid development (e.g., the *vlas tepes* mutant affecting the *GATA-1* gene[12]) to structural defects in erythrocytes (e.g., the *sauternes* mutant affecting the *alas2*

gene[13]) and the *retsina* mutant affecting the *band3* gene.[14] Often, mutations in the orthologous genes are associated with human hematological disorders, which has led to the notion that the zebrafish provides useful models for human diseases.[15]

SITES OF ERYTHROPOIESIS IN THE ZEBRAFISH

The first erythroid cells arise in an area known as the intermediate cell mass, first evident at 16 hours postfertilization. This structure is a derivative of the lateral plate mesoderm that first appears approximately 10 hours postfertilization, at the end of gastrulation and the start of somatogenesis. The first erythroid cells become visible at 22 hours postfertilization and enter the circulation at 24 hours postfertilization. The primitive erythroid cells express embryonic *α-like* and *β-like globin* genes.[16] Although the anatomical location of the intermediate cell mass is not obviously related to the extraembryonic location in the yolk sac of the primitive erythroid progenitors in mammals, the intermediate cell mass is derived from two paraxial stripes of mesoderm arising during gastrulation, a location analogous to the mammalian site. Similar to mammals, the first definitive hematopoietic cells appear in the ventral wall of the dorsal aorta, approximately 48 hours postfertilization.[17] These cells can be identified by the expression of transcription factors such as runx1 and myb.[18–20] setting them apart from the primitive erythroid cells, which can be identified by the expression of embryonic globins.[16] In the adult zebrafish, the kidney is the site of erythropoiesis. This is clearly different from the situation in mammals, in which the bone marrow is the main site of adult erythropoiesis. Possibly, the production of erythropoietin (Epo), the main hormone regulating erythropoiesis, in the mammalian kidney is a remnant of the erythropoietic function of this organ in their ancestors.[21]

ERYTHROPOIESIS IN *Xenopus*

There is a long tradition of using the African clawed frog *Xenopus laevis* as a model system to study vertebrate development.[22] *Xenopus* eggs are polarized, and unlike mammals, the cells in the early embryo are highly organized as a result of oriented cleavage planes.[23] Thus, lineage-tracing experiments can be performed in 32-cell stage embryos by injecting single blastomeres with a reporter, such as a fluorescent dye or in vitro synthesized RNA encoding β-galactosidase. This has been applied to demonstrate that primitive hematopoiesis and definitive hematopoiesis are derived from independent cell lineages.[24,25] *Xenopus laevis* has a tetraploid genome, which limits its use in genetic experiments due to the presence of a duplicate copy of each gene, which may or may not have identical functions. Its close relative *Xenopus tropicalis* has a diploid genome and is therefore increasingly used by developmental biologists.[26] The full scala of molecular tools can be applied to *Xenopus*, similar to zebrafish. An advantage of *Xenopus* is that morpholino-mediated knockdown and RNA-mediated protein overexpression can be targeted to single blastomeres at the 32-cell stage. In this way, gene function can be studied more specifically in the lineage giving rise to the tissue of interest, without interfering directly with the rest of the embryo. Primitive erythropoiesis in *Xenopus* occurs in structures known as ventral blood islands (VBIs), which can be further subdivided into anterior and posterior VBIs. VBIs are analogous to the mammalian yolk sac blood islands, although they are an integral part of the embryo. Anterior VBIs are derived from mesodermal cells originating from the C1 and D1 blastomeres, whereas posterior VBIs are derived from the D4 blastomere. Definitive hematopoietic cells are derived from a single blastomere, C3, which gives rise to a mesodermal structure known as the dorsal lateral plate.[24] The dorsal lateral plate serves as an intermediate structure; after extensive cell migration and tissue remodeling, the first definitive hematopoietic cells are observed as hematopoietic clusters closely associated with the ventral wall of the dorsal aorta.[25] Anatomically, the dorsal lateral plate is the equivalent of the paraaortic splanchnopleura in mammals.[27] Later in development and during adult life, the liver and spleen are the main sites of erythropoiesis; there is no evidence for hematopoietic activity in the bone marrow.[28] At all stages, erythroid cells of *Xenopus* remain nucleated.

ERYTHROID DEVELOPMENT IN THE CHICKEN (*Gallus gallus*)

Developing avian embryos are easily accessible and can be subjected to experimental manipulation in ovo. A particularly powerful procedure is the grafting of quail tissue in orthopic or ectopic locations in the chick embryo. Quail-derived cells can be traced later in the developing chimeric embryos with species-specific monoclonal antibodies.[29,30] The most extreme version of this grafting procedure is the replacement of the entire chick embryo by the quail embryo. Such experiments performed with embryos isolated before the onset of circulation revealed that definitive hematopoiesis arises intraembryonically, independent of the first wave of extraembryonic primitive hematopoiesis.[31] Thus, primitive erythrocytes are formed in the yolk sac blood islands from stem cells generated in situ. Definitive HSCs are born in the ventral side of the dorsal aorta. Furthermore, it has been demonstrated that the allantois, an endodermal and mesodermal embryonic appendage, is also a source of definitive HSCs.[32] The bone marrow is seeded with HSCs as soon as it is formed and is the location of erythropoiesis in the adult bird.[33,34] Like in the other model organisms, primitive chicken erythrocytes express embryonic globins, whereas definitive cells express adult-type globins.[35,36] Remarkably, definitive erythrocytes of birds remain nucleated, despite the high demand for

oxygen during flight. Possibly, the highly efficient respiratory system of birds alleviates the need for enucleated erythrocytes to support their high metabolic rate.

Although the chicken is a great experimental system to investigate early developmental processes, genetic approaches can only be applied to a very limited extent in this organism. The chicken has therefore not become a widely used model system to study erythropoiesis in vivo. Nevertheless, lineage-tracing studies combined with detailed morphological analyses are still expected to contribute significantly to the understanding of the ontogeny of vertebrate hematopoiesis.[37]

MAMMALIAN ERYTHROPOIESIS

The first erythroid cells appearing during mammalian development emerge in the extraembryonic location of the yolk sac (Fig. 2.1a,b). These cells are formed in close association with the endothelial lining of the emerging blood vessels, before the vasculature is connected to the embryo and the onset of blood circulation.[38] Once released in the bloodstream, the macrocytic primitive erythrocytes retain proliferative capacity and mitotic figures are observed in the circulating blood of early mammalian embryos (Fig. 2.1c).[39] Intravascular erythropoiesis is not normally observed at any other developmental stage; both fetal and adult erythrocytes are enucleated before they enter the circulation. The view has long been held that primitive erythrocytes remain nucleated and that they disappear from the circulation very quickly during the embryonic to fetal transition period. Until recently, the fate of these cells was a mystery, but more recent work has shown that the primitive cells in fact enucleate very efficiently between days 12.5 and 14.5 of mouse development, resulting in macrocytic, enucleated, erythrocytes.[40] At this stage, the first fetal liver-derived definitive erythrocytes appear in the circulation and their numbers increase rapidly (Fig. 2.1e–h). This has made it particularly difficult to trace the remaining primitive erythrocytes. The use of transgenes that specifically label the primitive cells with a green fluorescent reporter protein has demonstrated that the primitive cells are a stable population that persist through the end of gestation.[40] The primitive cells are characterized by the expression of embryonic globins (εy, βh1, and ζ in the mouse, ε, γ, and ζ in human) resulting in a variety of hemoglobin tetramers in man ($\zeta_2\varepsilon_2$ (Gower1); $\alpha_2\varepsilon_2$ (Gower2), $\zeta_2\gamma_2$ (Portland1) $\zeta_2\beta_2$ (Portland2)). Mice immediately switch to adult globins when definitive erythropoiesis starts in the fetal liver. Expression of a specific fetal β-like-globin (γ-globin) is a feature of anthropoid primates. Hemoglobin tetramers consisting of α- and γ-globin chains ($\alpha_2\gamma_2$) are known as fetal hemoglobin (HbF) in humans. These specialized hemoglobins allow the developing fetus to extract oxygen more efficiently from the maternal blood. Near the time of birth, the site of erythropoiesis switches to the bone marrow and the spleen. Humans rely mainly on the bone marrow for steady-state adult erythropoiesis, but in mice the spleen remains an important erythropoietic organ during adult life (Fig. 2.1k,l). Under stress conditions, for instance caused by low oxygen pressure or anemia, the spleen is used to expand the erythropoietic capacity in both species.[41] Fetal globin expression is silenced in adult erythropoiesis. Hemoglobin tetramers composed of α- and β-globin ($\alpha_2\beta_2$, HbA) account for approximately 97% of all hemoglobin in adult erythrocytes. HbA_2 ($\alpha_2\delta_2$) and HbF account, respectively, for approximately 2% and <1% of total hemoglobin in most adults. HbF is restricted to a few cells, termed F cells, in normal adults.[42] Clonal analysis has shown that F cells are derived from the same progenitor cells as the cells containing adult globin, which rules out that fetal and adult stem cell lineages coexist.[43] Some individuals maintain higher levels of HbF throughout adult life. This condition is known as hereditary persistence of fetal hemoglobin (HPFH) and is caused in the majority of cases by deletions in the β-*globin* locus, but also by point mutations in the γ-*globin* gene promoters.[44] In rare cases, the HPFH phenotype does not segregate with the β-*globin* locus, suggesting a *trans*-regulatory mechanism (see also Chapter 14). The HPFH condition is not clinically manifest, but it is a factor ameliorating the effects of β thalassemia and sickle cell disease. Reactivation of γ-*globin* expression in adults with these disorders is therefore a very attractive therapeutic approach, because the majority of patients will have normal *γ*-globin genes that they have switched off after birth. Despite the fact that mice do not have a fetal *β-like* globin gene, the γ-globin genes in human β-*globin* locus transgenes are expressed in the early fetal liver, and silenced later in development.[45,46] Furthermore, γ-*globin* transgenes with HPFH mutations in the promoter recreate the HPFH condition in mice.[47,48] The use of transgenic mice for the study of human globin gene regulation is described in detail in Chapter 5.

ERYTHROID DIFFERENTIATION

Erythroid cells are derived from HSCs but the path they follow is still a matter of debate (Fig. 2.2).[49] There is no evidence for direct feedback of committed progenitors to the HSC compartment since the number of stem and early progenitor cells is little affected by extreme fluctuations in numbers of end-stage cells of any of the lineages. This protects the stem cell compartment from depletion by differentiation. Indeed, lineage fate decisions may be a more stochastic process in which there are probabilities of outcome dictating differentiation among the various lineages while the fate of an individual cell remains undirected and unpredictable.[50] The interplay of the internal transcription program and epigenetic alterations (such as DNA methylation and chromatin modifications) on the one hand with the external environment (such as localized growth factor concentrations and cell–cell interactions) on the other is complex as discussed extensively in Chapter 1.

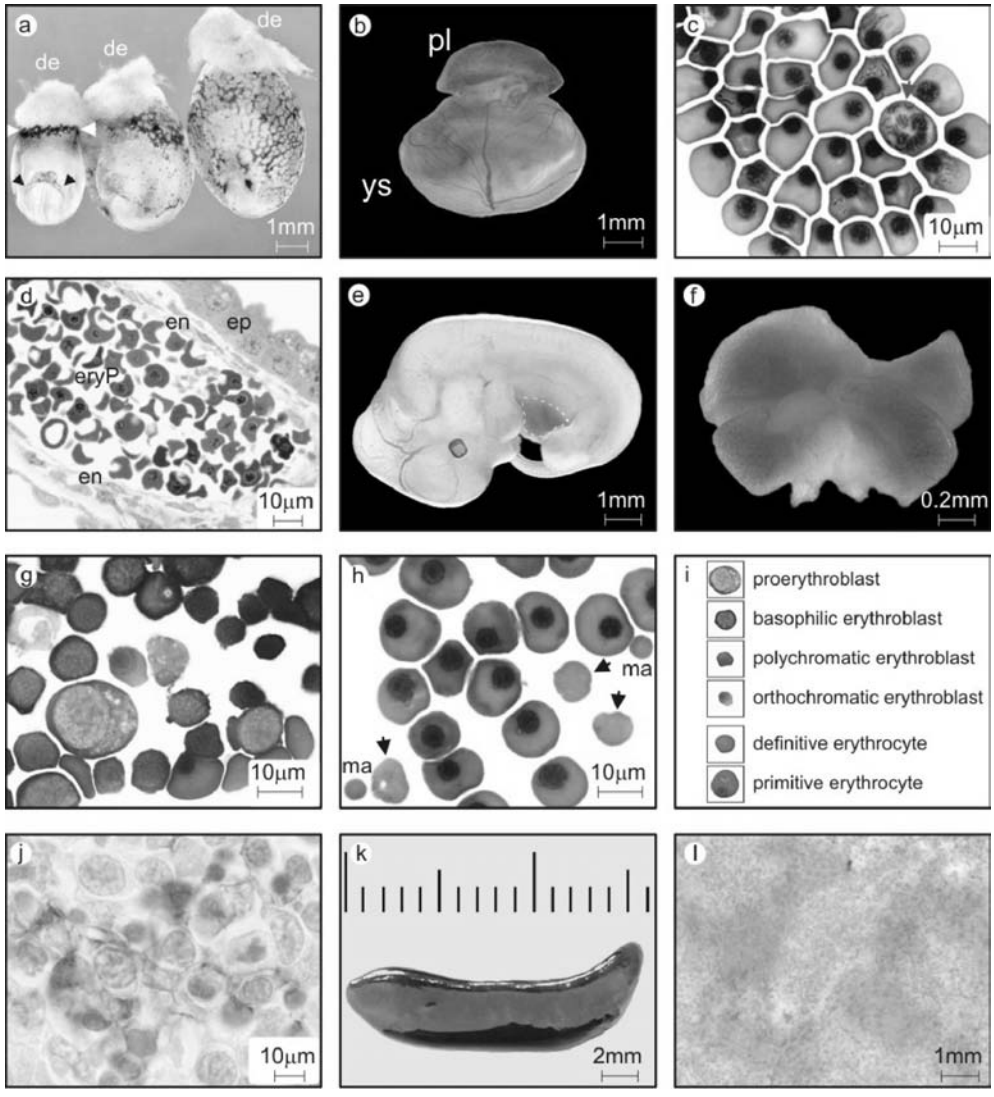

Figure 2.1. Erythropoiesis during mouse development. **(a)** E8.5 embryos, inside their yolk sacs, carrying a *LacZ* reporter gene driven by β*-globin* regulatory elements. Erythroid cells appear dark after staining for LacZ activity. White arrowheads point at the blood islands emerging as a ring at the top of the yolk sac. These are spreading through the developing vasculature, illustrated by the two embryos on the right that are progressively more advanced in development. The black arrowheads indicate the linear heart tube that already appears to contain erythroid cells before the yolk sac cells have reached the embryo. de = decidua, remaining maternal tissue. **(b)** E11.5 embryo inside its yolk sac. The blood-filled yolk sac vasculature is apparent. ys = yolk sac; pl = placenta. **(c)** Cytospin of E11.5 peripheral blood, stained with dianisidine and histological dyes.[207] Nuclei are dark, the hemoglobin-filled cytoplasm brown. Red arrow: cell in mitosis. **(d)** Section of a yolk sac vessel at E12.5, stained with toluidine/methylene blue. eryP = primitive erythrocytes; en = endothelial cells; ep = columnar epithelial cells. **(e)** E12.5 mouse embryo; the fetal liver area is indicated by a dotted line. **(f)** E12.5 fetal liver. **(g)** Cytospin of E12.5 fetal liver cells, stained as in (c). **(h)** Cytospin of E12.5 blood, stained as in (c). ma = contaminating maternal erythrocyte **(i)** key to (g) and (h). **(j)** Erythroblastic island in E13.5 fetal liver. The cytoplasmic extensions of the central macrophage (stained with the F4/80 antibody [brown]) are surrounding erythroid cells at various stages of differentiation. **(k)** Spleen of an adult mouse. **(l)** Section of adult mouse spleen stained as in (c). Red pulp, containing the erythroid cells, is stained brown; white pulp is stained blue. (See color plate 2.1.)

Early progenitors are capable of giving rise to multilineage colonies but whether there is a fixed order to cell fate decisions (i.e., at each stage a cell has limited choices) or whether there is greater plasticity to a cell's potential fates remains to be resolved. Among the models proposed, the one put forward by the Weissman group has been perhaps the most accepted (Fig. 2.2). It posits a decision between two fates at each step in differentiation, thereby gradually diminishing the lineage potential. The initial decision separates the lymphoid and myeloid lineages with commitment to either a common lymphoid progenitor (CLP) or a common myeloid progenitor (CMP). The CLP can give rise to either B or T lymphocytes whereas the fate of the CMP is to give rise to either of two bipotential cells,

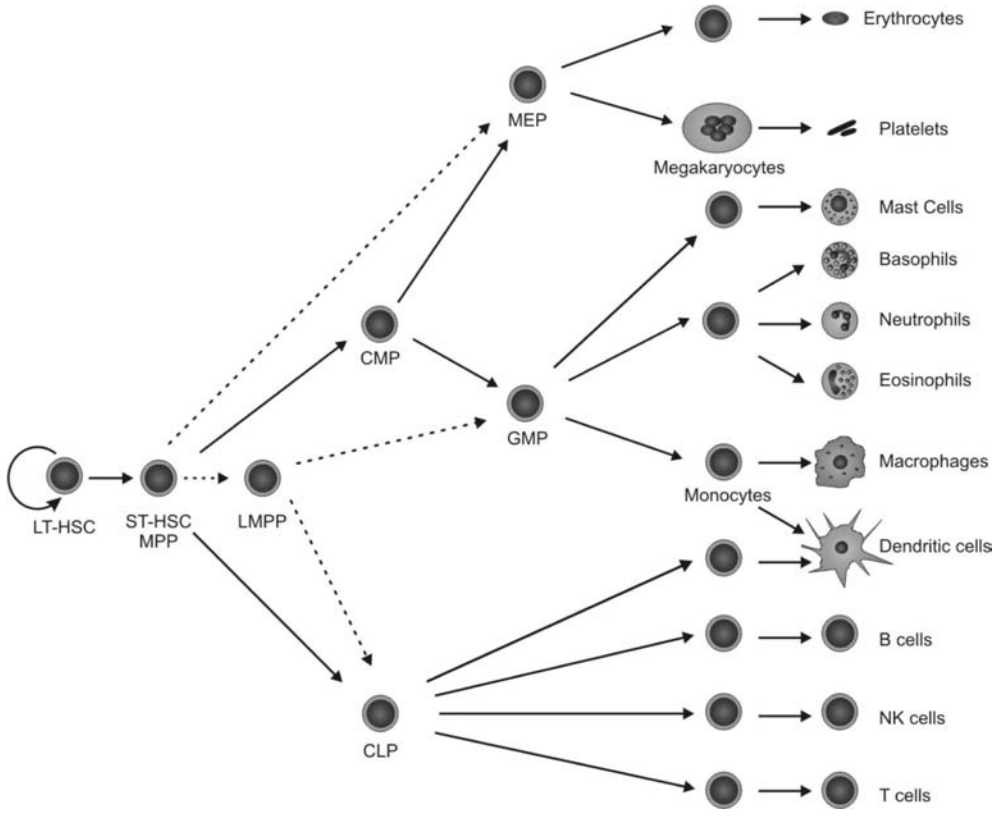

Figure 2.2. Possible pathways of hematopoietic differentiation from the HSC. In the scheme proposed by the Weissman group[51–53] (solid arrows), multipotential progenitors (MPP or short-term HSC [ST-HSC]) give rise to either a CLP or a CMP, which in turn gives rise to either a GMP (equivalent to CFU-GM) or an MEP. The scheme suggested by Adolfsson et al.[54] (dotted arrows) involves the generation of MEPs directly from the MPP/ST-HSC, whereas a LMPP has the potential to generate both CLPs and GMPs. These schemes are not necessarily exclusive and alternate schemes have been proposed (see text). LT-HSC = long-term HSC; NK cell = natural killer cell. Adapted from ref. 148.

the colony-forming unit (CFU)–granulocyte macrophage (GM) (ultimately producing macrophages or granulocytes) or the CFU-erythrocyte/megakaryocyte (E/Meg) leading to erythrocyte or megakaryocyte cells.[51–53] Alternate schemes have been proposed. Adolfsson et al.[54] first identified a highly proliferative lymphoid primed multipotent progenitor (LMPP) with GM potential but that was devoid of the ability to adopt erythroid or megakaryocytic lineage fates (Fig. 2.2). Transcription profiling confirmed a close relationship of early lymphoid and early GM precursors and Meg/E cells showed an early divergence and their own gene expression signature.[55,56] Cells expressing a *Gata-1* or *Pu.1* reporter gene have also been used to analyze early hemopoietic differentiation. *Gata-1* and *Pu.1* are mutually antagonistic, inhibiting each other's expression and transactivation domains and are believed to be critical in GM/lymphoid versus Meg/E lineage commitment. *Pu.1* is expressed in the HSC and upregulated expression of the *Pu.1* reporter was observed in progenitors that included granulocyte-macrophage–lymphoid progenitors (LMPP or GMLP) as well as CMPs. In contrast, cells marked by a *Gata-1* reporter gene gave rise to CMPs that could generate megakaryocyte–erythroid progenitors (MEPs) and granulocyte–macrophage progenitors (GMPs). These various schemes are discussed and compared by Ye and Graf[57] and Murre.[58]

Populations of cells corresponding to these progenitors can be purified by fluorescence-activated cell sorting (FACS) based on the expression of various cell surface markers, and the lineage output of these cells is determined by the phenotype of the colonies emerging from colony assays in the presence of growth factors. The results, therefore, are dependent on the cell surface markers chosen and on the assumption that the culture conditions are adequate to identify all lineage potentials of an individual cell. The differentiation schemes described previously demonstrate possible routes to terminal differentiation without precluding alternatives and need not represent the preferred route in vivo, as opposed to the in vitro route imposed by the experimental conditions. They are qualitative (or semiquantitative) assessments of the possible outputs, but to know what occurs in the in vivo processes would require a quantitative audit of stem and progenitor cell outputs that is beyond what is currently attainable.

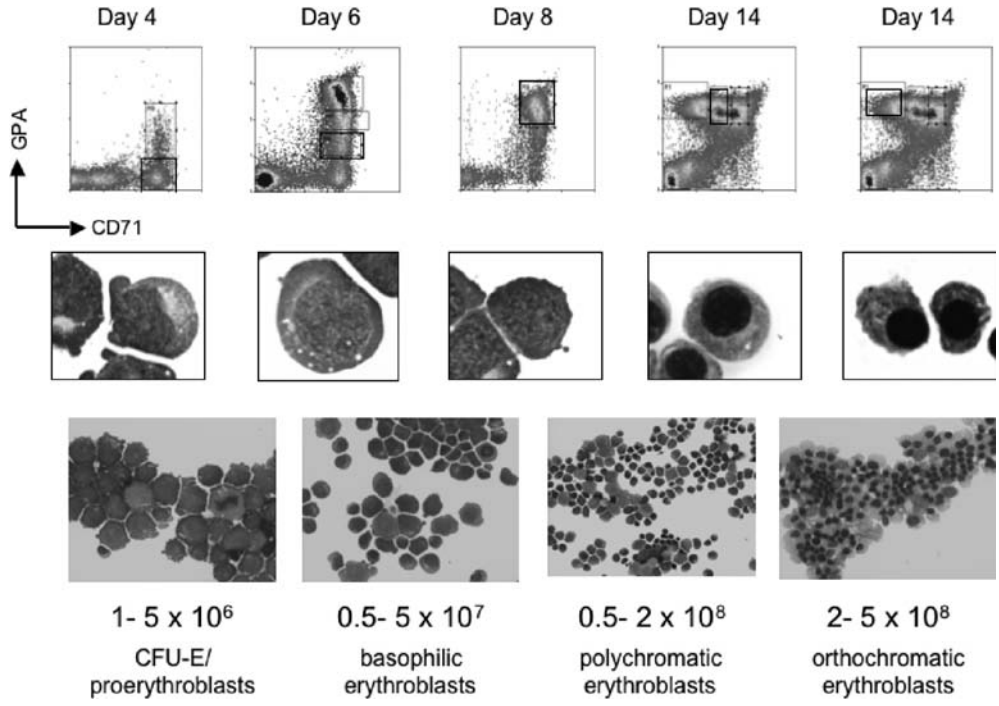

Figure 2.3. Purification of human erythroblasts. Top: FACS analysis of human erythroblasts grown in vitro by the method of Fibach et al;[61] days refers to the time in phase 2 of culture. Middle: High-power view of cells sorted from the gate shown as a bold rectangle in the plot above. Bottom: Low-power view of the same sorted cells, together with representative cell numbers obtainable from mononuclear cells from 1 U of blood. (See color plate 2.3.)

ERYTHROID PROGENITORS

The earliest erythroid progenitor identified is the burst-forming unit-erythroid (BFU-E), so called because of its appearance; the earliest progeny are motile, giving rise to a multisubunit colony (or burst). These appear as large colonies containing up to several thousand hemoglobinized cells after 5–8 (mouse) or 10–14 (human) days in methylcellulose cultures. Their growth is dependent on several growth factors of which stem cell factor ([SCF] also known as Steel factor or Kit ligand), thrombopoietin (Tpo), interleukin-3 (IL-3), IL-11, and Flt3 ligand are among the most important. They are not initially dependent on Epo, which may be withheld for a few days but then becomes essential to complete terminal differentiation to hemoglobinized cells. BFU-E occur at a frequency of 40–120/10^5 bone marrow cells and also circulate in the peripheral blood at a frequency of 10–40/10^5 light density mononuclear cells.[59]

The late erythroid progenitors, CFU-erythroid (CFU-E), consist of small colonies of 16– 125 cells that appear after 2–3 (mouse) or 5–8 (human) days in culture. They are approximately 5–8 times as abundant as BFU-E in bone marrow and, under normal circumstances, they do not appear in the circulation. The division of erythroid progenitors into BFU-Es and CFU-Es is useful, but somewhat arbitrary because it masks the fact that there is a continuum of progenitors from the earliest multisubunit BFU-Es to late BFU-Es (large single colonies) to the smallest colonies derived from late CFU-Es. As progenitors undergo this differentiation process their numbers increase, with their proliferative potential simultaneously decreasing.

LIQUID CULTURE OF ERYTHROID CELLS

After the development of semisolid cultures for the growth of BFU-E and CFU-E, a number of techniques have been described for the production of erythroblasts in liquid cultures.[60–62] The cells proliferate and differentiate in a one-phase or two-phase system and although culture conditions differ in each protocol, SCF, Epo, dexamethasone, and transferrin are commonly present, frequently supplemented by insulin or insulin-like growth factor–I (IGF-I). The starting material may be CD34 positive cells or mononuclear cells. Discarded buffy coat samples obtained from a blood bank may produce a total of up to 5×10^8 erythroblasts from 1 U with a purity of up to 90% (Fig. 2.3). The great advantage of these techniques is that they allow the production of large numbers of erythroblasts from peripheral blood samples, enabling functional analyses of normal or abnormal erythropoiesis without the need for bone marrow sampling. In addition, erythroid cultures can also be obtained using mouse or human embryonic stem cells as the starting material,[63–65] and there has been significant progress in development of culture techniques that enable large-scale production of fully matured human

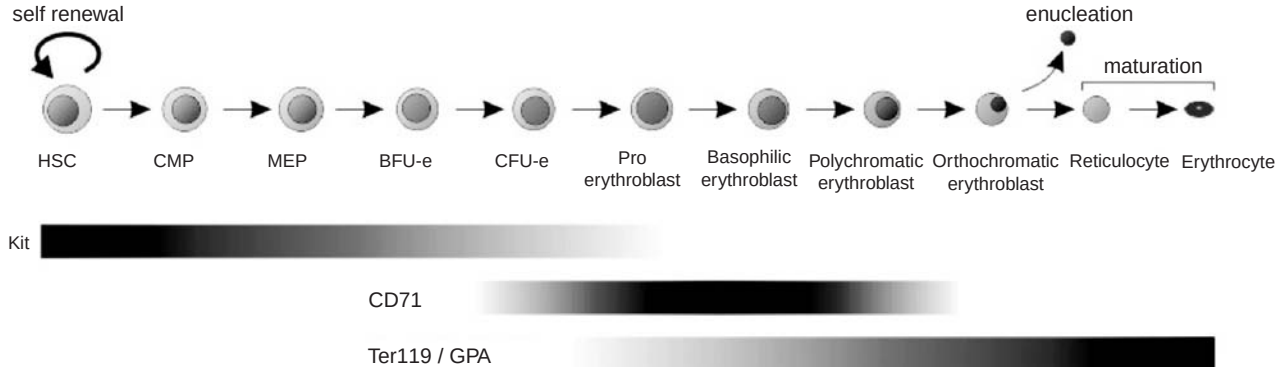

Figure 2.4. Schematic representation of the erythroid differentiation series in the mouse. The expression of the most commonly used cell surface markers to identify the various stages is indicated by the bars. Gray = low expression; black = high expression. Cells at the CFU-E and proerythroblast stages are the most sensitive to, and dependent on, the presence of Epo. We refer to Chapter 1 for a description of cell surface markers used to characterize the HSC compartment.

erythrocytes.[66,67] Although this raises the prospects of producing completely defined erythrocytes for transfusion purposes, it is prohibitively expensive and a daunting task to generate the vast numbers of cells required for clinical practice.[68]

ERYTHROID CELL PURIFICATION

Purification techniques for populations highly enriched for CFU-E/Megs have been described for both human[53] and murine[51] bone marrow, but purifying BFU-E alone has been less successful. CFU-E can be obtained as a pure population, either by physical techniques[69] or by FACS. CD36 positive cells with very high levels of CD71 (transferrin receptor) expression but negative for glycophorin A define the CFU-E population (Fig. 2.4). Low levels of glycophorin A appear at the proerythroblast stage and increase, reaching maximum fluorescence levels in basophilic erythroblasts. CD71 remains high throughout this phase but then declines as maturation proceeds, becoming undetectable in orthochromatic erythroblasts and reticulocytes, whereas glycophorin A levels are maintained. Thus, the stages of erythroid maturation from CFU-E onward can be analyzed, quantitated, and even sorted by this method. Because this results in a rather crude division of the differentiation stages, there remains the need for additional cell surface markers to define these in more detail.

REGULATION OF ERYTHROPOIESIS

It is clear that in hypoxia or anemia, increased output of red cells is strongly correlated with the levels of circulating Epo; however, the earliest erythroid progenitors are responsive to a number of hemopoietic cytokines including Tpo, GM-CSF, IL-3, and IL-11, and in particular to SCF. SCF binds to its receptor Kit, a tyrosine kinase that signals through several pathways including phosphoinositide-3 (PI-3) kinase, Src kinases, and phospholipase Cγ (see later), after dimerization and autophosphorylation. At later stages, SCF acts synergistically with Epo in the proliferation and expansion of the developing erythroid progenitors and may play a role in phosphorylating the EpoR itself.[70]

HYPOXIA SENSING

In response to reduced oxygen availability, the body responds in many ways, such as increasing Epo production, by altering the glycolytic pathway, and by inducing new blood vessel formation via the vascular endothelial growth factor and upregulating transferrin receptor levels. But how is hypoxia sensed and measured? Hypoxia response elements are found in many different genes, displaying a range of tissue-specific expression patterns. The elements are bound by a heterodimeric transcription factor 1 (HIF1), comprising HIF1-α (the regulatory partner) and HIF1-β (identical to the aryl hydrocarbon receptor translocator protein).[71] Under normoxic conditions, prolyl residues in HIF1-α become hydroxylated, targeting it for binding by the von Hippel–Lindau ubiquitin ligase complex.[72] This results in proteolytic destruction of HIF1-α by the proteasome. The hydroxylases responsible have an absolute requirement for dioxygen, thus linking their function to the availability of molecular oxygen.[73] Hypoxia, therefore, suppresses the hydroxylation allowing the assembly of a transcriptionally active HIF1 complex. In the kidney and liver, a cooperative interaction of HIF with hepatic nuclear factor-4, including recruitment of the coactivator CBP/p300, occurs in the 3′ end of the *Epo* gene, leading to a significant increase in transcription (Fig. 2.5).[74,75]

ERYTHROPOIETIN

A humoral factor controlling red cell production was first demonstrated in 1906, its source was shown to be the kidney, and the Epo protein was purified in 1977.[76] When the *Epo* gene was cloned, a hypoxia response element was

identified in the DNA at its 3′ end and it soon became clear that this element was not restricted to this gene but that a specific, sensitive hypoxia response was a general feature of mammalian cells.[77] Epo acts on its receptor to trigger several different signal transduction systems, which allow the survival, proliferation, and maturation of the erythroid cells.[78] In the absence of Epo, the cells rapidly undergo apoptosis and the antiapoptotic function of Epo is clearly an important facet of its action.[39] The main initial site of Epo production is the fetal liver, with production largely switching to the kidney shortly after birth. Under normoxic conditions, little or no Epo mRNA is detectable in the kidneys but hypoxia results in its accumulation within 30 min in the peritubular interstitial cells and levels can increase 200-fold over baseline.[79] Epo is a 166–amino acid, 34.4-kD glycoprotein found in serum at baseline levels of 1–30 mU/mL that can be elevated 1000-fold by severe anemia. It contains approximately 40% carbohydrate, rich in sialic acid residues, and has a half-life of 7–8 hours in plasma, whereas nonglycosylated Epo is cleared rapidly from the circulation.

The cloning of the *Epo* gene allowed expression of a recombinant human Epo in mammalian cells that could be harvested for clinical use. It immediately found therapeutic application in end-stage renal disease. Its use has now expanded to many neoplastic (hematological and nonhematological) conditions associated with anemia as an underlying condition or as a result of cytotoxic treatment. Modified forms of Epo, with a higher carbohydrate content and longer half-lives in vivo have been developed and approved for clinical usage, and small-molecule Epo mimetics with higher affinity for the EpoR are under investigation.[80,81]

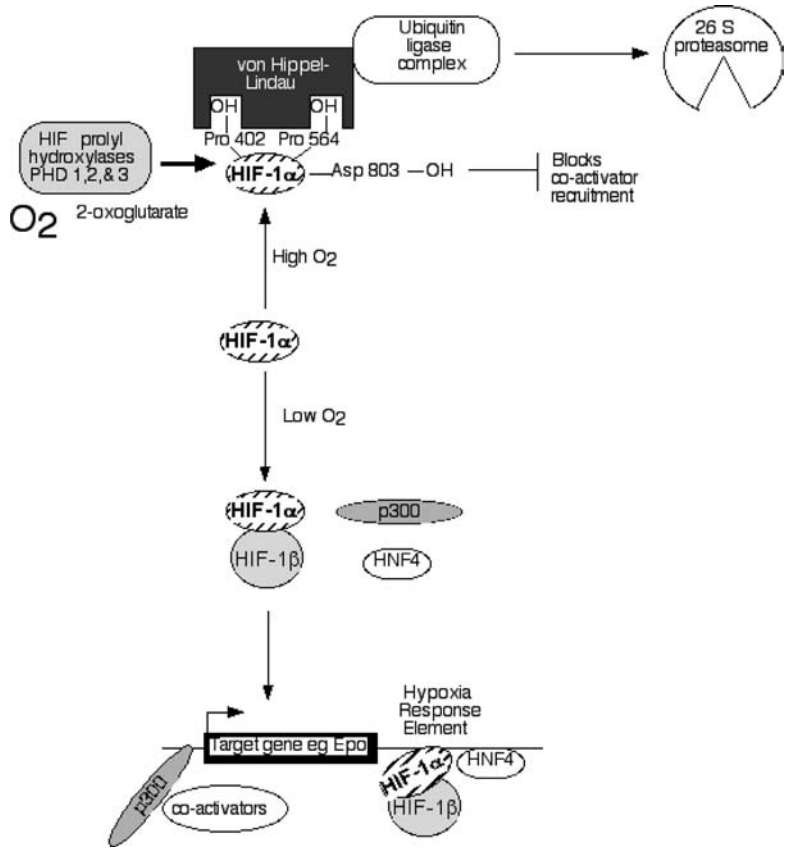

Figure 2.5. The regulation of *Epo* gene expression. The *Epo* gene is primarily regulated by HIF. The HIF1α subunit is highly unstable under normal or raised oxygen levels and is readily hydroxylated by the three HIF prolyl hydroxylases, PHD1-3, reactions which are directly dependent on oxygen. Hydroxylated HIF1α is rapidly destroyed by the proteasome after binding to the von Hippel–Lindau protein and ubiquitination. Under low oxygen conditions, HIF1α binds with the stable but limiting HIF1β subunit and translocates to hypoxia response elements in its target genes including, in the kidney, the *Epo* gene. In conjunction with other transcription factors and coactivators such as CBP/p300, gene expression is activated.

ERYTHROPOIETIN RECEPTOR AND CELL SIGNALING

Epo exerts its effects on erythroid cells via the EpoR. The low numbers (20–50) of EpoRs on BFU-E explain the relative Epo nonresponsiveness of these cells, and much higher levels (300–500) are found in CFU-E, proerythroblasts, and basophilic erythroblasts. The EpoR is a member of a cytokine receptor superfamily that includes growth hormone, prolactin, G-CSF, GM-CSF, and M-CSF receptors.[82] The 507–amino acid molecule contains an N-terminal extracellular domain consisting of a fibronectin type III repeat divided into two subdomains, each containing two cysteine residues that form an intradomain disulfide bond. A highly conserved WSXWS motif lies close to the transmembrane segment. The intracellular C-terminal end of the molecule contains eight tyrosine residues with potential for phosphorylation, associated with the binding of several proteins containing Src homology 2 (SH2) domains. Knock-in mice with a truncation of the final 108 amino acids of this domain, including seven of the Tyr residues (EpoR-H), as well as the same truncation plus a Y343F substitution (EpoR-HM), are viable and fertile with normal hematology.[83] Abnormalities in signaling under low Epo levels and under stress suggest that redundancy in signal transduction means that this part of the receptor is not essential for red cell production.[84,85] The EpoR exists in a nonliganded dimeric form which, on binding Epo, undergoes a conformational change bringing together the intracellular parts of the dimer (Fig. 2.6). Bound to the EpoR, close to the transmembrane region, is the tyrosine kinase Janus kinase 2 (JAK2). Increasing the proximity of the JAK2 molecules activates them to transphosphorylate each other and also to phosphorylate the tyrosine residues on the EpoR itself. This provides docking sites for signal transducers and activators of transcription proteins (STAT, principally STAT

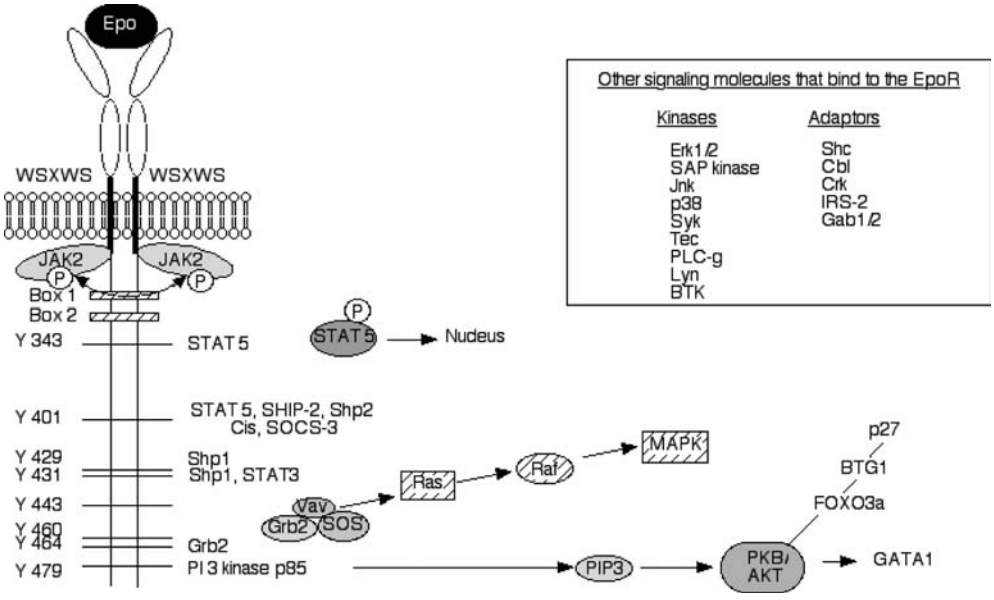

Figure 2.6. Schematic diagram of the Epo receptor showing some of the signal transduction pathways initiated when Epo binds. Multiple signals are transduced and many have been observed only in cell lines rather than in primary erythroblasts. The complexity and redundancy is demonstrated by the lack of an erythroid phenotype when many of the molecules are mutated or knocked out in mice. For a more detailed discussion see ref. 208.

5a and 5b in erythroid cells) to bind via their SH2 domains. They too become phosphorylated by JAK2 kinase, whereupon the STATs dimerize and move to the nucleus to stimulate gene transcription.

Phosphorylation of the EpoR allows the recruitment of other proteins containing SH2 domains to the receptor, including SHP1, SHP2, SHIP, PI-3 kinase, Lnk, PLC-γ, and suppressor of cytokine signaling, which contribute to alternative transduction pathways having effector or repressor effects on erythropoiesis. The Ras-mitogen-activated protein kinase and PI-3 kinase transduction pathways in particular appear to play important roles in erythroid cell production. Protein kinase B or AKT is a major downstream effector of PI-3 kinase–activated by Epo binding and is responsible for phosphorylation of a serine residue in GATA-1, a transcription factor necessary for maturation of the erythroid cells.[86,87] Germline mutations of some of these components suggest overlap or redundancy of function,[88] which makes the interpretation of results complex, and a phenotype may only be exposed under stress conditions or at early stages in development when erythropoiesis is maximal. Understanding the relative contributions of each pathway to red cell proliferation and maturation will be an important consideration of future research (Fig. 2.6). The effects of dysregulated signal transduction on red cell production are graphically illustrated by patients with mutations in the C-terminal inhibitory domain of the EpoR, causing erythrocytosis,[89,90] and patients with activating mutations in the JAK2 kinase, causing polycythemia vera.[91,92]

Epo signaling is negatively regulated by suppressor of cytokine signaling proteins and several phosphatases, including SHP1, SHP2, and protein tyrosine phosphatase 1B, which can modulate the activity of JAK2 kinase. Null mutants of some of these regulators may display increased numbers of erythroid progenitors or increased sensitivity to Epo levels, but a complete understanding of their regulatory roles awaits further analysis. Among the target genes of Epo stimulation, antiapoptotic genes have an important role. In particular, *Bcl-X$_L$* expression is markedly stimulated by Epo via STAT5, acting principally at the later stages of erythroid maturation.[93,94] Bcl-X$_L$ knockout mice die at approximately embryonic day 13 (E13), displaying apoptotic hematopoietic cells in the fetal liver.[95] Ablation of Bcl-X$_L$ in erythroid cells causes anemia in adult mice,[93,94] although it is still under debate whether Bcl-X$_L$ mediates the antiapoptotic effects of Epo.[93]

KNOCKOUT PHENOTYPES OF SIGNAL TRANSDUCTION MOLECULES INVOLVED IN ERYTHROPOIESIS

The central role of Epo and the EpoR in red cell production is emphasized by the similarity of the phenotypes of animals homozygous for their knockouts.[39,96] In both cases, there are reduced numbers of primitive erythrocytes but the embryos die at E12.5–13.5 due to a failure of definitive erythropoiesis. The fetal liver contains both BFU-E and CFU-E, in increased numbers in Epo$^{-/-}$ embryos, indicating that erythroid cells can develop to this stage without Epo signaling. The survival, proliferation, and terminal differentiation of these cells are dependent on Epo and the transduction of its signals. JAK2 knockout homozygotes die a day earlier than Epo and EpoR knockouts with fewer erythroid progenitors, suggesting that signaling via JAK2

operates earlier in erythropoiesis.[97,98] In contrast, mice deficient in STAT5a and 5b are viable, albeit with reduced numbers of early erythroblasts, particularly in fetal life in which erythropoiesis is maximal.[99] Bcl-x null mice die at day 13 with a neuronal and hemopoietic phenotype.[95] Mice with a conditional knockout of Bcl-x exhibited splenic erythroblastosis and severe anemia due to apoptosis of late-stage erythroblasts.[93,94] Day 14.5 mice deficient for the p85a subunit of PI-3 kinase are pale with a marked reduction of mature erythrocytes in their peripheral blood. Furthermore, the absolute number and frequency of both BFU-E and CFU-E are reduced in $p85^{-/-}$ fetal livers compared with wild-type controls, which is associated with reduced proliferation.[100] Complete deletion of the *SCF* gene or its receptor tyrosine kinase Kit results in death at E14–16 from severe anemia.[101]

OTHER HORMONAL INFLUENCES ON ERYTHROPOIESIS

A positive effect of androgenic steroids on erythropoiesis has long been recognized and used in the treatment of various disorders with red cell production failures, including renal disease before the introduction of recombinant Epo. Their activity includes increased Epo production in vivo[102,103] and increased numbers of BFU-E and CFU-E in vitro.[104,105] Glucocorticoids, such as dexamethasone, massively increase erythroid progenitor proliferation in cell culture systems from chick, mouse, and human hemopoietic cells.[60,106] Removal of dexamethasone is necessary to move from the proliferation stage to erythroblast maturation in some in vitro systems[107] but not others.[61] That thyroid disorders are frequently associated with anemia and modulation of erythropoiesis, particularly by triiodothyronine, is long established,[108,109] possibly acting through a receptor with β_2 adrenergic properties.[110] In proliferation/maturation systems, T_3 reduces proliferation, increases maturation, and may play a role in enucleation.[107] T_3 signaling through the nuclear receptor TRα is also essential for the transient spleen erythropoiesis in the mouse at birth.[111] Cortisol, estrogen, and progesterone do not promote erythropoiesis. The effects of insulin, IGF-I, and IGF-II, frequently included in in vitro systems, remain to be clarified.

STEADY-STATE ERYTHROPOIESIS

Erythrocytes represent the most common cell type in adult blood. Human blood contains approximately 5×10^6 erythrocytes/μL (normal range 4.7–6.1 $\times 10^6$ for males and 4.2–5.4 $\times 10^6$ for females); these cells have an average lifespan of 120 days. Erythroid cells at the terminal stages of differentiation have shed their nucleus, endoplasmic reticulum, and mitochondria, and consequently they are no longer able to proliferate. To maintain the red blood cell count in approximately 5 L of blood of an adult individual, approximately 2.4×10^6 new erythrocytes have to be produced each second. The new cells enter the circulation as reticulocytes that are still engaged in protein translation. In humans, it takes approximately 1 week for reticulocytes to complete the maturation process. In the bone marrow, a series of intermediate erythroid precursors can be recognized that progressively gain erythroid characteristics (Fig. 2.4). Development from the proerythroblast to the reticulocyte involves four–five rapid cell divisions, resulting in a progressive reduction in cell size. Mature erythrocytes have a diameter of only 6–8 μm. Their small size and biconcave shape create a large surface area for gas exchange and allow the cells to enter the microcapillaries in the tissues.

ERYTHROBLASTIC ISLANDS ARE THE STRUCTURAL UNITS OF DEFINITIVE ERYTHROPOIESIS

In the bone marrow, the structural unit where erythropoiesis takes place is termed the erythroblastic island.[112] It consists of a central macrophage (also known as the nurse cell) surrounded by differentiating erythroid progenitors. Erythroblastic islands are also found in the mouse fetal liver (Fig. 2.1j), but a role for an analogous structure has not been identified in yolk sac erythropoiesis. The fact that yolk sac cells enter the circulation while they are still nucleated, a process in which the macrophage plays an important role, supports the notion that primitive erythropoiesis does not take place in islands. Efficient enucleation of definitive cells can be observed in vitro in colony assays and bulk cultures of primary cells, in the absence of macrophages. Macrophages are formed during primitive hematopoiesis, and it will therefore require further investigation to determine the role of these cells in primitive erythropoiesis. A number of proteins on the surface of the macrophage and the erythroblasts mediate interactions between the macrophage and the erythroblasts, and between the erythroblasts themselves.

The erythroblast–macrophage protein ([EMP] or macrophage–erythroblast attacher [MAEA]) is expressed on both cell types and mediates adhesion between the cells. Maea knockout mice survive until birth, displaying defects in terminal erythroid maturation.[113] Formation of erythroblastic islands is impaired and Maea null macrophages appear to lack the extensive cytoplasmic extensions typical of mature macrophages. Maea null macrophages are unable to interact with wild-type erythroblasts. In contrast, Maea null erythroblasts can interact with wild-type macrophages, but this does not rescue the enucleation defect of these erythroblasts. In enucleating wild-type erythroblasts, Maea colocalizes with F-actin aggregates present at the constriction between the extruding nucleus and the reticulocyte. The actin cytoskeleton in Maea null erythroblasts is predominantly localized to the cell membrane, and very little cytoplasmic actin is observed. Maea-deficient macrophages display condensed, less organized actin filaments and are unable to efficiently develop long cytoplasmic extensions. Collectively, it can be

concluded that Maea is required for the organization of the erythroblastic island and for efficient enucleation of erythroblasts.

Maea is likely involved in the organization of the actin cytoskeleton in both macrophages and erythroblasts. Of note, disruption of F-actin bundles with cytochalasin D treatment inhibits enucleation.[114] Furthermore, ablation of paladin (Plld), a protein involved in the organization of the actin cytoskeleton, causes a dramatic reduction in the number of definitive fetal liver erythrocytes. Plld-deficient macrophages are unable to interact with erythroblasts,[115] providing evidence for autonomous macrophage-specific functions in the islands. This is further emphasized by studies of Dnase2a knockout mice. This lysosomal enzyme digests the large amounts of DNA taken up by the macrophages when they engulf the nuclei expelled from the erythroblasts. Dnase2a-deficient macrophages accumulate nuclear DNA from phagocytosed nuclei and appear to lose progressively the ability to support erythropoiesis. At E17.5, Dnase2a knockout fetuses are severely anemic, owing to the failure of definitive erythropoiesis, and no surviving newborn animals are found. Transplantation experiments demonstrated that Dnase2a$^{-/-}$ erythroid cells can develop to mature erythrocytes, supporting the notion that the primary defect is in the macrophage lineage.[116] Induction of interferon (IFN)-α expression in the affected macrophages appears to be the primary cause of the lethal anemia as breeding of the Dnase2a-deficient mice to mice deficient in the type I IFN receptor resulted in compound mutants that were born healthy.[117]

The role of other cell adhesion molecules and interactions with extracellular matrix proteins such as laminin and fibronectin is less clearly defined. Erythroblasts express α_4 (*Itga4*)/CD29/β_1 integrin (*Itgb1*), and the CD242 ([*Icam4*] LW blood group) counterreceptor. Macrophages express CD51 (α_v integrin, *Itgav*) and the vascular cell adhesion molecule 1 (Vcam1) counter receptor. Perturbation of the integrin system can adversely affect erythroblastic island formation[118] and stress erythropoiesis,[119] but the generic role of cell adhesion in tissue integrity and the considerable potential for redundancy precludes the assignment of specific functions to individual factors.

A role for signaling between erythroid cells in the island has been most convincingly demonstrated for death ligand–death receptor interactions. Erythroid cells express the CD95 (*Fas*) death receptor throughout differentiation. Only mature cells express the ligand CD95L (*Fasl*), but these cells are insensitive to Fas signaling. In contrast, immature cells activate proapoptotic proteases in response to Fasl exposure. The levels of the essential transcription factors Tal1 and Gata1 are reduced through cleavage by activated caspases, most notably by caspase 3 (Casp3).[120–122] This cleavage will stop progression along the erythroid differentiation pathway and may induce cell death. A decreased survival rate of erythroid progenitor cells is a hallmark of many acquired and hereditary anemias. Patients with rheumatoid arthritis develop anemia in approximately 50% of cases, and treatment with a blocking antibody directed against the death receptor ligand TNFα improved the anemia and decreased the elevated numbers of apoptotic erythroid progenitors in the bone marrow.[123] An increased rate of apoptosis is also observed in β thalassemia patients. This results in a phenomenon known as ineffective erythropoiesis.[123–126] Up to 80% of erythroid progenitors may be lost due to apoptosis occurring at the polychromatic erythroblast stage.[125] Precipitating α-globin chains may accelerate the apoptotic response.[126] The apoptotic erythroblasts are cleared very rapidly by macrophages. These cells are activated by increased IFNγ levels in approximately one-third of the patients,[127] and this may contribute to the quantitative differences in ineffective erythropoiesis between different patients. In normal erythropoiesis, expelled nuclei are also phagocytosed very rapidly by the central macrophages. Once released, the nuclei contain very low levels of adenosine triphosphate and start to expose phosphatidylserine on their surface very quickly because it requires energy to maintain phosphatidylserine exclusively localized to the inner leaflet of the cell membrane. Surface exposure of phosphatidylserine is an early event in apoptosis and serves as an “eat me” signal for apoptotic cells. This signal is also used for the engulfment of expelled nuclei by the macrophages.[128]

Mice overexpressing the Gata1 transcription factor in late erythroblasts have provided genetic evidence for the occurrence of signaling in the erythroblastic island. Pancellular overexpression of Gata1 causes impaired terminal differentiation, resulting in an embryonic lethal anemia; however, Gata1-overexpressing erythroid cells differentiate normally in vivo when wild-type cells are present, indicating that these cells produce a red cell differentiation signal (REDS) that rescues the defect in Gata1-overexpressing cells.[129] Genetic experiments, combining a tissue-specific Cre/loxP system and X inactivation, were used to produce mice in which half the erythroid cells overexpress Gata1 and half are Gata1 null. These embryos are anemic and die by E14, supporting a homotypic signaling mechanism in which mature erythroid cells produce REDS.[130] The REDS mechanism is reminiscent of the death receptor–death ligand interactions occurring in the erythroblastic island, but whether these are the same or parallel pathways remains to be proven; the large number of possible death receptor–death ligand combinations has not yet been exhaustively tested.[130]

STRESS ERYTHROPOIESIS

Under steady-state conditions, approximately 1% of the erythrocytes are cleared every day and replaced by new cells. Remarkably, the rate of erythropoiesis can increase very significantly from this base line level in response to hypoxia. Hypoxic stress occurs when adequate oxygen

supply to all tissues is compromised by insufficient numbers of functional erythrocytes. In a natural setting, this occurs when traveling from sea level to high altitudes. In the clinic, hypoxic stress is a major problem in the large variety of clinical conditions that have anemia as a hallmark. Increasing red cell production is the primary response to counteract hypoxic stress. Epo production in the kidneys is directly regulated by tissue oxygen tension through the activity of the hypoxia-inducible transcription factor complex, discussed earlier in this chapter. It is estimated that less then 10% of the EpoR molecules are liganded with Epo under normal conditions.[131] Because Epo levels may increase up to a 1,000-fold under conditions of severe tissue hypoxia,[77] increased occupancy of EpoR molecules appears to contribute directly to the higher erythropoietic rate. Although Epo is the main regulator of red cell production, other factors have an auxiliary role in the expansion of the erythroid progenitor compartment through their support of progenitor self-renewal. In particular, bone morphogenetic protein-4 ([Bmp4]/Smad5,[132] Stat5,[133] SCF (Kit ligand, Kitl)/Kit,[134] and the glucocorticoid receptor (GR)[135] are known to be involved. The analysis of mouse mutants has revealed distinct requirements for stress erythropoiesis, thus setting it apart from steady-state erythropoiesis. Mice with mutations in the intracellular domain of the EpoR, or expressing EpoR at a reduced level, display virtually normal steady-state erythropoiesis but have an impaired stress erythropoietic response.[83] EpoR signaling promotes erythropoiesis, but it also triggers events that counteract this activity. Mutations that affect this negative feedback loop may result in erythrocytosis. Hyperactive Jak2, the major cytoplasmic target of EpoR that activates multiple downstream pathways, causes polycythemia vera.[91,92] Mice lacking Lnk, a negative regulator of Jak2 activity, display increased numbers of erythroid progenitors and an enhanced response to erythropoietic stress.[136] Shifting the balance between the negative and positive effects of EpoR signaling may therefore be another factor contributing to the increased rate of erythropoiesis under hypoxic stress. The up to 100-fold increase in the numbers of BFU-Es and CFU-Es that occurs in the mouse spleen upon erythropoietic stress is due to the increase of a distinct type of BFU-Es that are unique to the spleen. Steady-state BFU-Es require, in addition to Epo, at least one other growth factor such as SCF. In contrast, high Epo levels alone suffice for stress BFU-E. Their formation is dependent on the Bmp4/Smad5 axis: *Flexed tail* mice, carrying a mutation in Smad5, have an inadequate stress response and are unable to form stress BFU-E.[132] The earlier observation that a GR-dependent progenitor is responsible for the stress response suggests that stress BFU-Es also require an intact GR.[135]

A decreased apoptotic rate of erythroid progenitors may also contribute to the increase in red cell production that occurs under erythropoietic stress. It is believed that under steady-state conditions up to 60% of proerythroblasts succumb to apoptosis in the mouse spleen.[137] Mice deficient for the Stat5 transcription factor, the major downstream signaling target of EpoR, have a blunted stress erythropoietic response. The erythroid progenitors have an increased rate of apoptosis attributed to their failure to upregulate expression of the antiapoptotic Bcl-X_L protein.[99,133] Furthermore, the Fas/Fasl death receptor–death ligand system has been proposed to regulate erythroid homeostasis.[120] Under stress conditions, expression of Fas and Fasl is reduced in erythroid cells and this may therefore contribute to the enhanced survival of these cells observed under these conditions. Interestingly, the expression of Fas and Fasl is repressed by Epo, further indicating that the survival function of the EpoR/Stat5 pathway is an important modulator of the erythropoietic rate.[137]

TRANSCRIPTIONAL REGULATION OF ERYTHROPOIESIS

TRANSCRIPTION FACTORS REQUIRED FOR THE STEM CELL/EARLY PROGENITOR COMPARTMENT AFFECT ERYTHROPOIESIS

A wide variety of transcription factors is known to be involved in the establishment of hematopoietic cell lineages. For example, Tal1, a basic helix-loop-helix transcription factor, and Lmo2, a LIM-domain transcription factor, are critical for the onset of hematopoiesis because null embryos show complete absence of primitive and definitive hematopoiesis.[138–141] The zinc-finger transcription factor Gata2 is also essential for the early stages of hematopoiesis. Both primitive and definitive hematopoiesis are abrogated when the *Gata2* gene is deleted, and it appears to play a role in the proliferation of the early precursors rather than in their differentiation.[142,143] Runx1 is crucial for the early stages of definitive hematopoiesis. In Runx1 null embryos yolk sac hematopoiesis is normal but fetal liver hematopoiesis is absent.[144] Once multipotent progenitors arise from the HSC and proliferate, the process of lineage restriction starts. The first step in this process involves restriction to either the myeloid or the lymphoid lineage. A number of transcription factors that are preferentially expressed in cells destined to one of those fates have been identified but few have been extensively studied. Pu.1, a member of the Ets family of transcription factors, is the best-studied transcription factor known to be involved in lineage restriction at this stage. Pu.1's effect on lineage commitment is dependent on its expression level: A high level of expression leads to commitment to the myeloid lineage whereas lower levels of expression lead to commitment to the lymphoid lineage.[145–147]

Thus, due to their role in the stem cell/progenitor compartment, inactivation of these factors also affects erythropoiesis. Because the number of transcription factors with identifiable functions during hematopoiesis is too vast to allow a thorough discussion of every one of them, we will focus on two examples of factors with an important role in terminal differentiation of erythroid cells. As erythroid cells proceed through differentiation, their nucleus becomes

progressively condensed and they shut down expression of many genes that are no longer required. Upregulation of erythroid-specific genes therefore occurs in an increasingly repressive environment, providing a particular challenge to the transcriptional regulators. The role of several transcriptional regulators in erythropoiesis has been mentioned in previous sections of this chapter. Here, we will discuss the transcription factor Gata1, which is essential for expansion and survival of erythroid progenitors, and erythroid Krüppel-like factor (EKLF), a transcription factor required for terminal erythroid differentiation, in more detail because these proteins provide the best-studied examples of erythroid transcriptional regulators.

GATA1

Gata1 is expressed in primitive and definitive erythroid cells and in megakaryocytes, eosinophils, mast cells, dendritic cells, and in the Sertoli cells of the testis.[148] Gene targeting studies have shown that Gata1 is essential for normal erythropoiesis. Gata1 null mouse embryos die of severe anemia between E10.5 and E11.5.[149] Gata1 knockdown embryos (Gata1.05), which express only approximately 5% of the wild-type Gata1 levels, also show an arrest of primitive erythropoiesis and die between E11.5 and E12.5.[150] Other Gata1 knockdown mice (Gata1-low),[151] which express approximately 20% of the wild-type Gata1 levels, show a somewhat milder phenotype. Despite the fact that the majority of Gata1-low mice die between E13.5 and E14.5, due to ineffective primitive and definitive erythroid differentiation, some are born alive (2% of the expected 25%) and a small number survive to adulthood. These mice are anemic at birth but they recover from the anemia and have a normal lifespan. From the analysis of these different mouse models a direct relationship between the expression levels of Gata1 and the severity of the phenotype is evident. Based on the observation that Gata1 null erythroid cells undergo apoptosis, it has been suggested that Gata1 is directly involved in cell survival. One of the known target genes of Gata1 is *Bcl-X_L*, a gene encoding an antiapoptotic protein.[152] Another possible Gata1 function is the regulation of G_1/S cell cycle progression. Cell cycle control is very important for erythroid differentiation because progenitors must be able to proliferate to proceed through development, but for terminal differentiation to occur cells must exit the cell cycle.[153] This idea is reinforced by the identification of a variety of Gata1 target genes involved in cell cycle regulation.[154]

Gata1 has also been implicated in the reprogramming of hematopoietic precursors. Forced expression of Gata1 was shown to reprogram myeloblasts and $CD34^+$ bone marrow cells to develop into eosinophils.[155,156] Furthermore, forced expression of Gata1 was also shown to reprogram GMPs to give rise to erythroid, eosinophilic, and basophilic-like cells.[157] Another report[158] shows that ectopic Gata1 expression guides hematopoietic precursors to commitment to the erythrocyte megakaryocytic lineage. Gata1 is known to interact with a variety of cofactors and other transcription factors. Gata1 can homodimerize[159] and has been shown to interact with transcription factors such as EKLF/Sp1,[160] Fog1,[161] PU.1,[162] Rb, [153] and CBP/p300.[163,164] Interestingly, Gata1 can form different protein complexes with distinct transcriptional activity.[165] Gata1 can interact via FOG-1 with the repressive MeCP1 complex, which results in the formation of a complex with histone deacetylase activity that binds to repressed early hematopoietic genes and genes of the eosinophilic lineage. Gata1 can also interact with the essential hematopoietic transcription factor Gfi1b and bind to repressed proliferative genes, while an activating complex of Gata1 with Tal1, and Ldb1 was found at the enhancer of the active erythroid *EKLF* gene. Gata1 also interacts with the Mediator complex, which forms a bridge between transcriptional activators and RNA polymerase II. The mediator subunit Med1 is a coactivator of Gata1 during erythroid development.[166] Thus, Gata1 can acts as a repressor and an activator, regulating multiple target genes that are essential for normal erythropoiesis.[154,167]

GATA-1 MUTATIONS IN HUMAN DISEASE

Mutations in the N-terminal transactivation domain and the N-finger of GATA-1 have been linked to human disease (Fig. 2.7a,b). Missense mutations in the N-finger of GATA-1 have been found in patients with X-linked thrombocytopenia and anemia. The majority of these mutations affect the FOG-1 interaction surface of the N-finger (Fig. 2.7b), adversely affecting the binding of FOG-1.[168–173] This further emphasizes the importance of the FOG-1–GATA-1 interaction. One mutation, R216Q, displays normal FOG-1 interaction. Compared with wild-type GATA-1, this mutant binds with comparable affinity to single GATA sites but with decreased affinity to palindromic sites.[168,172] This indicates that the DNA binding properties of the N-finger contribute to the overall function of GATA-1. The severity of disease depends on the particular mutation: D218G results in macrothrombocytopenia and mild dyserythropoietic features but no marked anemia, whereas D218Y is a more severe mutation resulting in deep macrothrombocytopenia, marked anemia, and early mortality.[170] These phenotypic differences correlate well with the stronger loss of affinity of the D218Y mutant for FOG-1 binding, compared with the D218G mutant. Another class of mutations affects the N terminus of the protein, resulting in the synthesis of a shorter isoform of GATA-1 lacking the first 84 amino acids (GATA-1s; Fig. 2.7a). Acquired mutations leading to the formation of GATA-1s are associated with megakaryoblastic leukemia in the context of trisomy 21 (Down syndrome).[174] One family with a germline GATA-1s mutation has been described. Affected individuals displayed macrocytic anemia and were often neutropenic, but no signs of megakaryoblastic leukemia were observed.[175] In summary, only a few mutations in GATA-1 causing human disease have been

reported thus far. This likely reflects the lethality of mutations affecting the function of GATA-1 more severely, as can be deduced from the studies in the mouse.

EKLF

Expression of the EKLF or Klf1 transcription factor is largely restricted to the erythroid cell lineage, where it is present in both primitive and definitive cells.[176] The promoter of the *EKLF* gene contains a functional binding site for the transcription factor Gata1, suggesting that the expression of EKLF is dependent on and downstream of Gata1.[177] EKLF binds DNA at CACC-boxes, which are found in many erythroid gene promoters.[178] EKLF specifically binds the sequence 5′-CCA CAC CCT-3′.[179] The strong affinity for this specific site is illustrated by β thalassemia patients who carry mutations in the EKLF binding site in the *β-globin* promoter. The loss in specificity for binding of EKLF strongly reduces the expression of *β-globin*.[180–182] Furthermore, EKLF has a higher affinity for the human *β-globin* promoter then the γ-*globin* promoter, which has a similar but not identical CACC-box.[183] To determine the role of EKLF in vivo, the gene has been knocked out in mice.[184,185] Mice heterozygous for the EKLF gene appear completely healthy. In the absence of EKLF, however, the developing fetuses die around E14 (Fig. 2.8a,b). The primitive erythroid cells function sufficiently for normal survival of the EKLF knockout mice during embryonic development up to approximately E12. The expression of embryonic globins is not influenced by the absence EKLF (Fig. 2.8c), even though EKLF binds these genes in vivo.[186] When the embryos switch to definitive erythropoiesis in the fetal liver, EKLF null mutants rapidly develop fatal anemia, because of a deficiency in β-globin expression. This is in contrast to α-globin expression that is not dependent on EKLF. Remarkably, the number of CFU-E in the EKLF null fetal livers is similar of those found in wild-type fetal livers, showing that EKLF deficiency causes a very late erythroid defect.[184,185] Furthermore, fetal liver–derived erythroid cells of EKLF$^{-/-}$ fetuses have an abnormal morphology, and most of the cells retain a nucleus. Interestingly, definitive erythroid cells of mice with deleted adult *β-globin* genes have morphological abnormalities that are more like those found in human β thalassemia than those found in EKLF$^{-/-}$ fetuses.[187] This was the first indication that the adult *β-globin* genes are not the only target genes of EKLF. Stronger evidence that nonglobin EKLF target genes contribute to the definitive red blood cell abnormalities and prenatal death in EKLF$^{-/-}$ fetuses came from a transgenic rescue study. EKLF$^{-/-}$ mice could not be rescued by expression of exogenous human γ-globin. Despite efficient production of hybrid hemoglobin, consisting of mouse α- and human γ-globin in the fetal livers, hemolysis was not corrected and survival was not prolonged.[188] This strongly suggested that EKLF regulates more essential genes in erythropoiesis. Indeed, genome-wide expression analyses of EKLF$^{-/-}$ erythroid cells have demonstrated that EKLF activates the expression of many other erythroid-specific genes. Although there are some indications that EKLF may repress transcription in some contexts,[189,190] the genome-wide expression analyses provided little evidence that EKLF acts as a repressor.[191–193] Examples of genes activated by EKLF are the gene encoding AHSP, a protein involved in stabilization of free α-globin chains, and genes encoding proteins associated with the erythroid cell membrane, such as band 4.9/dematin. These proteins are important for the function and stability of the erythrocytes, and consistent with this notion EKLF null primitive erythrocytes were found to display morphological abnormalities (Fig. 2.8d,e). In addition, EKLF appears to have a role in cell cycle regulation linked to the proliferation arrest required for terminal differentiation.[194]

Thus, EKLF is an activator of essential erythroid genes that are upregulated during terminal erythroid differentiation. This suggests that mutations affecting the function of the EKLF transcription factor would have a major impact on the severity of disease in thalassemia and sickle cell

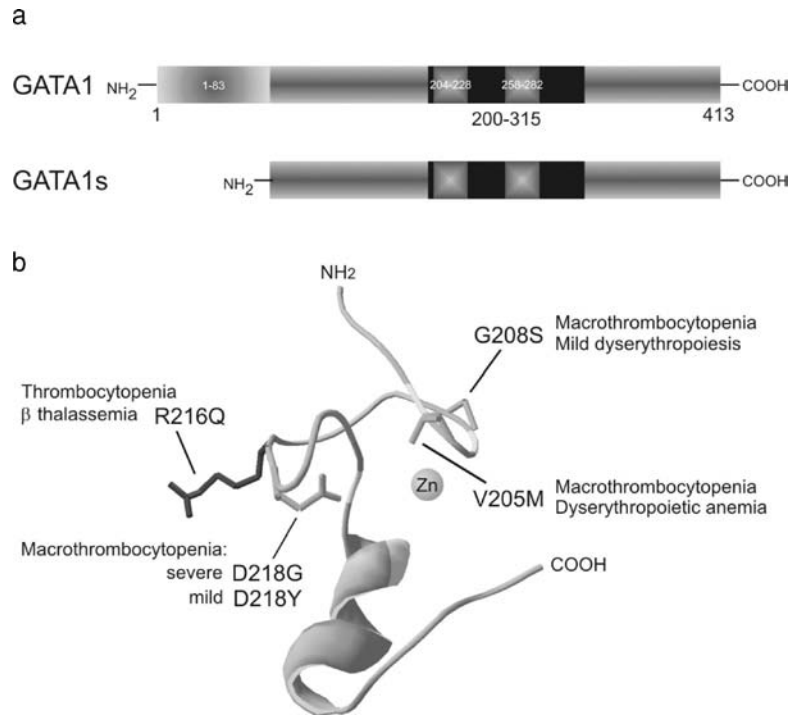

Figure 2.7. Mutations in the GATA-1 transcription factor associated with human disease. **(a)** Schematic drawing of the GATA-1 protein with the N-terminal transactivation domain, lacking in the GATA-1s isoform, and the N- and C-terminal zinc fingers indicated. **(b)** Three-dimensional structure of the N-terminal zinc finger, with the positions of disease-causing mutations shown. Mutation of arginine 216 to glutamine (R216Q) affects DNA binding; the other mutations affect interactions with the essential GATA-1 cofactor FOG-1. (Adapted from ref. 148.)

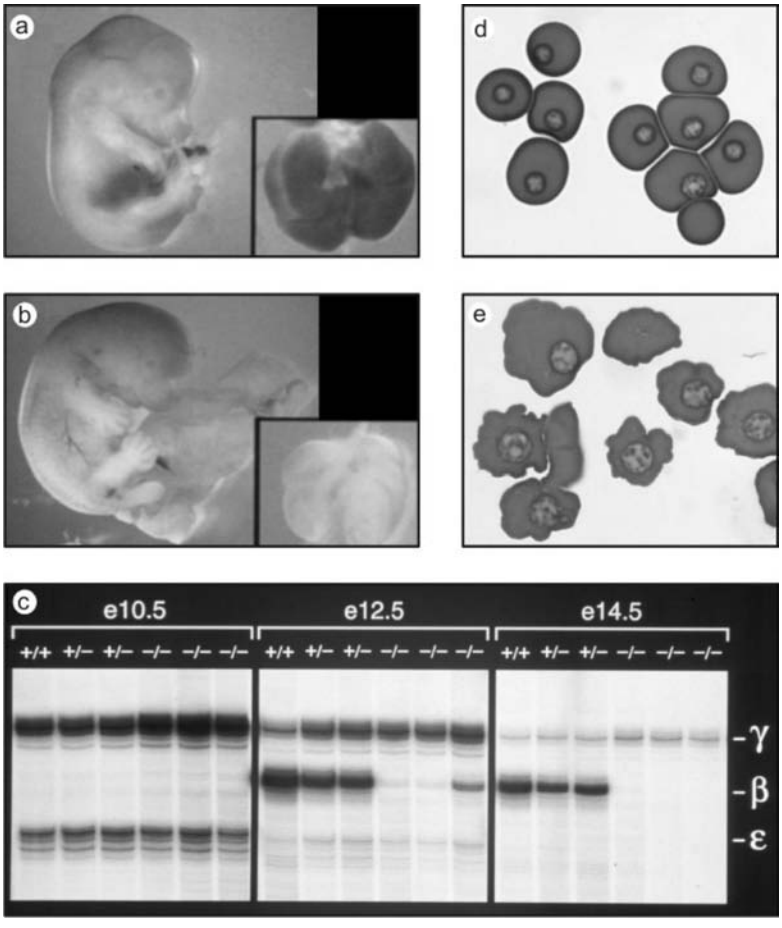

Figure 2.8. Phenotype of EKLF knockout fetuses. **(a)** E13.5 wild-type fetus. Inset: fetal liver. **(b)** E13.5 EKLF knockout fetus, displaying obvious pallor of the fetal liver (inset). **(c)** Mice carrying a human β-globin locus transgene were crossed with EKLF knockout mice. Expression analysis of the human *β-like globin* genes is shown at various gestational ages. Note that in the EKLF knockout background (−/−) the adult *β-globin* gene fails to be activated, whereas expression of the embryonic *ε-globin* and *fetal γ-globin* genes is not affected. **(d)** Cytospin of E12.5 blood from wild-type fetus, displaying primitive erythrocytes. **(e)** Cytospin of E12.5 blood from EKLF knockout fetus displaying primitive erythrocytes. Note the irregular shape of the cell membranes, compared with (d). ((d) and (e) Adapted from ref. 191.) (See color plate 2.8.)

anemia patients. Thus far, mutations in *EKLF* have not been found in the human population, but the experimental data suggest that it is worth investigating the occurrence of such mutations.

EKLF AFFECTS CHROMATIN CONFORMATION IN ERYTHROID CELLS

DNA is packaged in chromatin, which has a repressive effect on transcription. A number of complexes have been described that counteract this repressive effect. One of these complexes is the SWI/SNF complex; an adenosine triphosphate–dependent chromatin-remodeling complex that changes the chromatin structure by altering DNA–histone contacts within nucleosomes. EKLF requires a SWI/SNF-related chromatin-remodeling complex for transactivation of the *β-globin* gene when the DNA template is packaged in chromatin.[195] The EKLF-SWI/SNF complex generates a transcriptionally active β-globin promoter in vitro. The SWI/SNF complex contains homologs of the yeast BRG1, BAF170, BAF155, and BAF47 proteins, and a subunit that is unique to higher eukaryotes, BAF57. EKLF is necessary for recruitment of two of these subunits, BRG1 and BAF170, near the transcription initiation site of the β-globin promoter, suggesting that the complex uses EKLF for specific targeting.[196] We note that BRG1-mutant mice display an erythroid phenotype that bears similarity to that of EKLF null mutants.[197] In addition to interactions with SWI/SNF complex, EKLF works together with other nuclear factors, and interactions with Gata1, CBP/p300, Sin3A, and histone deacetylase 1 have been described.[160,189,198,199] Interestingly, both EKLF and Gata1 are involved in the spatial organization of the *β-globin* locus, bringing remote regulatory elements in the vicinity of the active promoters of the globin genes.[200,201] We refer to Chapter 4 for a detailed discussion of the regulation of *globin* gene expression.

GENE EXPRESSION DURING ERYTHROID MATURATION

As erythroid maturation proceeds, red cell protein synthesis becomes more concentrated on hemoglobin production. In general, mRNAs encoding red cell proteins are upregulated after erythroid commitment, including red cell membrane proteins, blood group antigens, glycolytic enzymes, carbonic anhydrase and enzymes of the heme synthesis pathway. Globin gene transcription occurs from the proerythroblast stage onward, reaching a maximum in polychromatic erythroblasts before declining in orthochromatic erythroblasts. The high stability

of globin RNA results in the accumulation of approximately 20,000 copies per cell which, as a result of selective destruction of nonglobin RNAs, comprise more than 90% of the mRNA in reticulocytes. Globin chain synthesis parallels mRNA accumulation. The changes in gene expression may be found in Goh et al.[202] and Keller et al.[203] and effects on cell cycle regulatory genes in Fang et al.[84] A catalogue of erythroid gene expression may be found at http://hembase.niddk.nih.gov. Finally, mass spectrometry–based analysis of the erythrocyte proteome has identified 751 proteins.[204–206] This unexpected complexity forms the basis for future research aimed at understanding how red blood cells actually work.

The Normal Structure and Regulation of Human Globin Gene Clusters

Bernard G. Forget and Ross C. Hardison

The genes encoding the different globin chains of hemoglobin are members of an ancient gene family. In this chapter we will review the structural features of the globin genes, with particular attention to the sequences needed for proper regulation of gene expression. Some of these have been well conserved during mammalian evolution and therefore are likely to provide a common function in many mammals. Others are only found in higher primates and may play roles in lineage-specific regulation. We will first describe the structural characteristics of the human globin genes and then provide a comparative analysis of the genomic contexts, regulatory regions, and evolutionary conservation of features present in the globin gene clusters.

NUMBER AND CHROMOSOMAL LOCALIZATION OF HUMAN GLOBIN GENES

Hemoglobin is a heterotetramer that contains two polypeptide subunits related to the α-globin gene subfamily (referred to here as α-like globins) and two polypeptide subunits related to the β-globin gene subfamily (β-like globins). Globin polypeptides bind heme, which in turn allows the hemoglobin in erythrocytes to bind oxygen reversibly and transport it from the lungs to respiring tissues. In humans, as in all vertebrate species studied, different α-like and β-like globin chains are synthesized at progressive stages of development to produce hemoglobins characteristic of primitive (embryonic) and definitive (fetal and adult) erythroid cells (Fig. 3.1).

Before precise knowledge of globin gene organization was gained by gene mapping and molecular cloning, a general picture of the number and arrangement of the human globin genes emerged from the genetic analysis of normal and abnormal hemoglobins and their pattern of inheritance. The number and subunit composition of the different normal human hemoglobins (Fig. 3.1) suggested that there must exist at least one globin gene for each of the different globin chains: α, β, γ, δ, ε, and ζ. Evidence from the study of hemoglobin variants and the biochemical heterogeneity of the chains in fetal hemoglobin (HbF) showed that the α- and γ-globin genes were duplicated. Persons were identified whose red cells contained more than two structurally different α-globin chains that could be best explained by duplication of the α-globin gene locus, and the characterization of the structurally different $^{G}\gamma$- and $^{A}\gamma$-globin chains of HbF imposed a requirement for duplication of the γ-globin gene locus.

Studies of the pattern of inheritance of hemoglobin variants from persons carrying both an α chain and a β chain variant revealed that the α- and β-globin genes are on different chromosomes (or very widely separated if on the same chromosome). Variants of α-globin and β-globin chains were always observed to segregate independently in offspring of doubly affected parents (reviewed in ref. 1). Linkage of the various β-like globin genes to one another was established from the study of interesting hemoglobin variants that contained fused globin chains, presumably resulting from nonhomologous crossover between different β-like globin genes. Characterization of Hb Lepore,[2] with its δβ fusion chain, established that the δ-globin gene was linked to and located on the 5′ (or N-terminal) side of the β-globin gene. Analysis of Hb Kenya,[3] with its $^{A}\gamma\beta$ fusion chain, provided evidence for linkage of the $^{A}\gamma$ gene, and presumably the $^{G}\gamma$ gene as well, to the 5′ side of the δ- and β-globin genes.

Thus, the general arrangement of the globin genes that emerged from these various genetic analyses can be represented as illustrated in Figure 3.1. It was also assumed, but unsupported by genetic evidence, that the embryonic α-like (ζ) and β-like (ε) globin genes were likely to be linked to the loci encoding their adult counterparts.

By using rodent–human somatic hybrid cells containing only one or a few human chromosomes, Deisseroth and colleagues[4,5] clearly established that the human α- and β-globin genes resided on different chromosomes. The α-like globin genes are located on chromosome 16, whereas the β-like globin genes are on chromosome 11. The latter results were obtained by hybridizing a solution of total cellular DNA from the various somatic hybrid cells to radioactive cDNAs, synthesized from α- and β-globin mRNAs by reverse transcriptase. These results were later confirmed and extended by various groups using the gene mapping procedure of Southern blot analysis with DNA from various hybrid cell lines containing different translocations or deletions of the involved chromosomes.

These studies also localized the globin gene loci to specific regions on their respective chromosomes: the β-globin gene cluster to the short arm of chromosome 11, and the α-globin gene cluster to the short arm of chromosome 16 (Fig. 3.1). These chromosomal assignments were further confirmed and refined by in situ hybridization of radioactive cloned globin gene probes to metaphase chromosomes and by fluorescence-based in situ hybridization. Thus, the β-globin gene cluster was assigned to 11p15.5 and the

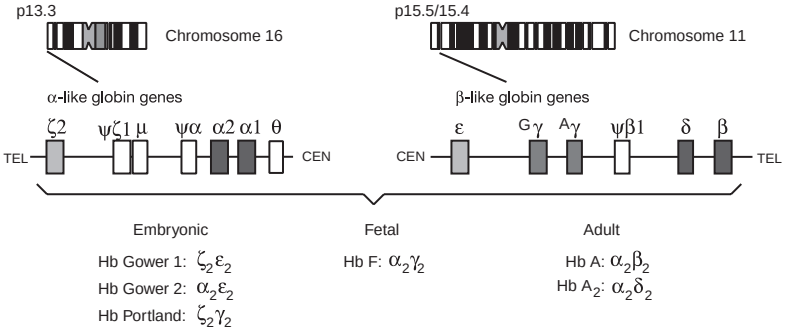

Figure 3.1. Basic organization of human globin gene complexes. The locations of the α-globin gene complex very close to the telomere of the short arm of chromosome 16 and the β-globin gene complex on the short arm of chromosome 11 are shown at the top. The genes are shown as boxes on the second line, named according to the globin polypeptide that is encoded. In both diagrams, the 5′–3′ transcriptional orientation is from left to right. Note that the orientations with respect to the centromere (CEN) and telomere (TEL) are opposite; the α-like globin genes are transcribed toward CEN, whereas the β-like globin genes are transcribed toward TEL. The composition of hemoglobins produced at progressive developmental stages is given at the bottom.

α-globin gene cluster to 16p13.3. Subsequent DNA sequencing of entire human chromosomes and alignment with maps of chromosome bands places the β-globin gene cluster in 11p15.4. The α-globin gene cluster is only approximately 150 kb from the telomere of the short arm of chromosome 16.

GLOBIN GENE STRUCTURE: INTRONS AND THEIR REMOVAL

The coding region of each globin gene in humans and other vertebrates is interrupted at two positions by stretches of noncoding DNA called intervening sequences (IVSs) or introns.[6] In the β-like globin genes, the introns interrupt the sequence between codons 30 and 31 and between codons 104 and 105; in the α-globin gene family, the intervening sequences interrupt the coding sequence between codons 31 and 32 and between codons 99 and 100 (Fig. 3.2.A). Although the precise codon position numbers at which the interruption occurs differ between the α- and β-like globin genes, the introns occur at precisely the same position in the aligned primary sequence of the α- and β-globin chains. Thus, given the likely possibility that the α- and β-globin gene families originally evolved from a single ancestral globin gene,[7] these gene sequences are homologous, and we infer that the presence of the introns at these positions predates the separation of α-globin and β-globin genes approximately 500 million years ago (in an ancestral jawed vertebrate). The first intervening sequence (IVS-1) is shorter than the second intervening sequence (IVS-2) in both α- and β-globin genes, but IVS-2 of the human β-globin gene is much larger than that of the α-globin gene (Fig. 3.2.A).

The pattern of intron sizes of the ζ-like globin genes differs from that of the other α-like globin genes. Whereas the introns in the α and ψα genes are small, that is, fewer than 150 bp, those of the ζ and ψζ genes are larger.[8] Furthermore, the first introns of the ζ and ψζ genes are much larger than their second introns; in fact they are 8–10 times larger than the first introns of any other globin gene.

The presence of intervening sequences that interrupt the coding sequences of structural genes imposes a requirement for some cellular process to remove these sequences in the mature mRNA. As illustrated in Figure 3.2.B, intervening sequences are transcribed into globin (and other) precursor mRNA molecules,[9] but they are subsequently excised and the proper ends of the coding sequences joined to yield the mature mRNA.[10] This posttranscriptional processing of mRNA precursors to remove introns has been termed splicing. A crucial prerequisite for the proper splicing of globin (and other) precursor mRNA molecules is the presence of specific nucleotide sequences at the junctions between coding sequences (exons) and intervening sequences (introns). Comparison of these sequences in many different genes has permitted the derivation of two different consensus sequences, which are almost universally found at the 5′ (donor) and 3′ (acceptor) splice sites of introns.[11,12] The consensus sequences thus derived are shown in Figure 3.2A, along with the consensus surrounding the branch point A involved in the initiation of splicing. The dinucleotides GT and AG shown in boldface, at the 5′ and 3′ ends, respectively, of the intron, are essentially invariant and are thought to be absolutely required for proper splicing. This is the so-called GT-AG rule. Rare examples have been described in which GC instead of GT is found at the donor splice site junction.

The importance of these consensus sequences is underscored by the fact that mutations that either alter them or create similar consensus sequences at new sites in a globin gene can lead to abnormal processing of globin mRNA precursors; these constitute the molecular basis for many types of thalassemia (Chapters 13 and 16). Throughout this chapter we will refer to human mutations that affect some aspect of the pathway for gene expression. Readers desiring more information may want to use databases such as HbVar (http://www.bx.psu.edu)[13] or the Phencode project (http://phencode.bx.psu.edu)[14] to find positions, genotypes, and phenotypes for the greater than 1,000 known globin gene variants.

DETAILED CHROMOSOMAL ORGANIZATION OF THE HUMAN GLOBIN GENES

A precise picture of the chromosomal organization of the α- and β-like human globin gene clusters, with respect to the number of structural loci and intergenic distances, was obtained by a number of different techniques: 1) restriction

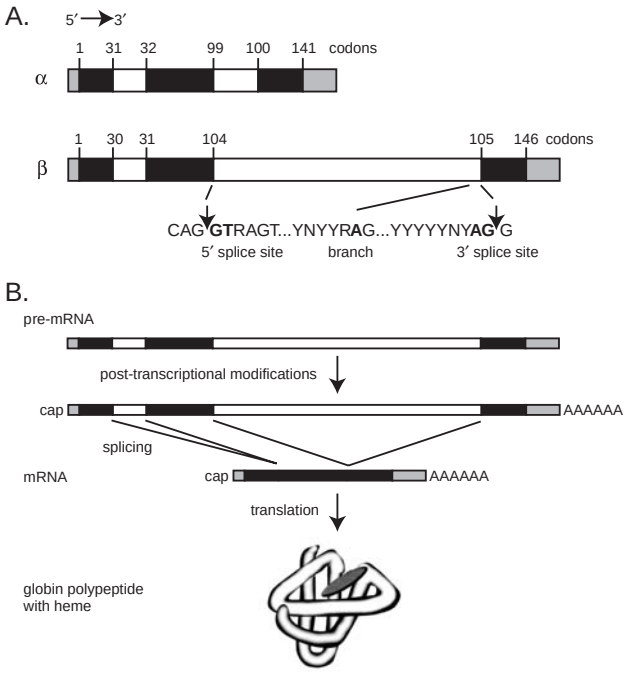

Figure 3.2. Structure and expression pathway of globin genes. (**A**) General structure of globin genes. The coding sequences of all globin genes in humans and other animals are separated by two introns (white boxes) into three exons. The first exon has a short 5′ untranslated region (gray box) followed by a coding region (black box). All of the central exon codes for protein, whereas the third exon begins with coding sequences and ends with a 3′ untranslated region. The relative sizes of the portions of the genes are indicated by the sizes of the boxes, and codon numbers are given above the boxes. The consensus sequence for critical sequences used in splicing are shown under the second intron of the β-globin gene, and similar sequences are present in all introns. The vertical arrows show the splice site junctions within the consensus sequences where cleavage occurs during the process of joining the exons. (**B**) The pathway for expression of globin genes. The RNA transcript is shown with short boxes corresponding to the untranslated regions (gray), coding regions (black), and introns (white) as in (A), with processing and splicing steps occurring in the nucleus to form the mature mRNA. The mRNA is translated in the cytoplasm to generate a globin polypeptide to which the heme (gray disk) will bind. The diagram of the folded globin structure was provided by Dr. John Blamire at the Brooklyn College of the City University of New York.

endonuclease mapping of genomic DNA (e.g., refs. 15, 16) using the gel blotting procedure of Southern,[17] and, 2) gene isolation and sequencing using recombinant DNA technology (e.g., ref. 18). Sets of overlapping genomic DNA fragments spanning the entire α- and β-globin gene clusters were obtained by gene cloning, initially in bacteriophage λ and larger fragments in cosmid vectors. Detailed analysis of these recombinant DNA clones and complete DNA sequencing led to the determination of the gene organization illustrated in Figure 3.3. Some results were expected, such as the finding of single δ- and β-globin gene loci and duplication of the α- and γ-globin gene loci. In addition, single loci for the embryonic ζ- and ε-globin chains were found linked to the α- and β-globin gene clusters, respectively. It is noteworthy that the genes in each cluster are in the same transcriptional orientation and are arranged, in a 5′ to 3′ direction, in the same order as their expression during development.

An unexpected finding was the presence in the globin gene clusters of additional gene-like structures with sequence homology and an exon–intron structure similar to the actively expressed globin genes. These DNA segments have been called pseudogenes.[19] One, called ψβ1, is in the β-like globin gene cluster between the γ- and δ-globin genes. At least two (and possibly four) are in the α-like globin gene cluster. The two clear examples are ψζ1 and ψα1, located between the active ζ-globin and α-globin genes (Fig. 3.3). All three (ψβ1, ψζ1, and ψα1) are characterized by the presence of one or more mutations that render them incapable of encoding a functional globin chain. This inability to encode a functional globin polypeptide does not necessarily render the pseudogenes inactive for transcription. The pseudogene ψβ1 is transcribed and spliced, as shown by several spliced expressed sequence tags, whereas no evidence has been provided that ψα1 is transcribed. These pseudogenes appear to have arisen by gene duplication events within the globin gene clusters followed by mutation and inactivation of the duplicated gene and subsequent accumulation of additional mutations through loss of selective pressure.

Two other α-like globin genes have been identified and characterized in the α-globin gene cluster, but their roles, if any, in encoding globin polypeptides are still uncertain. The θ-globin gene is located to the 3′ or C-terminal side of the duplicated α-globin genes.[20] It is more closely related to the α-globin genes than to the ζ-globin genes and is expressed at low levels in erythroid cells.[21,22] Clear homologs to the θ-globin gene are found in the homologous position in other mammalian α-like globin gene clusters. The μ-globin gene is located just 3′ of the ψζ1-globin pseudogene;[23,24] it was initially called ψα2[25] but with more accurate sequencing it is clear that this gene does not contain mutations that would render it inactive. It is a distant relative, being equally divergent from both α-globin and ζ-globin genes. Its closest relatives are the α^D-globin genes, which are actively expressed in red cells of reptiles and birds.[24,26] DNA sequences similar to that of the human μ-globin gene are found in other mammals, but in some species, such as mouse, the sequence has diverged so much that no obvious gene structure is found. Thus the presence of the θ-globin gene is conserved in all mammals examined but the μ-globin gene has been lost in some but not all lineages. Transcripts from both the θ-globin gene and the μ-globin gene are produced and spliced in erythroid cells, albeit at much lower levels than the α-globin gene. Curiously, no hemoglobin containing the θ-globin chain or the μ-globin chain has been identified, even by sensitive mass spectrometry.[23] Furthermore, the predicted structure (translated amino acid sequence) of the θ-globin chain suggests that it would be unlikely to function normally as a hemoglobin subunit.[27] Thus these genes remain a puzzle. They tend to be retained over mammalian

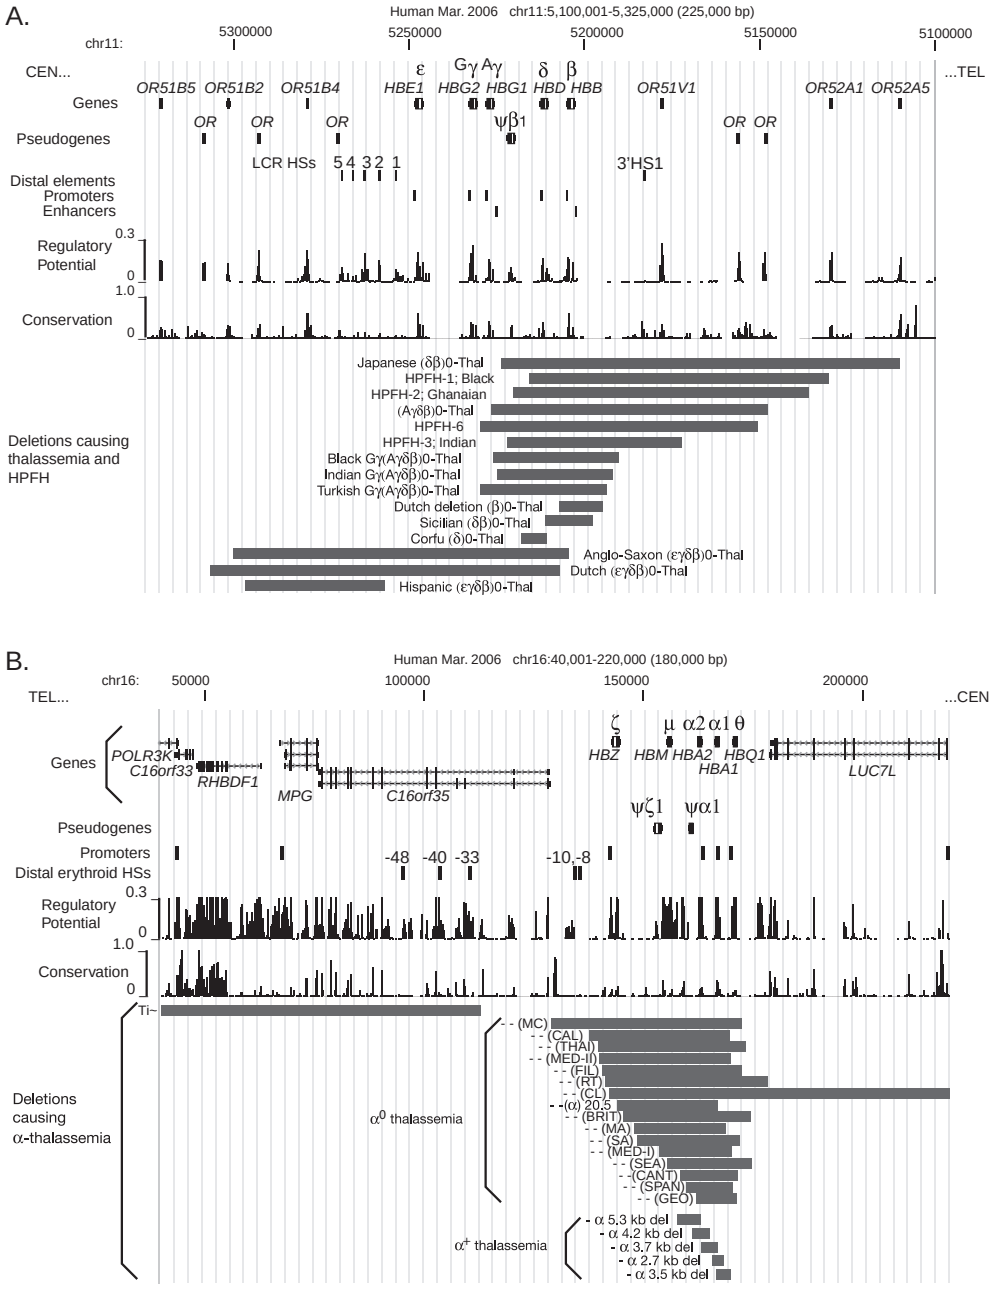

Figure 3.3. Detailed maps of the human globin gene complexes, including genomic features and representative deletions. (**A**) Detailed map of the β-like globin gene complex and surrounding olfactory receptor genes. The globin genes are named both by the encoded globin polypeptide and the official gene name. Pseudogenes are shown on a line below the genes. The known *cis*-regulatory modules are separated into distal elements such as the locus control region (shown as five DNase hypersensitive sites or HSs), promoters and enhancers close to the 3′ ends of *HBG1* and *HBB*. The next two tracks show two features derived from multiple alignments of the human genomic sequence with sequences from six other placental mammals (chimpanzee, rhesus macaque, mouse, rat, dog, and cow). The regulatory potential measures the similarity of patterns in the alignments to those that are distinctive for known regulatory regions versus neutral DNA.[57] The conservation score estimates the likelihood that an alignment is in the most constrained portion of the genome, likely reflecting purifying selection (phastCons).[56] Positions of deletions that cause δβ thalassemia or hereditary persistence of fetal hemoglobin (HPFH) are shown in the lower portion. (**B**) Detailed map of the α-like globin gene complex and surrounding genes. The conventions and tracks are similar to those in (A) Positions of the distal erythroid HSs are from Hughes et al.[26] The deletions are grouped by those with deletion of a single α-globin gene (α^+ thalassemia), deletion of both α-globin genes (α^0 thalassemia), and a representative deletion (Ti∼) that removes the distal enhancer (HS-40) but no structural genes. Coordinates of the deletions were provided by Dr. Jim Hughes. These figures were generated starting with output from the UCSC Genome Browser,[121] using the following tracks in addition to ones already mentioned: UCSC Known Genes,[122] ORegAnno for *cis*-regulatory modules,[123] and Locus Variants for the deletions.[14] For panel A, the Genome Browser output was rotated 180° so that the 5′–3′ transcriptional orientation is left to right (note that the genome coordinates are decreasing from left to right). Both figures were edited for clarity.

evolution, suggesting that their sequences are constrained to preserve some function. They are expressed at the RNA level but do not appear to be translated into a polypeptide. Perhaps they or their RNA transcripts play some role that has yet to be discovered.

GENOMIC CONTEXT OF THE α-GLOBIN AND β-GLOBIN GENE CLUSTERS

The separation of α- and β-globin gene clusters to different chromosomes has allowed them to diverge into strikingly different genomic contexts, with paradoxical consequences for our understanding of their regulation. Given that all contemporary vertebrates have developmentally regulated hemoglobin genes encoding proteins used for oxygen transport in erythrocytes, it would have been reasonable to expect that the molecular mechanisms of globin gene regulation would be conserved in vertebrates. Certainly, the coordinated and balanced expression of α- and β-globin genes to produce the heterotypic tetramer $\alpha_2\beta_2$ in erythrocytes should be a particularly easy aspect of regulation to explain. Because the two genes would have been identical after the initial duplication in the ancestral vertebrate, with identical regulatory elements, it is parsimonious to expect selection to keep the regulatory elements very similar.

Much has changed between the α- and β-like globin gene clusters since their duplication. Not only are they now on separate chromosomes in birds and mammals, but in mammals they are in radically different genomic contexts.[28] A major determinant of the genomic environment is the G+C content. A G+C-rich DNA segment has a high mole fraction of the nucleotides guanidylic acid (G) and cytidylic acid (C), whereas an A+T-rich DNA segment has a high mole fraction of the nucleotides adenylic acid (A) and thymidylic acid (T). The G+C content for the human genome on average is low (~41%) but some segments can be much lower or higher, ranging from 30% to 65% in 20-kb windows.[29] Regions that are G+C rich tend to be enriched in genes, and those genes tend to be expressed in a broad range of tissues. They also tend to have islands with an abundance of the dinucleotide CpG.[30] This is in stark contrast to the bulk of the genome, which has very few CpGs because these are the sites for DNA methylation, and substitution of CpG to TpG or CpA is very rapid on an evolutionary time scale (as much as 10 times faster than the rates of other substitutions). The CpG islands are thus short regions (a few hundred base pairs) in which the CpG dinucleotides are not methylated; these have been associated with important functions such as promoters for transcription.

The β-globin gene clusters in humans and other mammals are A+T rich, with no CpG islands,[31] whereas the α-like globin gene clusters are highly G+C rich, with multiple CpG islands.[32] This correlates with several important differences in the structure and regulation of the two gene clusters. Tissue-specific gene expression of the β-like globin genes is correlated with an increased accessibility of the chromatin only in expressing cells,[33] and hence "opening" of a chromatin domain is a key step in activation of these genes. In contrast, there are the α-like globin genes, which are in constitutively open chromatin.[28] The β-globin gene cluster is subject to tissue-specific DNA methylation,[34] but, in keeping with the presence of CpG islands, the α-globin gene cluster is not methylated in any cell type.[35] The β-globin gene clusters are replicated early in S phase only in cells expressing them, whereas the human α-globin genes are replicated early in all cells.[36–38] Thus, the mammalian α-globin genes have several characteristics associated with constitutively expressed "housekeeping" genes. The strikingly different genomic contexts of the two gene clusters affect several aspects of DNA and chromatin metabolism, including timing of replication, extent of methylation, and the type of chromatin into which the loci are packaged. Rather than selecting for similarities to ensure coordinate and balanced expression, the processes of evolution at these two loci have made them quite different. The full implications of these differences may not yet be known. For instance, the two "healthy" genes with no known function in the α-like globin gene cluster, θ and μ, are themselves CpG islands. Could this be a clue to a role for these genes outside the conventional one of coding for proteins?

The types of genes that surround the α-like and β-like globin gene clusters are quite different (Fig. 3.3). The β-like globin gene cluster is surrounded by olfactory receptor (*OR*) genes, which encode G protein–coupled receptors expressed in olfactory epithelium.[39] Several *OR* gene clusters containing approximately 1,000 genes and pseudogenes are found in the human genome. The *OR* gene cluster surrounding the β-like globin genes is a particularly large one, with approximately 100 genes extending almost 1 million bp (Mb) past *HBB* (the β-globin gene) and over 3 Mb toward the centromere from *HBE1* (the ε-globin gene). This arrangement is found in homologous regions in mammals and in chickens. Thus the erythroid-specific regulation of the β-like globin gene cluster is exerted in a chromosomal environment that is largely devoted to olfactory-specific expression. Perhaps this has had an impact on selection for a particularly powerful enhancer, to override the olfactory-specific regulation. As shown in Figure 3.3A, some deletions causing δβ thalassemia or hereditary persistence of fetal hemoglobin not only remove β-like globin genes, but they also fuse the remaining genes with sequences close to an *OR* gene. The phenotype of patients carrying such deletions may be explained in part by bringing positive or negative regulatory elements normally associated with *OR* genes into proximity of the β-like globin genes[40–41] (see Chapter 16).

In contrast, the α-like globin genes are surrounded by a variety of genes (Fig. 3.3.B), many of which are widely expressed and carry out fundamental roles in cellular

metabolism and physiology, such as *MPG* (encoding the DNA repair enzyme methyl purine glycosylase) and *POLR3K* (encoding a subunit of RNA polymerase III).[42] Although the α-like globin gene cluster and surrounding DNA is in constitutively open chromatin, histones are hyperacetylated (another mark of active loci) in erythroid cells in a more restricted region encompassing the globin genes and their regulatory sequences.[43] The regions homologous to that surrounding the α-like globin gene cluster have undergone inter- and intrachromosomal rearrangements in various vertebrate lineages, but the genes from *POLR3K* through *HBQ1* have remained together in all species examined from fish to mammals.[44] This suggests that this region encompasses all the sequences needed in *cis* for appropriate regulation of the α-like globin genes.

Despite these many differences between α-like and β-like globin gene clusters in mammals, the appropriate genes are still expressed coordinately between the two loci, resulting in balanced production of α-like and β-like globins needed for the synthesis of normal hemoglobins. The mechanisms that accomplish this task still elude our understanding.

One important aspect that is common to the genomic contexts of both gene clusters is the presence of distal strong enhancers. The discovery of these enhancers was aided by mapping of deletions that result in β thalassemia or α thalassemia, which are inherited deficiencies in the amount of β-globin or α-globin, respectively (see Chapters 13 and 16). A number of these deletions removed distal sequences but retained all the globin genes, such as the deletions associated with Hispanic $(\varepsilon\gamma\delta\beta)^0$ thalassemia and the Ti~ α^0 thalassemia (Fig. 3.3), as well as other deletions (Figs. 13.7 and 16.5). Within the deleted intervals are critical long-range enhancers needed for high-level expression of any gene in the linked globin gene clusters. These are the locus control region (LCR) for the β-globin gene cluster and HS-40 or major regulatory element for the α-globin gene cluster. Thus regulation of expression of globin genes involves DNA sequences both close to the genes (proximal) and as much as 70 kb away from the genes (distal). These will be examined in more detail in the next section.

EVOLUTIONARY INSIGHTS INTO REGULATION OF GLOBIN GENE CLUSTERS

Motivation

One avenue for improving the conditions of patients with hemoglobinopathies could involve regulation of expression of the globin genes. This hope is based on the normal human variation in phenotypes presented for a given mutant genotype. For example, patients with naturally higher concentrations of HbF ($\alpha_2\gamma_2$) in their erythrocytes tend to have milder symptoms of either sickle cell disease or β thalassemia (Chapters 17 and 19). The α-globin gene status can affect the severity of β thalassemia, with more balanced production of α-globin and β-globin associated with milder disease. Thus considerable effort has gone into studying the stage-specific expression of the globin genes, with a long-term goal of enhancing or restoring production of embryonic or fetal hemoglobins in adult life or reducing expression of deleterious alleles. Although no current treatment by gene therapy is in practice as of this writing, much effort continues in this area. The use of hydroxyurea in the treatment of sickle cell disease is an outgrowth of studies on mechanisms of regulation of globin genes. Current studies aim to discover more sophisticated and directed pharmacological methods for enhancing production of embryonic and fetal hemoglobins.

Studies over the past three decades have revealed much about the regulation of the human globin genes. In this section, we will summarize some of the information about DNA sequences needed in *cis* (i.e., on the same chromosome) for regulation of the globin genes. Chapter 4 will cover the proteins interacting with these regulatory DNA sequences.

Common versus Lineage-specific Regulation

Comparison of noncoding genomic DNA sequences among related species is a powerful approach to identifying and better understanding *cis*-regulatory modules (CRMs). It is important to distinguish, however, what is similar and what is distinctive about the patterns of regulated expression of the genes in the species being compared. If one is searching for CRMs that perform a function common to most or all mammals, then conservation across all mammals and evidence of strong constraint in noncoding DNA will provide good candidates for further experimental tests (e.g., refs. 45–47). Such constrained noncoding sequences can have within them short, almost invariant regions that frequently correspond to transcription factor binding sites. These have been called phylogenetic footprints.[48] If one is studying a type of regulation that only occurs in higher primates, then searching for sequences conserved in other mammalian orders will be futile. Instead, the search should focus on sequences conserved in the species with a common mode of regulation but which differ from the homologous regions in species with a different regulation. These have been called differential phylogenetic footprints.[49]

Regulatory features of globin genes common to many vertebrate species include tissue specificity and some aspects of developmental specificity. Expression of the α-like and β-like globin genes in all vertebrate species examined is restricted to the erythroid lineage. Thus some determinants of tissue specificity should be common to all these genes. One example is binding by the transcription factor GATA-1. As will be detailed in the following sections, the promoter, enhancers, or both for all globin genes have binding sites for GATA-1. Another feature common to all mammals is the expression of the ε-globin and ζ-globin

genes exclusively in primitive erythroid cells, which are produced during embryonic life. Thus one might expect determinants of embryonic expression to be conserved in many species. Indeed, conservation of the upstream promoter regions of these genes in eutherian mammals is more extensive than is seen for other promoters in their globin gene clusters.[50]

An example of lineage-specific regulation is the recruitment of the γ-globin genes for expression in fetal erythroid cells. In most eutherian mammals, the γ-globin genes are expressed in primitive erythroid cells, similar to the ε-globin gene, and the β-globin gene is expressed in definitive erythroid cells both during fetal and adult life. Simian primates, including humans, express the γ-globin genes during fetal erythropoiesis, and the expression of the β-globin gene is delayed. The extent of delay varies in different primate clades, but in humans it is largely delayed until just before birth. Thus when examining interspecies alignments of the regulatory regions of the β-globin gene (*HBB*) and the γ-globin genes (*HBG1* and *HBG2*), one will be seeing a combination of CRMs used in common (e.g., for adult erythroid expression of *HBB*) and in a lineage-specific manner (e.g., fetal expression of *HBG1*).

Quantitative Analysis of Sequence Alignments

Alignments of genomic DNA sequences reveal the segments that are similar between species, and often these reflect homology (descent from a common ancestor). These sequence matches tend to have the highest similarity in the protein-coding exons, but significant stretches of noncoding sequences also align between mammalian species (for globin gene complexes, see refs. 51–53). Further analysis is required to discern which sequence matches simply reflect common ancestry (aligned neutral DNA) versus those in sequences that are under constraint (sequences with a common function).[54,55]

Several bioinformatic tools have been developed to help interpret the alignments of multiple sequences. Results from two of these, each analyzing alignments of several mammals (human, chimpanzee, rhesus macaque, mouse, rat, dog, cow, and sometimes additional ones), are shown in Figure 3.3. The Conservation track plots the phastCons score at each position of the human sequence. This score is an estimate of the posterior probability that a given nucleotide is in the most strongly constrained (i.e., most slowly changing) portion of the genome.[56] Higher scores are associated with a greater likelihood that a position or region is under strong purifying selection. Sequences that are needed for a feature that is common to these several placental mammals would be expected to have a high Conservation score.

A discriminatory analysis of the multiple alignments was used to generate a Regulatory Potential score.[57] This machine-learning approach estimates the likelihood that a given aligning segment is a CRM, given the frequency of patterns in the alignments that are distinctive for CRMs as opposed to neutral DNA. The patterns are strings of alignment columns, and their discriminatory power is determined by the frequency of the patterns in training sets of alignments in CRMs compared with alignments in neutral DNA. Although the Regulatory Potential score is influenced by features in addition to constraint, it is designed for finding CRMs that are common among species.

Basal Promoters

Promoters are DNA sequences needed for accurate initiation of transcription. For some promoters including the globin gene promoters, one DNA segment interacts with RNA polymerase II and its accessory factors (such as TFIID and TFIIB) to determine the start site of transcription; this is the basal promoter.[58] Five motifs have been associated with basal promoters, and these are found in the promoters of human globin genes (Fig. 3.4.A). They include the familiar TATA box to which TBP binds, along with the BRE to which TFIIB binds and the Inr and DPE motifs to which components of TFIID bind.[58]

Early studies revealed the presence of the ATAAA motif approximately 25–30 bp 5′ to the start site of transcription of the globin genes,[59] and this is by far the most restricted in its consensus, that is, this motif appears to be under evolutionary constraint in globin genes. Recent studies on other promoters are revealing the roles of additional motifs close to the start site of transcription, but on both sides. Matches to these motifs can be found readily at the appropriate positions in the human globin genes (Fig. 3.4.A). The motifs other than TATA do not have well-defined consensus sequences, either for genes in general or for the human globin genes, and thus their presence alone may not signify function. Also, only the TATA box, Inr, and DPE show evidence of constraint in homologs in other mammalian species (Fig. 3.5.A, conservation track). Each of the motifs except BRE has been implicated in function by finding a mutation in at least one case of β thalassemia. Every base in the TATA box has been altered in one or another β thalassemia, and mutations in Inr, MTE, and DPE also are associated with β thalassemia (Fig. 3.5.A, Compilation of Human Disease Variants and Other Mutations). The BRE overlaps with the β-direct repeat element (βDRE), which is a *cis*-regulatory element bound by βDRF and demonstrated to function in regulation of the β-globin gene by mutagenesis and expression in transfected cells.[60] Thus, the mutagenesis data (natural and directed) indicate that all five motifs are important for appropriate expression of the β-globin gene. The presence of similar motifs in the basal promoters for other human globin genes suggests that they are active in these genes as well.

Although it is common to describe promoters recognized by RNA polymerase II by the motifs shown in Figure 3.4.A, it is important to realize that this is true for only a minority of human genes. Globin gene promoters

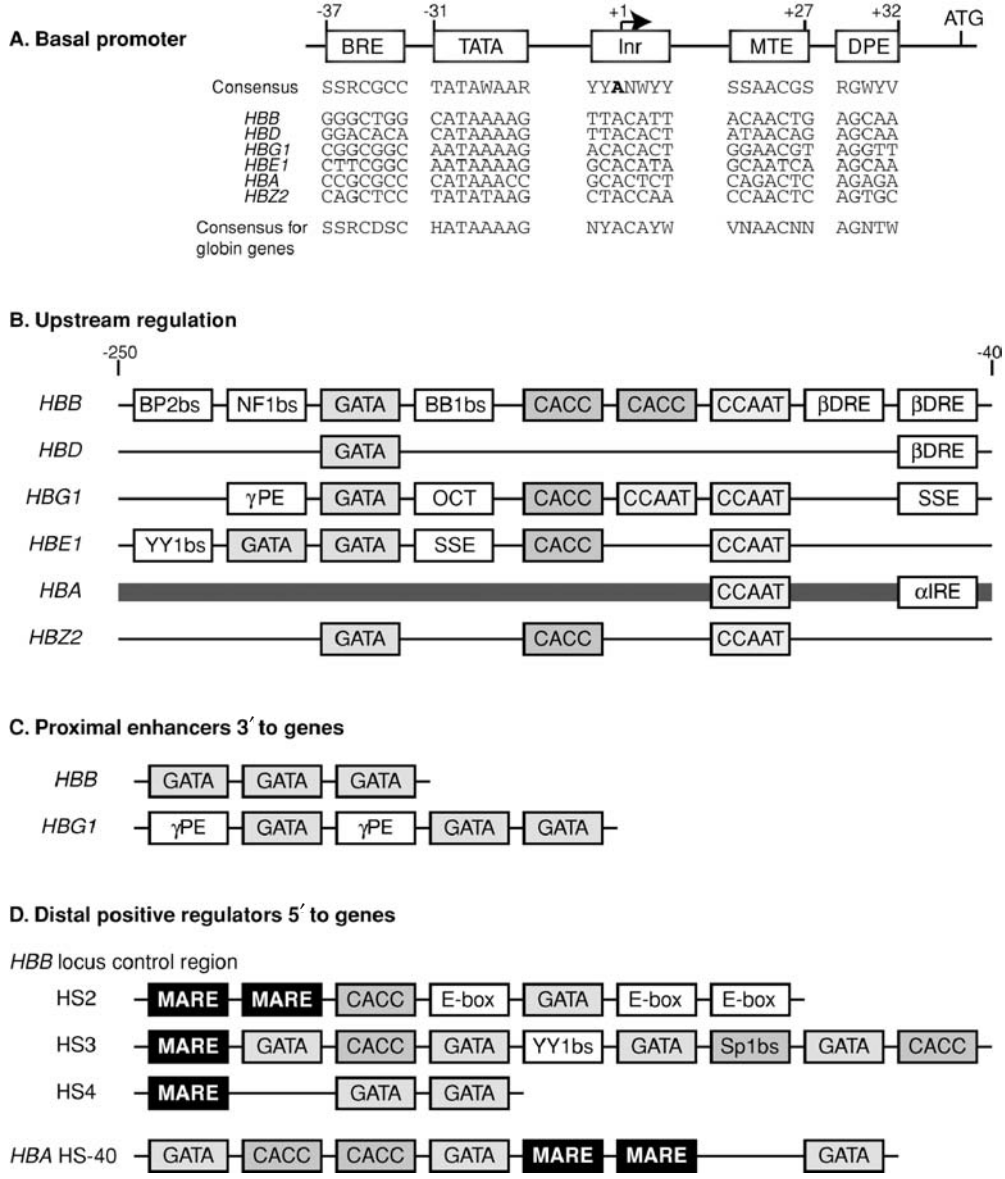

Figure 3.4. Motifs and binding sites in *cis*-regulatory modules of globin genes. (**A**) Motifs in the basal promoter, based on those defined in the review by Maston et al.[58] Numbers along the top are relative to the transcription start site as +1, and ATG denotes the translation start site. The top consensus sequence is from Maston et al. Corresponding positions in the globin genes are given for each motif, followed by the consensus derived for the globin genes. Symbols for ambiguous nucleotides are S = C or G, W = A or T, R = A or G, Y = C or T, D = A or G or T, H = A or C or T, V = A or C or G, and N = A or C or G or T. (**B**) Motifs in the regulatory regions immediately upstream of the basal promoters. Motifs are indicated by sequence (CCAAT, CACC, and GATA), the name of the element (βDRE, αIRE, γPE, and OCT) or the protein name followed by bs for "binding site" (BP2bs, NF1bs, and BB1bs). Boxes for motifs found in several upstream regions are shaded. The boxes were placed in the correct order but spacing is not indicated. The thick line for the *HBA* upstream regions (both *HBA1* and *HBA2*) denotes that it is a CpG island. (**C**) Motifs in the proximal enhancers. (**D**) Motifs in distal positive regulators, including three hypersensitive sites of the β-globin LCR and HS-40 for the α-globin gene cluster.

fall into the category of promoters with well-defined TATA boxes at a restricted location and one major start site for transcription. Recent studies show that these comprise a small minority of promoters, perhaps only 10%–20%. Most promoters are CpG islands with no obvious TATA box, and in some cases they have a broad distribution of start sites.[61]

Upstream Regulatory Sequences

Adjacent to the basal promoter is the upstream regulatory region,[58] which in globin genes runs from approximately positions -40 to -250 (Fig. 3.4.B). Only one motif in this region is found in all the highly expressed globin genes: the CCAAT box. Proteins such as NF-Y and CP1 bind to this

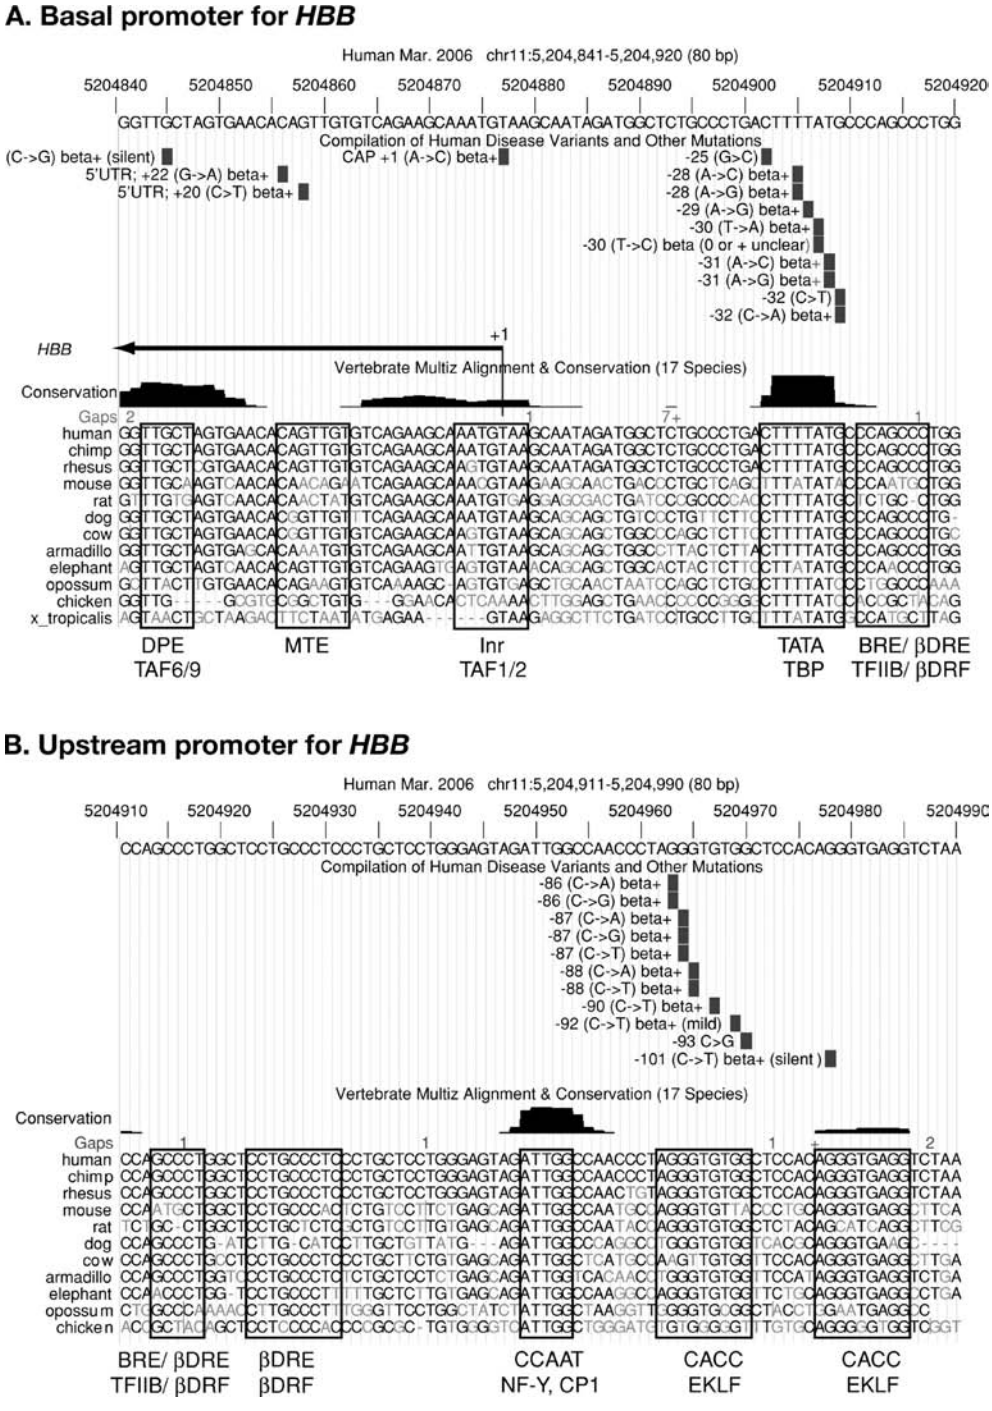

Figure 3.5. Conservation and mutations in globin gene promoters. (**A**) Basal promoter and (**B**) upstream promoter for *HBB*. In each panel, the sequence of an 80-bp segment is shown, along with positions of mutations associated with β thalassemia, conservation scores, and alignments with many mammals, chicken, and frog (*X. tropicalis*). The display is from the UCSC Genome Browser in genome coordinates (top line), and the direction of transcription is from right to left (opposite that used in previous figures). The start site of transcription is denoted by the vertical line leading to a leftward arrow. Boxes are drawn around motifs, which are labeled by name and proteins that bind to them (bottom line in each panel).

motif,[62,63] and it has been implicated in promoter function because of its presence in many promoters and the results of mutagenesis and binding studies.[59] It is missing from the δ-globin gene (*HBD*) promoter, but this gene is expressed at a low level (~1%–2% of *HBB*).

Two motifs are found in many but not all promoters. One is the CACC box, which is bound by transcription factors in the Krüppel-like zinc finger class (KLF). The first erythroid KLF discovered was erythroid Krüppel-like factor, which binds to the CACC box in the *HBB* promoter and is needed

for erythropoiesis.[64,65] The CACC boxes in globin promoters tend to be highly conserved in other mammals, albeit not as constrained as the CCAAT box (Fig. 3.5.B). Mutations in almost every position in the proximal CACC box have been associated with β thalassemia (Fig. 3.5.B). Thus many lines of evidence point to the importance of this motif. Other KLFs may bind to the CACC boxes in other globin gene promoters, such as FKLF or KLF13[66] for the *HBG1* and *HBG2* promoters.

The other motif occurring frequently in upstream regulatory regions is WGATAR, the binding site for GATA-1 and related proteins (Fig. 3.4.B). GATA-1 plays a critical role in erythroid-specific gene activation and repression,[67–69] and the binding sites in these upstream regions have been implicated in positive regulation of the respective genes.[70,71] The GATA-1 binding sites upstream of *HBE1*, *HBG1*, *HBG2*, and *HBZ2* are conserved in most mammals, but the ones upstream of *HBB* are not. GATA-1 binds to the promoter regions of β-globin genes in both human[63] and mouse,[72] but the binding site motif occurs in different places in the two promoters.[73] This is an example of alterations in the binding site being associated with changes in the pattern of regulation, such as the delay in onset of expression in humans.

A different set of binding sites is distinctive to each type of gene. For instance, βDRF[60] and BB1-binding protein[72,74] have been implicated in the regulation of the β-globin gene but not other globin genes (Fig. 3.4.B). Both binding sites are conserved in many placental mammals (Fig. 3.5.B).[73] Likewise, binding of OCT1 and γPE has been shown for the upstream regions of γ-globin genes but not others.[75]

The *cis*-elements close to the γ-globin genes are key determinants of fetal compared with embryonic expression. One of the clearest demonstrations of this is from transgenic mouse experiments in which a construct containing an LCR is used to enhance expression of globin genes. The γ-globin gene of prosimians, that is, the bushbaby galago, is expressed embryonically, and when it is included in the test construct in transgenic mice, the transgene is also expressed embryonically. In contrast, a human γ-globin gene, normally expressed during fetal life in humans, is expressed fetally when transferred into transgenic mice in an otherwise identical construct.[76] Thus one would expect to find alterations in the regulatory regions of anthropoid (monkey, ape, and human) γ-globin genes that are associated with this change in stage specificity (i.e., sequences that are conserved in anthropoid primates but are different in prosimians and nonprimate mammals). Examination of aligned sequences for differential phylogenetic footprints[49] led to the identification of a stage selector element in the human γ-globin gene promoter (Fig. 3.4.B). The stage selector element is a binding site for a factor called the stage selector protein, which has been implicated in the differential expression of γ- and β-globin genes.[77] Additional DNA sequences that bind several proteins have been implicated in fetal silencing of the γ-globin gene.[49] Parallel protein-binding and mutagenesis studies led to the discovery of a novel protein that binds to an element called the γPE, in the upstream regulatory region of the γ-globin genes, which has also been implicated in regulation of this gene.[75]

The most distinctive globin gene promoters are those of the α-globin genes (*HBA1* and *HBA2*). These promoters are CpG islands, and among the hemoglobin genes, only those encoding α-globin have this feature. (The θ-globin and μ-globin genes also have promoters in CpG islands, but as discussed previously, it is not clear that they encode components of hemoglobin.) Although the majority of mammalian promoters are CpG islands,[61] most of the associated genes are expressed in multiple tissues and few if any are expressed at such a high level as the α-globin gene. Thus the presence of a CpG island in the promoter for a globin gene is curious, and it leads to several unanswered questions about the α-globin gene promoters. What prevents their expression in nonerythroid tissues? What sequences in addition to the CpG island lead to very high-level expression in erythroid cells? No GATA-1-binding site is found in the α-globin gene promoters of most placental mammals (the mouse α-globin genes is a notable exception), so sequence-directed binding of this protein to the proximal sequences is not the answer. Several studies have shown that the CpG island is a key component of the *cis*-regulatory elements for the α-globin gene of humans and rabbits, possibly through its effects on chromatin structure.[78,79]

The differences in the arrays of proteins functioning at ε-, γ-, β-, and α-globin genes indicate that a distinct battery of proteins functions in the promoter for each type of gene. Indeed, this is consistent with the observation that *cis*-acting sequences needed for stage-specific regulation of expression map close to the genes.[80]

Proximal Enhancers

Enhancers are DNA sequences that increase the activity of promoters; they can be located on either side of a gene or internal to it, and they can act at considerable distances from genes.[81] Two enhancers have been found close to genes in the β-globin gene cluster, one that is 3′ to *HBB* and one that is 3′ to *HBG1* (Fig. 3.3.A). In both cases the enhancers are less than 1 kb downstream of the polyA additional signal for the respective genes. The *HBB* enhancer was discovered by its effect on developmental timing of expression of globin transgenes when introduced into mice. High-level expression of human γ- or β-globin transgene constructs in fetal erythroid cells (the normal onset of expression of mouse β-globin genes) is dependent on the presence of the enhancer.[74,82–84] The *HBG1* enhancer was discovered as the only DNA segment in a 22-kb region surrounding the γ-globin genes that boosted expression of a reporter gene driven by a γ-globin gene promoter in transfected erythroid cells.[85] Deletion of this enhancer from a large construct containing the human LCR and β-like

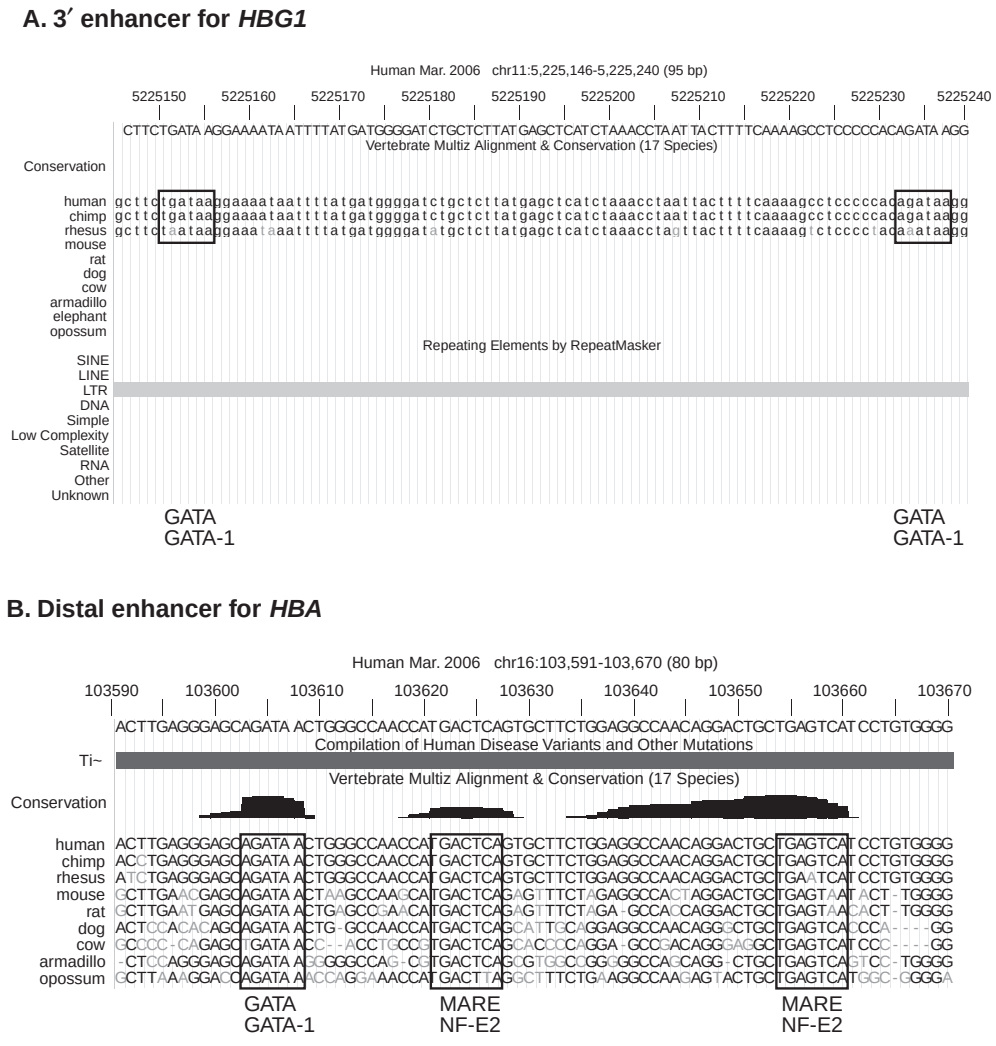

Figure 3.6. Wide range of conservation in globin gene enhancers. (**A**) Proximal enhancer for *HBG1*, showing the sequence of part of the 3′ enhancer, alignments with sequences of other anthropoid primates, the encompassing repetitive element, and binding motifs. (**B**) Distal enhancer for the α-globin gene cluster, HS-40. The panel shows an 80-bp segment of the enhancer, along with the Ti~α thalassemia deletion that removes this DNA and more, the conservation track and alignments with several eutherian mammals and the marsupial opossum. Binding sites are boxed and labeled by name and proteins binding to them.

globin genes had no effect on expression levels in transgenic mice,[86] which could mean that it actually has no function, or that other sequences compensate for its loss, or that its function is not apparent in mice.

Indeed, comparative sequence analysis of these proximal enhancers strongly supports the conclusion that both play roles in higher primates but not in other species. As illustrated in Figure 3.4.C, both enhancers contain binding sites for GATA-1,[87,88] and the *HBG1* enhancer also binds to the γPE protein.[75] The DNA homologous to the *HBB* enhancer in other mammals is not strongly conserved, even in the GATA motifs. Furthermore, two of the GATA-1–binding sites in the *HBG1* enhancer were introduced via an LTR-type transposable element that is present only in higher primates (Fig. 3.6.A). Thus the presence of the *HBG1* proximal enhancer correlates with the fetal recruitment of γ-globin gene expression in anthropoids, and its function may not be observed in transgenic mice. Likewise, the presence of GATA-1–binding sites only in higher primates suggests that the function of the *HBB* proximal enhancer may also be lineage-specific, perhaps related to the delay in expression of *HBB* in higher primates. In this case, an effect on developmental timing is readily demonstrable in transgenic mice, but because of the differences in timing of *HBB* expression in humans (the source of the transgene) and mouse (the host species), it is difficult to understand fully this function.

Distal Enhancers

In addition to the proximal promoters and enhancers, both the α-like and β-like globin gene clusters are regulated by distal control regions. The β-like globin cluster is regulated by the distal LCR (reviewed in refs. 89, 90), and the α-like

globin gene cluster is regulated by HS-40.[91] In both cases, deletion of the distal control region is associated with thalassemia (Fig. 3.3). Addition of the distal control regions has profound effects on expression of linked genes in transgenic mice. Without the LCR, erythroid expression of a β-globin transgene is not seen in all mouse lines,[92] presumably because of integration in a repressive region of a chromosome (a position effect). With the LCR, the β-globin transgene is expressed at a high level in erythroid cells in almost all mouse lines, indicating strong enhancement and a reduction in position effects.[93] HS-40 of the α-globin gene complex is a strong enhancer of globin gene expression, both in transgenic mice[91,94] and in transfected cells.[95]

The β-globin LCR is a very large regulatory region, containing at least five DNase hypersensitive sites in humans spread over approximately 17 kb[96–98] between *HBE1* and an *OR* gene (Fig. 3.3.A). This region is highly conserved in mammals, with highly similar sequences indicative of constraint found both in the hypersensitive sites and between them.[50,90] This can be seen in Figure 3.3.A as the string of peaks of conservation and RP in this region.

The distal enhancer for the α-globin gene, HS-40, is much smaller than the LCR. It is approximately 250 bp in length,[99] located in a widely expressed gene called *C16orf35* (Fig. 3.3.B). Additional erythroid DNase hypersensitive sites are present in this large gene, but none has been shown to play a role in regulation of globin genes.[26] HS-40 is sufficient for strong enhancement and high activity in erythroid cells of transgenic mice, especially during embryonic and fetal development.[91] It is very strongly conserved in mammals, with obvious matches to species as distant as opossum (Figs. 3.3.B and 3.6.B). Functional tests have shown that the homologous regions of chicken and fish also have enhancer activity, despite considerable divergence outside the protein-binding sites.[44]

Regulatory activities in addition to tissue-specific enhancement have been attributed to the β-globin LCR, but they are not seen consistently in multiple lines of investigation.[100] Examination of chromatin structure after deletion of the LCR led to the inference that the LCR is needed for tissue-specific chromosomal domain opening.[101] Chromosome 11 from a patient with the Hispanic $(\varepsilon\gamma\delta\beta)^0$ thalassemia (missing most of the LCR and some adjacent sequences, but leaving all of the β-like globin genes intact) (Fig. 3.3A) was transferred through multiple somatic cells to generate a hybrid murine erythroleukemia cell line containing the mutant human chromosome. The β-globin gene cluster in this hybrid cell line is inactive and is insensitive to DNase, indicating that the LCR is needed for opening a chromosomal domain.[101] An engineered mouse line carrying a deletion of the mouse β-globin LCR and the sequences homologous to those lost in the Hispanic deletion retains an open chromatin conformation (accessible to DNase) in the mouse β-globin gene.[102] Although expression of the mouse β-globin genes is reduced substantially, the locus is not silenced. Thus the repressive heterochromatin seen in the hybrid murine erythroleukemia cells carrying human chromosome 11 with the Hispanic deletion may have been produced during the chromosome transfers between cell lines. Currently, the DNA sequence determinants of chromatin opening have still not been discovered. The β-globin LCR has also been implicated in overcoming position effects in transgenic mice,[103] in keeping with the inferred effect on opening a chromatin domain. Transgene constructs containing the β-globin can still show position effect variegation.[104] Both the β-globin LCR and the α-globin HS-40 are very strong, erythroid-specific enhancers needed for the expression of any of the linked globin genes. They also can overcome some but not all repressive effects after integration at a variety of chromosomal locations. This could be a consequence of the strong enhancement.

Three transcription factor–binding motifs are present in almost all DNase hypersensitive sites that have a strong function in the distal enhancers (Fig. 3.4.D). All contain Maf-response elements (MAREs) to which transcriptional activator proteins of the basic leucine zipper class can bind.[105] A subfamily of proteins related to AP1, such as NF-E2, LCRF1/Nrf1, and Bach1, bind to this element (reviewed in refs. 106, 107). All are heterodimers containing a Maf protein as one subunit, which is the basis for the name of the response element. All the hypersensitive sites have GATA motifs, to which GATA-1 and its relatives bind.[108] The third common motif is CACC, to which a family of Zinc-finger proteins including erythroid Krüppel-like factor can bind.[64] At HS3 in the β-globin LCR, there is evidence that motifs related to CACC are bound by additional KLFs, such as Sp1.[109] HS2 of the β-globin LCR also has three E-boxes, which are the binding sites for TAL-1 and its heterodimeric partners.[47] This protein has been implicated in regulation of hematopoiesis, and it appears to also play a role in enhancement by HS2.

Initial studies of protein binding at these and other CRMs used various in vitro methods and in vivo footprinting.[99,110–112] Recent experiments using chromatin immunoprecipitation have demonstrated occupancy of the CRMs by several of these proteins in erythroid cells.[113–116] Many of the sites have been implicated directly in activity by mutagenesis and gene transfer.[47,117–119]

The protein binding sites in the distal positive regulators show some common patterns (Fig. 3.4.D). A MARE plus two GATA motifs is present in most of the CRMs, and this arrangement has been shown to be needed for formation of a hypersensitive site at HS4.[120] The strongest enhancers (as assayed by gene transfer in somatic cells) are HS2 and HS-40. Both of these have two MAREs, and mutation of those MAREs removes much of the enhancing activity.[117,119] Thus the MAREs and proteins binding to them are critical for high-level enhancement, but the other binding sites contribute to function as well.

The CRMs marked by these hypersensitive sites in the distal positive regulators are conserved across almost all mammals.[26,90] The portion of the alignments for HS-40 shown in Figure 3.6.B indicates the very strong constraint

seen in the known binding sites and additional short segments both for this enhancer and for HS2. Most of the binding sites in HS3 are also highly conserved, but some are not, likely reflecting both common and lineage-specific functions. HS4, with the MARE and two GATA motifs, is conserved across a wide span of placental mammals, but this DNA sequence is part of an LTR-type repeat, a member of the ERV1 repeat family. This appears to be an old transposable element (predating most of the mammalian radiation), but one that continues to provide a regulatory function.

CONCLUDING REMARKS

Molecular clones containing mammalian globin gene clusters were isolated approximately 30 years ago. Intense study since then has revealed much about their structure, evolution, and regulation; however, understanding sufficient to lead to clinical applications continues to elude us. The myriad levels of regulation and function that operate within these gene clusters certainly confound attempts to find simplifying conclusions. Despite these challenges, studies of the globin gene clusters have consistently provided new insights into function, regulation, and evolution. The lessons being learned as we try to integrate information from classic molecular biology and genetics, new high-through-put biochemical assays, and extensive interspecies sequence comparisons are paving the way for applying these approaches genome wide. The globin gene clusters illustrate the need to distinguish common from lineage-specific regulation. Although simple generalizations are rare, the extensive information that one needs for interpreting data in the context of comparative genomics is readily accessible. Throughout this chapter, we have illustrated points using output from the UCSC Genome Browser (http://genome.ucsc.edu), with special emphasis on the tracks showing Conservation, Regulatory Potential, and Locus Variants. Deeper information on the variants associated with disorders of the hemoglobins can be obtained from HbVar (http://www.bx.psu.edu). We hope that the examples presented here will be helpful in guiding interpretation of the multitude of data available to the readers now and in the future.

Nuclear Factors That Regulate Erythropoiesis

Gerd A. Blobel and Mitchell J. Weiss

INTRODUCTION

Studies of erythroid transcription factors originate from efforts to identify and characterize the numerous tissue-specific and ubiquitous proteins that bind *cis*-regulatory motifs within the globin gene loci (Chapters 3 and 5). In addition to elucidating mechanisms of globin gene regulation and erythroid development, this approach has led to the discovery of nuclear proteins that function in a wide range of developmental processes. Experimental approaches and insights gained through studies of the globin loci have broad implications for understanding how transcription factors regulate the expression of individual genes and work together to coordinate cellular differentiation.

Erythrocyte formation in the vertebrate embryo occurs in several distinct waves[1,2] (see also Chapter 1). The first erythrocytes, termed primitive (EryP), arise in the extraembryonic yolk sac at mouse embryonic day 7.5 (E7.5) and weeks 3–4 in the human embryo. Later, erythropoiesis shifts to the fetal liver where adult-type (EryD, definitive) erythrocytes are produced. Finally, at birth, blood formation shifts to the bone marrow, and also the spleen in mice. EryPs and EryDs are distinguished by their unique cellular morphology, cytokine responsiveness, transcription factor requirements, and patterns of gene expression.[3–10] Most notably, the expression of individual globin genes is developmentally regulated (Chapter 3). Understanding how transcription factors regulate the temporal control of β-like globin genes during mammalian development is of general interest to the study of gene regulation in higher eukaryotes and could eventually lead to new approaches to reactivate the human fetal γ-globin genes in patients with β chain hemoglobinopathies, such as sickle cell anemia and β thalassemia.

The primary *cis*-acting determinants of individual globin gene expression reside in the promoter regions immediately upstream of each gene and act in concert with more distant regulatory elements (Chapters 3 and 5). For example, the β-globin locus control region (β–LCR) encompasses approximately 20 kb of DNA situated upstream of the β-globin gene cluster. Originally identified as a set of erythroid-specific DNase hypersensitive sites (HS), the β-LCR is now known to be essential for high-level erythroid expression of β-globin genes.[11–14] Detailed analysis of globin gene promoters and the β-LCR has revealed a number of conserved DNA motifs important for globin expression. Among these motifs, the best studied are the "GATA," "CACCC," and "TGA(C/G)TCA" (NF-E2/AP-1-like) elements (Fig. 4.1). Not surprisingly, identical motifs also function in the promoters and enhancers of many other erythroid genes such as heme biosynthetic enzymes, red cell membrane proteins, and α-globin. One or more transcription factors has been discovered to bind each of these *cis* elements in erythroid cells.

GENERAL PRINCIPLES

General studies of transcription factors have conveyed several important concepts and experimental approaches applicable to studies of erythroid nuclear proteins.

1) Transcription factors are modular proteins with distinct domains mediating DNA binding, transcriptional activation, repression, and protein interactions.[15] However, a single domain may have more than one function. For example, GATA and Krüppel zinc fingers mediate both DNA binding and protein interactions. Typically, domains are analyzed by determining the effects of various mutations and "domain swaps" on the ability to activate or repress synthetic promoter–reporter constructs in transient transfection assays using heterologous cells, such as 3T3 or COS. Such studies are useful but fail to provide the native chromosomal and cellular contexts in which a lineage-specific factor normally operates. In this regard, the availability of more biologically relevant cellular and in vivo models complements the use of conventional promoter–reporter studies.
2) Transcription factors function within multiprotein complexes.[16,17] Defining these complexes in erythroid cells is critical to understanding the mechanisms that underlie globin gene expression and erythroid differentiation. Several approaches, including yeast two-hybrid screening, classic biochemical purification, and affinity purification with molecular tags are commonly used to identify interacting proteins and delineate higher order transcription factor networks in erythroid cells.
3) Posttranslational alterations, such as phosphorylation, acetylation, ubiquitination, and sumoylation, can modulate transcription factor function. These chemical modifications establish additional levels of

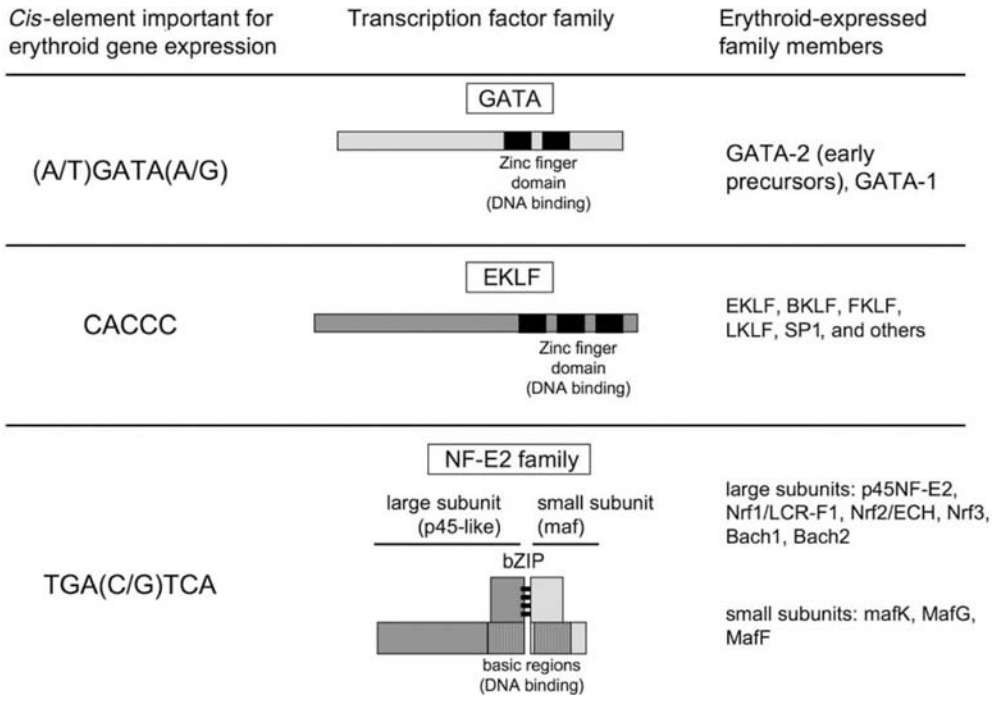

Figure 4.1. *Cis*-acting elements and corresponding transcription factor families important for erythroid gene expression.

control through which gene expression may be regulated rapidly in response to changes in the nuclear environment and/or extracellular signals. Examples relevant to erythroid biology are discussed later in this chapter.

4) Most transcription factors can both activate and repress gene expression. Among erythroid transcription factors, GATA-1, EKLF, and SCL/TAL-1 all have the capacity to activate and repress gene expression. These dual functions enhance the utility of transcription factors in several key stages of tissue development. For example, during terminal maturation, a single nuclear protein can simultaneously activate genes associated with the differentiated phenotype and silence those associated with the immature state. In addition, tissue-restricted transcription factors may participate in cell fate decisions of multipotent progenitors by activating genes for one lineage and silencing those of alternative lineages.

5) Cellular environment and target promoter context influence transcription factor activities by regulating the assembly of specific multiprotein complexes at individual genes. For example, the megakaryocyte-specific α-IIb gene contains a promoter that is activated by GATA-1 alone, but inhibited by GATA-1 bound to its cofactor FOG-1.[18,19] Binding of megakaryocyte-expressed Ets transcription factor, such as Fli1, to an adjacent DNA element converts FOG-1 into a coactivator. This identifies a mechanism by which GATA-1 and FOG-1 regulate the same gene differently in separate lineages.

6) As discussed in more detail later, transcription factors exert their functions in part by modifying chromatin, either directly or by assembling multiprotein complexes to establish and maintain active or repressive chromatin states. Many erythroid transcription factors associate with histone acetyltransferases. Hyperacetylation is typically found at sites of open chromatin that surround active genes. More recent work shows that erythroid nuclear factors facilitate the formation of long-range chromatin loops that bring critical regulatory elements into physical proximity.[20,21] How erythroid transcription factors regulate chromatin and DNA accessibility is an active area of research.

EXPERIMENTAL APPROACHES FOR STUDYING TRANSCRIPTION FACTORS

Several recently developed technologies have revolutionized the study of transcription factor function. Some of the technologies that have accelerated our understanding of erythropoiesis and globin gene expression are reviewed here.

Biochemical Purification

Transcription factors invariably interact chemically with cofactor complexes to modify histone proteins, to remodel nucleosomes, and to recruit basal transcription factors. Thus, one fruitful approach to define the functions of individual nuclear factors is to identify interacting

proteins. In particular, yeast two-hybrid screens and in vitro purification of transcription factor complexes by using conventional biochemistry have elucidated gene regulation by defining higher order regulatory networks. Such studies are greatly facilitated by recent advances in mass spectrometry that permit identification of small amounts of proteins in complex mixtures.

Tissue Culture Models for Erythroid Differentiation

Numerous tissue culture models recapitulate selected aspects of erythroid maturation of multiple species, including chicken, mouse, and human. These include murine erythroleukemia (MEL) cells, which represent definitive (adult-type) erythroid precursors and K562, a human erythroleukemia line that expresses embryonic and fetal globins. A variety of chemical agents can be used to induce erythroid maturation of K562 and MEL cells.[23,24] Mouse G1E cells are arrested at the proerythroblast stage due to a lack of transcription factor GATA-1.[25] Conditional expression of GATA-1 in these cells induces synchronous erythroid maturation. Numerous avian cell lines have also provided useful models for erythropoiesis.[26,27] Established erythroid cell lines provide unlimited quantities of material for biochemical purification studies and frequently allow for synchronous differentiation on exposure to chemical compounds. Moreover, in established cell lines it is relatively simple to manipulate the expression of key transcription factors via overexpression or siRNA silencing and determine the effects on erythroid maturation and/or gene expression. Biological studies in cell lines are confounded by the effects of immortalization or outright transformation necessitating the use of primary cells for some studies. In mice and humans, primary erythroid progenitors can be purified from yolk sac, fetal liver, spleen, or bone marrow and expanded or differentiated in short-term cultures by using appropriate growth and differentiation factors.[28–32] It is also possible to generate primary erythroid cultures from in vitro differentiation of embryonic stem cells (ESCs).[33,34]

Chromatin Immunoprecipitation

Historically, interactions between DNA-binding proteins and their target sequences were demonstrated by electrophoretic mobility shift assay, in which binding of a transcription factor retards the migration of an oligonucleotide during polyacrylamide gel electrophoresis (see Fig. 4.6 for an example). This assay does not, however, assess transcription factor binding to chromatinized DNA in live cells. Chromatin immunoprecipitation (ChIP) is used to determine whether a nuclear factor is physically associated with a specific region of DNA sequence in vivo. The topic is described by Orlando and Paro[35] and experimental protocols are outlined by Boyd et al.[36] To perform ChIP, cells are treated with a crosslinking reagent that covalently attaches DNA to its associated proteins. Then, the cells are lysed and chromatin is purified and fragmented into defined sizes (typically 0.5–1 kb) by sonication or partial nuclease digestion. The resulting material is immunoprecipitated with antibodies against the nuclear protein of interest or control antibodies. Protein–DNA crosslinks are reversed and the protein-associated DNA is purified and analyzed by quantitative polymerase chain reaction (PCR) using specific primer pairs that flank putative transcription factor binding sites or control regions where binding is not expected to occur (Fig. 4.2). Global analysis of ChIP products can be performed by hybridizing them to DNA-based microarrays (see later) or by using high throughput DNA sequencing technologies.[37,38]

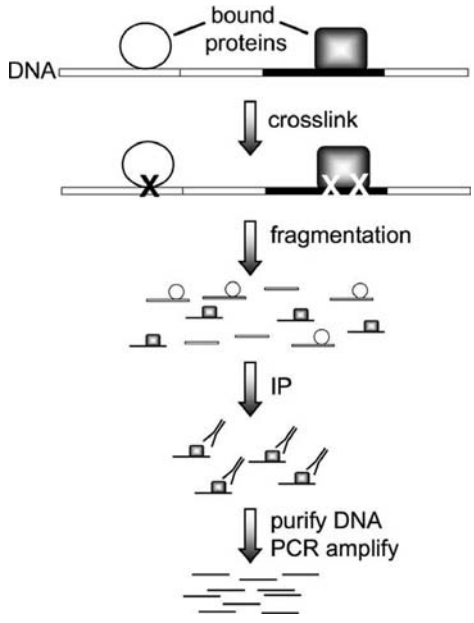

Figure 4.2. ChIP analysis. ChIP can identify histone and nonhistone proteins and protein modifications associated with genomic regions of interest. The first step of ChIP is to cross link proteins to DNA or other proteins. Following lysis of cells, extracts are sonicated to shear the DNA. Micrococcal nuclease can also be used to fragment the DNA. Proteins are immunoprecipitated with specific or control antibodies. Cross links are reversed; DNA is purified and amplified by PCR. For quantification, the amounts of PCR product are compared with those of unprecipitated PCR-amplified DNA (input). PCR reactions with primers against regions not bound by protein are used as additional controls.

In addition to determining transcription factor binding to specific genes, ChIP can be used to examine whether histone proteins or transcription factors are acetylated, methylated, or phosphorylated at specific chromosomal positions. Currently, ChIP analysis is the gold standard to determine transcription factor binding and posttranslational protein modifications at gene loci in vivo and has been used extensively at the globin loci to examine erythroid development.

MICROARRAY ANALYSIS TO IDENTIFY TRANSCRIPTION FACTOR TARGET GENES

In microarray or “gene chip” analysis, genomic DNA or cDNA derived from cells of interest is labeled with fluorescent probes and incubated with nucleic acids specifying

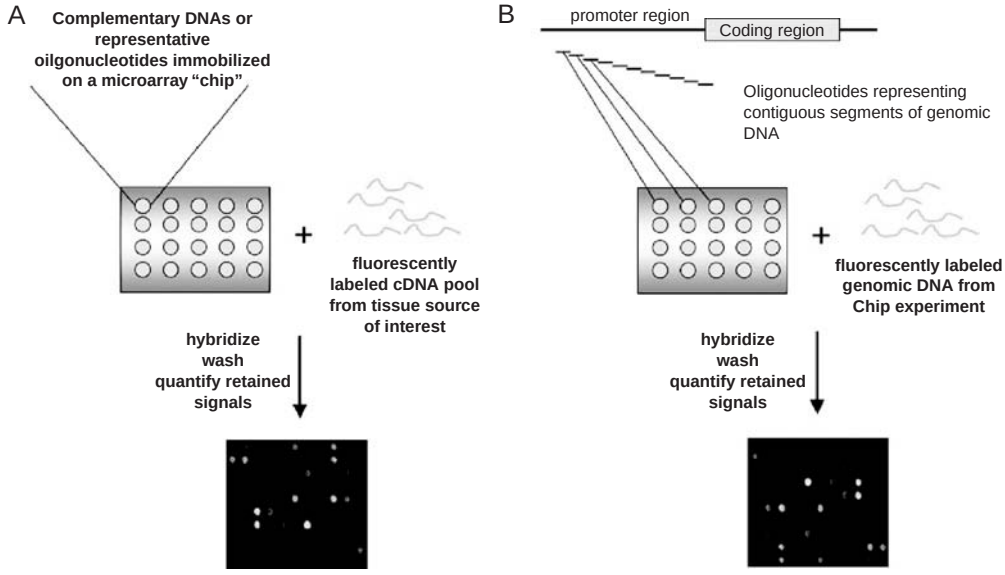

Figure 4.3. Microarray analysis. **(A)** Messenger RNA profiling. Complementary DNAs from a tissue source of interest are prepared, labeled with a fluorescent tag, and incubated with a slide or "chip" containing immobilized oligonucleotides or DNA segments that hybridize to specific cDNAs. The retained fluorescent signal at a fixed position or "address" on the chip reflects the relative expression level of a specific mRNA transcript. **(B)** ChIP–chip analysis. DNA from ChIP (Fig. 4.2) is amplified, labeled with a fluorescent tag, and incubated with a "tiled" microarray chip containing oligonucleotides that hybridize to contiguous segments of genomic DNA. Microarray chips representing all known promoter regions or even entire genomes are available commercially. In addition, it is possible to prepare microarray chips that specifically interrogate smaller genomic regions of interest.

unique chromosomal loci or mRNA transcripts that are immobilized on a solid surface (Fig. 4.3). Hybridization of the labeled cellular nucleic acids to sequences at specific locations on the chip is quantified and studied by optical scanning and computational analysis. This technology has advanced to a point where many thousands of different sequences can be examined in a single experiment.

Microarrays are used in two general approaches to identify transcription factor targets. First, transcriptome analysis can identify mRNAs that are up- or down-regulated in response to altered transcription factor activities (Fig. 4.3A). For example, it is possible to manipulate specific transcription factors in biologically relevant cells through gene targeting (discussed later in this chapter), viral transduction, dominant negative mutants, and by creating conditional alleles that are activated or silenced by drugs. Then, microarray studies can be used to compare mRNA expression patterns between identical cells in which the transcription factor function is specifically altered. Remarkably, commercially available microarray platforms can interrogate most or all expressed genes in many species including mice and humans. Using this approach, it is possible to define the actions of any transcription factor on global gene expression in biologically relevant contexts. Follow-up studies using ChIP can investigate whether effects on the expression of specific genes are direct or indirect consequences of transcription factor activities. Examples of mRNA profiling using microarrays or other methods to identify erythroid transcription factor targets are described.[39–42]

Another approach to identify transcription factor targets combines ChIP with microarrays (ChIP–Chip) (Fig. 4.3B). DNA derived from ChIP using a transcription factor specific antibody is labeled to generate probes for microarrays containing genomic DNA. For this purpose, microarrays containing promoter regions of most expressed genes are available. In addition, it is possible to represent large chromosomal regions of interest, or even the entire genome, in "tiling arrays" that contain contiguous segments of genomic DNA. In this fashion, it is possible to screen for regions of genomic DNA in which the transcription factor binds in vivo. Currently, these experiments, particularly those that survey the entire genome, are expensive and technologically challenging, but the field is advancing rapidly. One limitation of this assay is that occupancy of a genomic sequence by a transcription factor does not necessarily reflect function – a transcription factor bound to DNA in vivo can activate, repress, or have no effect. An example of ChIP–chip analysis using a tiled microarray representing the α-globin locus is described by De Gobbi et al.[43]

DEFINING PHYSICAL INTERACTIONS BETWEEN DISTANT DNA ELEMENTS

Several models are invoked to explain how transcription factors enhance or inhibit gene expression over substantial genomic distances. Tracking models propose that transcription factors bound at distant regulatory sites recruit RNA polymerase and/or basal transcription factors, which then move along the chromatin fiber until a promoter

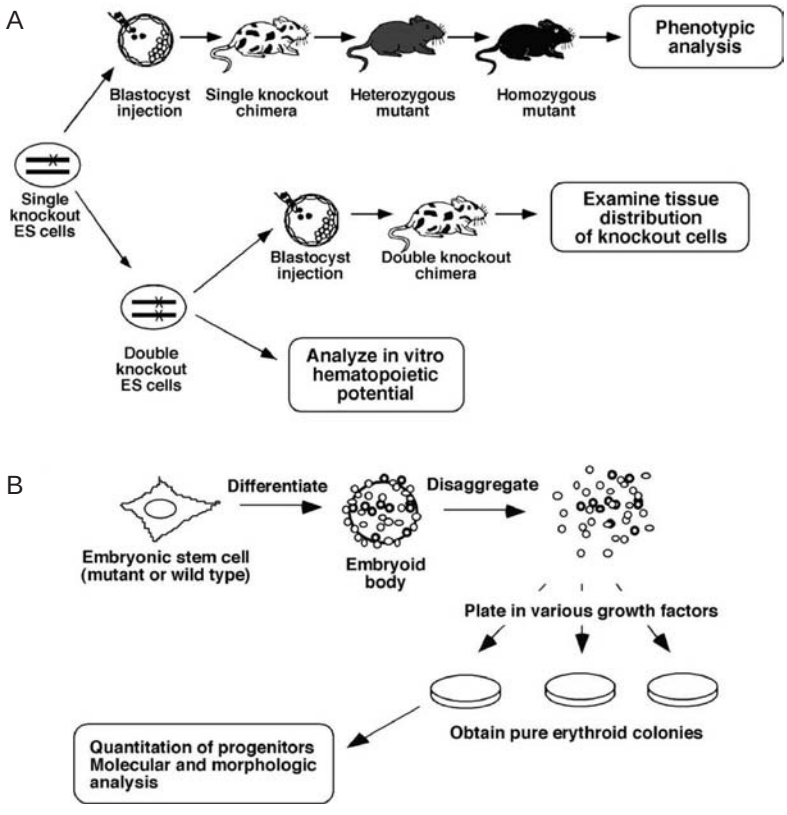

Figure 4.4. **(A)** Experimental strategies for studying gene knockouts. **(B)** In vitro differentiation of ESCs to obtain pure hematopoietic colonies. Reprinted from Weiss and Orkin[100] with permission from Elsevier Science, Copyright 1995.

is reached. Looping models posit that distal elements are brought in physical proximity with their dedicated promoters through the formation of chromatin loops. Although the latter model clearly applies to the α and β-globin gene loci,[44–46] tracking intermediates that precede loop formation remain a distinct possibility. Evidence to support this is found at the human ε-globin gene.[47] The most commonly used method to detect physical interactions among chromosomal fragments is called chromosome conformation capture ([3C] or nuclear ligation assay).[48,49] If performed with the appropriate controls, it can be used to demonstrate interactions among chromosomal fragments located in *cis* and on different chromosomes. 3C analysis has demonstrated that transcription factors GATA-1 and EKLF both promote folding of the β-globin locus to ensure physical proximity between the LCR and the active globin gene promoters.[20,21,50] 3C has also been used in the context of transgenic mice carrying versions of the human β-globin locus to delineate *cis*-acting sequences that organize the β-globin locus.[51]

ELUCIDATING GENE FUNCTION BY TARGETED MUTAGENESIS

Transcription factor functions identified in vitro must be examined in the context of primary cells and whole organisms. The advent of targeted gene disruption using homologous recombination in ESCs and mice has been instrumental in assessing transcription factor function by providing a means to inactivate (knockout) genes of interest or to modify them (knockin) and examine the biological consequences. Murine embryonic stem ESCs derived from the inner cell mass of blastocyst stage mouse embryos provide the basis for gene targeting.[52–54] ESCs can be maintained in a pluripotent state in culture and contribute to somatic and germ line tissues when introduced into blastocysts by microinjection. The first step toward studying a gene of interest is to disrupt a single allele by homologous recombination in ESCs to create a heterozygous, or "single knockout" state.[55,56] Several complementary experimental approaches are then available for further study (Fig. 4.4).

First, genetically altered ESCs may be injected into host blastocysts to produce chimeric mice, which may transmit the mutant allele to progeny. Through interbreeding of heterozygous offspring, homozygous null animals can be created for analysis. One limitation of this approach is that mutations causing early embryonic death can obscure the analysis of later developmental events. For example, direct examination of definitive hematopoiesis is difficult to assess in embryos that die prior to development of the fetal liver. Another potential problem in interpreting the phenotypes of knockout animals is failure to distinguish whether observed defects are cell autonomous or an indirect consequence of lesions in other cell types (noncell-autonomous). Both of these problems may be circumvented through chimera analysis or in vitro ESC differentiation assays (see later). In addition, more recent technology now permits developmental stage and tissue-specific gene targeting by expressing specific recombinases to excise or modify the target gene in a controlled spatiotemporal fashion.[57–60]

Second, heterozygous mutant ESCs can be converted to a homozygous-null state.[61–63] These mutant ESCs may be injected into wild-type host blastocysts to create chimeric animals in which the ability of the mutant donor ESCs to contribute to various tissues is assessed using polymorphic markers. For loci that are X-linked, such as *Gata1*, a single targeting event renders male ESCs null for the gene of interest. Failure of homozygous or hemizygous null ESCs to contribute to a specific cell type or tissue indicates a cell-autonomous requirement for the disrupted gene in the formation of that tissue.

Finally, the hematopoietic potential of genetically modified ESCs may be examined by in vitro techniques (Fig. 4.4). Under appropriate conditions, ESCs form embryoid bodies, spherical aggregates containing numerous differentiated cell types, including mature hematopoietic cells that can be

studied directly.[64] Embryoid bodies may be disaggregated into a single cell suspension and analyzed for hematopoietic progenitors by using standard methylcellulose-based colony assays.[33] Wild-type and genetically manipulated ESCs can also be induced to form hematopoietic lineages by cocultivation on the stromal line OP9.[65,66] More recently, in vitro differentiation techniques have been used to generate hematopoietic cells from human ESCs.[67–72] Of note, human ESC-derived definitive erythroid cells produced by current methods express mainly embryonic and fetal globins, but not adult globins. In the future, this experimental system may provide a useful tool to study the mechanisms of globin gene switching.

SPECIFIC ERYTHROID TRANSCRIPTION FACTORS

GATA-1 and Related Proteins

The abundant erythroid nuclear protein GATA-1 was identified through its ability to bind the (T/A)GATA(A/G) consensus motif found in regulatory regions of virtually all erythroid-specific genes including α- and β-globins, heme biosynthetic enzymes, red cell membrane proteins, and transcription factors.[73,74] GATA-1 recognizes DNA through two related, tandemly arranged zinc fingers of the configuration Cys-X2-Cys-X17-Cys-X2-Cys. The carboxyl (C) finger is necessary and sufficient for DNA binding, whereas the amino (N) finger stabilizes protein–DNA interactions at a subset of sites, in particular those that contain two GATA motifs arranged as direct or inverted repeats.[75–78] In addition, both zinc fingers serve as docking sites for various protein interaction partners.[79,80]

GATA-1 is Required for Terminal Erythroid Maturation and Platelet Formation

Gene targeting studies demonstrate that GATA-1 is essential for the production of mature erythrocytes. In chimeric mice, *Gata1*-donor ESCs contribute to all tissues examined except red blood cells; reintroduction of GATA-1 cDNA into the mutant ESCs restores their ability to contribute circulating red blood cells.[81,82] *Gata1* embryos die of anemia between E10.5 and E11.5 (Fig. 4.5A).[83] Examination of these embryos, combined with in vitro differentiation of *Gata1*-ESCs revealed a block to erythroid maturation and apoptosis at the proerythroblast stage (Fig. 4.4B).[84,85] Together, these experiments demonstrated an essential, cell-autonomous role for GATA-1 in the production of mature erythrocytes. Subsequently, additional studies showed that GATA-1 is also important for the formation and/or function of platelets,[86–88] eosinophils,[89] mast cells,[90] and dendritic cells.[91]

The GATA Protein Family

The discovery of GATA-1 led to the identification of several related proteins with highly conserved zinc finger

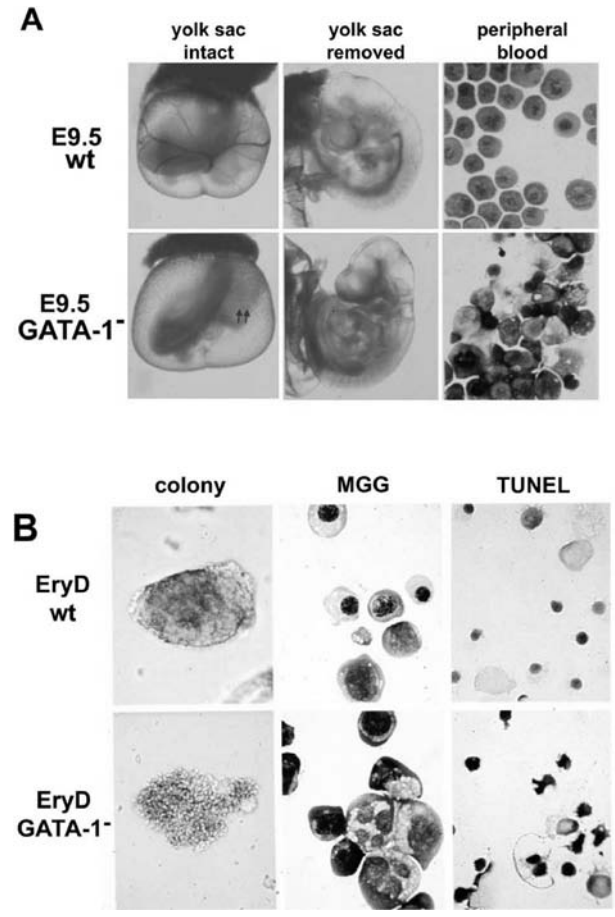

Figure 4.5. Loss of GATA-1 blocks erythroid maturation. **(A)** Impaired primitive erythropoiesis in *Gata1*-embryos. **(B)** Developmental arrest and apoptosis of cells within definitive erythroid (EryD) colonies generated by in vitro differentiation of *Gata1*-ESCs. Modified from Weiss et al.[84] and Fujiwara et al.[83] Copyright 1995 and 1996, National Academy of Sciences, U.S.A. Photographs in panel A provided by Yuko Fujiwara and Stuart Orkin. (See color plate 4.5.)

domains but little similarity outside of this region.[92–98] (for reviewed see refs. 99–102). Six vertebrate GATA proteins, named in the order of their discovery, function in the development of various tissues. GATA-1 and GATA-2 are most relevant for erythroid maturation and appear to act sequentially and coordinately during this process. Both are expressed in hematopoietic stem cells and multipotential progenitors, although GATA-2 function predominates at these early stages.[103–105] Concurrent with erythroid differentiation, GATA-2 expression declines as that of GATA-1 increases. Most likely, GATA-2 initiates the erythroid program in early progenitors and subsequently becomes replaced by GATA-1 during terminal maturation.[100,106] Presumably, these two transcription factors have both unique and overlapping functions at different stages of erythropoiesis. In this regard, GATA-2 probably activates its own gene by binding to an upstream enhancer.[107] GATA-1 displaces GATA-2 at this position to repress GATA-2 transcription.[107] These studies highlight molecular crosstalk between the GATA factors during erythropoiesis and illustrate one target gene (*Gata2*) where GATA-1 and GATA-2 have opposing functions.

GATA-1 Represses Transcription

GATA-1 was originally viewed as a positive regulator of erythroid gene expression. As noted earlier, GATA-1 also functions as a transcriptional repressor. For example, GATA-1 negatively regulates human ε-globin expression by interacting with one or more silencer elements within the 5′ flanking region of the ε gene.[108,109] Interestingly, GATA-1 binding to a region upstream of the Gγ-globin gene is required for developmental silencing of fetal globin synthesis. Although there is no obvious GATA consensus site in this region, patients with a mutation that abrogates GATA-1 binding display hereditary persistence of fetal hemoglobin.[110] Transcriptome analysis in erythroid cells indicates that the repertoire of GATA-1 repressed target genes may be quite extensive.[39] Among these targets are *Gata2, Kit, Myc*, and *Myb*, which mark early progenitors.[107,111–113] The latter three are all protooncogenes that stimulate proliferation and their repression likely reflects a mechanism through which GATA-1 coordinates division arrest with terminal maturation.

Structure–Function Analysis of GATA-1

GATA-1 acts as a potent transcriptional activator when cotransfected into heterologous cells (such as COS or 3T3) with a reporter gene containing a promoter with one or more GATA motifs.[75,114] In this assay, several domains of murine GATA-1 are required for activity.[75] In particular, the amino terminus contains an acidic domain that is required for transactivation of reporter constructs, and functions as an independent activator when fused to a heterologous GAL4 DNA binding domain. This domain is a target for somatic mutations associated with megakaryoblastic leukemias in patients with Down syndrome (discussed later in this chapter). The GATA-1 C-finger, which is required for DNA binding, is also essential for reporter gene activation.

A strikingly different view emerges from structure-function analyses that exploit GATA-1's ability to influence hematopoietic lineage selection or maturation. Remarkably, the GATA-1 zinc finger region alone is sufficient to induce megakaryocytic differentiation of 416B myeloid cells[115] and restore erythropoiesis in GATA-1–embryoid bodies.[116] Hence, the amino terminal activation domain that is critical for activity in promotor–reporter assays is dispensable for at least some functions in hematopoietic cells. These findings demonstrate that structure–function relationships within the GATA-1 protein are context-dependent, and reveal potent biological activity within the zinc finger region. Further dissection of the GATA-1 DNA binding domain revealed that the N-finger is essential for activity in erythroid cells.[25,117] One critical role of the N-finger is to mediate the interaction between GATA-1 and FOG-1.[118] The N-finger also functions through its ability to stabilize in vivo DNA interactions at a subset of bipartite GATA-1 motifs.[75–78,119]

Posttranslational Modifications of GATA-1

Murine GATA-1 is phosphorylated constitutively on six serine residues within the amino terminus. An additional serine, at position 310, which lies in a conserved region near the carboxyl boundary of the DNA binding domain, is phosphorylated upon chemically induced differentiation of MEL cells. Extensive mutagenesis experiments have shown that phosphorylation at these sites does not significantly influence DNA binding, DNA bending, or transcriptional activation by GATA-1.[120] Phosphorylation of GATA-1 has been reported to influence DNA binding in human K562 cells.[121] GATA-1 is also phosphorylated through erythropoietin-mediated activation of AKT in erythroid cells,[122–124] although mutation of the target serine residues in mice has minimal effects on erythroid development.[125]

GATA-1 is acetylated in vivo at two highly conserved, lysine-rich motifs at the C-terminal tails of both fingers, adjacent to regions that contact DNA. Acetylation within these regions is mediated by interaction with the ubiquitous transcriptional cofactors CREB-binding protein (CBP) and its relative, P300.[126,127] These modifications appear to be functionally important as mutation of the acetylated lysine motifs reduces the ability of GATA-1 to rescue erythroid maturation in a tissue culture model.[127] It has been proposed that acetylation augments the affinity of GATA-1 for DNA,[126] although this was not confirmed by another study.[127] Rather, acetylation of GATA-1 might be required for its stable association with chromatin.[128] Finally, ubiquitination and sumoylation of GATA-1 are reported, although it remains uncertain to what extent these modifications affect GATA-1 function in vivo.[129,130]

GATA-1–Interacting Proteins

GATA-1 participates in erythroid gene activation and repression through interactions with numerous erythroid specific and ubiquitous nuclear factors (for review see ref. 80). For instance, GATA-1 physically interacts with zinc finger proteins such as GATA-1 itself, other GATA factors, EKLF, and SP1.[131–134] In each case, protein interactions occur through the zinc finger regions of the respective proteins and potentiate GATA-1 transcriptional activity at defined promoters. Unique combinations of interacting transcription factors might establish target gene specificity by synergistically enhancing transcription at erythroid enhancers. It is also possible that they mediate physical interactions between erythroid gene promoters and more distant regulatory regions (Chapter 3). For example, promoters of genes within the β-globin locus and the core elements of the LCR each contain CACCC and GATA motifs. Interactions between proteins bound to these elements appear to facilitate direct communication via looping between the LCR and specific globin genes.[20,21]

Interaction between the N-terminal finger of GATA-1 and FOG-1 (Zfpm1) particularly important for erythroid and megakaryocytic development.[118,135] Disruption of the *Fog1/2fpm1* gene produces an erythroid defect similar to that of GATA-1 loss, albeit not as severe, suggesting the possibility of both FOG-1-dependent and-independent functions of GATA-1 in red blood cells. In contrast, *Fog1/2fpm1*$^{-/-}$ mice and ESCs exhibit a complete block to megakaryocytopoiesis, indicating that GATA-1-independent functions for FOG-1 exist in megakaryocytes.[135]

The mechanisms of FOG-1 actions are likely to be complex; for example, FOG-1 can either activate or repress transcription, depending on promoter and cell context.[118,136] FOG-1 itself participates in several important protein interactions that help to assemble higher order complexes at GATA-1 target sites. For example, different regions of FOG-1 interact with the corepressor CtBP2 and the NuRD corepressor complex.[136–138] NuRD is present at GATA-1-repressed genes and is required for efficient repression of the GATA-1 target gene *Kit*.[138,139] Point mutations that abrogate the FOG–CtBP2 interaction have no obvious erythroid effects in mice, indicating the possibility of functional redundancy with other repressors, including NuRD.[140] Preliminary gene targeting studies indicate that the FOG-1–NuRD interaction is essential for normal erythroid and megakaryocytic development (Blobel GA, unpublished data).

Tissue-restricted nuclear factors must communicate with the general transcriptional machinery. For GATA-1, a direct and functionally important interaction with TRAP220, a component of the basal transcription factor complex called "mediator," has been described.[141] Moreover, GATA-1 interacts with the highly related general coactivators CBP and p300, which both interact with numerous basal transcription factors.[126,142–144] In addition, CBP and p300 possess intrinsic and associated histone acetyltransferase activities. Histone acetylation is associated with an "open" chromatin configuration characteristic of the β-globin locus in erythroid cells. Indeed, GATA-1 may stimulate histone acetylation at this locus and other active genes by recruiting CBP.[144,145] As noted earlier, CBP-mediated acetylation of GATA-1 itself is also of functional importance in erythroid cells. Moreover, CBP interacts with additional erythroid transcription factors (see later) and may therefore participate in the formation of large multiprotein complexes.

GATA-1 also physically interacts with the Ets family transcription factor PU.1, which is normally expressed in multipotential progenitors, myeloid cells, and B lymphocytes and is required for normal myelopoiesis and lymphopoiesis (for review see ref. 146). Inappropriate expression of PU.1 by retroviral insertion and transgenesis causes erythroleukemia[147–149] and forced expression of PU.1 blocks differentiation in erythroid cell lines and primary progenitors.[150–153] Hence, it has been postulated that downregulation of PU.1 is essential for normal erythropoiesis. One underlying mechanism stems from recent observations that PU.1 and GATA-1 cross antagonize each other through direct physical interaction.[154,155] In support, overexpression of GATA-1 relieves the PU.1-induced block to chemical-induced maturation of erythroleukemia cells. It is proposed that inhibition of PU.1 inhibits GATA-1 via formation of a RB-containing corepressor complex.[156,157] PU.1 has also been shown to inhibit CBP-mediated GATA-1 acetylation.[158] Conversely, GATA-1 (and GATA-2) inhibit PU.1 transactivation activity, in part by displacing the PU.1 coactivator, c-Jun.[159] Together, these data suggest that GATA-1 and PU.1 oppose each other's actions and that their relative stoichiometry may influence differentiation decisions in multipotent myelo–erythroid progenitors.

The SCL protein complex binds DNA directly, but can also associate with genes indirectly through interaction with GATA-1.[160] This complex, which contains numerous proteins including LMO2, Ldb, and E2A is recruited to GATA-1-regulated genes via the LMO2 subunit. These proteins were also shown to cooccupy some erythroid regulatory elements in vivo.[106,161] It is likely that SCL and associated proteins function as activators of GATA-1-dependent transcription, likely by recruiting additional coregulators. The role of SCL in erythroid development is discussed in greater detail later in this chapter.

GATA-1 and Human Disease

Two major classes of human disease are caused by mutations in the X-linked *GATA1* gene. A comprehensive review can be found at the following URL: http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=gene.chapter.gata1. First, germline *GATA1* missense mutations cause various cytopenias.[119,162–167] Most commonly, these mutations occur in the N-finger, either at the FOG-1-interaction surface or at the region involved in DNA binding. Affected patients usually exhibit anemia and/or thrombocytopenia of variable severity. Interestingly, the nature of the phenotype varies considerably depending on the exact mutation, presumably reflecting varying structural requirements for GATA-1 at different target genes. For example, some mutations spare the erythroid lineage and affect platelet function and production more prominently. One interesting mutation, R216W, causes congenital erythropoietic porphyria due to reduced production of the GATA-1 target gene uroporphyrinogen III synthase.[168] The same patient was also noted to have very high levels of fetal hemoglobin, consistent with the possibility that GATA-1 may be involved in the γ- to β-globin gene switch.

Second, somatic mutations in the *GATA1* are associated with transient myeloproliferative disorder and acute megakaryoblastic leukemia in patients with trisomy 21 (Down syndrome).[169–175] All of these mutations occur in the first coding exon (exon 2) and cause splicing abnormalities or premature termination of translation that interferes with the production of full-length protein. In these cases,

translation initiation at an internal methionine results in the production of a GATA-1 variant (termed "GATA-1 short" or "GATA-1s") that is truncated at the amino terminus. Because the *GATA1* gene is X-linked, a single mutation leads to exclusive production of GATA-1s in male cells and in female cells with unfavorable Lyonization. Of note, one extended pedigree with a similar exon 2 mutation in the germline has been described.[176] Affected males, who do not have trisomy 21, exhibit anemia and neutropenia, but do not develop leukemias. This suggests that altered GATA-1 somehow synergizes with trisomy 21 to cause leukemia through unknown mechanisms. One interesting problem relates to the cellular functions of the amino terminus of GATA-1, which is absent in the short form. In gene-targeted mice this domain is dispensable for erythropoiesis, but is required to restrain the proliferation of embryonic megakaryocytic precursors.

Stem Cell Leukemia (SCL, TAL1, TCL5)

The *SCL/TAL1* gene was originally identified via chromosomal rearrangements involving 11p13 in acute T-cell leukemias (for review see ref. 177) SCL, a member of the basic helix-loop-helix class of transcription factors, functions as a heterodimer in association with a variety of widely expressed partner proteins including E2A, E2-2, or HEB (for review see ref. 178). The SCL complex recognizes a cognate DNA element termed E box (consensus CANNTG). Gene-targeting studies have demonstrated that SCL is critical for the establishment of all primitive and definitive blood lineages and for organization of the yolk sac vasculature in early embryos.[179–183] These studies indicate that SCL functions at the onset of hematopoiesis, possibly within the hemangioblast, a bipotential hematopoietic endothelial cell precursor (Chapter 2). Genetic studies indicate that SCL is dispensable for formation of hemangioblasts, but required for their subsequent maturation.[184–186] Interestingly, although SCL is required for the onset of hematopoiesis in the embryo, conditional gene-targeting studies indicate that SCL is dispensable for the maintenance of adult hematopoietic stem cells.[187–189]

The role of SCL in erythroid development is supported by numerous lines of investigation. First, SCL is expressed at a relatively high level in erythroid precursors and erythroid cell lines.[190–192] Second, overexpression of SCL stimulates erythroid differentiation of murine erythroleukemia cells and the multipotential myeloid cell line, TF-1.[193,194] Moreover, forced expression of SCL in human CD34+ cells stimulates formation of erythroid and megakaryocyte progenitors and an increase in the size of erythroid colonies.[195,196] Third, ablation of the SCL gene in adult hematopoietic stem cells causes erythroid and megakaryocytic defects.[183,188,189] Notably, the erythroid defects resemble that of GATA-1 or FOG-1 loss, consistent with physical and functional interactions between GATA-1, SCL, and associated proteins. Fourth, conserved, functionally important E box motifs are present at numerous erythroid genes including *EKLF/KLF1*, the HS2 core of the β-*globin* LCR, Band 3/*SLC4A*1, Band 4.2/*EPB42*, Glycophorin A/*GYPA* and the *GATA1* gene itself.[106,197–202] In some cases these E boxes are juxtaposed to GATA sites, and binding of both factors is thought to facilitate assembly of a larger complex containing GATA-1 (or GATA-2), SCL, E2A, and two non-DNA-binding nuclear proteins, Lmo-2 and Ldb-1.[160,203]

SCL complexes can activate and repress transcription in part through recruitment of coactivators such as p300/CBP or corepressors such as Sin3A or Eto-2.[204–209] How these activities are controlled is unclear, although acetylation of SCL by PCAF, which reduces binding to Sin3A, might play a role in this process.[206] Moreover, Eto-2 binding to SCL diminishes during erythroid differentiation, thus changing the composition of SCL-associated complexes, perhaps tipping the balance in favor of transcriptional activation.[207,208] Transcriptional activation by SCL–GATA complexes also appears to be enhanced by single-stranded DNA-binding proteins, which bind and protect Lmo2 and Lbd1 from proteosomal degradation.[209] Given the combinatorial complexity of SCL- and GATA-1-associated proteins, understanding the exact functional interplay among all of these subunits in vivo remains a long-term challenge.

EKLF and Other CACCC Box-binding Proteins

Functionally important GC-rich elements, also referred to as CACCC boxes, are found in many erythroid gene regulatory elements including several globin gene promoters and the LCR (Chapter 3). The importance of an intact CACCC box in the β-globin gene promoter is underscored by the observation that certain thalassemias are associated with mutations in these elements.[210–212] CACCC boxes, which vary somewhat in their sequence, are recognized by a diverse set of transcription factors that share a related DNA-binding domain composed of three zinc fingers with homology to the *Drosophila melanogaster* Krüppel protein (for reviews see refs. 213–215). These factors include the Sp1 family and proteins related to EKLF (Fig. 4.6).

EKLF is of particular interest to studies of globin gene regulation because its expression is restricted mainly to erythroid cells, with low-level expression in mast cells.[216,217] EKLF binds to the β-globin CACCC box with high affinity and mutations found in CACCC boxes of β thalassemia patients abrogate EKLF binding.[218]

EKLF is Required for β-globin Gene Expression

The presence of numerous erythroid factors that bind the same CACCC elements suggested considerable functional redundancy at a given promoter or enhancer in vivo. Therefore, it was surprising to discover that targeted disruption of the *Eklf* (*Klf1*) gene leads to significant loss of adult-type β-globin expression with resultant anemia

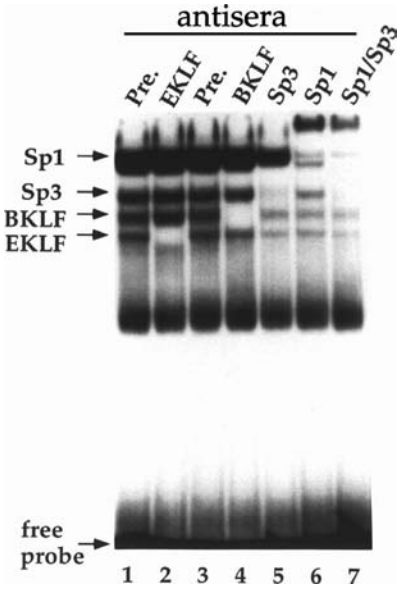

Figure 4.6. Gel mobility shift experiment showing multiple CACCC box–binding proteins in erythroid cells. In this assay, CACCC binding proteins present in nuclear extracts of murine erythroleukemia cells bind a radiolabeled oligonucleotide containing a single CACCC box, retarding its electrophoretic mobility. Migration of individual protein–DNA complexes is altered by incubation with specific antisera, as shown (Pre, preimmune serum). Note the presence of four major complexes, the most prominent one being Sp1. Despite the low abundance of EKLF in this assay, loss of EKLF function leads to a pronounced defect in β-globin gene transcription, which cannot be compensated for by other CACCC box–binding factors (see text). Although gel mobility shift experiments such as this identify factors that can bind to a CACCC box in vitro, they do not permit conclusions as to which factor(s) binds to a given CACCC box–containing promoter in vivo. Photograph provided by Merlin Crossley.

and embryonic lethality of homozygous null animals at E14–E16.[219,220] *Klf1*$^{-/-}$ definitive erythrocytes exhibit molecular and morphological features typical of severe β thalassemia including hypochromia, poikilocytosis and markedly elevated α/β globin ratio with Heinz body formation and ineffective erythropoiesis. Although EKLF can be detected at the embryonic β-like globin genes β*H1* (*Hbb-hh1*) and *Epsilon (Hbb-y)* by ChIP,[221] their expression is unaffected by the loss of EKLF, and primitive erythropoiesis appears to be normal in the mutant mice. Notably, there is a loss of the low, but detectable, levels of adult-type β-globin (beta adult major, Hbb-b1) in E11 yolk sac.[220] Hence, EKLF appears to be selectively required for high-level expression of adult β-globin. One mechanism may be to facilitate the formation of a DNA loop that brings the β-globin gene into contact with LCR.[20] Recently, EKLF has been found to occupy the α-globin locus and participate in its expression, although to a lesser extent than for β-globin.[222]

A Role for EKLF in β-Globin Switching

Selective loss of adult β-globin gene expression in mutant embryos suggested that EKLF might participate in the switch from γ- to β-globin in humans. Indeed, when transgenic mice bearing an extended human β-globin gene cluster were crossed with *Klf1*$^{-/-}$ mice, the resulting EKLF-deficient fetal liver cells displayed dramatically reduced human β-globin levels with a concomitant increase in the levels of γ-globin.[223,224] In addition, human γ- to β-globin switching was delayed in *Klf1*$^{-/+}$ heterozygous mice[224] and accelerated by transgenic overexpression of EKLF.[225] These studies are consistent with a model in which the γ- and β-globin gene promoters compete for the action of the LCR. Hence, EKLF might contribute to a more stable interaction between the LCR and the β-globin promoter to accelerate shutoff of γ-globin. γ-Globin gene silencing can also occur independent of a competing β promoter.[226]

Loss of EKLF also leads to reduced DNase1 hypersensitivity at HS3 and the β-globin promoter of both transgenic human and endogenous globin loci.[224] This suggests that EKLF might contribute to changes in the chromatin configuration at selected sites at the β-globin gene locus. These alterations might facilitate binding of transcription factors to DNA or increase the interaction between the β-globin promoter and the LCR. Alternatively, they might merely be a secondary consequence of promoter–LCR interactions and transcriptional activity. The former possibility is supported by observations that EKLF associates with factors that have chromatin remodeling activity (see later).

Broader Roles for EKLF in Erythroid Development

Initially, it was believed that EKLF might only regulate adult-type β-globin gene expression. Subsequent studies, however, demonstrated that EKLF controls numerous other erythroid genes. This possibility was raised initially by experiments showing that enforced expression of γ-globin fails to rescue the defects in survival and maturation of *Klf1*$^{-/-}$ erythroid precursors.[227,228] Subsequently, microarray-based studies examining mRNA expression in *Klf1*$^{-/-}$ erythroblasts identified numerous potential EKLF targets with important roles in erythropoiesis. These include genes encoding α-hemoglobin stabilizing protein AHSP (*Eraf*), the erythroid membrane skeletal protein band 4.9, ankyrin, and heme biosynthetic enzymes.[40,228] In follow-up studies, ChIP experiments demonstrated that EKLF directly occupies its regulatory regions of *Ahsp/Eraf* and Band 4.9 genes in erythroid cells.[41,42,229,230] Of note, microarray studies suggested that EKLF functions predominantly as an activator of gene expression. However, EKLF interacts with corepressor proteins and has been shown to repress transcription in several experimental contexts.

Recent overexpression and loss of function studies raised the possibility that EKLF not only promotes erythropoiesis, but also suppresses megakaryocyte formation.[231] This indicates that EKLF might play a role in the developmental bifurcation between these two lineages from common bipotential megakaryocyte–erythroid progenitors. One mechanism may be through EKLF-mediated repression of the gene encoding the megakaryocyte Ets

nuclear factor Fli1, the first candidate target for biologically relevant EKLF-mediated transcriptional repression.[231]

An interesting question remains as to why some erythroid genes containing CACC boxes are more sensitive to the loss of EKLF than others. In particular, adult-type globin genes require EKLF but the embryonic ones do not, despite findings that EKLF binds to these genes in primitive erythroid cells in vivo.[221] This cannot simply be explained by general loss of EKLF function in a primitive environment because adult β-globin expression is selectively impaired in *Klf1*$^{-/-}$ primitive erythroid cells.[220] Early biochemical studies suggest that this selectivity might be explained by the higher affinity of EKLF for the β-globin CACCC box when compared with the γ-globin CACCC box.[232] In GAL4 fusion constructs, however, the activation domain of EKLF, but not that of Sp1, can activate a β-globin–containing reporter construct in erythroid cells, suggesting that DNA binding affinity is not the sole determinant of EKLF specificity.[233] In agreement with this interpretation, when the β- and γ-globin CACCC boxes are switched, EKLF still only activates the β- but not γ-globin gene promoter. Hence, the specificity of EKLF depends, at least in part, on the surrounding DNA and protein context of its binding site. It is also noteworthy that the activation domains of EKLF and other Krüppel proteins such as Sp1 share no obvious homology, the former being proline rich and the latter being glutamine rich, suggesting that they interact with different coactivator/adaptor molecules.

Posttranslational Modifications of ELKF

Terminal differentiation of MEL cells is accompanied by dramatic increases in α- and β-globin gene expression, whereas EKLF protein levels remain largely unchanged.[233] This raises the possibility that EKLF activity might be subject to regulation by posttranslational modifications. Indeed, EKLF is phosphorylated at its N-terminal activation domain, and mutation of the phosphorylation site leads to reduced activity.[234] Furthermore, EKLF is also acetylated by CBP and p300. CBP and p300 bind to EKLF and stimulate its activity in transient transfection assays.[235] Although acetylation does not alter EKLF DNA binding it does regulate its interaction with SWI/SNF, an adenosine triphosphate–dependent chromatin-remodeling complex.[236] EKLF is also sumoylated, and this modification appears to be important for its function as transcriptional repressor, which may relate to inhibition of megakaryopoiesis.[237]

EKLF Remodels Chromatin Structure

ELKF interacts with the mammalian SWI/SNF chromatin-remodeling complex (also referred to as EKLF coactivator-remodeling complex 1, E-RC1).[238] E-RC1 is required for EKLF-dependent formation of a DNase1 hypersensitive, transcriptionally active, chromatinized β-globin promoter template in vitro. Another mechanism by which EKLF could modify chromatin structure is by recruiting the acetyltransferases CBP and p300, similar to what has been described for GATA-1 (as described previously) and NF-E2 (see later).

EKLF-related Transcription Factors

If EKLF acts at the β-globin gene promoter to participate in its stage-specific activation, what are the factors that control expression of the embryonic and fetal globin genes at their respective CACCC boxes? Candidates include fetal Krüppel-like factors (FKLFs), which share homology to EKLF.[239,240] FKLFs activate the ε-, γ-, and β-globin gene promoters in transient transfection assays with the embryonic and fetal gene promoters showing the strongest response. This suggests that FKLFs might be important for embryonic/fetal globin gene expression in vivo. In contrast to the globin genes, regulatory regions of several other erythroid-expressed genes that contain functional CACCC boxes are not activated by FKLF.[239]

Another major CACCC box–binding activity found in embryonic yolk sac and fetal liver erythroid cells is basic Krüppel-like factor (BKLF).[240] BKLF is a widely expressed protein that activates or represses transcription depending on cell and promoter context. Repression by BKLF is mediated through the association with a corepressor, CtBP2.[137] Of note, EKLF-deficient erythroid cells display dramatically reduced BKLF levels,[220,240] and EKLF directly activates BKLF expression.[241] In light of the complexity of proteins bound to the β-globin CACCC box, this finding underscores the difficulty in directly linking a transcription factor to a specific target gene in vivo and in interpreting the phenotype of a gene knockout experiment on a molecular level. Targeted mutation of BKLF does not dramatically alter globin gene expression, suggesting that the ELKF null phenotype is not solely attributable to secondary loss of BLKF.[242] The role of BKLF, if any, in regulating β-globin gene expression remains to be determined.

Sp1, which was the first CACCC binding factor to be cloned, is expressed in a wide variety of cell types. Mice lacking Sp1 die approximately day 10 of embryogenesis with a multitude of defects.[243] Embryonic α- and β-like globin genes are expressed normally in the mutant mice, which was somewhat surprising considering the relative abundance of Sp1 in erythroid cells. Mouse embryos that are heterozygous for null mutations in Sp1 and Sp3, a related Krüppel protein, exhibit multiple defects in organogenesis, including anemia.[244] This underscores the complex functional interactions and redundancy of CACC binding factors for global tissue development, including erythropoiesis.

It is clear from these previously noted studies that a formidable effort is required to establish which transcription factor operates at any given CACCC box. Combined gene knockouts are one approach to address this issue.

Of equal importance will be to investigate further the mechanisms by which CACCC factors regulate transcription. The identification of novel interacting proteins and their analysis in vivo and in vitro will contribute to the understanding of the function of CACCC box binding proteins.

NF-E2 and Related Proteins

AP-1-like motifs [(T/C)GCTGA(G/C)TCA(T/C)], now called maf recognition elements (MAREs), are functionally important cis elements within HS2 and HS3 of the *β-globin* LCR (Chapters XX). Although GATA elements are mostly associated with the position independence conferred by the LCR, MAREs contribute to LCR-mediated enhancer activity.[245] Factors binding to MAREs contribute to the formation of DNase1 hypersensitivity, suggesting that these proteins modify chromatin.[246–249] MAREs are also found in some nonglobin genes such as those encoding porphobilinogen deaminase and ferrochelatase.[250,251] Careful analysis of these elements led to the realization that they are bound by an erythroid-specific transcription factor, called NF-E2.[250,252] Affinity purification of NF-E2 from erythroleukemia cells identified a simple heterodimer with subunits named according to their molecular weights: p45 and p18 (now referred to as MafK).[253–255] Both subunits contain a basic-zipper (b-Zip) domain, which mediates dimerization and DNA binding. p45 is expressed predominantly in erythroid cells and megakaryocytes, whereas p18 is found in a variety of cell types. It is now appreciated that both p45 and p18 belong to multiprotein families that are expressed in distinct but overlapping patterns, generating a large number of possible combinations of NF-E2–related protein–DNA complexes in different cell types.

The p45 Family of Proteins

p45 is the founding member of a family of proteins that contain a region of similarity to the Drosophila Cap'n'collar (CNC) protein. This family includes Nrf-1 (LCRF1, TCF11), Nrf-2 (ECH), Nrf-3, Bach1 and Bach2. These proteins bind DNA as obligate heterodimers with Maf proteins (see later) (for reviews see refs. 256, 257).

Expression of p45 is restricted to the hematopoietic system.[253,255] Erythroid cells and megakaryocytes express high levels of p45 mRNA whereas little or no p45 mRNA is found in macrophages and B and T cells. This expression pattern suggests that p45 is a critical regulator of globin gene expression. Consistent with this idea, the murine erythroleukemia cell line CB3, which lacks both functional alleles of p45, expresses very low levels of α- and β-globin. Upon introduction of an intact p45 gene, globin gene expression is restored.[258,259] Surprisingly, however, targeted inactivation of the p45 gene in mice has little effect on erythropoiesis or globin gene expression. In contrast p45 null mice exhibit a profound defect in megakaryocyte maturation resulting in severe thrombocytopenia and frequent fatal hemorrhage.[260,261]

Given the large body of evidence implicating MARE elements in globin gene transcription, the minimal effect of p45 gene disruption on erythropoiesis suggested the potential for compensation by other CNC family members; however, homozygous disruption of the *Nfe2/2/Nrf 2* gene does not reduce globin gene expression in mice,[262] and the combined loss of Nrf-2 and p45 is no more severe than the p45 knock out alone.[263,264] Disruption of the *Nrf1* gene causes anemia and embryonic lethality, but the defect in erythropoiesis is not cell autonomous.[265,266] Thus, the exact contribution of each CNC-b-Zip protein to globin gene expression in vivo remains to be determined.

Bach1 and Bach2 are additional p45-related molecules that bind MAREs as heterodimers with Maf family members.[267] Bach1 is expressed in hematopoietic cells starting at the earliest progenitor stages.[267,268] Bach-Maf complexes are transcriptional repressors that bind MARE elements in a heme-regulated fashion.[269] Heme binding to Bach–Maf complexes stimulates their release from DNA, export from the nucleus, ubiquitination, and subsequent proteolysis.[270,271] In this fashion, Bach transcription factors provide an elegant mechanism to coordinate heme availability with gene expression in numerous tissues. For example, in erythroid cells depleted of heme, Bach1–Maf complexes bind MARE elements in the α- and β-*globin* genes to repress their transcription.[272,273]

The Maf Family

The small subunit of NF-E2 (p18, MafK) belongs to the Maf family of proteins, which share homology with the c-Maf protooncoprotein. The small Maf proteins (MafF, MafG, and MafK) heterodimerize with CNC-b-Zip family and exhibit distinct temporal and spatial expression patterns. MafG and MafK are highly expressed in megakaryocytes and erythroid cells with a predominance of MafG in megakaryocytes and MafK in erythroid cells.[256,257] Small Maf proteins lack an activation domain and are thought to stimulate transcription as heterodimers with CNC-b-Zip (p45-like) molecules. Small Maf proteins can also form homodimers on DNA and repress transcription, presumably by competing with activating transcription factor complexes.[274]

Surprisingly, *MafK*$^{-/-}$ mice develop normally and display no obvious defects in erythroid maturation, globin gene expression, or platelet formation,[275] and NF-E2-like DNA binding activity is still detected in fetal liver erythroid cells, consistent with the presence of other compensating Maf family members. Moreover, *MafK*$^{-/-}$ *p45/Nfe2*$^{-/-}$ compound mutant mice exhibit minimal defects in erythropoiesis.[275] Presumably, other members of the *p45/Nfe2* and *MafK* gene families can provide sufficient NF-E2-like activity to support globin production in vivo. Targeting of the *MafG* gene produces no obvious defects in

erythropoiesis, but impairs megakaryocytic differentiation, although to a lesser extent than in p45 knockout mice.[276]

The exchange of partners for Maf proteins is critical for the control of MARE activity (see later). It has also been observed that MafG is sumoylated. Mutation of the critical N-terminal sumoylation sites impairs the ability of MafG to repress transcription in megakaryocytes but leaves intact its ability to interact with p45 NF-E2 and activate gene expression.[277]

Mechanisms of NF-E2 Action

Structure–function analysis of p45 in transient transfection experiments and in gene complementation assays using p45 null CB3 cells revealed that full NF-E2 activity requires an intact N-terminal activation domain and CNC domain.[259,278] The N terminus of p45 interacts with numerous proteins including CBP/p300,[279] ubiquitin ligase,[280,281] and the TBP-associated factor TAFII130.[282]

As is the case for GATA-1 and EKLF (noted previously), the implications for NF-E2 interactions with CBP/p300 are twofold: First, CBP and p300 might link NF-E2 with basal transcription factors (for review see ref. 283). p45 may also communicate with basal transcription machinery via interactions with TAFII130.[282] Second, recruitment of CBP/p300 and associated histone acetyltransferase activity to the LCR and other erythroid gene regulatory elements could promote the formation of "open" chromatin structure through histone acetylation. An additional role for NF-E2 in chromatin modification is indicated by the finding that NF-E2 can disrupt chromatin structure on in vitro assembled chromatinized templates containing the β-globin LCR HS2 site.[284] This adenosine triphosphate–dependent chromatin opening activity facilitates binding of GATA-1 to its nearby *cis* elements. It is not known whether this activity also contains histone acetyltransferases.

The N terminus of p45 harbors two PPXY motifs that mediate interactions with several ubiquitin ligases.[280,281] Mutations in these motifs reduce transcriptional activity of NF-E2,[281] raising the possibility that ubiquitin ligases might modify nearby histones to regulate chromatin structure. In addition, NF-E2 interacts with the MLL2 methyltransferase complex.[285] This complex is related to the MLL1 complex and methylates lysine 4 of histone H3, a chromatin mark that is found at most active genes. Thus, NF-E2 is linked with several histone-modifying enzymes, similar to other transcriptional regulators.

In an erythroid cell line, MafK associates with Bach1 in the immature state and with p45 NF-E2 after chemical-induced erythroid maturation. Notably, the exchange of MafK partner proteins was accompanied by redistribution of coregulator complexes.[286] Thus, components of the NuRD and SIN3A repressor complexes copurified with Bach1 in immature cells, whereas the p45 NF-E2–containing complex associated with a transcriptional activators including CBP/p300. This suggests that MARE binding proteins not only function during transcriptional activation but might also be involved in actively suppressing the expression of globin genes and perhaps other erythroid-specific genes in immature cells, consistent with findings that Bach1 binds and represses globin synthesis in low heme states.[272,273]

The onset of high level globin gene expression is coordinated with cellular differentiation and proliferation arrest, suggesting that these pathways may be mechanistically linked. Consistent with this idea is that NF-E2 is regulated by the MAP kinase pathway. In MEL cells, activation of MAP kinase potentiates NF-E2 DNA binding and transcriptional activation.[287] In addition, NF-E2 binding sites are required for MAP kinase inducibility of the HS2 region within the LCR.[288] The p45 subunit of NF-E2 is also phosphorylated by protein kinase A, but the physiological significance of this modification is unclear.[289]

It is interesting to consider that signals which trigger erythroid maturation might act in part by facilitating the exchange of partners for the small Maf proteins and their coregulator complexes. In addition, posttranslational modifications can modulate the activity of MARE binding proteins. For example, similar to certain Maf proteins, p45 NF-E2 is also subject to sumoylation, which reduces transcriptional activation by impairing the association of NF-E2 with its target sites in vivo.[290] Whether sumoylation of Maf and p45 NF-E2 can occur simultaneously within the same complex or whether it is targeted to distinct complexes is unknown. It is possible that cellular signaling events influence the targeting of the SUMO modification to the appropriate subunit.

In summary, MARE-associating factors are a heterogeneous group of proteins with distinct but overlapping functions and expression patterns. As an additional complexity, MARE factors activate transcription as heterodimers, leading to increased diversity through combinatorial associations. The major future challenge is to determine which combinations of MARE binding proteins act at a given gene regulatory element in vivo. In particular for erythroid biology, it will be important to learn the full complement of NF-E2-like proteins that activate the β-globin locus during normal erythropoiesis and in the background of various targeted mutations of MARE binding protein subunits.

Candidate Nuclear Factors Involved in Globin Switching

One model to account for developmental regulation of gene expression within the β-globin locus is based on the principle that individual globin genes compete for β-LCR enhancer activity, which is available only to a single gene at any given time.[291–293] These competitive interactions are believed to be influenced by variations in the relative concentrations and/or posttranslational modifications of transcription factors that are expressed at all developmental stages.[294,295]

In addition to EKLF and GATA-1, other protein complexes have been invoked to play direct roles in hemoglobin switching. One example is human stage selector protein (SSP), which recognizes a DNA motif, termed stage selector element (SSE), found in the proximal γ-globin gene promoter. SSE was identified through its ability to allow the γ-promoter to function in preference to a linked β-globin gene in plasmid constructs containing the HS-2 portion of the β-LCR.[296] SSP DNA binding activity appears to be relatively restricted to fetal erythroid cells. Thus, it is believed that γ-globin synthesis is stimulated in part by expression of SSP, which binds SSE to impart a competitive advantage for recruitment of the LCR to the γ-promoter. This is supported by recent studies showing that transgenic overexpression of the p22 NF-E4 SSP subunit can increase the ratio of γ-globin to β-globin gene expression in mice carrying the human β-globin locus.[297] The SSE, however, is neither necessary nor sufficient for competitive inhibition of β-globin gene expression in immortalized erythroid cell lines.[296,298,299] Therefore, it is particularly important to determine the extent to which this *cis*-acting element influences γ gene expression in vivo.

Another protein complex with potential roles in β-globin gene switching is direct repeat erythroid definitive (DRED). DRED was isolated through its affinity for direct repeat (DR) elements that cluster near the ε-globin and γ-globin promoters and contains the orphan nuclear receptors TR2 and TR4.[300] Notably, another nuclear receptor, COUP-TFII also binds the DR elements.[301] DR sequences are of interest because mutations in this region are associated with several cases of hereditary persistence of fetal hemoglobin.[302] Gain- and loss-of-function studies support a model in which DRED subunits TR2 and TR4 cooperate to silence directly endogenous embryonic mouse β-globin genes and transgenic human embryonic and γ-globin genes. As is the case for studies on SSP, the effects of altered transcription factor levels on globin gene expression are gradual but not absolute, suggesting that multiple protein complexes operate in concert to modulate hemoglobin switching.

Summary and Perspective

Studies of globin gene regulation are paradigms for investigating tissue-specific and developmental control of eukaryotic gene expression. Therefore, it is no surprise that pursuit of nuclear factors that coordinate globin gene transcription has produced a complexity of information with important implications for a variety of developmental processes. For example, GATA-1 regulates many aspects of terminal erythropoiesis and megakaryocyte maturation, presumably by controlling a number of as yet unidentified target genes. Moreover, discovery of GATA-1 led to the identification of several related proteins important for the formation of hematopoietic stem cells, T lymphocytes, heart, nervous system, and endodermally derived tissues. NF-E2, originally believed to be red blood cell specific, was shown by knockout studies to be largely dispensable for globin synthesis and erythroid development, yet critical for platelet formation. In addition, studies of NF-E2 have focused attention on the large family of MARE binding proteins that participate in numerous processes including cognitive development and formation of early embryonic mesoderm. Likewise, the discovery and characterization of several Krüppel-related proteins with diverse functions was initiated largely by studies of globin regulation.

Discovery of numerous tissue-restricted and widely expressed transcription factors that function in red blood cells provides a solid foundation for understanding globin gene expression and erythroid differentiation. The current challenge is to better understand the mechanistic basis for transcription factor function in intact organisms. Presumably, insights will be gained through continued investigation of the dynamic developmental stage and tissue-specific regulatory networks that exist among erythroid nuclear factors, basal transcription machinery, and chromatin.

In addition, it is important to examine the hierarchical order by which transcription factors regulate each other's expression. For example, GATA-1 activates its own expression but represses GATA-2, which may be prerequisite for terminal erythroid maturation.[100] Prior to repression by GATA-1, GATA-2 appears to autoregulate.[107] Moreover, GATA-1 positively regulates expression of the EKLF gene,[303] and EKLF is required for full expression of BKLF.[220,240] Such cross-regulation imposes a tissue-restricted and developmental order on the erythroid gene expression program. Analysis of *cis*-acting regulatory regions of erythroid transcription factor genes is beginning to explore how their expression is regulated.

One ultimate goal is to exploit basic knowledge of transcription factor function for manipulating gene expression in the treatment of human diseases. In this regard, pharmacological alteration of transcription factor–DNA interactions may be difficult because these usually occur over extended surfaces and the affinities are usually high. Transcription cofactor complexes, however, typically contain one or more enzymatically active subunits (adenosine triphosphatases, deacetylases, acetyltransferases, and methyltransferases etc.) that might lend themselves to pharmacological intervention. For example the drug butyrate, which is used to activate fetal globin gene expression in patients with sickle cell anemia or β thalassemia (Chapter 3) inhibits histone deacetylases.[304] More potent agents with similar activity are now under study.[305,306] Histone deacetylase inhibitors have also been shown to reactivate silenced globin transgenes delivered by retroviral vectors designed for gene therapy.[307] Together, these results define an interface through which basic studies of gene regulation might ultimately impinge on clinical management of hematological disorders.

Recent genetic association studies indicate that polymorphisms in the *BCL11A* gene influence fetal hemoglobin

levels significantly. *BCL11A* encodes a zinc finger nuclear protein that binds to DNA but can also associate with other erythroid nuclear factors such GATA-1 and FOG-1. Using a knock-down approach in human erythroid cells, it was shown that deplection of BCL11A leads to a significant up-regulation of gamma-globin expression. These levels could be therapetatic if achieved in hemoglobinopathy patients. How BCL11A regulates gamma globin expression in still nuclear. Thus, BCL11A represents a newly discovered target protein for better understanding and manipulating fetal hemoglobin expression.[308–312]

Molecular and Cellular Basis of Hemoglobin Switching

George Stamatoyannopoulos, Patrick A. Navas, and Qiliang Li

INTRODUCTION

Hemoglobin switching is characteristic of all animal species that use hemoglobin for oxygen transport. Most species have only one switch, from embryonic to adult globin formation. Humans and a few other mammals have two globin gene switches, from embryonic to fetal globin coinciding with the transition from embryonic (yolk sac) to definitive (fetal liver) hematopoiesis and from fetal to adult globin formation, occurring around the perinatal period (Fig. 5.1; see Chapters 1 and 2). The switch from ε- to γ-globin production begins very early in gestation, as fetal hemoglobin (HbF) is readily detected in 5-week-old human embryos,[1,2] and it is completed well before the 10th week of gestation.[1,3] β-globin expression starts early in human development, and small amounts of adult hemoglobin (HbA) have been detected by biosynthetic or immunochemical methods even in the smallest human fetuses studied. In these fetuses γ- and β-globins are present in the same fetal red cells.[4] β-chain synthesis increases to approximately 10% of total hemoglobin by 30–35 weeks of gestation. At birth, HbF comprises 60%–80% of the total hemoglobin. It takes approximately 2 years to reach the level of 0.5%–1% HbF that is characteristic of adult red cells. HbF in the adult is restricted to a few erythrocytes called "F cells" (see chapter 7).[5,6] Approximately 3%–7% of erythrocytes are F cells[6] and each contains approximately 4–8 pg of HbF.[5]

Hemoglobin switching has been the target of intensive investigation for two reasons. First, it provides an excellent model for studying the control of gene activity during development. Indeed, until the late 1970s, hemoglobin switching was the only developmental system that could be investigated in detail at the protein level. Second, understanding of the control of switching is expected to lead to the development of treatments of hemoglobinopathies. The β-chain hemoglobinopathies, sickle cell disease, and thalassemia are unique among genetic disorders in that nature has shown an effective means of treatment: the production of HbF that can compensate for the loss of β-chain activity or can decrease the propensity for sickling. Research on the cell and molecular control of switching is expected to lead to discoveries that will cure these disorders through abundant production of HbF in the patient's red cells.

CELLULAR CONTROL OF SWITCHING

Before the era of molecular biology, insights on the cellular mechanisms of hemoglobin switching were obtained through phenomenological observations in human and animal models and from cell biological studies. The observation that human fetuses have different hemoglobin than adults was made more than 100 years ago when it was discovered that the hemoglobin of neonates is alkali resistant. The observation that amphibia have different hemoglobins in the embryonic and the adult stages was made in the 1930s when the oxygen affinity of frog and tadpole blood was examined. The two types of hemoglobin were actually separated by Svedberg while he was developing the ultracentrifuge. Hemoglobin switching was more intensely investigated when the introduction of electrophoretic techniques allowed detailed studies of hemoglobin during the development of many species. Several questions on the cellular control of switching were asked during that time and, amazingly, clonal models of switching (see later) were proposed even before it became possible to analyze hemoglobin switching at the protein level. Systematic investigation of the cellular control of switching, however, started only when modern methods of cell biology became available in the 1970s.

Models of Cellular Control

The first models of hemoglobin switching assumed that it represents an epiphenomenon due to replacement of hematopoietic stem cell lineages. The model was eloquently formulated by the late Vernon Ingram.[7] To explain hemoglobin switching in the mouse or in the chicken, it was postulated that there is an embryonic stem cell lineage that is committed to embryonic globin gene formation and this is replaced by an adult stem cell lineage committed to expression of the adult globin genes. In the case of the human hemoglobin switching, three lineages were thought to exist: an embryonic, a fetal, and an adult stem cell lineage. The fetal (γ-) to adult (β-) switch was attributed to the replacement of the fetal stem cell lineage by the adult stem cell lineage.[8–12] The transitions in major erythropoietic sites during ontogeny (see Chapter 1) seemed to support the clonal hypothesis of switching. The clonal hypothesis was also appealing because of the restriction of HbF in few red cells, the F cells, in the adult blood. When, in adult individuals, HbF was elevated, the number of F cells was elevated. Hence it was thought that F cells and A cells (i.e., cells that did not contain HbF) were derived from two distinct stem cell lineages.[9]

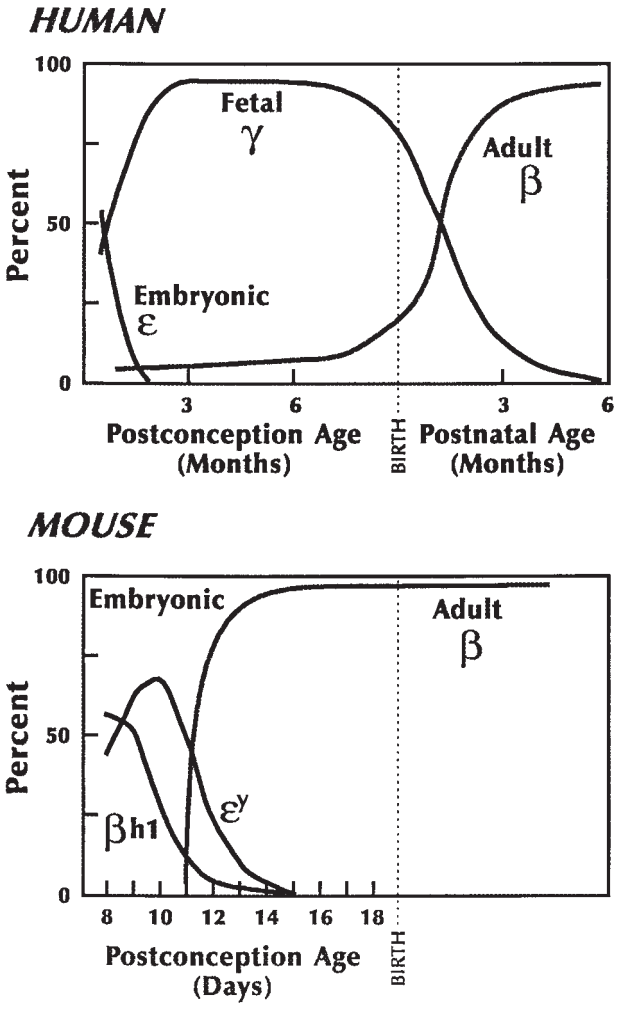

Figure 5.1. Hemoglobin switching in humans and mice. The human ε gene is homologous to murine εy. The γ-globin gene is homologous to βh1 whereas the β-globin gene is homologous to murine βminor and βmajor.

An alternative model was elaborated in the mid-1970s.[13] It proposed that fetal to adult globin gene switching is not due to changes in stem cell populations but to changes in programs of gene expression that occur in the progeny of a single stem cell population. A fetal program is activated in the progenitor cells of the fetus and an adult program in the progenitor cells of the adult.

Finding out which of the two models (i.e., changes in stem cell populations or changes in programs) is correct was important from the theoretical and the therapeutic point of view. In the 1970s it was thought that it was difficult to manipulate stem cell populations; on the other hand, it was possible that manipulation of gene expression programs could be achieved with pharmacological means. Therefore, a systematic investigation of the two models was conducted.

The lineage models assume an absolute restriction of embryonic globins to primitive cells and of adult globins to definitive cells. During switching in chickens,[14] in the mouse,[15] and in quail–chick chimeras,[16,17] there are cell populations coexpressing both embryonic and adult hemoglobins. The hematopoietic cells of human embryos can be used to produce erythroid colonies, each of which originates from a single progenitor cell; typically, these colonies coexpress ε- and γ-globins.[18,19] Thus, a single progenitor cell can form progeny producing adult and embryonic globins, contrary to the expectations of the lineage models.

Three types of experiments provided evidence against the model of replacement of stem cell lineages as an explanation of the γ- to β-switch. First, studies of individuals with clonal hemopoietic stem cell disorders (polycythemia vera, chronic myelogenous leukemia, or paroxysmal nocturnal hemoglobinuria) clearly showed that both F cells and A cells are produced by a single stem cell clone (summarized in Stamatoyannopoulos and Grosveld[20]). Second, studies in culture showed that erythroid colonies derived from single progenitor cells of fetuses, neonates, or adults, contain both fetal and adult globins.[20] Third, direct evidence came from analyses of somatic cell hybrids produced by fusion of mouse erythroleukemia (MEL) cells with human cells. These hybrids initially synthesize only (or predominantly) fetal human globin, and after 20–40 weeks in culture they switch to β-globin chain formation. Since each hybrid originated from a single cell, these results provided direct evidence that γ- to β-switching can occur in cells of a single lineage.[21]

It is thus clear that the fetal to adult hemoglobin switching takes place in the progeny of a single stem cell lineage. It represents changes in transcriptional environments at the level of committed cells rather than changes in stem cell populations "frozen" in a single gene expression program. It is of interest that despite the extensive evidence, even today the cellular phenotypes of HbF elevations in the adult are attributed by some authors to the presence of a fetal stem cell population in the adult marrow!

The Question of Developmental Clock of Switching

If switching takes place in the cells of a single lineage, how do these cells know when to switch their globin gene expression program? Many changes occur during development and there is ample evidence that the cell's microenvironment can determine the fate of a cell. Initially, inductive mechanisms were thought to trigger hemoglobin switching, and several experiments have been done to test whether changes in the environment of the developing fetus, especially hormonal changes, are responsible for the γ- to β-switch. The summary of this work indicates that there is no evidence that there exists a specific environmental signal that is responsible for the switch. On the other hand, there is evidence that the environment can influence the rate of the γ- to β-switching. Thus, in sheep, removal of the adrenals abolishes the increase in plasma cortisol that precedes birth.[22] The γ- to β-switch in such

adrenalectomized animals is delayed, although the animals are normal with respect to developmental progression. Administration of cortisol allows the switch to progress with normal kinetics. Also, external factors can influence the rate of the γ- to β-switch in MEL/fetal erythroid hybrids: serum deprivation or addition of dexamethasone in the culture media strikingly accelerates, while addition of butyrate inhibits, the γ- to β-switch.[23,24]

Considerable evidence suggests that the rate and the timing of switching is inherently controlled, perhaps through the action of a developmental clock type of mechanism. Three arguments in favor of a clock-type of mechanism will be mentioned here. First, in vivo observations in humans indicate that the level of HbF in newborns is related to their developmental age from conception rather than to the time of birth itself.[25,26] Thus, the switch is independent of the intrauterine or extrauterine status of the individual; rather, the degree of developmental maturity of the fetus determines the rate as well as the timing of the γ- to β-switch. Second, the rate of γ- to β-switching of the MEL/human fetal erythroid hybrids correlates with the age of the fetus from which the human erythroblasts were derived.[21] Thus, hybrids produced using cells of younger fetuses switch more slowly than do hybrids produced using cells of older fetuses, as if the human fetal erythroid cells "know" whether they belong to an early or to a late developmental stage, and transmit this information to the hybrid cells. Third, transplantation experiments of hematopoietic stem cells have been done in sheep to determine whether the hematopoietic environment can influence the rate of the switch in transplanted cells. Adult stem cells were transplanted into fetuses and fetal stem cells into adult animals, and hemoglobin production in the engrafted donor cells was monitored. The adult cells transplanted into fetuses continued to produce adult globin, suggesting that the fetal environment cannot change the program of the adult cells.[27] Transplantation of fetal sheep stem cells into lethally irradiated adult recipients showed that the donor cells switch.[28] The rate of switching of the transplanted fetal cells, however, depended on the gestational age of the donor fetus, suggesting that switching reflects the action of a mechanism that in some fashion can count developmental time.

Presumably, a clock determining the rate of switching is set sometime during embryogenesis and proceeds to execute a preset program as development advances. It has been difficult to test experimentally the molecular basis of this phenomenon. There are several examples of developmental clocks in drosophila, but these are usually associated with circadian rhythms. It is difficult to conceive how a "clock" that can operate for several months (as in the case of human γ- to β-globin gene switching) is controlled; although hypotheses on how cells can count developmental time have been proposed.[29] The available evidence suggests that the clock of human γ- to β-switching is located on chromosome 11.[30] It acts in *cis* and certain findings,[31] although interpreted differently by these authors, suggest that the clock may be controlled through sequences located in the β-globin gene cluster.

MOLECULAR CONTROL OF SWITCHING

The last 20 years have witnessed considerable progress in the understanding of the molecular control of globin gene switching. Several tools have been used. Transgenic mice have provided information on the sequences of the locus that are responsible for developmental control and on the mechanisms that control switching in vivo. Traditional biochemistry and gene cloning techniques have led to the discovery of *trans* factors that interact with motifs of globin gene promoters and the locus control region (LCR). Essentially, we know today, in very broad terms, the mechanisms that regulate globin gene activity during development. There is, however, a vast amount of specific information that still needs to be learned until the phenomenon is completely understood at the molecular level.

Regulatory Elements of the ε-Globin Gene

In vitro experiments indicate that the CACCC and CCAAT boxes in conjunction with the GATA sites of the ε-globin gene promoter are required for expression expression.[32–35] However, it is not known which factors interact with these sequences in vivo. The CACCC box binds the ubiquitous factor Sp1,[36] but inactivation of Sp1 in vivo[37] does not result in defective ε-gene expression. Two factors belonging to the erythroid Krüppel-like factor (EKLF)/Sp1 family, designated fetal Krüppel-like factor (FKLF)[38] and FKLF-2,[39] have been shown to interact with the ε-gene CACCC box and activate gene transcription in transient expression assays and in stably transfected red cells. The CAAT box of the ε gene binds CP1; binding of CP1 activates in vitro gene expression. In the region of the CCAAT box of the embryonic and fetal, but not of adult, globin-gene promoters there exist direct repeats of a short motif that is analogous to DR-1 binding sites for nonsteroid nuclear hormone receptors.[35] In vitro experiments and studies in transgenic mice have demonstrated that COUP-TF, an orphan nuclear receptor, binds to the DR-1 element of the gene promoter and acts as a developmental repressor.[35] The role of the DR-1 element in ε-gene silencing was confirmed in a study performed in βYAC transgenic mice.[40] Furthermore, this study demonstrated that the DR-1 element binds a 540-kD complex named DRED (direct repeat erythroid-definitive), which contains nuclear orphan receptors TR2 and TR4.[40,41] TR2 and TR4 form a heterodimer and are able to bind to the ε- and γ-globin gene promoters. In TR2 and TR4 null mutant mice, silencing of both the ε- and γ-globin genes is delayed in definitive erythroid cells. In transgenic mice expressing a dominant-negative TR4, the ε gene is activated in primitive and definitive erythroid cells.[42] Forced expression of wild-type TR2 and TR4 leads to precocious

repression of the ε-globin gene; however, γ-globin expression is increased in definitive erythroid cells.[42] The ε-globin gene promoter also contains a number of GATA sites. Studies in transgenic mice suggest that when GATA-1 binds at the −163 or −269 site it acts as a gene activator, but when it binds to the −208 site it acts as a repressor.[43] Several binding sites for factors that can act either as repressors or activators in vitro have been identified in the upstream ε-gene promoter.[44,45] Sox6, a member of the Sox transcription factor family, is able to bind at the proximal promoter of the mouse εy-globin gene and to silence directly expression of the gene in definitive erythroid cells.[46,47] It remains to be seen whether Sox6 is involved in the autonomous silencing of the human ε-globin gene in adult erythropoiesis.

Regulatory Elements of the γ-Globin Genes

Evidence that the γ-globin gene promoter contains elements important for developmental control is provided by the point mutations that produce phenotypes of hereditary persistence of fetal hemoglobin (HPFH) (see Chapter 16). Most of these HPFH mutations occur in transcription factor binding motifs. Between the CAAT box and the TATA box of the γ-gene promoter there exists a G-rich sequence designated as stage selector element. This sequence is conserved in species that express the γ gene in the fetal stage, but diverges in species in which the γ-gene homolog is expressed in embryonic cells.[48] A binding activity, called stage selector protein,[49,50] binds to this sequence. Stage selector protein is composed of the ubiquitously expressed factor CP2 and a recently cloned protein, NF-E4, which is erythroid specific and activates γ-gene expression in transfection experiments in vitro.[51,52]

Several proteins bind to the CAAT box region of the promoter.[53–58] CP1, a ubiquitously expressed protein, acts as a positive transcriptional activator in vitro. CAAT displacement protein (CDP) binds to both CAAT boxes, competitively displacing CP1 and, in vitro, acts as a transcriptional repressor.[59] NF-E3 and GATA-1 bind in the CAAT box region[53,54,58,60] and are considered to act as gene suppressors, but this hypothesis is not supported by experiments in transgenic mice.[61] Studies in transgenic mice indicate that the CACCC box plays an important role in gene expression at the fetal stage of definitive hematopoiesis when the major synthesis of fetal hemoglobin takes place in humans.[62] FKLF[38] and FKLF-2[39] bind to the γ-globin gene CACCC box in vitro but their in vivo role has not yet been determined. As mentioned previously, a DR-1 element is also identified in the γ-globin gene promoter.[35,40] The DR-1 binding site is disrupted by the HPFH-117 mutation in support of the hypothesis that the DR-1 element is implicated in γ-gene silencing.

Other developmentally important sites have been revealed in the upstream promoter by HPFH mutants. GATA and octamer 1 sites are located near position −175. The −175 HPFH mutation alters the interaction with GATA-1 and removes the binding site for octamer 1,[63,64] but the relevance of these in vitro effects to the HPFH phenotype remains unknown. Several HPFH mutations are located in the −200 region. This region of the promoter is capable of forming a triple-stranded structure, which is thought to be the binding site for a repressor complex that is displaced by the transcription factors that bind to the novel sequences created by the HPFH mutations mutations.[65,66] Other potential binding sites are located further upstream in the promoter promoter.[48,67] Transgenic mouse experiments have localized a potential silencer element in the –382 to –730 region.[68] Also, this region contains a butyrate response element element.[69] That the −382 to −730 region may contain a silencer has also been shown by the finding of an HPFH mutation at position −567. This mutation alters a GATA site and in vitro experiments showed a complete loss of GATA-1 binding,[70] a phenotype recapitulated in transgenic mice.[71] Chromatin immunoprecipitation experiments using fetal liver tissue from βYAC transgenic mice showed a recruitment of GATA-1, FOG-1, and Mi2 to the –567 GATA site late in fetal development when γ-gene expression is silenced.[71] Mi2 is a member of the NuRD complex whose functions include nucleosome remodeling and histone deacetylase activities resulting in transcription repression.[72–74]

An "enhancer" has been located downstream from the $^{A}\gamma$ gene on the basis of transient transfection experiments.[75] This element contains binding sites for various transcription factors,[76,77] but it appears to have no effect on γ-globin gene expression in vivo.[78] In transgenic mice, presence of this 3′ element protects the γ gene from position effects,[79,80] suggesting that its likely role is stabilization of the interaction between the γ-globin gene and the LCR.

The effects of the three basic *cis* elements of the γ-globin gene promoter, CACCC, CCAAT, and TATA, on the transcriptional potentials of the promoter at different developmental stages have been studied in transgenic mice. Mutations in each box disrupt γ-gene expression in adult erythropoiesis, but have no effect on γ-gene expression in embryonic erythropoiesis.[62,81–83] These results imply that the transcriptional machinery in embryonic and adult erythroid cells may differ; thus, an intact promoter is required for highly effective transcription in adult erythroid cells whereas a partially defective γ-globin promoter can initiate high levels of transcription in embryonic erythroid cells.

Regulatory Elements of the β-Globin Gene

Several factors have been shown to bind in the CAAT box region of the β-globin gene;[84–86] CP1 behaves as a positive regulator of the CAAT box in vitro. The CACCC box binds several factors in vitro[87] but the protein that appears to be the most important in vivo is EKLF.[88,89] The β-globin CACC box has a higher binding affinity for EKLF than the ε- or γ-globin CACC boxes.[90]

Studies using transgenic mice have identified two regions that could enhance β-globin gene expression.[84,91–93] An enhancer is located downstream from the poly A site of the β-globin gene.[84,91–93] Its deletion markedly decreases β-gene expression in transgenic mice,[94] indicating that this element plays an important role in β-globin gene expression. Another enhancer is located in intron 2 of the β gene.[95,96]

The β-Globin Locus Control Region

This region is described in Chapter 3 of this book. It is located 6–25 kb upstream from the ε-globin gene and contains a series of developmentally stable DNase I hypersensitive sites.[97,98] A large body of data indicates that the activities of the LCR are mostly localized to the core elements of the hypersensitive sites, which are approximately 300 bp long. The regions flanking the hypersensitive site core elements of the LCR are also important for function. The current concept is that the LCR functions as a complex formed by interaction of the transcriptional factors that bind to the individual hypersensitive site elements.

The unique property of the LCR is its activating function, which "opens" the chromatin domain and provides the possibility for gene transcription. In transgenic mice, the LCR is recognized by its capacity to confer integration site- or position-independent expression of a linked gene.[99,100] Position effects are always overcome by the LCR in a dominant manner.[101,100] Experiments in knockout mice have been recently interpreted to indicate that the LCR is not required for opening the chromatin domain.[102–104] In ε-γ-δ-β thalassemia mutants due to LCR deletions,[105–109] there is total inactivation of the β-locus chromatin and total absence of transcription of the β-cluster genes in *cis*. However, when the LCR is deleted from the endogenous murine locus by homologous recombination, the globin genes continue to show some low levels of expression, and the chromatin of the β locus remains in the open configuration.[102,104,110] Why the phenotypes of the LCR deletions in humans and the LCR knockouts in mice differ is still unknown.[111,112] Among the possible reasons are differences in the composition and organization of the murine and the human LCRs. Alternatively, the total silencing of the β locus in the human LCR deletions might not be due to the deletion of the LCR per se, but the juxtaposition to the locus of heterochromatic regions, located upstream, that silence the genes of the locus.

The DNase I hypersensitive sites of the LCR have developmental specificity.[113] This was unequivocally shown in the studies of transgenic mice carrying β locus yeast artificial chromosomes (YAC mice). Deletion of the core element of HS3 in the context of a β locus YAC results in total absence of ε-globin gene expression in day-9 embryonic cells,[114] suggesting that sequences of the core element of HS3 are necessary for activation of ε-globin gene transcription. γ-Gene expression in embryonic cells is normal, suggesting that a hypersensitive site other than HS3 interacts with the γ promoter in embryonic cells. However, γ-globin gene expression, is totally absent in fetal liver cells, indicating that the core of HS3 is necessary for γ-gene transcription in the fetal stage of definitive erythropoiesis. These results are also compatible with the possibility that the LCR changes conformation during the course of development.[114]

Molecular Control of Switching

Major insights on the molecular control of switching have been obtained through studies of transgenic mice. As mentioned earlier, in the mouse there is only one switch during development – the switch from embryonic to definitive globin gene expression, which coincides with the transition from yolk sac to definitive, fetal liver, erythropoiesis. The murine εy and βh1 genes are expressed exclusively in the yolk sac and they are silenced in the fetal liver where βmajor- and βminor-globin gene expression occurs. The εy gene is homologous to human ε whereas the βh1 is homologous to human γ. Studies of transgenic mice carrying human γ- or β-globin transgenes, performed before the discovery of the LCR, have shown that the human γ and β transgenes are regulated similarly to their murine homologous genes (references in Stamatoyannopoulos and Grosveld[20]). Thus, the γ genes, like the murine βh1, are expressed only in the yolk sac cells whereas the β genes are expressed only in the definitive cells, indicating that all the elements required for correct developmental regulation are included in the sequences of the genes or their flanking sequences.

With the discovery of the LCR, questions arose about how the globin genes are developmentally regulated in the presence of this powerful regulatory element. Studies in transgenic mice revealed that two mechanisms, gene silencing and gene competition, control hemoglobin switching.

Globin Gene Silencing

The studies of *cis* elements and *trans* factors involved in turning off the embryonic globin gene provide a good example of the complexity of the control of gene silencing during development. ε-Globin gene expression is totally restricted in the embryonic yolk sac cells and its developmental control is autonomous, that is, all the sequences required for silencing of the ε gene in definitive erythropoietic cells are contained in the sequences flanking the gene.[115,116] Regulatory sequences mediating this autonomous silencing have been mapped to the distal and proximal ε-gene promoter.[40,43,44,117,118]

Controversy has been generated with the studies of a putative negative regulatory element initially identified in the upstream gene promoter by using transient transfection assays.[119] This element is located between −182 and

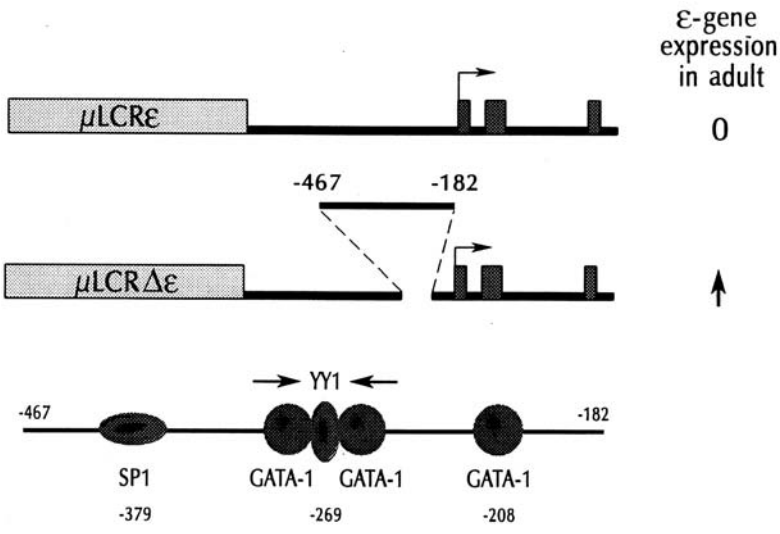

Figure 5.2. Globin gene silencing. The middle diagram shows the sequence of the upstream gene promoter, which when deleted results in continuation of γ-gene expression in the adult. The lower diagram shows the binding sites for transcriptional factors contained in this silencer.

−467 bp from the initiation site and contains three binding motifs: a GATA site at −208, a YY1 site at −269, and a CACC motif at −379[43,120] (Fig. 5.2). Deletion of the element resulted in ε gene expression in the red cells of adult transgenic mice carrying an ε gene with an upstream micro LCR.[121] Disruption of either the −208 GATA-1 or the −269 YY1 binding site also resulted in ε-gene expression in adult transgenic mice.[43] Presumably, several transcriptional factors interact to form the silencing complex and disruption of any of these factors results in inhibition of silencing. ε-Gene silencing, therefore, is probably combinatorial (Fig. 5.3). The fact that GATA-1 binding at −208 results in ε-gene suppression was subsequently shown using a binary transgenic mouse system: Overexpression of GATA-1 in transgenic mice carrying a human β locus YAC resulted in a specific decrease of human ε-globin expression.[122] The function of this ε-gene silencer was, however, questioned by studies in transgenic mice containing an intact human β-globin locus. Thus, deletion of a portion (125 bp) of the sequence of the ε silencer in a βYAC construct did not lead to expression of the ε gene in definitive erythropoietic cells.[94] In contrast, the deletion resulted in a significant decrease of ε-gene expression in the yolk sac, suggesting that the deleted sequence could harbor a cryptic activity that is required for stimulation of ε-globin RNA synthesis. Transgenic mice carrying a βYAC construct harboring a slightly larger (224 bp vs. 125 bp) deletion of the silencer[123] had no abnormalities in ε-gene expression in either embryonic or in definitive erythropoietic cells, and there was no continuation of ε-gene expression in fetal or adult erythroid cells. The function of this sequence of the ε-gene promoter is thus still unclear. As mentioned earlier, COUP-TF and/or DRED binding in the DR repeats near the CAAT box has suppressive effects and there is evidence that sequences having silencing properties are located further upstream in the ε-gene promoter.

The mechanism that turns off the γ-globin gene has been more difficult to determine. Initially, the silencing of the γ gene was attributed solely to gene competition.[124,125] Other experiments in transgenic mice suggested that the gene turns off solely through an autonomous silencing mechanism.[126] It seems that autonomous silencing is the main mechanism whereby the γ genes are turned off during development. Evidence was provided by two types of experiments. First, in transgenic mice carrying βYAC constructs from which the β gene has been deleted,[127] the γ genes turn off after birth, even though the β genes are absent, thus arguing against the hypothesis that γ-gene silencing is solely the result of competition for *trans* factors and/or the LCR by the β gene. Second, when the β-globin gene is placed close to the LCR, it is expressed throughout development.[128,129] When the γ gene is placed in the same position, it is expressed in the embryonic and the early fetal liver cells, but it is turned off postnatally, as expected if γ-gene silencing is autonomous.[129] However, the story is not that simple: other transgenic studies[130] as well as the increase in γ-globin gene expression in patients with β thalassemia due to β-gene promoter deletions,[20] suggest that competition by the β-gene promoter, in addition to autonomous silencing, contributes to the turning off of the γ-globin gene.

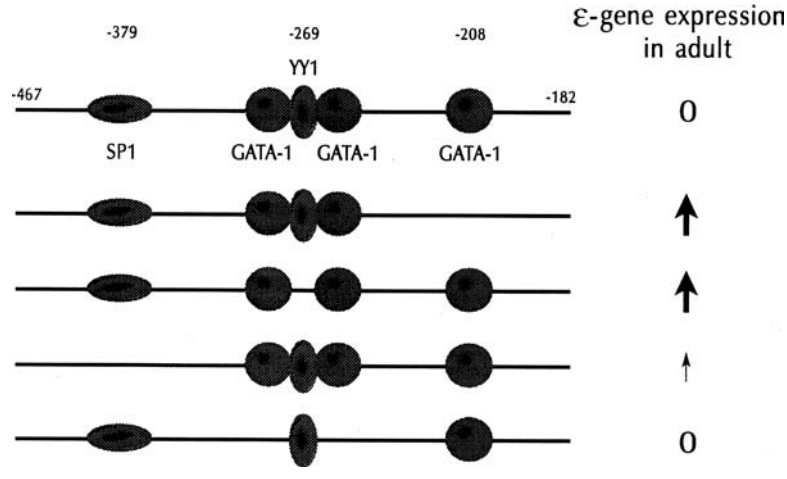

Figure 5.3. Evidence that the silencing of the ε gene is combinatorial. Mutations that affect binding of GATA-1 at −208 or YY1 at −269 or a CACCC binding protein at −379 result in continuation of ε-globin gene expression in the adult. Other transcriptional factors involved in silencing include COUP-TF that binds to the DR-1 element near the gene's CAAT box.

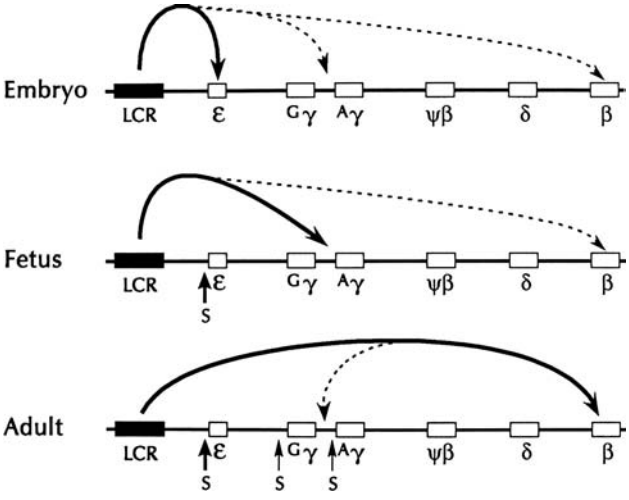

Figure 5.4. Model of the competitive control of hemoglobin switching. "S" indicates the activity of a silencer element.

Gene Competition

The initial observation that led to the formulation of the competition model was made in transgenic mice carrying either the γ- or the β-globin gene or both genes linked to the LCR. When the genes were alone, developmental control was lost. When the genes were linked together, developmental control was restored. Such findings led to the proposal that the γ-globin gene is regulated through competition with the β-globin gene and vice versa.[124,125] The hypothesis is that in the embryonic stage, the LCR interacts with the ε-globin gene; the downstream genes are being turned off competitively. In the fetus, the ε gene is silenced, and the LCR interacts with the $^{G}\gamma$ and $^{A}\gamma$ genes. In the adult, the γ genes are silenced, and the LCR now interacts with the β-globin gene, the last gene of the locus (Fig. 5.4).

Two conditions influence the probability of interaction of a gene with the LCR: the prevailing transcriptional environment and the distance from the LCR. Among the *trans*-acting factors that are likely to facilitate the interaction of the LCR with the γ- or β-gene promoters is EKLF and perhaps other factors of the KLF/SP1 family. In addition to the *trans*-acting factors, gene order and proximity to the LCR are important in determining a gene's competitive advantage for interaction with the LCR.[131,132] The closer the gene, the higher is the advantage. Its placement at the 3′ end of the locus might explain why the β gene is totally shut off in embryonic cells when it is located in its normal chromosomal position, whereas it is always expressed in the embryo if it is placed next to the LCR.

In situ hybridization methods have allowed the visualization of the interaction of globin genes with the LCR.[100,133] This element interacts with only one promoter of the locus at a given time, and switching essentially represents a change in frequency of interaction of the LCR with either the γ- or the β-gene promoter. Results from newly developed technologies, such as 3C[134] and RNA trap assays, demonstrate that actively transcribed globin genes are located in proximity to the LCR, suggesting that a chromatin loop is formed when a globin gene is enhanced by the LCR.[135–137] The formation of the loop between the LCR and the β-globin gene requires erythroid-specific *trans*-acting factors EKLF, GATA-1, and its cofactor FOG-1, but not NF-E2.[138–140] Binding of these factors to their cognate *cis* elements is not sufficient for loop formation,[140] and binding of *trans*-acting factors represents an independent event that occurs prior to loop formation.[139] Thus, although EKLF, GATA-1, and FOG are indispensable for loop formation, they use a complex pathway to regulate the process.

Control of HbF in the Adult

One of the most interesting characteristics of human γ- to β-switching is its leakiness and the continuation of synthesis of small amounts of HbF in the adult. This has been known since the time the alkali denaturation method was used for HbF quantitation, but its significance was only realized when immunofluorescent methods were used to stain peripheral blood smears. These methods were first applied in the mid-1960s and they were rediscovered in the 1970s. It was then realized that this residual γ-globin expression is restricted to a minority of cells, the F cells. The question was then raised about how these F cells are formed. Initially, clonal hypotheses (reviewed earlier in this chapter) were proposed to explain the origin of F cells: They could be the progeny of fetal stem cell clones. Major insights into the understanding of the control of HbF in the adult were obtained through analyses of HbF expression in erythroid cultures and through observations in patients with activated erythropoiesis.

The first clue on mechanisms came from studies in erythroid cultures, which showed that high levels of HbF are characteristic of colonies produced by erythroid burst-forming units (BFU-E) of adult origin.[13,141] In erythroid cells of these colonies, HbF was not uniformly distributed but the colonies were usually composed of erythroblasts that contained both HbF and HbA, and erythroblasts that contained only HbA. These observations were interpreted to indicate that the production of F cells was related to the phenomenon of erythroid cell differentiation.[13]

The second clue on mechanisms came from studies showing that rapid regeneration of the erythroid marrow induces F-cell production (reviewed in Stamatoyannopoulos et al.[142]). For example, increased F-cell production is characteristic of bone marrow regeneration following bone marrow transplantation,[10] or following recovery from the aplastic phase of erythroblastopenia of childhood,[143] or following chemotherapeutic ablation of the bone marrow,[144] and following acute hemolysis.[143] Experimental acute bleeding in baboons activated γ-globin production.[145,146] Acute phlebotomy and decrease of hematocrit in humans stimulated F-cell production.[143] Proof that acute erythropoietic stress can induce HbF production was obtained

when baboons were treated with high doses of recombinant erythropoietin: These animals responded with striking elevation of F-cell production.[147,148]

It should be mentioned that in contrast to the consistent activation of HbF in acute erythropoietic expansion, with the exception of hemoglobinopathies and congenital hypoplastic anemias, there is no elevation of HbF in most patients with chronic anemias.[149] Administration of low doses of erythropoietin to baboons increases the hematocrit but fails to induce HbF.[147] Following acute bleeding, there is a surge of F-reticulocyte production, but when chronic anemia is instituted, the number of F-reticulocytes falls.[142,146] The difference in the rates of F-cell formation between acute and chronic erythropoietic stress provided strong evidence that the kinetics of erythroid regeneration determine whether a cell will become an F cell or an A cell.

The mechanism proposed to explain the induction of HbF in response to erythropoietic stress assumes that early progenitors encode a program allowing expression of fetal globin genes, but this program is changed to one allowing only adult globin expression during the downstream differentiation of erythroid progenitor cells (Fig. 5.5).[13,150] Presumably, the earlier progenitor cells contain a combination of *trans*-acting factors that favors γ-globin gene expression, whereas the late progenitors have a combination of *trans*-acting factors that favors β-globin gene expression. F cells are produced when earlier progenitors become committed to terminal differentiation prematurely.[150] In acute erythropoietic stress, the accelerated erythropoiesis increases the chance of premature commitment of early progenitors, resulting in increased production of F cells. Experimental evidence in support of this hypothesis was obtained by daily measurements of erythroid progenitor pools in baboons treated with high doses of recombinant erythropoietin.[148] The major effect of erythropoietin in vivo is an acute expansion of colony-forming unit (CFU-E) and a mobilization of BFU-E. Umemura et al.[148] showed that following the administration of high doses of erythropoietin, an increase in F-programmed CFU-E accounts for almost all of the expansion of CFU-E. The increase in these F-programmed CFU-E is followed by a striking increase in F-positive early erythroblasts, which precedes the appearance of F reticulocytes in the circulation.[148]

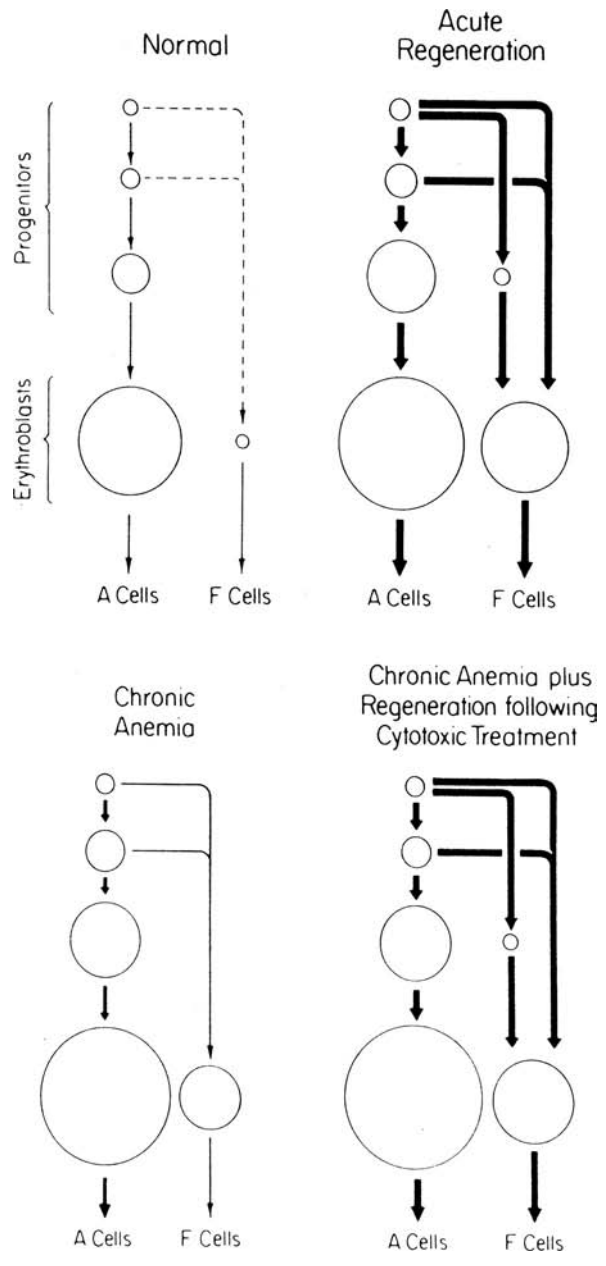

Figure 5.5. Model of regulation of fetal hemoglobin and F-cell production in the adult following acute erythroid regeneration or treatment with cytotoxic drugs such as hydroxyurea.

THE CONCEPTUAL BASIS OF PHARMACOLOGICAL INDUCTION OF FETAL HEMOGLOBIN SYNTHESIS

The pharmacological induction of HbF synthesis was a direct consequence of the studies on the cellular control of HbF production in the adult. Cytotoxic drugs were initially used to test, in primates, whether acute regeneration will induce HbF synthesis in the adult. The use of cytotoxic drugs in patients with sickle cell disease or with β thalassemia followed.

The origin of the use of cytotoxic drugs for HbF induction can be traced to the debate about the mechanism whereby 5-azacytidine stimulates HbF production. To test the hypothesis that DNA demethylation can activate γ-globin gene expression, DeSimone et al.[151] treated anemic juvenile baboons with escalating doses of 5-azacytidine; a striking augmentation of HbF production was observed. Induction of HbF synthesis was subsequently demonstrated in β thalassemia patients treated with 5-azacytidine.[152] At this stage, a debate about the mechanism of this phenomenon started. 5-azacytidine, a cytotoxic compound, is expected to kill the most actively cycling erythroid cells. The resulting decrease in late erythroid progenitor cells could trigger rapid erythroid regeneration and induce F-cell formation. Therefore, it was argued that

the induction of HbF was not simply due to the demethylating effect of 5-azacytidine but to its cytotoxicity that triggers secondary erythroid regeneration. Measurements of erythroid progenitor cell pools in baboons treated with 5-azacytidine supported this hypothesis.[153]

To test whether cytoreduction and the ensuing secondary erythroid regeneration were the cause of HbF induction by 5-azacytidine, Papayannopoulou et al.[154] asked whether other cytotoxic compounds producing erythroid regeneration but not DNA demethylation would also induce F-cell formation. Baboons were treated with cytotoxic doses of ara-C and responded with striking elevations of F reticulocytes, with kinetics indistinguishable from those elicited by 5-azacytidine.[154] Induction of γ-globin gene expression was also observed in monkeys or baboons treated with hydroxyurea.[154,155] Vinblastine, a cell cycle–specific agent that arrests cells in mitosis, also produces secondary erythroid regeneration and stimulates HbF synthesis in baboons.[156] Following these studies, hydroxyurea was used for induction of HbF production in humans (see Chapter 30). Although other hypotheses for the mechanisms of action of hydroxyurea have been proposed, its activation of HbF synthesis through stimulation of erythroid regeneration is broadly accepted, although the initial rational for using cytotoxic drugs for stimulation of HbF production has been forgotten.[157–159]

Short-Chain Fatty Acids

The seminal observation that eventually led to the discovery that short-chain fatty acids induce the synthesis of HbF was the finding by Perrine et al.[160] that the γ- to β-switch is delayed in infants of diabetic mothers. Perrine and coworkers hypothesized that a metabolite in the blood of diabetic mothers was responsible for this finding and, using experiments in clonal erythroid cell cultures, they showed that γ-aminobutyric acid, which is elevated in the blood of diabetic mothers, is an inducer of HbF production.[161] Subsequent studies showed that butyrate stimulated γ-globin chain production in adult baboons,[162] and it induced γ-globin gene expression in erythroid progenitors of adult animals or of patients with sickle cell anemia.[162,163] Several other short-chain fatty acids were found to increase HbF in adult BFU-E cultures and in baboons.[164,165] Derivatives of short-chain fatty acids such as phenylbutyrate[166] and valproic acid[165,167] induce HbF production in vivo. Increased levels of HbF were also recorded in patients with metabolic disorders resulting in accumulation of short-chain fatty acids.[168,169] Butyrate and various short chain fatty acid derivatives have been used in a number of clinical trials (see Chapter 30).

The induction of HbF production by short-chain fatty acids is very interesting from the practical and biological points of view. The practical significance lies in the fact that there are very large numbers of short-chain fatty acid derivatives that are potential inducers of HbF synthesis.[170,171] Therefore, there are ample opportunities for discovering HbF inducers that can be administered orally and are more potent than butyrate.

The prevailing hypothesis is that short-chain fatty acids activate γ-globin gene expression through inhibition of histone deacetylases. Histone acetyltransferases catalyze histone acetylation through the transfer of acetyl groups to lysine residues of the core histones.[172–174] It is believed that histone acetylation leads to gene activation by weakening the binding of histones to nucleosomal DNA, which makes the DNA subsequently accessible to transcription factors.[175] Conversely, histone deacetylases are believed to largely mediate gene repression, as deacetylation of histones would allow the histone to bind more tightly to the nucleosomal DNA and displace transcription factors. Thus, histone deacetylase inhibitors may induce γ-globin gene activity by increasing the accessibility of chromatin around the γ-globin gene promoter to activating transcription factors. The exact mechanism whereby the short-chain fatty acids affect gene transcription remains unknown. Studies in transgenic mice are compatible with the assumption that the stimulation of HbF synthesis reflects inhibition of silencing rather than activation of transcription,[176] but the evidence is indirect. It is obvious that the delineation of the mechanisms of stimulation of HbF synthesis by short-chain fatty acids will provide new insights into the control of silencing or activation of γ-globin gene expression.

Role of the BCL11A Locus

Recent studies have identified the BCL11A locus as a major locus regulating the levels of fetal hemoglobin in β-thalassemia or sickle cell disease. A SNP located in the second intron of the BCL11A gene was found to be correlated with HbF levels in patients with β-thalassemia suggesting that this genetic polymorphism is an important indicator of disease severity.[177,178] The BCL11A gene encodes three isoforms of a multi-zinc finger transcription factor and is developmentally regulated such that only the two largest isoforms (X and XL) are exclusively expressed during adult erythropoiesis.[179] BCL11A binds to GG-rich motifs and has been shown to function as a transcription repressor.[180,181] BCL11A knockdown experiments in adult erythroid progenitor cells resulted in a dramatic increase in F-cells numbers and HbF levels suggesting that BCL11A is involved in γ-globin gene silencing.[179] Chromatin immunoprecipitation experiments showed that BCL11A directly binds to several locations of the β-globin locus in adult erythroid progenitor cells.[179] Electromobility shift assays using extracts from BCL11A over expressing K562 cells showed BCL11A binding to a GGCCGG motif at position −56 to −51 of the $^{G}\gamma$ gene promoter.[182] Collectively the studies of patients and the biochemical investigations strongly suggest that BCL11A acts as a stage specific repressor of γ-globin expression. Thus, BCL11A has emerged as an attractive target for reactivation of HbF in patients with β-thalassemia or sickle cell disease.

Structure and Function of Hemoglobin and Its Dysfunction in Sickle Cell Disease

Daniel B. Kim-Shapiro

INTRODUCTION

Hemoglobin has evolved to be an efficient oxygen (O_2) transporter. Its function, understood in terms of a two-state model of allostery, serves as a paradigm for many other proteins. A single β-globin gene (*HBB* glu6val) point mutation resulting in sickle hemoglobin (HbS) is the proximate cause of sickle cell disease (Chapter 19). The primary cause of the disease is HbS polymerization that injures and deforms the sickle erythrocyte, causing many pathological consequences discussed elsewhere in this book.

STRUCTURAL ASPECTS OF HEMOGLOBIN

Hemoglobin is a 64-kD, nearly spherical protein with a diameter of approximately 5.5 nm. Its three-dimensional structure was solved by Max F. Perutz who discussed the molecular anatomy and physiology of hemoglobin in the first edition of this book.[1] It is a dimer of dimers, with two α subunits and two β subunits (Fig. 6.1). The α chains have 141 amino acid residues and the β chains have 146 residues. Each of the α and β chains resemble each other closely in both secondary (α helical) and tertiary structure. Moreover, even though the primary amino acid sequence is different, each subunit also resembles myoglobin, a heme-containing globin having only one subunit in both secondary and tertiary structure. Generally, nonpolar groups are found in the interior of the subunits and polar residues are found on the surface. The SH group of the cysteine at position 93 of the β chain is exposed to solvent in the oxygenated form of hemoglobin, but it is partially hidden when hemoglobin is deoxygenated. This is due to the change in quaternary structure of the protein when hemoglobin binds O_2. One αβ dimer rotates approximately 12^0 with respect to the other and moves approximately 0.1 nm along the rotation axis.

Each of the subunits of the tetramer contains a heme prosthetic group (Figs. 6.1 and 6.2). Hemes are attached to the globin protein via a histidine side chain (Fig. 6.2). Heme is an iron-containing protoporphyrin IX, a tetrapyrrole with an iron atom at its center. The iron is usually ferrous, having a valency of +2. It can be oxidized to the ferric form (+3) and is then commonly referred to as methemoglobin. In the ferrous form, the heme group can bind to gaseous ligands including O_2, CO, and NO and can also bind alkylisocyanides.[2] In the ferric form, hemoglobin does not bind to O_2 or CO. It binds to NO, but with a much lower affinity than ferrous heme. Ferric hemoglobin also reversibly binds nitrite, nitrate, azide, and binds to cyanide very tightly, forming cyanomethemoglobin.

In addition to the heme group, there are several other sites within hemoglobin through which it interacts with small molecules. Bisphosphoglycerate (BPG) and inositol hexaphosphate (IHP) bind in the central cavity of hemoglobin, crosslinking the four subunits. The β-93 cysteine binds N-ethylmaleimide, iodoacetamide, and nitrosonium ion (NO^+), the latter forming S-nitrosated hemoglobin or SNO–hemoglobin. Carbon dioxide binds to the terminal amino groups.

NORMAL HEMOGLOBIN FUNCTION

Oxygen Transport

The primary function of hemoglobin is to transport O_2 from the lungs to the tissues. The pressure and solubility of O_2 in liquids make it such that only 200 μmol/L, at most, could be carried by blood in the absence of an O_2-carrying protein such as hemoglobin. Whole blood contains approximately 10 mmol/L hemoglobin (in heme), thus greatly increasing the O_2-carrying capacity of blood. The ability of hemoglobin to transport O_2 effectively is illustrated by plotting its fractional O_2 saturation (hemoglobin bound to O_2/total hemoglobin) against O_2 pressure (Fig. 6.3). Hemoglobin binds O_2 cooperatively, a phenomenon discovered by Christian Bohr, the father of the famous physicist Niels Bohr.[3] Cooperative binding means that the affinity of a hemoglobin tetramer for O_2 increases as more O_2 is bound. Myoglobin binds O_2 noncooperatively. In Figure 6.3, we see that at pressure of 20 mm Hg (close to that of metabolically active tissue), myoglobin is almost completely saturated with O_2, whereas hemoglobin is less than 40% saturated. Thus, hemoglobin has a lower affinity for O_2 at this pressure. As the O_2 pressure is raised to 90 mm Hg, which is close to that in the lungs, both hemoglobin and myoglobin are fully saturated with O_2 so that the hemoglobin–O_2 affinity has caught up to that of myoglobin. If myoglobin were contained in red blood cells instead of hemoglobin, then the red blood cells would be fully O_2

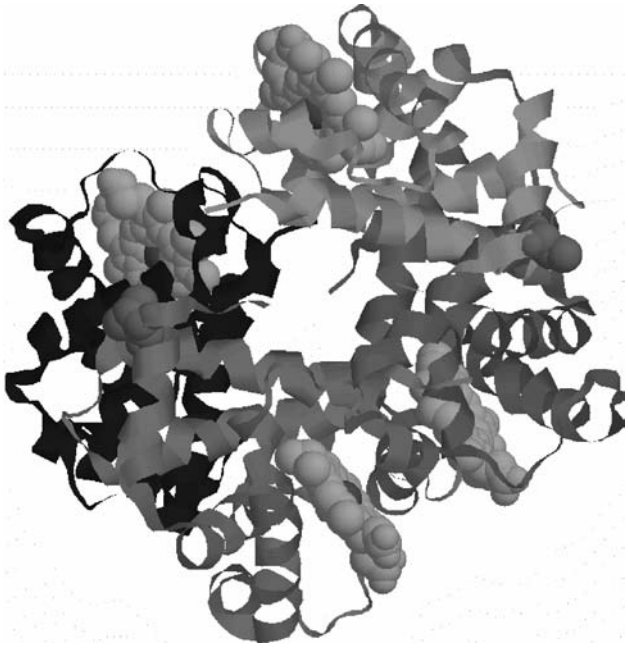

Figure 6.1. Ribbon diagram of a sickle cell hemoglobin tetramer. Each of the four subunits is shown in a different color. Four heme groups (yellow-orange) are shown with an iron (red) atom in the middle. The valine residues resulting from the single point mutation causing sickle cell disease are shown at the β6 position on each β subunit (purple). The molecule is shown looking down the axis where 2,3 bisphosphoglycerate binds. Except for the substitution of valine for glutamate, normal HbA would appear the same as the molecule shown. (The illustration was derived from the Protein Explorer (http://www.umass.edu/microbio/rasmol/) and data from the Protein Data Bank.) (See color plate 6.1.)

loaded in the lungs, but they would not release sufficient O_2 in the tissues. By combining four myoglobin-like chains into a single tetramer, hemoglobin is able to function as an efficient O_2 transporter.

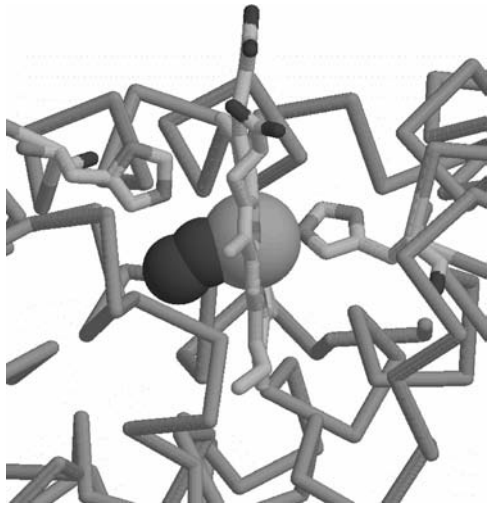

Figure 6.2. Close up of oxygen bound to the heme. Looking down the heme, the iron atom (yellow-orange) is shown bound to an oxygen molecule (red). The proximal histidine side chain is also shown bound to the iron and the distal histidine is also clearly visible on the other side of the proximal one. (The illustration derived from the Protein Explorer (http://www.umass.edu/microbio/rasmol/) and data from the Protein Data Bank.) (See color plate 6.2.)

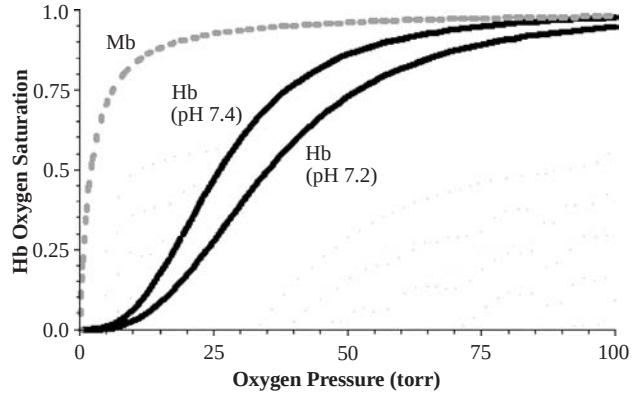

Figure 6.3. Hemoglobin and myoglobin oxygen binding curves. The myoglobin oxygen binding curve was drawn according to Equation 6.1 with P_{50} taken as 2 mm Hg. The hemoglobin oxygen binding curves were drawn using Equation 6.2 with $n = 2.8$ and P_{50} taken as 26 mm Hg at pH 7.4 and as 35 mm Hg for pH 7.2. (See color plate 6.3.)

The myoglobin O_2 saturation, Y, as a function of O_2 pressure can be described by the simple relation

$$Y = \frac{MbO_2}{MbO_2 + Mb} = \frac{pO_2}{pO_2 + P_{50}}, \tag{6.1}$$

where pO_2 is the O_2 pressure and P_{50} is the O_2 pressure where $Y = 0.5$ (the myoglobin is half saturated with O_2). The hemoglobin O_2 saturation dependence on O_2 pressure is more complicated and can be described by

$$Y = \frac{HbO_2}{HbO_2 + Hb} = \frac{(pO_2)^n}{(pO_2)^n + (P_{50})^n}, \tag{6.2}$$

where the exponent n is called the Hill coefficient. The Hill coefficient describes the degree of cooperativity in O_2 binding. For myoglobin, where there is no cooperativity, $n = 1$. For hemoglobin, several factors could affect the value of n, but it is usually found to be approximately 2.8 under normal conditions.

The ability of hemoglobin to bind O_2 cooperatively is well-described in terms of a two-state model developed by Monod, Wyman, and Changeux (MWC).[4] According to the model, there are two states of hemoglobin defined by the quaternary structure: the relaxed, high-O_2 affinity R-state and the tense, low-O_2 affinity T-state. When hemoglobin is completely deoxygenated, it is essentially all in the T-state and thereby has a low affinity. As O_2 binds, a hemoglobin tetramer that has 2–3 O_2 molecules bound will be likely to undergo the allosteric transition to the R-state, gaining a higher affinity for O_2. Thus, the allostery, whereby binding at one heme site affects binding at another site, explains the cooperative O_2 binding of hemoglobin.

One of the beautiful aspects of the MWC model is its simplicity. It is assumed that the affinity of a particular subunit heme group is only a function of the quaternary state (R or T) of the tetramer. Only three parameters are needed to apply the model. These are K_R, the R-state association constant; K_T, the T-state association constant; and L, the quaternary equilibrium constant between unligated tetramers (how much T-state there is vs. R-state in the absence of O_2 or

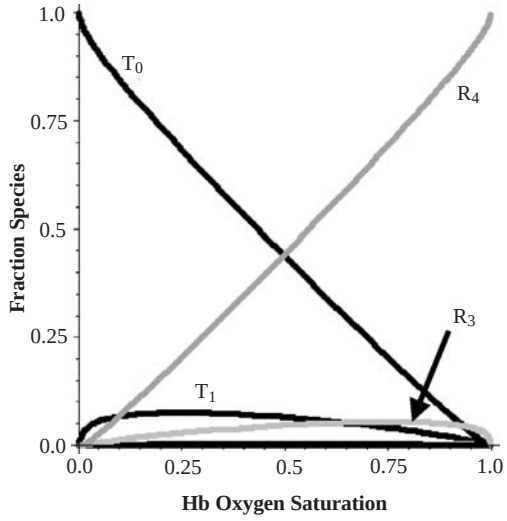

Figure 6.4. Fraction of hemoglobin states. The fraction of each state is plotted vs. hemoglobin oxygen saturation. Only the species T_0, T_1, R_3, and R_4 are present at large enough fractions to be visible. At zero oxygen saturation the hemoglobin is virtually all in the T_0 state and at 100% oxygen saturation it is all in the R_4 state. The parameters used were $L = 2 \times 10^6$, $c = 0.001$, and $K_T = 1/(75$ mm Hg). (See color plate 6.4.)

other ligands). The equilibrium constants between R_x and T_x are determined by Lc^x, where x represents the number of ligands bound (so R_3 is a hemoglobin molecule with three ligands bound in the R quaternary state) and $c = K_T/K_R$. As hemes in R-state hemoglobin have a much higher affinity than T-state hemes, the only species that are effectively present at any O_2 tension are T_0, R_4, T_1, and R_3 (Fig. 6.4).

The phenomenon of allostery, action at a distance, whereby binding at one heme site affects the affinity at another is explained by motions of the heme iron coupled to the globin and communicated to other subunits via salt bridges and other interactions.[5,6] When O_2 binds to the heme iron, the iron moves approximately 0.05 nm into the plane of the heme, pulling along the proximal histidine. This movement is transmitted to the subunit interfaces and leads to disruption of the salt links. Binding of the first O_2 molecule to hemoglobin is the most difficult because the many salt links must be broken. As these salt links break, the (tense) tetramer relaxes so that there are fewer salt links. At this point, binding of O_2 to the R-state molecule is easier. This relative "relaxed" nature of R-state hemoglobin is evidenced by the fact that the dissociation constant for ligated hemoglobin tetramers into dimers is approximately 1 mM but deoxygenated (T-state) hemoglobin has an extremely low tendency for dimer formation.

The MWC–Perutz model is supported by a large amount of theoretical and experimental evidence.[7] One of the key elements comes from kinetics studies showing that the rate of ligand binding by a heme depends on the quaternary state of the hemoglobin and not on the number of ligands bound.[8] The equilibrium constant describing the ligand affinity, such as that plotted for O_2 in Figure 6.3, depends on the rate of association and dissociation, $K = k_{on}/k_{off}$. The cooperativity in equilibrium binding of O_2 to hemoglobin is mainly due to the differences in the rate of O_2 dissociation, that is approximately 100 times slower for R-state than T-state, rather than differences in the rate of O_2 association, that is approximately 10 times faster for R-state than T-state.[9,10]

Several compounds greatly affect the ligand-binding properties of hemoglobin. These are classified as homotropic effectors (those that effect like ligands) and heterotrophic effectors, such as BPG, protons, chloride, and phosphate. Without BPG, the P_{50} of hemoglobin (partial pressure of O_2 at which the hemoglobin molecule is half saturated) for O_2 binding would be approximately 2 mm Hg, rather than approximately 25 mm Hg. According to the MWC–Perutz model, effectors alter the ligand binding by affecting L. BPG binding in the central cavity stabilizes the T-state. N-ethylmaleimide or NO^+ binding at the β93 cysteine stabilizes the R-state. Thus, SNO–hemoglobin has a higher O_2 affinity than hemoglobin that is not nitrosated.[11] Lowering the pH also stabilizes the T-state, so that more O_2 can be given off under acidic conditions (Fig. 6.3).

The two-state MWC–Perutz model is capable of explaining many of the phenomena associated with ligand binding. When applied with more rigor to a variety of phenomenon, however, the need for modification is clear. This should not be a surprise as hemoglobin is not a homotetramer. Thus, a clearly necessary modification of the MWC–Perutz model is to account for chain differences.[12,13] The α subunits have a higher equilibrium affinity for O_2 than the β subunits, mainly due to faster dissociation rates from β subunits.[10,14] These differences in chain affinities are not consistent with a strict interpretation of a two-state model in which the ligand affinity is only a function of quaternary state (T or R). A further, commonly accepted modification involves a slight cooperativity within αβ dimers in the T quaternary state.[15,16] This modified two-state model is sufficient to explain a large variety of quantitative equilibrium and kinetic data. Exceptions to these have lead to further extended or alternative models.[16–18]

The effect of hemoglobin binding of gaseous ligands on O_2 affinity is particularly interesting. CO_2 reduces the ligand affinity of hemoglobin, similarly to protons. This combination leads to effective O_2 delivery to metabolically active tissue. When NO is bound to the α subunits forming α nitrosyl hemoglobin, it acts as a negative allosteric effector, lowering the O_2 affinity of the β subunits.[19] This is an example of how, in some cases, hemoglobin function at vacant hemes is dependent on the subunits to which ligand is bound and the type of ligand. Thus, α nitrosyl hemoglobin function is not consistent with the MWC–Perutz model.

The two-state model is formulated in terms of two structures obtained from x-ray crystallography. In 1992, a new crystal structure of liganded hemoglobin was discovered called R2.[20] More recently, other liganded crystal structures have been determined.[21] One might wonder which of these is the one present in solution and how

this information relates to the two-state model.[22,23] Using multidimensional and multinuclear nuclear magnetic resonance, it has been found that the solution structure of liganded hemoglobin is actually a dynamic ensemble of states that include those determined by x-ray crystallography.[23–25] Similarly, the structure of deoxyhemoglobin in solution is likely to comprise several quaternary states that include the many ones found by x-ray crystallography.[26] Thus, the actual picture of how hemoglobin functions is significantly more complicated than that described by a two-state model. For many applications, however, a two-state MWC–Perutz model is sufficient to explain biological phenomena. Nevertheless, it should be kept in mind that, like all models, especially simple ones that are applied to many complex behaviors, it has limitations.

Transport of Other Gases

Hemoglobin also transports CO_2, which binds more tightly to deoxyhemoglobin than to oxyhemoglobin, so it is taken up in the tissues and given off in the lungs. In addition, deoxyhemoglobin uptake of protons helps transport CO_2 as bicarbonate, HCO_3^-, which is more soluble than CO_2.

$$CO_2 + H_2O \leftrightarrow HCO_3^- + H^+ \tag{6.3}$$

Without uptake of protons by deoxyhemoglobin, the equilibrium in Equation 6.3, would shift to the left, limiting bicarbonate formation. Thus, cooperative binding of O_2 links to that of CO_2 so that hemoglobin is an effective transporter of both molecules.

CO is produced by heme oxygenase during heme metabolism. The equilibrium affinity of hemoglobin for CO is approximately 200 times higher than that for O_2. This is due to the slow dissociation rate of CO from hemoglobin; O_2 actually binds to hemoglobin faster than does CO. Due to its high O_2 affinity and slow dissociation rate, CO has been recognized as a poison that disturbs O_2 delivery (Chapter 24); however, potential beneficial effects of CO have recently been recognized.[27–30] CO has been shown to have antiinflammatory effects and diminish apoptosis.[28–30] Recently, infusion of red cells saturated with CO at 25% of blood volume was shown to be effective in hemorrhagic shock resuscitation.[27] These beneficial effects of CO and hemoglobin's role in transporting such activity demand more study.

The ability of hemoglobin to destroy NO activity was an important element in the identification of NO as the endothelial-derived relaxing factor.[31,32] This is due to the rapid dioxygenation of NO with oxyhemoglobin to form nitrate (Chapter 10). NO can also bind to the heme, and the degree to which this reaction preserves biological activity has been debated. One certainty is that the equilibrium binding affinity of hemoglobin for NO is extremely high, approximately 1,500 times stronger than CO and 500,000 times stronger than O_2.[2]

Because of its high affinity, little knowledge about NO binding to deoxyhemoglobin can be obtained from equilibrium studies. Virtually any NO added to molar excess hemoglobin will bind the heme – there will be essentially none left in solution. Thus, binding studies have focused on kinetics. Early studies showed that the rate of dissociation of NO from T-state hemoglobin is 100-fold faster than from R-state hemoglobin, with the T-state rate being approximately 10^{-3}/s.[9,33,34] A difference in the dissociation rates from different subunits was also recognized.[33,34] A unique feature of NO binding to the α subunits is that when the α nitrosyl hemoglobin is in the T-state, a proportion of iron–proximal histidine bonds break, resulting in a characteristic triplet hyperfine structure in electron paramagnetic resonance spectra.[19,34–38] Recently, the dissociation rate of NO from this pentacoordinate α nitrosyl hemoglobin was measured to be 4×10^{-4}/s.[39] Thus, the rate of dissociation of NO from hemoglobin is faster for T-state hemoglobin and faster for β subunits than α subunits.

Early stopped-flow absorption experiments mixing NO and deoxyhemoglobin found that the association rate of NO with hemoglobin is noncooperative and occurs at a rate of 3×10^7 M/s.[40] Experiments examining the rate of release of a fluorescent BPG analog and the rate that partially NO-ligated hemoglobin binds CO indicated that a T- to R-state transition does take place after two–three NO molecules bind a tetramer.[40] The rate of NO binding to α and β chains was also found to be identical.[41] One study has suggested that although NO binds to R-state hemoglobin at the same rate as T-state hemoglobin, when the R-state transition has been caused by binding of two–three NO molecules, the rate of R-state association of NO is 100 times faster when the R-state transition has been invoked by O_2 binding.[42] In other words, NO would bind R_3 at the same rate as T_0 when the three ligands on R-state are NO but it would bind 100 times faster if they were O_2. Such a phenomenon would violate the tenet of the two-state model whereby binding properties at one heme only depends on the quaternary state of the protein. Subsequent studies have challenged the idea that the binding rate of NO to R-state oxyhemoglobin is faster than to R-state NO hemoglobin.[43,44] In addition, photolysis studies using a commonly accepted model of CO bound hemoglobin for oxyhemoglobin have also found that R-state hemoglobin binds NO at the same rate as T-state hemoglobin.[45,46] Thus, the preponderance of evidence indicates that the association rate of NO to hemoglobin is independent of the quaternary state. This is likely to be because once in the heme pocket, NO binds the heme extremely quickly in both cases so that the rate-limiting step in NO binding is diffusion of the ligand through the protein to the heme pocket.

Examination of both association and dissociation rates of NO shows that hemoglobin binds NO cooperatively, with all of the cooperativity being manifest in the dissociation rates. This is similar to O_2 where most of the cooperativity is in the dissociation rates. Due to the faster dissociation

rate from β subunits, α nitrosyl hemoglobin is the primary form found in equilibrium. The association rate of NO to hemoglobin is only approximately 1.5-fold slower than the rate of the dioxygenation reaction.[47] Thus, even at high O_2 tensions, some NO will escape destruction via the dioxygention reaction to form NO bound hemoglobin. Another mechanism of potential preservation of NO activity via the formation of SNO–hemoglobin is discussed in Chapter 10, as it is a mechanism whereby NO activity is created via hemoglobin reduction of nitrite. Simple binding of NO to the heme is unlikely to constitute a mechanism of transport due to the very slow dissociation rate. However, a recent study suggests that NO-bound hemoglobin might be dislodged more quickly because of oxidation of the heme due to concurrent reactions of nitrite with oxyhemoglobin.[48] The potential of hemoglobin to transport NO, discussed in more depth in Chapter 10, is an area of current intense study.

Methemoglobin

In normal physiology, approximately 0.25% of hemes contain ferric iron (methemoglobin). Free heme oxidizes rapidly and aggregates. Incorporation of the heme into hemoglobin prevents aggregation and greatly slows autooxidation, facilitating O_2 transport, as methemoglobin does not bind O_2. Low levels of methemoglobin are also maintained by reducing systems within the red blood cell.[49–51] Although excessive formation of methemoglobin has been viewed strictly in terms of pathology (Chapter 24), some potential positive roles for methemoglobin have been discussed.

Two studies have suggested a role of NO bound to methemoglobin (methemoglobin–NO) in potential transport or delivery of NO activity.[52,53] It is likely that methemoglobin–NO forms transiently in the reaction of nitrite with deoxyhemoglobin, in analogy to some bacterial nitrite reductases.[54] The dissociation rate of NO from methemoglobin is, however, relatively fast ($\sim 1\ s^{-1}$)[55] and methemoglobin also undergoes reductive nitrosylation to form ferrous iron nitrosyl hemoglobin.[56] The overall affinity of ferrous hemoglobin for NO is approximately 1 million times higher than that of ferric hemoglobin for NO.[55] Given that more than 99% of hemoglobin in the red blood cell is ferrous hemoglobin and that NO in the red cell is quickly destroyed via the dioxygenation reaction, it is extremely unlikely that there is any stable methemoglobin–NO in a red cell. The contention that NO is transported in the red cell bound to methemoglobin is untenable due to the relative stability of this species, as demonstrated recently.[57]

Some ligands bind methemoglobin more tightly than ferrous hemoglobin. Given recent evidence for a role of nitrite in physiology, disease, and therapeutics[58] and the potential involvement of hemoglobin (see Chapter 10), the role of nitrite-bound methemoglobin might be worth exploring. At the very least, this could be one way that nitrite is stored in a red blood cell because, even though oxyhemoglobin and deoxyhemoglobin are in great excess to methemoglobin, nitrite will preferentially bind to methemoglobin given the relative affinities.

SICKLE CELL HEMOGLOBIN

HbS differs from normal adult hemoglobin (HbA) by a single amino acid residue (Fig. 6.1). A variety of physical methods including x-ray diffraction, nuclear magnetic resonance, and circular dichroism all indicate that the protein conformation of a HbS tetramer in solution is the same or at least very similar to that to that of HbA.[59] Some evidence exists for subtle changes in the structure of central cavity BPG binding site.[60] Similar structure in solution phase HbS and HbA is supported by similar function. The equilibrium binding of solution phase HbS is the same as HbA.[61] The bimolecular ligand rebinding rates of solution phase HbS are also the same as those of HbA.[62,63] Finally, tertiary and quaternary changes that are induced on CO photolysis of solution phase HbS–CO exhibit the same kinetics as HbA–CO.[64]

The pathological consequences typical of sickle cell disease must derive, in part, due to a difference in function of HbS compared with HbA. Only one notable exception to the notion that, in the solution phase, HbS tetramers have very similar function as HbA exists: the propensity for HbS autooxidation.[65–68] Although increased propensity to form methemoglobin and associated oxidative damage could contribute to several aspects of the disease, this propensity is not likely to be of primary importance in sickle cell disease and HbS polymerization seems paramount.

HbS Polymer

The HbS polymer is made of seven twisted double stands (Fig. 6.5).[59,69–71] It has a diameter of 21 nm and a mean helical pitch length of 270 nm.[59] Each of the double strands is believed to be similar to ones formed by deoxyHbS when it crystallizes (Fig. 6.6). Having the structure of the double strand at 0.2 nm resolution greatly aids in understanding the structure of the 21 nm fiber because information on these larger structures cannot be obtained directly at the atomic level. A variety of techniques including mutational analysis, linear dichroism spectroscopy, resonance Raman spectroscopy, and x-ray diffraction support the idea that the basic building block of the polymer is the double strand with each of these twisted around one another.[59,72]

Contact sites between tetramers within double strands are known in the most detail.[70] Valine at the β6 position makes a lateral contact with a hydrophobic pocket formed by Leu β88, Phe β85, and the heme of tetramer on the other strand within the double strand. Only one of the two Val β6 residues per tetramer is involved in the double strand formation. In addition to these hydrophobic interactions, there are some neighboring hydrophilic ones and bridging water contacts that have been recently observed.[70] Lateral

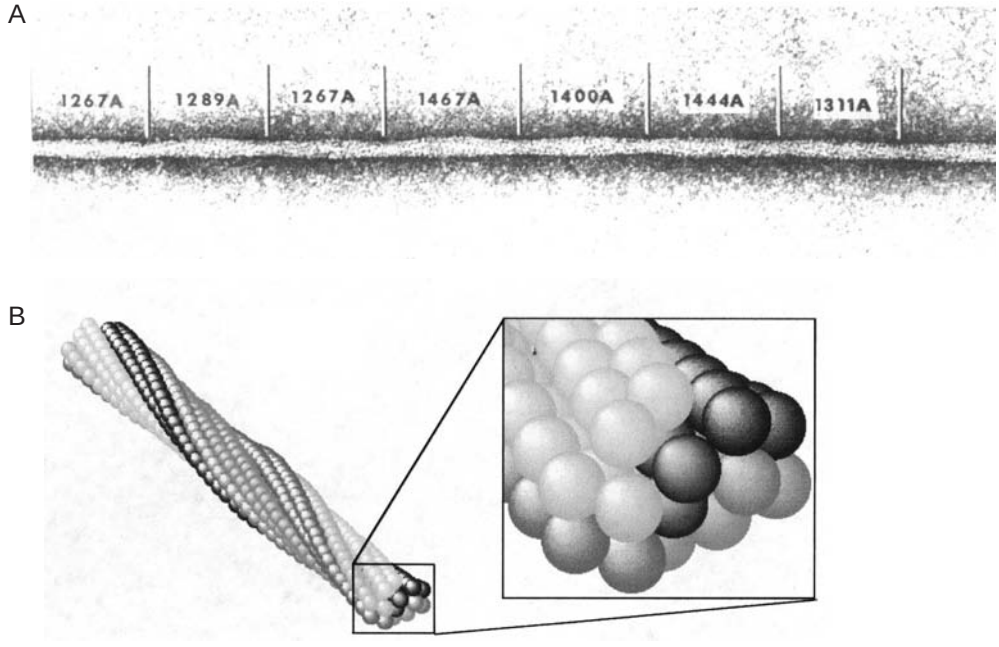

Figure 6.5. (A) Electron micrograph of a fiber. The pitch of the fiber is not fixed, but varies as indicated by the different distances between the minimum diameter points. **(B)** Fiber model with double strands. The model is built according to the description of Watowich et al.[75] This 14-strand model (whose end is shown in the inset) was first proposed by Dykes et al. (1978) and is now universally accepted as the basic fiber description.[17] Note the double strands that are a basic structural element of the fiber and are based on a structure determined by crystallography (see Fig. 6.6). The wrapping of the 14 strands leads to a structure that gently varies from narrow to wide along the fiber.

and axial contacts are mostly between β subunits. Nonpolar interactions involving Pro α114 and Ala α115 of one tetramer form an axial contact with His β116, His β117, and Phe β118 of a second tetramer.

In deoxy Hbs crystals, the double strands are linear. How these double strands twist around each other to make up the 21-nm fiber is incompletely understood. Interdouble strand contacts are believed to mainly involve α subunits,[59] but the second Val β6 has also recently been proposed to play a role.[73] Electron microscopy has provided useful information that has lead to two detailed models that agree on overall architecture.[74,75] but differ in some details, including overall density and water content.[76]

Recent theoretical calculations show that the twist in the HbS polymer plays an important role in its stabilization.[77] Confirmed by experimental observations, the torsional rigidity of HbS fibers is found to be approximately 100-fold less than the bending rigidity.[77,78] The resistance to twisting compared with bending is usually approximately the same for isotropic materials. Linear double strands are the lowest equilibrium form and the relative ease for these to twist is proposed as an explanation for the metastability of the 21-nm fibers.[78]

Higher Order Aggregation of HbS

Further aggregation of the 21-nm fibers can take several forms. Understanding the nature of these aggregates has been aided recently by novel applications of differential interference (DIC) microscopy.[79–81] Analysis of DIC microscopy data collected on two 21-nm fibers zippering up has allowed estimations of the interaction energies between two fibers. Two such fibers can be strongly bonded to each other.[81] As described in detail later, HbS polymerization involves both de novo fiber formation through homogeneous nucleation and fiber formation on the surface of a second one through heterogeneous nucleation.[82,83] It has been proposed that the same intermolecular mutation contact sites that are involved within a fiber are available in 4 of 10 HbS surface tetramers in each layer of the 21-nm fiber.[84] This proposal has recently been confirmed by studying cross-linked hybrid molecules.[85]

HbS polymer formation deforms the red cell, decreases its deformability, and increases its fragility. Aggregation of fibers into fascicles or bundles is of great interest because these are likely to exacerbate these phenomena. The fascicles are composed of twisted 21-nm fibers as shown in Figure 6.7.[86] These fascicles form crystals in vitro, probably through release of twist in the double strands with concomitant loss of polarity.[86] The fascicles always form first. The system of aligned fibers and HbS tetramers is referred to as a gel and this is thought to be what is formed inside of red blood cells. Crystals are not formed even though they are the lowest energy state. The gel is highly viscous and semisolid and, due to alignment of the polymers, it is birefringent. Because the hemes of hemoglobin are largely parallel to each other, and the hemoglobin tetramers are arranged so that the hemes are nearly perpendicular to the

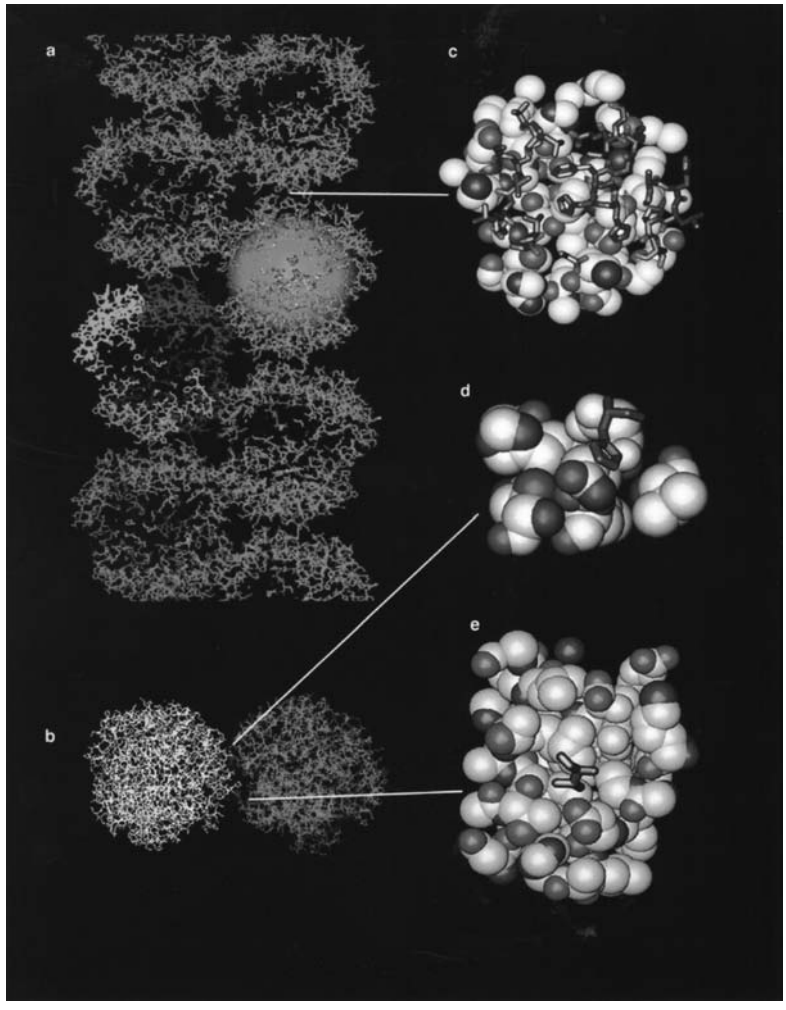

Figure 6.6. (a) The double strand of deoxyHbS, based on the crystal structure of Harrington et al.[70] The tetramers of HbS have been drawn with the central region excluded for clarity; one tetramer illustrates the exclusion region as a solid green sphere in the center of the molecule. Another tetramer is shown with the four subunits colored differently to differentiate them. Red and purple are β-globin chains; blue and orange are α-globin chains. Contacts along the axis of the double strand (vertical here) are denoted as axial, whereas those that connect diagonally are denoted as lateral. The β6 mutation site is in a lateral contact. Note that both the axial and the lateral contacts are dominated by interactions between the beta chains. **(b)** An end view of the double strand. The two molecules, with all amino acids now showing, are colored differently to aid the eye. The β6 contact is shown on the bottom (expanded view in **(E)**), and the salt bridge between αHis50 and βAsp79 is above (expanded view in **(d)**). **(c).** The axial contact region in **A** has been enlarged to allow a better view. Unlike the lateral contact, no single amino acid dominates the geometry. Carbon atoms that are filled to van der Waals radii are yellow, oxygen atoms are red, and nitrogen atoms are blue. **(d)** The salt bridge between Asp β79 and His α50 in the lateral contact area viewed from the α-globin chain. The His is shown as a green licorice stick drawing in the foreground. **(e)** The lateral contact region showing the β6 Val (green stick figure, foreground) in the receptor pocket on its complementary chain. (Note that in the crystal there are two such regions.) β88Leu is just forward and above Val; β85Phe is then just below β88 Leu and behind the Val. (See color plate 6.6.)

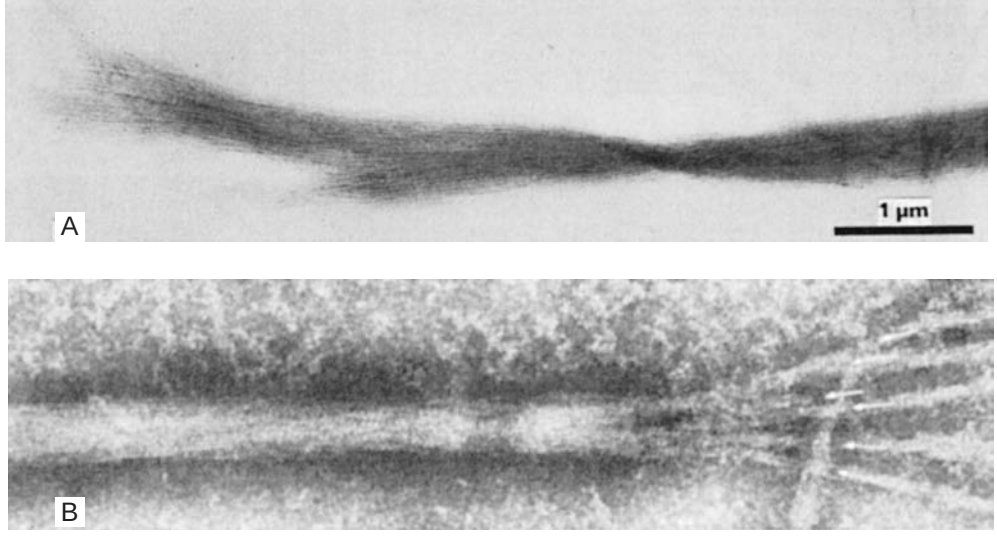

Figure 6.7. Sickle hemoglobin assembly creates structures larger than the fibers shown in Fig. 6.5. **(A)** Fibers can associate in bundles or fascicles.[86] Fascicles ultimately form into crystals. The fascicle shown here has a twist, which also appears in crystals. **(B)** A macrofiber with six fibers extending from the end. Macrofibers are composed of double strands in antiparallel rows, and such structures appear at low pH (below 6.7 in 0.05 mol/L phosphate buffer). (This macrofiber is from the unpublished work of Wellems and Josephs.)

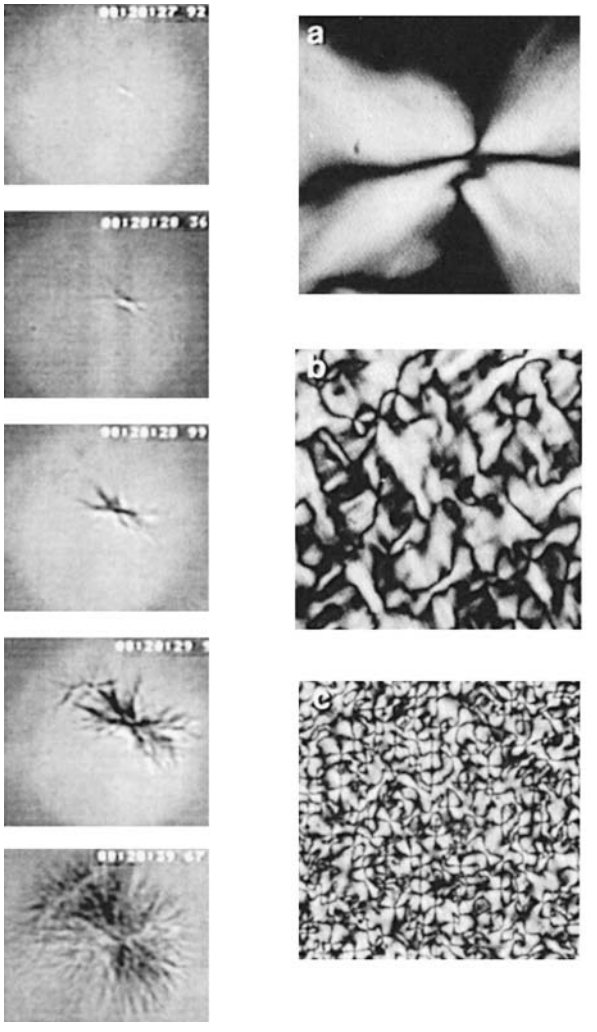

Figure 6.8. Polymer domains. As seen in the DIC images in the left sequence of panels, polymerization produces fibers in attached arrays called domains. In these pictures laser photolysis (as evidenced by the light-colored circles, of approximately 15 μm diameter) creates deoxyHb, which generates fibers.[80] The attached fibers form twofold symmetrical patterns that spread to form larger structures with nearly radial symmetry. These patterns are also visible in birefringence seen as transmission of light when the sample is placed between crossed polarizers and is shown in panels **a** through **c** on the right. Each cross or bow-tie defines a polymer domain. Each domain is formed from a single homogeneous nucleation event. The size of the polymer domains is inversely related to the speed of their formation, and speed of formation in turn is related to concentration. The concentrations were 23.4 g/dL, 25.7 g/dL and 27.4 g/dL, respectively. Samples were gelled by temperature jump from 3°C to 23°C.

fiber, the index of refraction is greater perpendicular to the fiber axis than parallel, resulting in birefringence and linear dichroism (where light is more strongly absorbed when polarized perpendicular to the fiber axis than parallel). The result is that, as observed both in solution and in red cells, gels are visible when viewed through crossed polarizers. Because of the way that clusters of polymers or domains form, they can have a large degree of radial symmetry, which produces a Maltese cross pattern when viewed through crossed polarizers (Fig. 6.8). The formation of radially symmetrical polymer domains has been confirmed using DIC microscopy (Fig. 6.9).

HbS Polymer Rheology

As rigidification of the red blood cell is probably the most important immediate affect of polymerization, it is useful to understand the rheology of the gel. A full understanding of the mechanical properties of the gel begins with understanding those of single fibers. Recently, DIC microscopy was used to determine the intrinsic Young modulus as well the persistence lengths of individual fibers and bundles.[87] The Young modulus (a measure of stiffness) was found to be approximately 0.1 GPa, much less than structural proteins like actin fibers and microtubules but greater than fibers that are meant to bend, like elastin. The persistence length was found to vary from 0.24 to 13 mm, increasing as the radius of bundles increased. These values are much larger than the length of a red blood cell so that one can conclude that the fibers are stiff on the scale of a red blood cell.

Macroscopic measurements of gel rheology are difficult due to the fact that shear applied in the measurement can disturb the mechanical properties of the gel itself. The rheology of the gel will depend on the number of cross links, which will be different for a few long fibers compared with many short ones. Breaking fibers, followed by additional growth, changes rigidity.[88–90] In the absence of shear, the gel behaves like a solid and at low shear it behaves like an elastic solid in which all deformations are reversible.[59] At higher shear, the gel can become irreversibly deformed. The rheological properties of sickle cell gels and their understanding in terms of single-fiber rheology, gel architecture, and quantitative contribution to vasoocclusion events remains an area in need of investigation.

HbS Thermodynamics

It has been widely accepted that the gel is made of two phases: a polymer phase and a solution phase where the

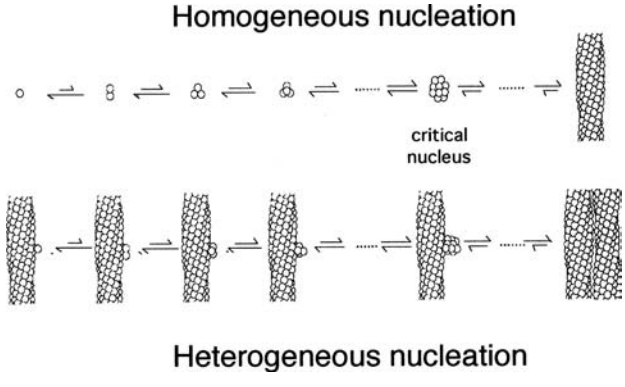

Figure 6.9. The double nucleation mechanism.[83] Polymers may form by homogeneous nucleation or heterogeneous nucleation onto other polymers. In either case, the initial steps are unfavorable, as indicated by the arrows, until a critical nucleus is formed. The critical nucleus is the first aggregrate that is equally likely to add monomers or to lose them. No special structure is assumed for the nuclei.

solution phase contains HbS tetramers (which can be referred to as monomers in the context of single building blocks of the polymer). In equilibrium, no intermediate aggregates are generally observed.[59,91] The thermodynamics of polymerization can be understood within this two-phase model in terms of the solubility of HbS known as c_s or c_{sat}. When the total concentration of HbS, c_0, is below the solubility, there will be no polymers. In equilibrium, when $c_0 > c_s$, the concentration of HbS tetramers in the solution phase is c_s, and the concentration of HbS tetramers in the polymer phase is equal to the total concentration of HbS minus the solubility ($c_0 - c_s$). Although individual tetramers might exchange between the two phases, once equilibrium is reached, the concentration in each phase will not change unless environmental conditions that affect the solubility (discussed later) are altered. The solubility is easily measured by sedimenting the polymers in an ultracentrifuge, for example, at 150,000 g for 2 hours, and taking the concentration of HbS in the supernatant as the solubility.

Recently, evidence from light scattering and DIC microscopy has been presented that suggests the existence of a third phase prior to and during HbS gelation.[92–96] This phase consists of metastable clusters of liquid phase molecules or dense liquid droplets that have been implicated in the initial formation of homogeneous nuclei discussed further later.[94] The clusters form within a few seconds of solution formation and are several hundred nm in diameter.[94,95] These clusters also form in solutions of HbA and oxygenated HbS but do not lead to polymer nucleation as in HbS.[94,95]

A major factor that must be taken into account when evaluating polymerization is crowding.[97] In most biochemical experiments, protein solutions are dilute enough so that they can be considered to be ideal, that is, when interactions between the molecules can be ignored, like in an ideal gas. The concentration of hemoglobin in a red cell is so high, however, ($\sim$ 20 mmol/L in heme which is 32 g/dL or 0.32 g/cm^3) that the solution is nonideal and interactions need to be accounted for. Theoretical treatments of nonideality in sickle cell hemoglobin polymerization have been worked out and agree very well with experiments.[59,97] Generally, one needs to include the activity coefficient, γ, when evaluating the potential for HbS to polymerize so that $c_0 \rightarrow \gamma c_0$ and $c_s \rightarrow \gamma_s c_s$, where γ_s is the activity coefficient at the solubility concentration. These activity coefficients are close to one in dilute solutions. For hemoglobin concentrations found in red blood cells, γ is quite large, equal to 70 for 0.35 g/cm^3.[59] For HbS concentrations found in very dense cells with 0.45 g/cm^3, γ is 900! The relevance of these crowding effects to sickle cell hemoglobin polymerization thermodynamics and kinetics cannot be overstated (for a fuller discussion see references 59, 97, 98). Increased crowding leads to increased polymerization, so that dehydration of red cells can have a dramatic effect where by γc_0 increases much faster than c_0. Any other solutes that take up significant volume also increase γ. Thus, replacing HbS with hemoglobin molecules that do not polymerize can reduce c_s but γ remains unchanged, diminishing the effect of the substitution.

Effectors of Polymerization

Generally, only T-state HbS molecules will polymerize.[99,100] Because only T-state hemoglobin polymerizes, any effectors that stabilize the T-state tend to decrease HbS solubility or increase polymerization.[59] Thus, BPG and IHP increase polymerization. In the physiological pH range, increasing proton concentration increases polymerization, but as the pH is lowered below 6.5, the solubility increases. The solubility is lowest around body temperature. This fact has been used extensively to prepare HbS gel samples where the solutions are prepared at 0°C and then temperature-jumped to 37°C.

The effect of phosphate on solubility is quite interesting and useful. The solubility of HbS decreases dramatically in concentrated phosphate buffers.[101–105] In 1.8 M phosphate the solubility is 0.04 g/dL (4×10^{-4} g/cm^3 or 0.025 mmol/L) at 30°C.[103] The effect of phosphate is likely to be due largely to increasing the activity by volume exclusion but there are also likely to be electrostatic interactions.[106] The ability to study polymerization at such low concentrations is beneficial as the volume of HbS is required for studies under physiological conditions is large and this requirement is very restrictive when studying new modified hemoglobins and those from mouse models. Another method to study polymerization with lower total hemoglobin concentrations is to use dextran to exclude volume and decrease the solubility.[106] With 12 g/dL of dextran, the solubility can be decreased approximately 5-fold.[106] This is a much smaller effect than using 1.8 M phosphate but some differences in polymerization in high phosphate and physiological phosphate have been reported.[106–111] It has recently been noted that a small amount of protein aggregates form in high phosphate that are not due to polymerization so that care is warranted in making sure that these are not misconstrued as HbS polymers.[111] In general, use of high phosphate can be recommended as an excellent initial screening method for effects on polymerization with subsequent experiments with dextran being more likely to provide physiologically relevant data. Finally, all such effects should be confirmed using physiological conditions.

The most important physiologically relevant variable involved in HbS polymerization is the O_2 pressure. As O_2 binding promotes R-state hemoglobin, it decreases polymerization. The effect of CO on polymerization is very similar to that of O_2 – the solubility as a function of solution phase hemoglobin ligand saturation is the same for O_2 as it is for CO.[99] This is consistent both with the idea that only T-state HbS polymerizes and the MWC–Perutz model of hemoglobin cooperativity. To understand fully the effect of O_2 saturation on solubility, the affinity of polymer

phase HbS for O_2 must be determined. Using linear dichroism spectroscopy, because the linear dichroism of solution phase HbS averages out, it was found that polymer phase HbS has approximately one third the O_2 affinity as solution phase T-state hemoglobin.[99] Using data for the solubility of HbS at a variety of temperatures and ligand saturations, Eaton and Hofrichter[59] derived an empirical equation for the solubility as a function of these variables,

$$c_s\,(g/cm^3) = 0.321 - 0.00883\,T + 0.000125\,T^2 + 0.0924\,Y_s + 0.098\,Y_s^3 + 0.235\,Y_s^{15}, \quad (6.4)$$

where T is the temperature in degrees Celsius and Y_s is the fractional hemoglobin O_2 saturation of the solution phase HbS. In the absence of O_2 ($Y_s = 0$), the solubility is calculated to be 0.17 g/cm^3 (10 mmol/L in heme) at 37°C, and 0.32 g/cm^3 (20 mmol/L in heme) at 0°C. When the solution phase O_2 saturation is 0.7, the solubility is 0.26 g/cm^3 (17 mmol/L in heme) at 37°C.

The effects of NO on polymerization have been controversial. NO inhalation therapy is being studied as treatment for sickle cell disease. One of the main ways of benefiting patients is likely to be by reducing the NO scavenging ability of cell-free hemoglobin that results from intravascular hemolysis (Chapter 11)[112] and possibly due to induction of fetal hemoglobin (HbF) production.[113,114] It has also been proposed that NO binding to the heme would reduce HbS polymerization, like O_2 does.[115] In early work, Briehl and Salhany showed that tetranitrosyl hemoglobin (where all four hemes have NO bound) polymerizes in the presence of IHP but does not polymerize when the hemoglobin is stripped of organic phosphates. More recently, it was shown that when HbS polymerization is studied in conditions mimicking those in vivo (with BPG present), the solubilizing or sparing effect of NO binding to the heme is much less than that of O_2.[38] The minimal effects of iron nitrosylation can be understood in terms of the ability of NO compared with that of O_2, to convert T-state hemoglobin to R-state hemoglobin, because R-state hemoglobin has a much higher affinity for O_2 than T-state hemoglobin, and 25% oxygenated hemoglobin will be nearly 25% R-state (Fig. 6.3). On the other hand, NO tends to favor binding to the α subunits and α nitrosyl hemoglobin has properties like T-state hemoglobin. Thus, a given amount of NO will tend to reduce polymerization less than the same amount of O_2.

Another important factor to consider is that iron nitrosylation of hemoglobin through NO inhalation or other means is not likely to ever yield a significant fraction of the total hemoglobin bound to NO (<0.02%[116]). The best effect of any direct antipolymerizing agent would be to make HbS molecules disappear in the red cell. When an antisickling/antipolymerization agent binds to a hemoglobin molecule and converts it from one that enters the polymer phase (like T-state HbS) to one that does not or is less likely to (like R-state HbS), that HbS molecule still contributes to polymerization by its affects on crowding – increasing the activity coefficient. The fact that there is so much hemoglobin in the red blood cell (~10 mmol/L) and that one needs to achieve a conversion of so much HbS to a type that does not polymerize (at least a few percent to have any effect) has been a great challenge for the development of antisickling agents. Because so little iron nitrosylation can be achieved and that it does not have a great sparing effect provide very strong arguments against the idea that NO binding to the heme will benefit patients by reducing polymerization.

Controversy over the effect on polymerization of S-nitrosation of the β-93 cysteine by nitrosonium (one electron oxidation of NO) is also present. Several studies have shown that ligands that bind the β-93 cysteine stabilize the R-state and thereby increase O_2 affinity and increase HbS solubility or reduce polymerization.[117,118] In particular, Bonaventura and colleagues reported that incubation of S-nitrosated cysteine with HbS, which forms SNO–hemoglobin, decreases polymerization.[118] This result has been challenged in studies, using NEM as a model for NO^+. A single modification at the β-93 cysteine, as in SNO-hemoglobin, actually enhanced polymerization and modification at α-104 cysteine stabilized the R-state and decreased polymerization.[119] It was argued that previous studies in which higher O_2 affinities and reduced polymerization were observed actually involved modifications both at the β-93 and the α-104 cysteines.[119] Nevertheless, the work by Bonaventura and colleagues included careful analysis of the sites of modification by using mass spectrometry[118] and the sites of modification were also examined in other studies of polymerization.[117] They did find that an excess of CysNO (10:1) leads to some modification of the α-104 residue in addition to β-93, but their examinations of effects on polymerization did not include these samples. The effect of chemical modification at the β-93 cysteine was also studied using hemoglobin mutations and the increase in O_2 affinity was confirmed[120] Exposure of HbCO crystals to NO gas leads to S-nitrosation, probably via the intermediacy of N_2O_3, and x-ray diffraction has shown that only the β-93 cysteines are nitrosated.[121] Although the recent study stating otherwise calls for further investigation,[119] the preponderance of data at this time suggest that nitrosation occurs primarily at the β-93 cysteine unless the protein is denatured, or has formed a large percentage of dimers, and that SNO–HbS is more soluble than unmodified HbS. That being said, as in the case of HbS with NO bound at the heme, the small amounts of SNO–hemoglobin achievable in vivo (without deleterious effects), combined with the null effect on crowding, makes SNO–hemoglobin formation an unlikely means to effectively reduce polymerization in vivo.

Copolymerization of HbS with Other Hemoglobins

Individuals with sickle cell trait (HbAS) are rarely ill (chapter 22) and very high levels of HbF benefit individuals with sickle cell anemia.[122–126] The sparing effect of HbA and

HbF and the degree to which they reduce polymerization depend on the extent to which they enter the polymer phase or copolymerize with HbS.[59,127,128] Tetramers of HbF, HbA_2 ($\alpha_2\delta_2$), and HbA do not enter the polymer phase. The sparing effects of HbF and HbA_2 are enhanced by their ability to form hybrids with HbS. Hybrids form by the dimerization of hemoglobin wherein the tetramer, particularly when in the R-state, breaks into two αβ dimers. The dissociation constant for dimerization is low when compared with the concentration of hemoglobin under physiological conditions (~1 μmol/L) but because the tetramers are constantly dimerizing and coming back together, an equilibrium mixture consisting of a binomial distribution of hybrids is obtained in less than a minute when different hemoglobins are mixed.[59] Hybrids of HbS with HbF and HbA_2, in which one dimer is from HbS and one is from HbF or HbA_2, do not enter the polymer phase so that replacing one HbS tetramer in a mixture with one HbF or HbA_2 tetramer can result in more than one hemoglobin tetramer being excluded from the polymer phase.[129–131] Hybrids of HbS and HbA enter the polymer phase with approximately half the frequency of HbS tetramers.[132–134] Thus, HbF and HbA_2 are more effective than HbA at decreasing polymerization.

Patients with HbAS have approximately 40% HbS and 60% HbA. In the absence of ligand like O_2 or CO used as a model for O_2, the solubility of 70% HbS and 30% HbF or HbA_2 was found to be equivalent to the solubility of a hemoglobin mixture from patients with HbAS.[128] It was also found that as hemoglobin saturation with CO increased, less HbF or HbA_2 was necessary to achieve the solubility of HbAS blood.[128] These data suggest that if one were to achieve 30% HbF or HbA_2 uniformly among erythrocytes, it would essentially alleviate all the symptoms of sickle cell anemia; however, HbA_2, because of its positive charge, could have deleterious affects (Chapter 7).

Kinetics of Polymerization

The kinetics of polymerization has been studied by taking a solution of HbS and rapidly changing the conditions so that the solubility is decreased. For example, the sample can be temperature jumped from 0°C to 37°C or HbCO can be converted to deoxyhemoglobin by photolysis. When this is done, observations of the kinetics of polymerization present an astounding result, whether by examining light scattering, calorimetry, birefringence or other indicators of polymer content. There is a long period of time when no polymer is detected, followed by relatively rapid growth in detected polymer.[59] This delay time before polymerization is detected has been described by an empirical equation,[59,135,136]

$$\frac{1}{t_d} = \lambda \left(\frac{c_0}{c_s}\right)^n, \tag{6.5}$$

where t_d is the delay time, λ is a proportionality factor, and the exponent, n is found to be approximately as high as 30–40, but is significantly lower (15 or lower) when the hemoglobin concentration is very high. For studies in conditions where n = 35, and t_d is 1 minute, increasing the solubility by just 10% would increase the delay time to 28 minutes. This extreme dependence of the delay time on the supersaturation ratio, c_0/c_s or, more accurately, $\gamma_0 c_0/\gamma_s c_s$, is not only fascinating from a biophysical perspective, but also of great interest for its potential for treatment strategies whereby the delay time is increased by changing the solubility.[59]

Most phenomenon associated with polymerization kinetics can be understood in terms of the double nucleation theory (Fig. 6.9[82,83,137]). This mechanism is based on the idea that the aggregation of HbS monomers (a hemoglobin tetramer) into a polymer is initially thermodynamically unfavorable but becomes more favorable as the aggregate grows. The smallest aggregate for which growth is thermodynamically favorable is called the critical nucleus. After the critical nucleus has formed, the polymer grows, most likely at its ends,[79,80] and heterogeneous nucleation can occur. Heterogeneous nucleation involves the formation of additional polymer on the surface of an existing one. As the polymerization reaction proceeds, more surface area becomes available for heterogeneous nucleation to occur and the polymer phase grows exponentially. Because homogeneous nucleation is a rare event compared with heterogeneous nucleation, a network of polymers or a domain forms from each critical nucleus. The accuracy of the double-nucleation theory has been dramatically confirmed by observations of polymerization using DIC microscopy (Fig. 6.8).[80]

The interpretation of the delay time for polymerization seen in many in vitro experiments has often been misconstrued as the time necessary for formation of the critical nucleus.[138] Both homogeneous and heterogeneous nucleation occur during the time period when no polymers are detected, but the amount of polymer is too small to be observed. Processes that grow exponentially can appear to have taken much longer to begin than they actually do (Fig. 6.10). The beginning of polymerization can be approximately described by the relation[138]

$$\text{Polymerization} \sim \frac{A}{2}\exp(Bt), \tag{6.6}$$

where A and B are constants that depend on solution conditions. Figure 6.10 shows approximate progress curves based on this equation for two different HbS concentrations. Note that each curve appears to have a long period in which there is no polymer, but polymers are actually present throughout the entire time period plotted but the amounts are simply too small to observe. The delay time actually depends mostly on the constant B, which is dominated by the rate of heterogeneous nucleation.[138]

In microscopic situations, including red cells, where only a few if any nucleation events occur, the time before homogeneous nucleation does constitute part of the delay time.[138] The formation of an individual critical nucleus is a random event; an empirical equation like Equation 6.6

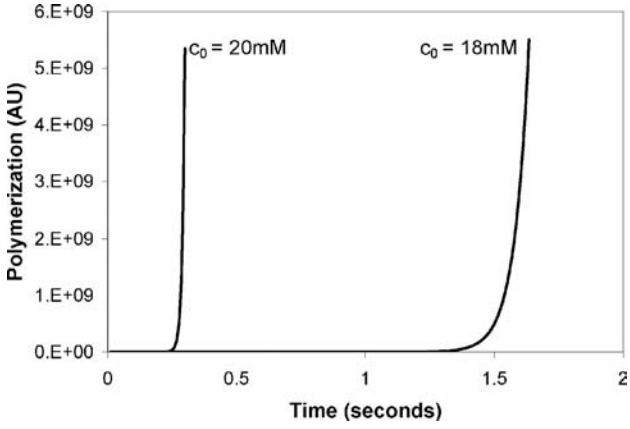

Figure 6.10. Polymerization progress curves. Each curve represents an estimation of the relative amount of polymer (in arbitrary units (AU)) vs. time for two concentrations of hemoglobin, 18 mM and 20 mM in heme. The amount of polymerization is plotted as $\frac{A}{2}$ exp(Bt) (138) where A and B were obtained by visual inspection of previously determined values (Figure 8 of (138)). Note that each curve displays a delay time, but there is polymer present throughout the time courses plotted. In addition, a small change in the total hemoglobin concentration, c_0, results in a large change in the delay time. Note that this figure is shown for pedagogical purposes to demonstrate the nature of exponential processes and it fails in quantitative aspects.

could only predict the average time for the formation of a critical nucleus. In these cases, the observed delay time will depend both on the time to form the critical nucleus and on the time for there to be enough polymer to give a large enough signal, for example, by light scattering. For a single set of conditions, the observed delay time can vary by almost an order of magnitude, from approximately 1–10 seconds, due to the stochastic nature of homogeneous nucleation.[138,139]

The rate of homogeneous nucleation was greatly enhanced by the presence of membranes from sickle erythrocytes, but much less so, if at all, from normal red cell membranes, but the cause of this is still unclear.[140] In a radical new development, it has been proposed that homogeneous nucleation is a two-step process involving dense metastable liquid clusters that serve as precursors for ordered HbS homogeneous nuclei.[94] It was further suggested that the formation of these dense liquid clusters is the rate-limiting step in homogeneous nucleation so that new treatment strategies might be developed around delaying or preventing their formation.[94]

Additional progress has been made in understanding the kinetics of heterogeneous nucleation, particularly with respect to the effects of crowding.[97,141] Improvements in the theory of how crowding affects heterogeneous nucleation have made it possible to predict kinetics in mixtures of nonpolymerizing hemoglobins.[141] The effect of crowding on the rates of polymer growth are great, where addition of 50% crowding agent increases exponential growth by a factor of 10,000–100,000.[97]

Crowding has also recently been found to play an unexpected role in reducing the effects of HbF on polymerization kinetics.[142] Generally, factors that reduce the solubility are expected to reduce the rate of polymerization as well, consistent with the empirical relation relating the delay time to the supersaturation ratio (Equation 6.5). As discussed in the context of NO binding to hemoglobin, however, one needs to account for the fact that a nonpolymerizing hemoglobin tetramer, whether it is R-state HbS or a T-state HbF/HbS hybrid, still contributes to polymerization by increasing the activity coefficient due to crowding. It has recently been determined that HbF/HbS exchange does not affect HbS polymerization kinetics as much as previously thought due to the fact that the HbF contributes to crowding.[142] Given that there is no reason to doubt the experiments on the sparing effect of HbF on solubility, these data suggest that the empirical relation given in Equation 6.4 needs to take activities into account and the exponential factor, n, gets significantly smaller in crowded solutions. The therapeutic goal of 30% HbF, based on its effects on solubility, remains reasonable. Interestingly, when examining the amounts of HbF formed by hydroxyurea treatment (Chapter 30) and the measured intracellular delay times,[143] an unknown effect of hydroxyurea on polymerization kinetics other than increased HbF production is implicated.[142]

HbS Polymer Melting

Less effort has gone into the study of HbS depolymerization, or melting, than has gone into the study of polymerization, but recent progress has been made. The mechanism and kinetics of HbS polymer melting are important in determining how much polymer, if any, persists in tissues after sickle erythrocytes are reoxygenated. As only T-state or deoxygenated HbS polymerizes, the delay time might prevent some or many red cells from causing vasoocclusion if it is long enough for significant polymerization to be delayed until the cells reach large veins and/or the lungs. If melting is slow, however, a significant amount of polymer present in the lungs could enter hypoxic tissues and any benefit from a delay time would be lost or diminished. Most early studies have found that when the solubility of HbS is quickly raised above the concentration of HbS by lowering the temperature or introducing O_2 or CO quickly, polymer melting proceeds without a delay time and is rather slow, on the order of seconds–minutes.[135,144–146]

Recent studies have done much to define the kinetics and mechanism of polymer melting.[80,147–152] Polymer melting can occur at both the sides and the ends of the polymer (Fig. 6.11).[148] On the ends, HbS tetramers constantly come on and off the polymer. During melting, the rate of tetramer dissociation is faster than the rate of association, so the fibers get shorter. The rate of dissociation or association depends on the quaternary state and hence ligation state. If tetramers on the fiber ends bind CO or O_2 (dark spheres in Fig. 6.11) they are likely to dissociate faster. Several studies have provided evidence for direct binding of CO to the polymers during melting.[148,150–152] R-state tetramers do not

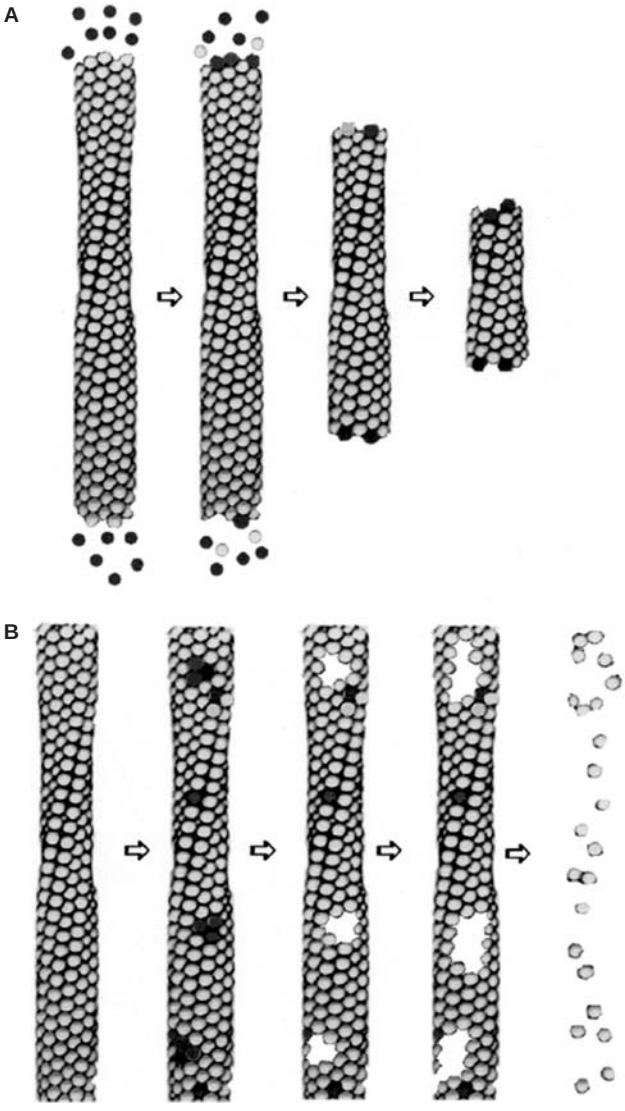

Figure 6.11. Mechanisms of HbS polymer melting. **(a)** Ends melting. Polymers get shorter at the ends through unligated (T-state) tetramers (open spheres) coming off the polymer and becoming ligated (binding CO or O_2, filled spheres) or by enhanced dissociation of ligated HbS tetramers on the fiber. **(b)** Side melting. Ligation of HbS tetramers on the sides of polymers can nucleate holes, which leads to rapid depolymerization. (From Figure 10 of ref. 148.)

effectively enter the polymer phase so that polymer melting at the ends can occur either through CO binding directly to tetramers at the fiber ends and expediting their dissociation or through binding to solution phase HbS tetramers and preventing their association.[148,150] When ligand pressure of CO, or presumably O_2, is higher, rapid melting can also occur at the sides of fibers (Fig. 6.11).[148] Here, it is believed that ligand binding to HbS tetramers at the surface of fibers can nucleate a hole in the fiber that leads to breaking it up and increases the rate of melting through increasing the number of polymer ends.[147,148] The rate of polymer melting has recently been addressed by examination of changes in red cell deformability upon oxygenation.[149] This rate is likely to be limited by the rate of HbS polymer melting because polymer content is related to poor deformability. It was concluded that the rate is sometimes likely to be too small for all existing polymers to melt upon reoxygenation in the lungs so that there will be some persistence of polymer during circulation.[149]

HbS Polymerization in Red Blood Cells

Polymerization of HbS in sickle erythrocytes is likely to have the same structure, thermodynamics, and kinetics as in solution, and except for modulation of ion content and hydration, which can have a large effect on polymerization as it greatly affects c_0, the red blood cell can be viewed as a "flexible microcuvette."[59] Using CO photolysis, it was determined that polymerization progresses with characteristic delay times and, based on theoretical analysis, it was proposed that most cells never contain polymer, because the delay time is long enough to allow cells to complete a cycle in the circulation, returning to the lungs before polymerization begins.[144] The relative importance of the delay time has been questioned based on careful studies using nuclear magnetic resonance to determine intracellular polymerization at various O_2 tensions.[127,153–156] In these studies, polymers were detected even when the hemoglobin O_2 saturation was above 90%.[154] Crowding of hemoglobin in the red blood cell is responsible for polymerization at these high O_2 tensions. In this model, the amount of polymer present in vivo for most cells is determined by the intracellular hemoglobin content and the O_2 tension along the circulation and is not rate limited by polymerization kinetics.[127,155]

The relative importance to pathology of the polymerization kinetics compared with polymer content defined by equilibrium conditions has been the subject of some controversy. It is currently not clear how much polymer needs to persist through the pulmonary circulation for a measurable delay time to be observed. In addition, although early work reported well-defined transit times through various parts of the circulation, more recent work has found that such times vary a great deal; 0.03–14.5 seconds was measured for the transit time in the pulmonary capillaries.[157] Importantly, it is also not known how much polymer is necessary to cause red cell damage or to contribute to microvascular occlusion. As polymerization is the primary cause of sickle cell disease, it must eventually lead to increased fragility and hemolysis, increased vascular adherence, disturbed hemostasis and all the other pathology associated with sickle cell disease. The degree of polymerization necessary to lead to these pathological consequences is not known. This author believes that polymerization kinetics (involving a delay time) plays a role in determining polymer content in some cells, whereas in others the amount of polymer for a given cell is defined by the oxygen tension at each point in the circulation. In any case, reducing polymerization by increasing HbS solubility is sure to effectively treat patients.

Hemoglobins of the Embryo, Fetus, and Adult

Martin H. Steinberg and Ronald L. Nagel

INTRODUCTION

During development, humans express six different hemoglobin types, the products of eight different globin genes (Fig. 3.1, Chapter 3). Hb Gower I ($\zeta_2\varepsilon_2$), Gower II ($\alpha_2\varepsilon_2$), and Portland ($\zeta_2\gamma_2$) are found in the embryo, fetal hemoglobin (HbF; $\alpha_2\gamma_2$) is present mainly in the fetus but also in the embryo and adult, whereas HbA ($\alpha_2\beta_2$) and HbA_2 ($\alpha_2\delta_2$) are seen primarily in adults. All hemoglobins undergo posttranslational modifications forming minor hemoglobins. Globin genes are discussed in Chapter 3, hemoglobin switching in Chapter 5, and the structure and function of hemoglobin in Chapter 6 and. In this chapter we discuss the clinical and physiological attributes of HbF, HbA_2, embryonic hemoglobins, and their posttranslational modifications.

HEMOGLOBIN F

The observation that hemoglobin in newborns' erythrocytes was resistant to alkaline denaturation provided the first suggestion that a hemoglobin existed that differed from normal HbA.[1]

Structure of the γ-Globin Genes and γ-Globin

γ-Globin chains differ from β-globin chains in either 39 or 40 amino acid residues, depending on whether a glycine or alanine residue is present at γ136.[2] γ-Globin is the product of two nearly identical γ-globin genes. A glycine codon is present in the 5′ or $^{G}\gamma$ gene (*HBG2*) and an alanine codon characterizes the 3′, or $^{A}\gamma$ gene (*HBG1*). Also, a common polymorphism is found in the $^{A}\gamma$ gene, where threonine ($^{A}\gamma^{T}$) replaces isoleucine ($^{A}\gamma^{I}$) at codon γ75 (HbF-Sardinia). This striking similarity in protein sequence and structure of the γ-globin genes reflect their concerted evolution from gene duplication and gene conversion.[3] Gene conversion of the γ-globin genes might be an ongoing process during evolution as suggested by the analysis of chromosomes in which the Bantu haplotype is linked to the sickle cell (β^{S}) gene; a subgroup of these chromosomes has undergone a recent gene conversion, eliminating several sequence differences between the two γ-globin genes.[4] Selection could maintain the sequence of γ-globin chains and the structure of HbF. Because HbF is present throughout fetal life and functionally critical sequence abnormalities could affect fetal development, maintaining the normal gene sequence could be vitally important.

Protein Conformation: Of the 39–amino acid residue differences between γ- and β-globin chains, 22 are on the molecule's surface. Four critical differences are present in the $\alpha_1\beta_1$ area of contact (the packing contact) that dissociates only under extreme conditions. Two differences, γ112 thr (β112 cys) and γ130 trp (β130 tyr), in the $\alpha_1\gamma_1$ interface could contribute to HbF's resistance to alkaline and acid compared with HbA and provide the structural basis for measuring HbF by alkali denaturation. Sequence differences are not present in the $\alpha_1\beta_2$ area of contact (the sliding contact) that is the center of ligand-dependent conformational changes (Chapter 6). At position 116 in the $\alpha_1\beta_1$ interface, the γ-globin chain contains isoleucine and the β-globin chain contains histidine. Using recombinant β chains with γ chain substitutions, it was suggested that amino acid hydrophobicity at the G-18 position in non-α chains plays a key role in homotetramer, dimer, and monomer formation, which in turn plays a critical role in assembly of HbA and HbF tetramers. It was also suggested that stable dimer formation of γ-globin chains must not occur in vivo because this would inhibit association with α chains to form HbF.[5] The increased tetramer strength of HbF compared with HbA is only partially caused by the amino acid differences at the αβ interfaces and tetramer strengthening is also contributed to by the 18–amino acid N-terminal A helix of the γ-globin chain. Greater tetramer strength permits HbF to obtain O_2 from maternal HbA and might account for the resistance of fetal red cells to the malaria parasite, as it less readily dissociates into digestible dimers. Three amino acid differences at positions 1, 5, and 7 of the γ-globin chain account for practically all of the tetramer strength of HbF.[6]

Crystallographic studies of HbF at 2.5-Å resolution showed almost complete isomorphism between HbA and HbF with the sole difference in the N-terminal portion of the γ-globin chain.[7] This change increases the distance from 2,3 bisphosphoglycerate (2,3 BPG) inserted in the central cavity of the hemoglobin molecule to the γ2 histidine, possibly a secondary contributor to the reduction in 2,3 BPG effect exhibited by HbF.

Functional Properties

Erythrocytes of newborns have higher O_2 affinity than adult red cells, but in hemolysates, the O_2 affinity of HbF and HbA are identical. This suggests that HbF and HbA have

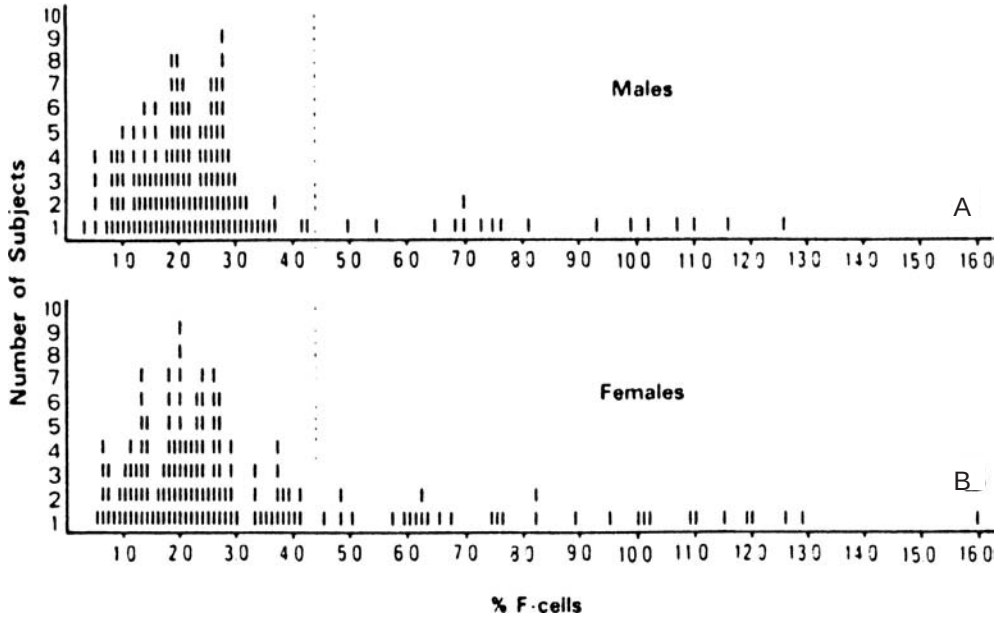

Figure 7.1. Distribution of F cells in 150 normal men and 150 normal women. The vertical broken lines are at 4.4% F cells.[12]

the same intrinsic O_2-binding properties but interact differentially with heterotopic modifiers of hemoglobin function. 2,3 BPG has decreased binding to HbF due to the replacement of β143 histidine, a phosphate-binding site in the central cavity, with a serine residue at γ143. Displacement of the N-terminal portion of the γ-globin chain alters phosphate binding with γ2 his; acetylation at the N terminus of the γ-globin chain also inhibits 2,3 BPG binding.

HbF-containing erythrocytes have an impaired Cl^- effect. Chloride binds at the 2,3 BPG binding site in the central cavity. At low NaCl concentrations, HbF has a lower affinity for O_2 than HbA. At higher Cl^- concentrations this difference disappears. This effect might be due to the diminution of positive charges in the central cavity with a reduction in the binding affinity for anions and destabilization of the T-state. Increased stability of the T-state induced by the absence of anion neutralizing positive charges would favor low ligand affinity.

CO_2 binding by HbF is drastically decreased. Fewer carbamates are formed at the N terminus at a wide range of pCO_2. The γ chain N terminus has a higher pKa than the β chain, making 90% of the site protonated at physiological conditions and unable to bind CO_2.

The alkaline Bohr effect (relation between high pH and ligand affinity) is increased 20% in HbF-containing red cells. This might be a Cl^- effect because at low anion concentration HbF and HbA have an identical Bohr effect, whereas the Bohr effect of HbF increases with the Cl^- concentration. A plausible explanation is that the binding of Cl^- at low pH at the β143 histidine stabilizes the R-state. The absence of this Cl^- site would reduce the low-pH Bohr effect because this condition favors the T-state. Consequently, the alkaline Bohr effect is favored in HbF.

When HbS was made "HbF-like" by substituting the four differences between HbA and HbF in the $\alpha_1\beta_1$ interface, the hybrid molecule had decreased binding with 2,3 BPG, much like HbF, although the central cavity was entirely HbA and dissociation into dimers was intermediate between HbA and HbF.[8] These results suggested that 2,3 BPG binding and dimerization are not simply dependent on the so-called critical residues, but that other long-range interactions could be important.

Physiology of HbF-containing Erythrocytes

O_2 loading in the fetal circulation is done via a liquid–liquid interface compared with the gas–liquid interface found postnatally. As fetal tissue has a high metabolic rate, O_2 loading rather than O_2 delivery might be limiting because it is likely that a blood/tissue pO_2 gradient exists. The high O_2 affinity of fetal erythrocytes promotes uptake of O_2 in the placenta. Despite the increased P_{50} and reduced 2,3 BPG response of HbF, O_2 delivery is compensated for by an increased Bohr effect. The pH of HbF increases when red cells pass through the intravillous spaces of the placenta because HbF releases CO_2. Fifty percent of O_2 delivery to tissues is accounted for by the increased Bohr effect. An increased Bohr effect also could explain the paradox of mothers with high-O_2 affinity hemoglobin variants who have neither pregnancy-related complications nor increased fetal morbidity (Chapter 24).[9] Heat release could also be an important function of HbF in the fetus.[10,11]

Modulation of HbF Levels

In healthy Japanese adults, the range of HbF and F cells was affected by sex and had a dominant X-linked pattern of inheritance (Fig. 7.1).[12] In sickle cell anemia, males had HbF of 6.1% ± 4.3% compared with 8.6% ± 7.5% in females,

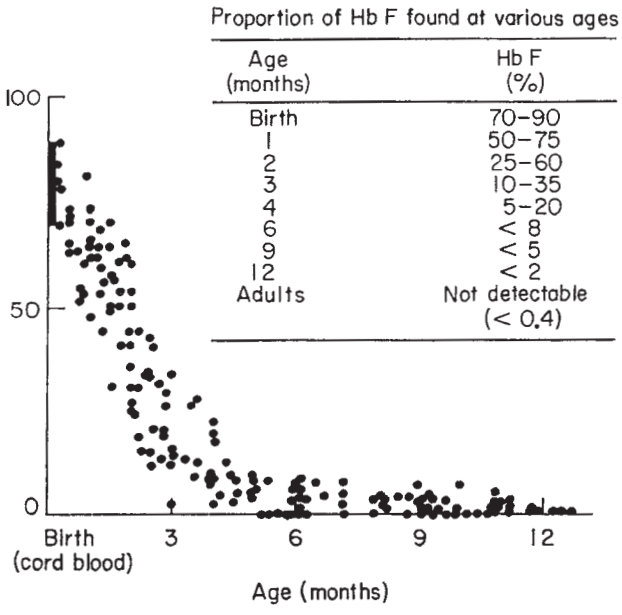

Figure 7.2. Fall in HbF concentration in normal infants from birth to age 1 year.

a result confirmed in other studies.[13–15] These observations were among the first to suggest that the modulation of HbF levels could occur from *trans*-acting factors and *cis*-acting elements. Many factors modulate the final concentration of HbF and these are discussed in detail in Chapters 5 and 27.[16,17]

Hemoglobin Switching

In normal newborns, it takes approximately 1 year for HbF to fall from 55% to 85% at birth to less than 1%, the HbF concentration that is present in most adults (Fig. 7.2). In early life a switch occurs in the expression of the $^{G}\gamma$- and $^{A}\gamma$-globin genes (Fig. 7.3). Most individuals have a decline in $^{G}\gamma$-globin chains in the first 3 months of life with a reciprocal rise in $^{A}\gamma$-globin chains, but a minority of infants maintains the neonatal pattern of γ-globin chain expression, especially when the *HBG2* −158 C-T SNP is present (Fig. 7.3).

Fetal cells decrease in number rapidly after birth as shown by the decrease in mean cell volume (MCV), an event followed by the progressive decrease in the number of F cells. Sickle cell anemia patients have a much-delayed switch from γ-globin gene expression to β^{S}-globin gene expression and from HbF to HbS. A stable HbF level in these patients might not be reached for 20 years.[18] A delay in the decline of γ-globin gene expression could be due to anemia because thalassemia trait individuals with very slight anemia also exhibit a delay in HbF switching, albeit much more moderate, than sickle cell anemia patients (Fig. 7.4).

Cellular Heterogeneity of HbF

Fetal Cells: HbF makes up close to 100% of the hemoglobin in fetal erythrocytes. During the first 10 days of life, hemoglobin synthesis decreases 10-fold from antenatal levels, and the bulk of this fall occurs in the first 2–3 postnatal days. Characteristics of neonatal erythrocytes are shown in Table 7.1.

F Cells: HbF is distributed unevenly among nonfetal or "adult" erythrocytes. The elution of HbF at low pH, leaving HbA that can be stained with acid hematoxylin, forms the basis for the acid–elution or "Betke" test for HbF. Boyer and coworkers[19,20] delineated the origins, genetics, and physiology of F cells.

By definition F cells contain measurable HbF, implying that the sensitivity of the method used for detecting HbF, of which there are many, will determine the number of F cells.[21] Relatively insensitive, the acid–elution method can detect a minimum of 5–6 pg of HbF per cell; radial immunoprecipitation methods can detect 3 pg of HbF per cell; flow cytometry, the most commonly used means of enumerating F cells, can detect cells with a HbF content of 6 pg.

Depending on the methodology used, Caucasian adult blood contained 1.7% ± 2.2% to 2.6% ± 1.6% F cells and normal African Americans had 2.8% ± 1.6% F cells. Establishing precisely the average concentration of HbF per F cell has been difficult because cells with HbF levels below the limits of detection will not be counted. Mature F cells contained an average of 4.4 ± 0.3 pg HbF. In African Americans with sickle cell anemia, the range of F cells was between 2% and 80% and the average HbF per F cell was 6.4 ± 1.6 pg. Patients with β thalassemia also have increased numbers of F cells.[22] In one study of sickle cell trait, in which the mean HbF level was 1.4% as determined by high-performance liquid chromatography (HPLC), F cells were 14.1% ± 7.5% (normal 4.5%).[23]

Rare, apparently normal individuals have more than 8% F cells in their blood. In most of these cases, one parent of the proband had similar numbers of F cells. Many of these high–F cell individuals have a form of nongene deletion hereditary persistence of fetal hemoglobin ([HPFH]; discussed later). F cell numbers are affected by age, although

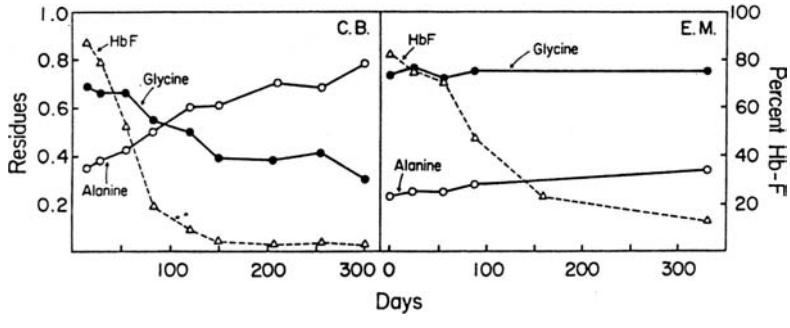

Figure 7.3 $^{G}\gamma$-globin chains are approximately 70% at birth and fall to approximately 40% at age 150 days when $^{A}\gamma$-globin chains become predominant (left panel). A decline in $^{G}\gamma$-globin gene expression might not always happen. This is associated with the presence of a −158 C → T mutation 5′ to the $^{G}\gamma$-globin gene, and its linked to the Senegal haplotype and the Arab–India haplotype.

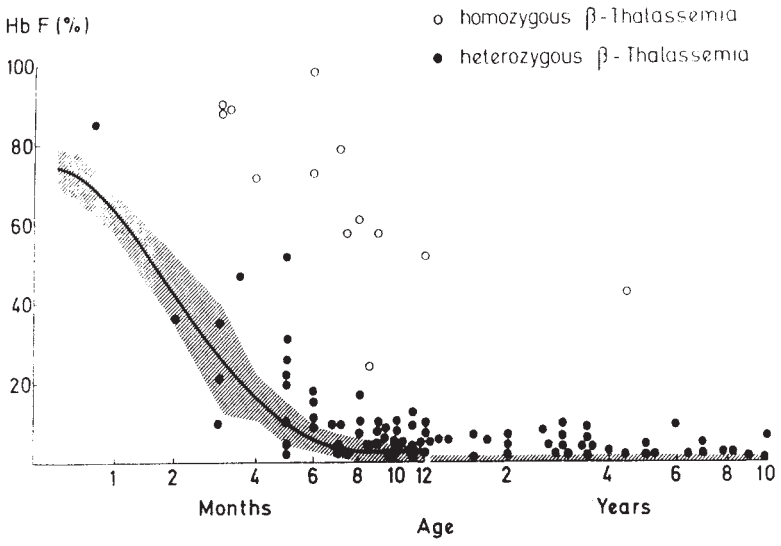

Figure 7.4. Decline in HbF concentration in normal individuals and patients with homozygous (○) and heterozygous (●) β thalassemia. Shaded area is the range for normal controls.

this has been incompletely studied, and acutely increased erythropoiesis can cause transient increases in HbF and F cells.

For any level of HbF in the hemolysate, the distribution and concentration of HbF in F cells can differ. Patients with sickle cell anemia have individually characteristic distributions of HbF per F cell.[24] This variance has pathophysiological implications, as concentrations of HbF in some cells sufficient to retard HbS polymerization could affect the disease differently than concentrations of HbF insufficient to retard HbS polymerization in many cells. When autologous sickle erythrocytes were labeled with biotin and reinfused, F cells survived longer in all individuals and non-F cell survival correlated inversely with the percentage of F cells. As labeled cells aged in the circulation, the HbF content of surviving cells increased, suggesting that high HbF content was related to cell survival.[25]

Most evidence suggests that F cells are not clonal but acquire their particular characteristics stochastically during development. In clonal disorders, including polycythemia vera, paroxysmal nocturnal hemoglobinuria, and Philadelphia chromosome–positive chronic granulocytic leukemia, F cells are present in the same proportion as in normal individuals. In adult red cells, no relationship exists between F cells and i-antigen, a maker for fetal like cells.

F Reticulocytes: Using a double-labeling technique that detects both HbF and reticulocytes (F reticulocytes), F reticulocytes in sickle cell anemia numbered 10.6% ± 7.0%. These observations raised the question of preferential survival of F cells in sickle cell anemia. Preferential survival was suggested by finding more F cells than F reticulocytes in most, but not all patients. Increased F cell survival could be the result of inhibition of HbS polymerization by HbF and differential susceptibility of F cells and non-F cells to phagocytosis and endothelial cell adherence.

Table 7.1. Characteristics of neonatal erythrocytes

Increased MCV (approximately 120–130 fl at birth)
Erythrocyte lifespan of 60–70 d (Premature babies have fetal red cell lifespans of 35–55 d
Decreased osmotic fragility
Increased numbers of abnormally shaped cells
Increased numbers of "pocked" cells
Increased membrane total lipid, phospholipid, and cholesterol (perhaps a result of macrocytosis)
Excess membrane sphingomyelin and decreased lecithin
Enhanced tendency toward lipid peroxidation
Antigenic differences from adult cells in the Lewis and ABO systems – A and B antigens are weakly expressed – reduced or absent I antigen and presence of i antigen
Increased glucose consumption and activity of many glycolytic enzymes
Tendency toward methemoglobin formation, probably reflecting decreased activity of methemoglobin reductase and increased glutathione stability
Decreased deformability
Low S-nitrosohemoglobin levels

Laboratory Detection of HbF

Different methods of measuring HbF can give different results on the same blood sample, and the most precise method for determining HbF varies according to the blood HbF concentration. Currently, the most prevalent means of measuring HbF is by HPLC. In normal adults, HbF concentrations measured by cation-exchange HPLC were between 0.1% and 0.4%.[26] Sex, polymorphisms in the β-globin gene like cluster, γ-globin gene duplications, and γ-globin gene promoter mutation can all increase HbF in otherwise normal individuals.

Medical Conditions Associated with Increased HbF

HPFH is a condition in which increased HbF levels persist into adult life. Several large deletions affecting the β- and δ-globin genes lead to pancellular HPFH syndromes with HbF levels of 20%–30% and to the closely related δβ thalassemias (Chapter 16). Point mutations within the promoters of the γ-globin genes lead to a heterocellular or a pancellular form of HPFH with increased HbF and F cell levels. In these conditions, the HbF concentration varies from slightly elevated to nearly 40% in heterozygotes (Table 7.2). These mutations could increase the promoter activity by effecting transcription factor binding.[27]

Pregnancy is associated with a modest increase in HbF in the second trimester. Hydatidiform moles are associated with up to 6% HbF. Although hormones secreted during

Table 7.2. Point mutations in the promoters of the γ-globin genes associated with an HPFH phenotype

Gene	Mutation	Percent $^{A}\gamma$ Globin	Percent HbF	Notes
HBG1 ($^{A}\gamma$)	C-202T	89–96	1.6–3.9	Seen with HbS
	T-198C	90–100	2–13	20% in homozygote
	C-201T		10.2	
	C-196T	80	12–16	also positive for $^{G}\gamma$-158 C-T
	C-195G	85	4–7	
	T-175G	60–80	38	in HbAS, 41% HbF, 17% HbS; also 40% HbF with HbC trait
	C-158T	51	3–5	
	G-117A	∼90	7–19	25% in homozygote
	C-114T	∼90	∼5	
HBG2 ($^{G}\gamma$)	C-202G	100	14–21	with HbAS 18%–24% HbF, 25%–35% HbA
	T-175C	100	22	with HbAS 30% HbF, 28% HbA
	C-196T		8.6	also positive for $^{G}\gamma$-158 C-T
	C-114A	90	0.6–3.5	4%–11% HbF with associated with β thalassemia
	C-114G	90	8.6	
	C-114T	∼90	11–14	also homozygous for $^{G}\gamma$-158 C-T
	A-110C	97	0.8	

Some of these mutations are also associated with β thalassemia. References to these polymorphisms can be found at http://globin.cse.psu.edu/.

pregnancy have been implicated in these effects, the mechanism of HbF elevation is not clear.

Premature infants and infants of diabetic mothers have a delayed γ→β switch and higher HbF levels than other neonates. This switch is accelerated in Down syndrome and other chromosomal translocations. Controversy exists regarding the relationship of HbF to sudden infant death syndrome (SIDS). In most studies carefully controlled for the postconceptual or gestational age, the prime determinant of neonatal HbF level, infants dying with SIDS aged between 8 and 16 weeks, had significantly higher levels of HbF than controls.[28] HbF, measured by different techniques, was between 28% and 65% in SIDS infants, whereas controls had HbF concentrations between 12% and 41%. HbF synthesis was increased in infants considered at risk for SIDS.[29] Perhaps the high O_2 affinity of HbF contributes to chronic hypoxia, a common finding in these patients. A recent study of SIDS and control cases found that they were not different with respect to mean age, sex, gestational age, method of delivery, birth weight, or mean autopsy interval and that the percentage of HbF levels in SIDS cases and control were not significantly different.[30]

HbF elevations can be seen in different cancers. HbF was detected immunohistologically in metastatic germ cell tumors such as embryonal carcinomas and teratomas, lymphoma, colorectal carcinoma, myelodysplastic syndrome, and myeloma.[31,32] Juvenile chronic myeloid leukemia and Fanconi anemia are often accompanied by HbF levels of up to 30% and levels are highest in patients with the C-T SNP at −158 5′ to the $^{G}\gamma$-globin gene. Kala-Azar and paroxysmal nocturnal hemoglobinuria, particularly when hemolysis is present, can have HbF levels of 5%–10%. The highest levels are found in DiGuglielmo disease and juvenile myeloid leukemia in which levels more than 50% have been reported.

Mutations of the γ-Globin Genes (*HBG2, HBG1*)

Nearly 100 mutations have been described in the $^{G}\gamma$-globin gene, the $^{A}\gamma$-globin gene, and the $^{A}\gamma^{T}$-globin gene. γ-Globin chain variants will alter a single major hemoglobin during fetal and neonatal life but, after the first year of life, will alter only the trace of HbF usually present and are therefore rarely detected. Mutations can be present in γ-globin loci of the usual $^{G}\gamma$-$^{A}\gamma$ arrangement, on chromosomes with $^{G}\gamma$-$^{G}\gamma$ loci and in *cis* or *trans* to the $^{A}\gamma^{T}$-globin gene. Depending on the chromosomal arrangement of the γ-globin genes, and many other factors, the levels of $^{G}\gamma$-globin gene variants can range from 5% to 30% of total hemoglobin present in neonates, with most accounting for approximately 25% of all hemoglobin. Levels of most $^{A}\gamma$-globin gene variants are approximately half this amount. This difference is due to the greater expression of the $^{G}\gamma$-globin gene in fetal erythroid cells. Very few γ-globin gene variants have been subjected to functional studies so that the numbers of mutants reported to have altered properties might be underestimated. A listing of variant γ-globin genes and γ thalassemia and the properties of the variants can be found at (http://globin.cse.psu.edu). These variants can be unstable, have high or low O_2 affinity and can be subject to oxidation and cause methemoglobinemia and neonatal "cyanosis" that disappears with maturation.

HbF-Sardinia (*HBG1* (E19) ile75thr) present in the $^{A}\gamma^{T}$ gene is a frequent polymorphism without functional or clinical abnormalities. Although present at high frequency in many populations, it has a low frequency among Africans and individuals of African descent, except among carriers of the Cameroon haplotype. A reason for the high frequency of this variant has not been established, but its low frequency in most of Africa and high frequency elsewhere suggest that it occurred after man left Africa, or that its advantage, if any, is related to selective pressure not existent in Africa. Mutants of HbF-Sardinia have been described.

γ *Thalassemia:* γ Thalassemia that results from the types of point mutations that typify β thalassemia, has not yet been described. Most instances of γ thalassemia are due to gene deletion and are better classified as γδβ thalassemias or εγδβ thalassemia. Their phenotypes and pathophysiology are discussed in Chapters 16 and 17. A γ^{+} thalassemia phenotype was proposed to result from an IVS II-115 A-G substitution in both the $^{A}\gamma$- and $^{G}\gamma$-globin genes and the deletion of an A at position -6 relative to the $^{G}\gamma$-globin gene polyadenylation site. Yet, the IVS II substitutions appear to have gene frequencies of 0.73 for the $^{A}\gamma$-globin gene and 0.86 for the $^{G}\gamma$-globin gene suggesting that they are common polymorphisms. One γ thalassemia resulted from an unequal crossover between the $^{G}\gamma$ and $^{A}\gamma$-globin genes, deleting one γ-globin gene from the affected chromosome, and leaving a hybrid γ-globin gene, akin to the Hb Lepore-type genes. Found in heterozygotes and in two homozygotes, newborns homozygous for this deletion had only 50% HbF, all of the $^{A}\gamma$ type.

HEMOGLOBIN A_2

HbA_2 ($\alpha_2\delta_2$) is a hemoglobin without an obvious physiological function. In normal hemolysates, HbA_2 represents between 2% and 3% of all hemoglobin.

Evolution of the δ-Globin Gene (*HBD*)

HbA_2 is present in humans, apes, and New World monkeys, but not Old World monkeys, a finding at variance with the evolutionary data that suggested that humans and Old World monkeys diverged after the divergence of New World monkeys. This inconsistency was resolved with the observation that δ-globin genes are present in Old World monkeys but have been inactivated by mutation.

Comparisons of δ-globin genes among mammals have shown that this locus has not evolved independently but has done so in concert with the β-globin gene and is the product of gene conversion. Three variants of the δ-globin gene could have arisen by gene conversion. HbA_2 Flatbush (*HBD* ala22glu), HbA_2 Coburg (*HBD* arg116his) and Hb Parchman (*HBD* ala22glu, ser50thr).[33,34]

It has been suggested that the δ-globin gene is a pseudogene in evolution, destined for the biological scrap heap of history. This presupposes that the sole functional role of all hemoglobins is O_2 transport but this is clearly not true. Increased binding of HbA_2 to the membrane might mask another functional role for this hemoglobin. The presence of a variant HbA_2 at polymorphic frequencies in the Dogon region of Mali at least hints at possible selection of this hemoglobin.

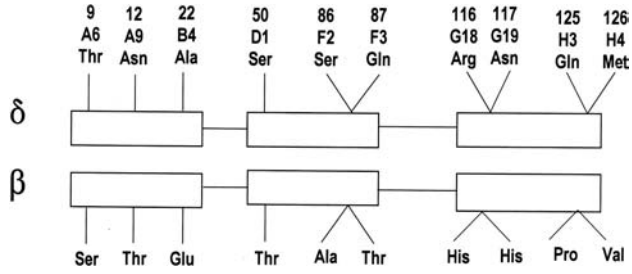

Figure 7.5. Amino acid differences in the δ- and β-globin genes.

The δ-Globin Gene and δ Globin

Linked to the β-globin gene on chromosome 11, the structure of the δ-globin gene is identical to all other expressed globin genes. δ-Globin chains of HbA_2 differ from β-globin chains of HbA by 10 amino acid residues, and 31 nucleotide differences are found between the coding regions of the β- and δ-globin genes (Fig. 7.5, Table 7.3). A high level of homology persists until 70 bp 5′ to the mRNA capping site. Greater sequence differences in the 5′ noncoding portion are found beyond this point, accounting, in part for the diminished transcription of the δ-compared with the β-globin gene.

The crystal structure of HbA_2 at 2.20 A in the R2-state has been solved and used to provide the probable explanations of its thermal stability. The structure of the T-state has also been modeled allowing the structural basis of the antisickling property of HbA_2 to be studied.[35]

Table 7.3. Nucleotide differences in the coding regions of the δ- and β-globin genes

	2 His	10 Ala	11 Val	30 Arg	31 Leu	66 Lys	68 Leu
β	CAC	GCC	GTT	AGG	CTG	AAA	CTC
δ	CAT	GCT	GTC	AGA	TTA	AAG	CTA
	84 Thr	106 Leu	108 Asn	111 Val	120 Lys	132 Lys	142 Ala
β	ACC	CTG	AAC	GTC	AAA	AAA	GCC
δ	ACT	TTG	AAT	GTG	AAG	AAG	GCT
	145 Tyr	146 His					
β	TAT	CAC					
δ	TAC	CAT					

Codon usage in the β- and the δ-globin genes. Codons of the amino acid that differ between the β- and the δ-globin chains are not included. Two of the codons that specify amino acid differences between the β- and the δ-globin chain contain two base pair differences and one codon contains three differences. Codon 31 Leu has a two base change.

δ-Globin Chain Synthesis: Quantitatively, the expression of the δ- and β-globin genes is strikingly different and the sequences responsible for this have been studied. Although HbA_2 comprises only 2%–3% of the hemolysate, it is synthesized in all erythroid progenitors and has a pancellular distribution in distinction to the heterocellular distribution of HbF. In bone marrow, δ-globin chains are synthesized at a reduced rate compared with β chains; δ-globin is not synthesized in reticulocytes and reticulocytes contain almost no δ-globin mRNA. Maturity-fractionated bone marrow erythroblasts showed a progressive decline of δ- in relation to β-globin chain synthesis as the maturity of the erythroid cell increased.

Relative instability of δ-globin mRNA was postulated to be responsible for the premature decline in δ-globin synthesis. The half-life of δ-globin mRNA was less than one third that of β-globin mRNA. Instability of δ mRNA might depend on the sequence of its 3′ untranslated region. Instability alone does not account for the vast reduction of HbA_2 compared with HbA concentration.

In vitro transcription of the δ-globin gene was 50 times less efficient than that of the β-globin gene. Studies of hybrid genes suggested that the δ-globin gene promoter was faulty. In the δ-globin gene promoter, the conserved CCAAT box is replaced by CCAAC. CCAAC binds the ubiquitous CCAAT-binding protein, CP1, less avidly than CCAAT and forms unstable complexes with other possible CCAAT binding proteins, reducing β-globin gene promoter activation by the locus control region (LCR). Another major difference between the β- and δ-globin gene promoters is the absence of the proximal CACC in the δ-globin gene. This sequence forms the binding site for the β-globin gene-specific transcription factor, erythroid Krüppel-like factor.

The transcriptional defect of the δ-globin gene was partially normalized when both the CCAAC and CACC sequences were "corrected" by substituting the CCAAT sequence of the β-globin gene promoter for the δ gene CCAAC motif. Introducing EKLF binding sites into the δ-globin gene promoter, increased expression 6.5- to 26.8-fold to 35% of the total δ and β chains produced.[36,37]

Mutations in the gene promoter do not totally explain the reduced accumulation of δ-globin mRNA suggesting that additional sites in the δ-globin gene could account for its reduced expression. IVS-II of the δ-globin gene also has been shown to reduce the δ-globin gene transcription but the mechanism of this effect is unclear. Further insight might come from the example of the Lepore hemoglobins, products of δβ fusion genes (Chapter 16) that contain δ-globin gene sequences in their 5′ portion that might explain their characteristically reduced rate of synthesis. Nevertheless, the Lepore δβ-globin chain is synthesized at a higher rate than the δ-globin chain, perhaps because of the presence of a β-globin-like IVS-II. A βδ chain variant, β-like through IVS-1 and then δ-like, was expressed at levels that were greater than the δ-globin gene, but less than the β-globin gene, again suggesting that δ IVS-II and 3′ sequences influence gene expression. The δ-globin gene IVS-II contains only a single GATA-I binding site, whereas β IVS-II has two GATA-I sites and an Oct-I site, perhaps accounting for the effects of δ IVS-II.

Functional Aspects of HbA_2: HbA_2 has functional properties nearly identical to HbA; ligand-binding curves are similar although HbA_2 has higher O_2 affinity, however Bohr effect, cooperativity, and response to 2,3 BPG are identical to HbA. Greater thermal stability of HbA_2 might be due to the δ116 arginine that can form a salt bridge with α114 proline, increasing even further the stability of the $\alpha_1\delta_1$ contact. HbA_2 has slightly increased autoxidation to methemoglobin and its hemichrome had increased stability. These differences could explain its increased membrane binding. The positive charge of HbA_2 could endow it with properties similar to other positively charged hemoglobins, like HbC, in its interaction with the erythrocyte membrane. HbA_2 has a higher affinity for erythrocyte membrane band 3 than HbA. Although the interaction of HbC with the membrane is believed to determine the red cell phenotype of HbC trait and HbC disease (Chapter 21), the very low concentration of HbA_2 makes it doubtful that it meaningfully affects cation transport and mean corpuscular hemoglobin concentration.

HbA_2 inhibits the polymerization of HbS and δ22 ala and δ87 gln might be the important inhibitory sites.[38] When HbA_2 levels are exceptionally high and in the presence of elevated HbF levels, the combination of these two hemoglobins could modulate the phenotype of HbS-β^0 thalassemia (Chapter 23). A δ6 valine mutation introduced into the δ-globin chain in the presence or absence of either or both δ22 glutamic acid and δ87 threonine, causes the deoxy molecule to polymerize without a delay time in the simple δ6 val variant and with delay times when other mutations are present.[39]

Mutations of the δ-Globin Gene: Far fewer than expected number of δ thalassemia–causing mutations and δ-globin chain variants have been described. Detecting δ-globin chain hemoglobinopathies is difficult because of the low concentration of δ-globin gene variants and the few clinical or hematological abnormalities that are expected with δ thalassemia. The inconsequential hematological changes of δ thalassemia appear to be an insufficient basis for natural selection to protect the carrier from *Falciparum* malaria

Approximately 60 variants of the δ-globin gene have been described (http://globin.cse.psu.edu). In individuals heterozygous for stable δ-globin chain variants, the concentration of the HbA_2 variant is equivalent to approximately half the usual HbA_2 concentration, and the sum of normal and variant HbA_2 is equal to the normal HbA_2 level. Homozygotes for these HbA_2 variants, unless they are unstable, have normal HbA_2 levels. δ-globin gene variants can also have increased O_2 affinity.

HbA_2' (*HBD* gly16arg), sometimes called HbB_2, is the most common variant of the δ-globin gene. Among more than 5,500 hemoglobin HPLC studies, 57 instances of

HbA_2' trait were found, making it the third most prevalent hemoglobin variant detected after HbS and HbC. The mean HbA_2 level was 1.7% and the mean HbA_2' level was 1.3%.[40] Present in approximately 1% of African Americans, both homozygotes and heterozygotes are found. In Africa, it has been described in samples from different geographical locations and has been described in *cis* and in *trans* to HbS and HbC. More recently, it has been found at polymorphic frequencies in one cast in the Dogon region of the Republic of Mali. Although haplotype analysis of the β-like globin gene cluster in individuals from Mali with HbA_2' showed that all unrelated individuals carried this mutation on the same haplotype, samples from unrelated African Americans with this mutation displayed haplotype heterogeneity. It is therefore possible that this mutation arose in Africa unicentrically and distributed itself to other regions of Africa by gene flow. HbA_2' is easily detectable by HPLC in the absence of HbS, C, or G.[40] It migrates cathodic to normal HbA_2 on alkaline electrophoresis.

Measurement of HbA_2

Separation of HbA_2 from HbA is simplified by the presence of two additional positive charges in the δ-globin chain compared with the β-globin chain. Different methods of measurement, including new and traditional methods of electrophoresis and spectrophotometric measurement of eluted fractions, HPLC, column chromatography, immunological detection, and enzyme-linked immunosorbent assay are available. HPLC hemoglobin separation is the preferred means of measuring HbA_2 but the results must be interpreted cautiously in the presence of HbS because the coelution of minor HbS species falsely elevates the HbA_2 fraction.[41,42] Newer HPLC analytical methods can reduce this inaccuracy.

Clinical Aspects of HbA_2

Developmental Changes in HbA_2 Level: Little δ-globin chain synthesis occurs in utero so that HbA_2 does not become easily measurable until late in gestation. In normal newborns, HbA_2 concentration is 0.27% ± 0.02%. HbA_2 levels vary with gestational age and are lowest in the least mature infants. HbA_2 levels do not rise synchronously with HbA, but lag behind; the HbA/HbA_2 ratio is approximately 100 by 32 weeks gestation, 75 by 45 weeks and "adult" ratios of approximately 40:1 are not reached until at least age 6 months. This sluggish response of HbA_2 during maturation can reduce its value for the diagnosis of β thalassemia in young infants. In the presence of an α-globin variant, such as $HbG^{Philadelphia}$, the variant α-chain combines with the δ-chain to form a hemoglobin tetramer with the structure, $\alpha^{Variant}{}_2\,\delta_2$. This tetramer, often called HbG_2, usually comprises less than one half the total amount of HbA_2. HbG_2 is more positively charged than HbA_2 because of the positive charge of the α^G chain and is easily separated from HbA_2.

Table 7.4. Low HbA_2 levels

Iron deficiency	lowest with increasing severity
G-6-PD deficiency	reports are conflicting – levels probably not reduced
α Thalassemia	related to severity of the thalassemia
Myelodysplastic syndromes	only in a minority of cases
Hb Lepore	half normal in heterozygotes
Gene deletion hereditary persistence of HbF	half normal in heterozygotes
δβ Thalassemia	half normal in heterozygotes
δ Thalassemia	usually approximately half normal
HbA_2 variants	variant can be poorly expressed
Sideroblastic anemia	due to impaired α-globin synthesis
Juvenile chronic granulocytic leukemia with increased HbF	only in a minority of cases
Acute myelocytic leukemia	minor reduction
α-Globin gene variants	hybrid HbA_2 might not separate

Extra HbA_2 bands are a valuable clue to the presence of variant α-globin chains, although, depending on the charge of the α-globin variant, they might or might not separate from the major hemoglobin bands (Chapter 23).

Low HbA_2 (Table 7.4): Low HbA_2 values are usually the result of either posttranslational modifications in the assembly of the HbA_2 tetramer, reduced synthesis of the δ-globin chain secondary to δ thalassemia or δ-globin chain mutants.

Among Greek Cypriots with an HbA_2 of less than 1.6%, all had of δ-globin mutants. Five of the 11 mutations were amino acid substitutions and the others were more typical thalassemia mutations. When HbA_2 was 1.7%–1.8%, 91% of subjects had a δ-globin variant and this percentage fell to 53% if the HbA_2 was 1.9%. Based on their screening, it was estimated that 1.26% of Greek Cypriots had a δ-globin gene mutation.[43] In 29 patients with a low HbA_2 level, 20 δ-globin gene mutations, including those causing δ thalassemia and structural abnormalities of the δ-globin gene, were found.[44]

Posttranslational Causes of Reduced HbA_2: Posttranslational causes of reduced HbA_2 can result from either acquired or genetic disorders. In either case, the underlying cause of the low HbA_2 level is insufficient synthesis of α-globin chains. Assembly of hemoglobin tetramers is dependent on charge differences of α- and non-α-globin chains (Chapter 22). Normal α- and β-globin monomers have nearly equivalent positive and negative charges, respectively, and are united by electrostatic attraction to form αβ dimers. δ-Globin chains are more positively charged than the β-globin chains (or γ-globin chains). Under normal conditions of α chain sufficiency or slight excess, HbA is formed in preference to HbA_2 because αβ dimers assemble more readily than αδ dimers. When the supply of α-globin chain is limited, this effect of monomer charge on dimer formation is exaggerated, as β chains (and γ-chains) compete more effectively than δ chains for scarce α-globin.[45–47]

Acquired conditions that reduce α-globin chain synthesis appear to work through the common mechanism of absolute or functional iron deficiency. Lacking sufficient iron, a repressor of initiation of protein synthesis is formed that preferentially effects α-, rather than non-α-globin chain initiation, resulting in a relative deficiency of α chains. Patients with iron deficiency anemia have reduced levels of HbA_2. This reduction is greatest in individuals with the most severe iron deficiency.[48 49] Individuals with anemia, microcytosis, and low levels of HbA_2 from iron deficiency might be mistaken for carriers of α thalassemia. When iron deficiency and β thalassemia coexist, the HbA_2 level has been occasionally reported to fall, although it can remain within the range expected for thalassemia heterozygotes. The iron utilization defect associated with sideroblastic anemias can also reduce HbA_2 levels.

In the α thalassemia/myelodysplasia syndrome (Chapter 15), inhibition of α-globin chain synthesis is associated with low HbA_2 levels. With acute myeloid leukemia, HbA_2 is lower than in acute lymphocytic leukemias, suggesting that the leukemic clone involves the erythroid lineage. Patients with juvenile chronic granulocytic leukemia can have a hemoglobin pattern very similar to fetal erythropoiesis, and high HbF is accompanied by low HbA_2 recapitulating normal neonatal findings. Erythroleukemia has also been associated with very low levels of HbA_2 without HbH. These acquired "α thalassemias" bridge the gap between reduced HbA_2 secondary to acquired diseases and low HbA_2 associated with genetic abnormalities of α-globin synthesis.

α Thalassemia is the common cause of a genetically determined reduction in HbA_2 level due to posttranslational mechanisms. HbA_2 concentration varies commensurately with the deficit in α-globin chain synthesis. With the mildest types of α thalassemia, HbA_2 values might be indistinguishable from normal. When α-globin production is impaired significantly, the reduction in HbA_2 is dramatic. In 21 patients with HbH disease, the HbA_2 ranged from 0.5% to 1.8% and averaged 0.8%.[50] Homotetramers of δ chains have been reported in α thalassemia hydrops fetalis.

δ *Thalassemia:* Approximately 20 different δ thalassemias due to the usual types of thalassemia-causing mutations have been described and cause either δ^+ or δ^0 thalassemia (http://globin.cse.psu.edu). Uncomplicated δ thalassemia has no clinical repercussions other than complicating the diagnosis of β thalassemia trait. By decreasing the level of HbA_2, δ thalassemia makes the use of HbA_2 levels less reliable. Homozygosity for δ^0 thalassemia causes absence of HbA_2.

Early descriptions of δ thalassemia were based on hematological and family studies and are often error prone. δ Thalassemias have been reported most often in Japanese, Italian, and Greek populations. Whether this represents their true distribution is not known because extensive surveys have not been done. In Italians and potentially in other ethnic groups in which β thalassemia is common, the coexistence of δ thalassemia and β thalassemia might cause the HbA_2 to be normal and complicate β thalassemia screening programs. In Greece, approximately 5% of individuals with β thalassemia can have borderline or normal HbA_2 concentrations and most of these cases also have δ thalassemia due to point mutations or the 7.2-kb Corfu deletion.[51] Interactions between α thalassemia and β thalassemia can also result in normal HbA_2 values. β Thalassemia can escape detection if the sole basis of diagnosis is the level of HbA_2.

Table 7.5. Increased HbA_2

Proven Cases	
β Thalassemia	4%–6%, rarely up to 12%, microcytosis
Sickle cell anemia–α thalassemia	4%–5%, microcytosis, similar to HbS–β^0 thalassemia
Megaloblastic anemia	modest increases
Unstable hemoglobinopathies	not uniformly found
Zidovudine-treated HIV patients	HbA_2 lower than in β thalassemia, macrocytosis
CDA, Type I	HbA_2 lower than in β thalassemia, macrocytosis
Hyperthyroidism	HbA_2 lower than in β thalassemia,
Normal individuals	rare, normal red blood cell indices, no thalassemia
Doubtful Cases	
Malaria	
Sickle cell trait	
Sickle cell anemia	
Hereditary spherocytosis	

In the Corfu 7.2-kb deletion, most of the δ-globin gene is absent. Although the initial molecular characterization of this deletion suggested that it inactivated the β-globin gene, subsequent studies revealed a β^+ thalassemia mutation that was responsible for the reduced expression of the β-globin gene in *cis* to this deletion.

Heterozygotes for δβ thalassemia, Hb Lepore, and gene-deletion HPFH have half-normal HbA_2 levels and homozygotes have no HbA_2. Although the percentage of HbA_2 might be low when δ-globin gene expression is abolished, the absolute level, expressed as pg HbA_2 per cell, is elevated, reflecting increased synthesis of HbA_2 from the chromosome in *trans* to the deleted gene.

High HbA_2 (Table 7.5): Heterozygous β thalassemia is the cause of at least 95% of the cases of high HbA_2 levels (Table 7.5). Only a few of the point mutations causing β thalassemia are not associated with a raised HbA_2 level. "Normal" or borderline HbA_2 thalassemias have multiple causes including triplicated α-globin loci, β thalassemia with α-globin gene deletion, and δ plus β thalassemia, usually in *trans* but rarely in *cis*.[52] Mean HbA_2 levels in 879 carriers of β thalassemia of diverse ethnic backgrounds were 5.08% ± 0.39%.[53] The highest observed value was 6.8%. In 184 African American patients with β thalassemia trait, the mean HbA_2 level was 4.97% ± 1.07%.[53] With the few exceptions mentioned previously, an elevated level of HbA_2, in the presence of microcytic erythrocytes, identifies patients

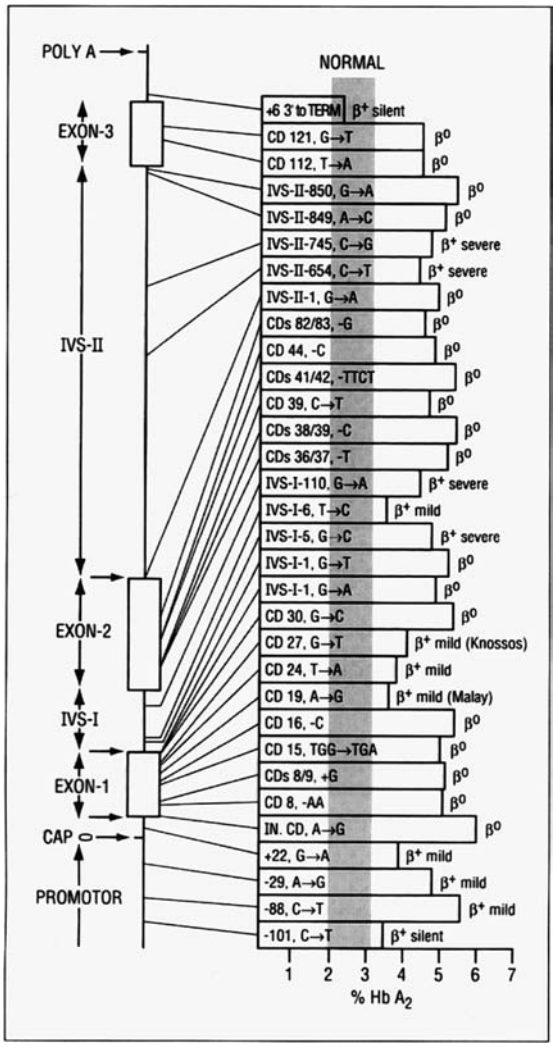

Figure 7.6. HbA_2 concentrations according to the β thalassemia mutation in more than 600 patients.[55]

with heterozygous β thalassemia. HbA_2 levels could be higher in heterozygous β^0 thalassemia and severe β^+ thalassemia than in mild β^+ thalassemia because of their greater impairment of β-globin chain synthesis.[54] Average levels of HbA_2 in heterozygotes for 32 different β alleles are shown in Figure 7.6.[55] In mild β thalassemia mutations, a nominal suppression of β chain synthesis and a minor excess of α-globin chains can lead to less αδ–dimer formation. It possible, however, that point mutations in the β-globin gene promoter might alter binding of transcription factors and augment δ-globin gene transcription in *cis* to the mutation. Nevertheless, in 10 heterozygotes with the −88 C→T β^+ thalassemia mutation, HbA_2 was 5.4% ± 0.4%; in another six heterozygotes HbA_2 was 4.9%; in a patient with the −88 C→T β^+ thalassemia and HbA_2' in *trans*, the total HbA_2 level was approximately 7%.

Because of the striking increases of HbF that typify the severe β thalassemias, HbA_2 levels in homozygous β thalassemia are variable and of little diagnostic value. The level of HbA_2 in homozygotes for the promoter mutations −88C→T and −29 A→G averaged 6.6% (4.0%–9.7%).[55] Transcription of the δ-globin gene appears to vary reciprocally with that of the γ-globin gene. This reciprocity is evident as HbF levels fall rapidly during the last trimester of gestation and is also observed in the β thalassemia syndromes. In homozygous β thalassemia, cells with the highest HbF levels have the lowest HbA_2 concentrations. One example of the relationship between HbA_2 and HbF was seen when chemotherapy for Hodgkin disease appeared to reactivate HbF synthesis in a patient with β thalassemia trait and the Swiss-type HPFH. HbF level rose from 4.5% to 26%, accompanied by a fall in HbA_2 from 4.5% to 2.4%. The mechanism of this effect has not been studied but could be a result of competition for the LCR and transcription factors.

Increased HbA_2 in heterozygous β thalassemia appears to result from both transcriptional and posttranslational mechanisms.[56] Both the percentage and absolute amount of HbA_2 are increased with the former approximately twice as great as the latter. Reduced production of β-globin chains, with a relative excess of α-globin chains, favors the formation of αδ dimers and the assembly of HbA_2 tetramers. Posttranslational effects occur in *cis* and in *trans* to the thalassemia mutation as suggested by studies in which a δ-globin variant was in *trans* to the β thalassemia mutation. Increased δ-globin gene transcription might be expected to occur only in *cis* to the thalassemia mutation.

Exceptionally High HbA_2: Some individuals with β thalassemia trait have HbA_2 concentrations much higher than usual. These exceptionally high HbA_2 levels are usually the result of a unique class of small deletions of DNA that usually begin within the β-globin gene and extend 5′, removing the gene promoter (Chapter 16). Removing the β-globin gene promoter sequences by the 5′ deletion might increase the likelihood that transcription factors bind the remaining δ- and γ-globin gene promoters, enhancing the transcription of these genes. Alternatively, deletion-induced disruption of higher-order DNA or chromatin structure could make γ- and δ-globin promoters more accessible to the LCR. The absence of a functional β promoter might permit the LCR to interact with the δ-globin gene in *cis*, enhancing its expression.

HbA_2 levels in heterozygotes for these 5′ β-gene deletion thalassemias have been reported to range from approximately 7%–12%. HbA_2 levels that exceed the top of this range have not been reported. Laboratory reports of HbA_2 values more than 15% or 20% are usually spurious or represent instances of HbC or HbE heterozygosity complicated by α thalassemia or iron deficiency.

Miscellaneous Causes of High HbA_2: Patients with either sickle cell anemia–α thalassemia or HbS–β^0 thalassemia have high HbA_2 concentrations (Chapter 23). In the former group of patients, the δ-globin chain competes more effectively than the β^S-globin chain for the limited quantities of α-globin chain.

HbA_2 levels are consistently elevated in hyperthyroidism, although not as markedly as in β thalassemia. Both the percentage and absolute amount of HbA_2 are increased, suggesting increased synthesis of the δ-globin chain and an effect of thyroid hormone on δ-globin gene transcription. The combination of high HbA_2 and low MCV can be confused with β thalassemia. Euthyroidism following treatment is accompanied by a fall in HbA_2 and rise in MCV. In untreated, nonanemic, hypothyroidism, HbA_2 levels cluster toward the low end of normal.[57]

Megaloblastic anemias have been associated with HbA_2 concentrations that exceed normal. The most severely anemic patients have the highest HbA_2 values. The incidence of this finding seems low, however, the amount of the increase above normal is slight, and in one study the mean HbA_2 levels in the normal and megaloblastic anemia groups were similar. Perhaps the high HbA_2 of megaloblastic anemia is a result of more hemoglobin synthesis occurring in less mature erythroid precursors.

Seventy-eight human immunodeficiency virus (HIV)–infected patients taking zidovudine had HbA_2 levels of 3.2% ± 0.5% compared with 2.7% ± 0.4% in HIV-positive controls not exposed to this drug. The MCV was higher in zidovudine-treated patients but evidence of folic acid or vitamin B_{12} deficiency was lacking. It was speculated that increased HbA_2 levels of the treated patients was secondary to drug-induced megaloblastic erythropoiesis.

In 14 Israeli Bedouins with congenital dyserythropoietic anemia, type I, the mean HbA_2 was 3.5% ± 0.5%. MCV was 98 ± 5 fl but biosynthesis studies showed a deficit of β-globin chain synthesis with a mean α/β synthesis ratio of 1.27, suggesting β thalassemia trait. The sequence of the β-globin gene in four individuals was normal however.

HbA_2 levels are increased in some examples of unstable hemoglobin. An unstable β-globin chain might have difficulty forming αβ dimers, increasing αδ dimer assembly.

In one report, 20% of individuals with pseudoxanthoma elasticum had increased HbA_2.[58]

Malaria infestation and elevated HbA_2 levels have been linked in some reports but not others. The best-controlled study casts doubt on such an association. An association of hereditary spherocytosis and very high HbA_2 levels has also not been proven.

EMBRYONIC HEMOGLOBINS (*HBE1*, *HBZ*)

Between 4 and 14 weeks gestation, the human embryo synthesizes three distinct hemoglobins in yolk sac–derived primitive nucleated erythroid cells: Hb Gower I ($\zeta_2\varepsilon_2$), Hb Gower II ($\alpha_2\varepsilon_2$), and Hb Portland ($\zeta_2\gamma_2$). ζ- and ε-globin are expressed before γ- and α-globin. By 14 days of development, after the establishment of the placenta, embryonic hemoglobins start to be replaced by HbF but some ζ- and ε-globin chains can be found in definitive and primitive erythrocytes.[59] At 15–22 weeks of gestation, 53% of fetal cells contained ζ-globin chains and 5% had ε-globin chains. At term, cord blood contained 34% ζ- and 0.6% ε-globin chain–positive cells. Erythrocytes from normal adults did not contain embryonic globins.

Recombinant technology using plasmid-based expression systems in yeast and transgenic mice have provided sufficient amounts of functional embryonic hemoglobin tetramer to permit studies of their structural and functional properties (reviewed in [11]).[60]

Presently, embryonic hemoglobins have little apparent clinical importance. Detection of the ζ-globin chain in blood provides a means of diagnosing α thalassemia due to the Southeast Asian mutation.[61–64] Hb Gower II can inhibit polymerization of HbS, suggesting that the reactivation of the gene could be therapeutically useful in sickle cell disease.[65]

Function

Embryonic hemoglobins exhibit cooperative O_2 binding with P_{50} values of 4, 12, and 6 mm Hg for Hb Gower I, Gower II, and Portland, compared with a P_{50} of 26 for HbA. Cooperativity of embryonic hemoglobins is less than that of HbF and HbA. The higher O_2 affinity of embryonic hemoglobins is likely to be a result of reduced relative stability of the T-state ascribed to the substitution of several residues that stabilize the T-state in HbA. The presence of the ζ 38 glycine has major significance in producing high O_2 affinity within the ζ chain–containing human embryonic hemoglobins.

In the presence of organic phosphates, the O_2 affinities of $\zeta_2\varepsilon_2$ and $\alpha_2\varepsilon_2$ suggest that whereas the ζ- and ε-globin chains bind 2,3-BPG, differences from binding to β-globin are present. Hb Portland, because its central cavity is formed by γ-globin chains and because of the N-terminal ζ-chain acetylation, binds organic phosphates poorly. The N-terminal acetylation of the ζ-globin chain makes it incapable of combining directly with CO_2 and accounts for its reduced Bohr effect. The rates of O_2 dissociation from the embryonic hemoglobins seem responsible for their high O_2-binding affinity compared with HbA. The pH dependence of the O_2 dissociation rate constants also accounts for the unusual Bohr effects of embryonic hemoglobins.[66–69] These differences and the difference in O_2 affinity among the embryonic hemoglobins are accounted for by differences in specific amino acids in the ε-, ζ-, and γ-globin chains.

Nuclear magnetic resonance studies show that the embryonic globins bind heme rapidly.[70] They also bind heme more tightly than HbA.[71,72] At pH 9.0, both embryonic hemoglobin and HbA dissociate into dimers with associated equilibrium constants in the micromolar range. At low pH, Hb Portland shows a high degree of globin dissociation and Hb Barts can be found in equilibrium with dimeric and monomeric globin chains.[73,74]

Embryonic hemoglobins show a similar pattern of O_2 dissociation to HbA, but with the ζ chains losing O_2 at approximately twice the rate of the α chains. The rate of conversion of deoxy dimers to tetramers is very similar for HbA and embryonic hemoglobins. Hb Portland has a lower rate of dissociation.

Structure

Only Hb Gower II and Portland have been crystallized and only the Gower II structure has been solved to 2.9-A resolution.[75] The quaternary structure of the CO form of hemoglobin Gower II lies between that reported for the R- and R2-states, lying closer to the R2 structure. The structure of the heme pocket of the α subunit of Gower II is, within experimental error, identical to that reported for the adult protein. The tertiary structure of the ε subunit is similar to that reported for the β chain. Some amino acid substitutions between the ε and β chains are within the internal core of the molecule but appear to have no major structural effects. The overall structure of the ε chain heme pocket is essentially identical to that of the β chain. Differences from the β chain include a position ala70ser substitution within the heme pocket and a gly83pro substitution at the beginning of the F helix that might reduce the flexibility of the EF loop and contribute to the destabilization of the T-state, causing an increase in O_2 affinity of hemoglobin Gower II. Compared with HbA, Gower II contains three amino acid substitutions at the $\alpha_2\beta_1$ interface, but the $\alpha_1\beta_2$ interface is more strongly conserved.

The crystal structure of Hb Portland has not yet been solved. The structure of Hb Barts has been solved at 1.7-A resolution in both the azide and CO state. The γ-globin chain has a structure similar to the β chain with a closer correspondence to the β structure in HbH than that in HbA. The major difference between the γ- and β-globin tertiary structure is in the N-terminal region of the protein, which is implicated in the greater stability of HbF.

In a chimeric $\zeta(\text{human})_2\,\beta(\text{mouse})_2$ protein, the ζ chain showed structural differences from the human α chain.[73]

Thalassemias and Hemoglobinopathies of the Embryonic Globin Genes

Thalassemic or structural variants of the embryonic ε- and ζ-globin chains due to point mutations have not been described at the DNA or protein level. Mutations in the ε-globin gene have yet to be found.[76] Some large deletions that affect the β- and the α-globin gene clusters remove embryonic genes. The phenotypes of these conditions, when expressed postnatally, derive from loss of the β- or the α-globin genes rather than the embryonic genes. Deletion of the ζ- and α-globin genes cause early embryonic loss, presumably because a functional hemoglobin tetramer cannot be synthesized.

POSTTRANSLATIONAL MODIFICATION OF NORMAL ADULT, FETAL, AND EMBRYONIC HEMOGLOBINS: THE "MINOR" HEMOGLOBINS

So-called "minor" components of normal hemoglobins are the result of posttranslational hemoglobin modifications that include nonenzymatic glycation (glycosylation), acetylation, pyruvatization, S-glutathionylation, and acetaldehyde adduct formation. Using ever more sensitive methods of mass spectrometry it seems likely that other modified hemoglobins will be found.

Modified HbA variants are termed HbA1a1, A1a2, A1b, A1c, and A1d (and its subtypes, A1d1, 2, and 3). HbS, HbF, HbC and other variant hemoglobins also have minor components. Separation of minor hemoglobins in neonates and in patients with sickle cell anemia, HbSC disease, HbC disease, and sickle cell trait by HPLC is shown in Figure 7.7. HbA1c is the best-studied minor hemoglobin and its clinical importance dwarfs that of other minor components whose major clinical significance is the confusion and uncertainty they cause in the interpretation of isoelectric focusing gel patterns, HPLC columns, and hemoglobin electrophoresis. Although the impact of glycated hemoglobin in diabetology is outside the purview of this book, we will describe some functional properties of HbA1c and provide a brief description of other minor normal hemoglobins components.

Minor hemoglobins can vary in quantity according to whether diseases such as diabetes or uremia are present and if an individual is exposed to external agents such as penicillin and aspirin. Minor components of normal hemoglobin have been suggested to be "reporters" of physiological and pathophysiological events. HbA1c levels in patients with acquired immunodeficiency syndrome and with normal glucose concentrations might be increased when compared with normal controls ($9.1\% \pm 0.5\%$ vs. $7.4\% \pm 0.2\%$); however a mechanism for this observation is not obvious. An inverse relationship existed between glycohemoglobin concentrations and the CD4 cell count and acquired immunodeficiency syndrome patients with the most advanced disease and lowest CD4 counts had glycohemoglobin levels of approximately 8%.[77]

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry identified pyruvatization, glycation, acetylation, carbamylation, and acetaldehyde adduct formation in all hemoglobins and found that a minor hemoglobin containing the carbamylated α- and β^S globin eluted with HbA_2 accounting for the falsely increased HbA_2 values in patients with HbS when blood is analyzed by HPLC.[42]

Glycated Hemoglobins

HbA1c: HbA1c is a result of posttranslational and nonenzymatic glycation of HbA. The most abundant minor hemoglobin component in human red cells, HbA1c is

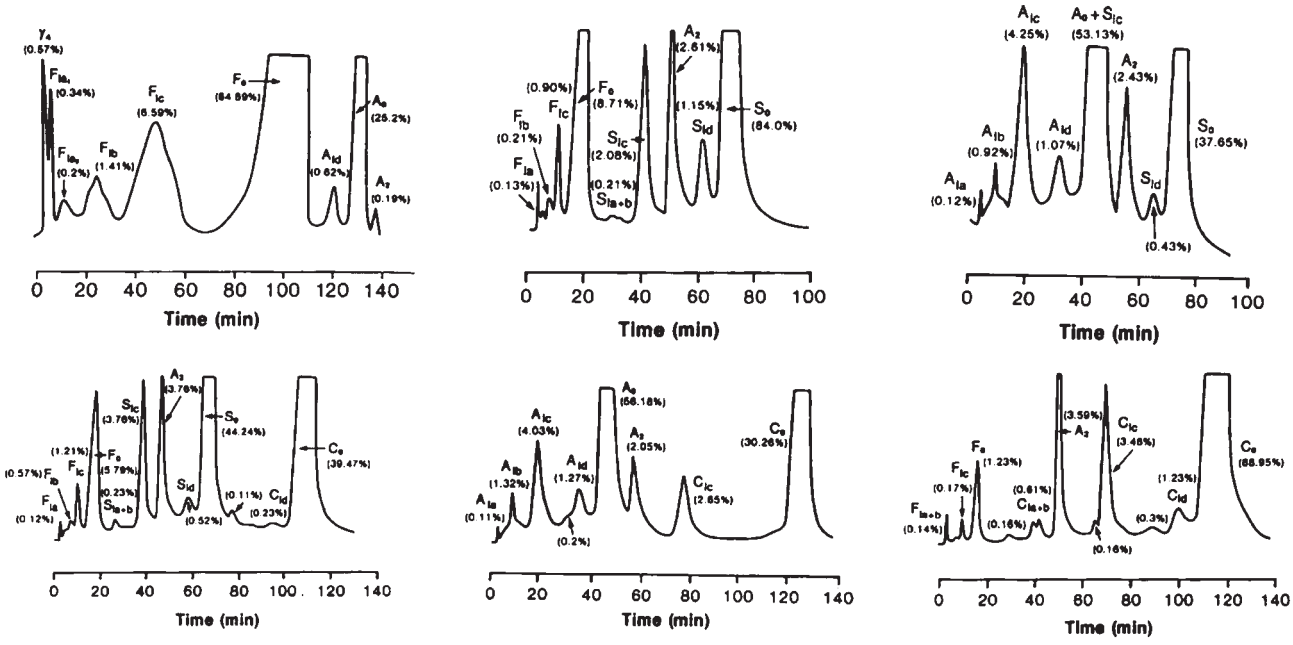

Figure 7.7. Separation by HPLC of the minor hemoglobins from neonates (top left), adults with sickle cell anemia (top center), adults with sickle cell trait (top right), HbSC disease (bottom left), HbC trait (bottom center), and HbC disease (bottom right).[85,86] These examples illustrate the complexity of patterns caused by the presence of minor hemoglobins on HPLC separation (and by isoelectrical focusing) and the difficulty of knowing, without DNA analysis or protein sequencing, whether one of these minor peaks represents or contains a genetically encoded hemoglobin variant that can be present in trace amounts.

formed by the rapid nonenzymatic condensation of glucose with the N terminus of the β-globin chain to form a Schiff base that undergoes a slow Amadori rearrangement to a stable ketoamine linkage (Fig. 7.8). This adduct is increased in patients with diabetes mellitus and its measurement is a useful index of diabetic glycemic control. Glucose also forms covalent attachments with the ε-amino groups of lysine residues of both the α- and the β-globin chain, although these adducts are not readily resolved by electrophoretic and chromatographic techniques. Nonenzymatic glycation also occurs in proteins with long turnover times exposed to high glucose concentrations. Examples are proteins of the red cell membrane, albumin, and lens crystallins. Nonenzymatic glycation of other proteins with the generation of advanced glycation endproducts (AGEs) could contribute significantly to the long-term complications of diabetes and other vascular diseases. Using AGE-specific antibodies, an AGE-modified form of human hemoglobin has also been identified. Hemoglobin-AGE (Hb-AGE) accounts for 0.42% of circulating hemoglobin in normal individuals but increases to 0.75% in patients with diabetes-induced hyperglycemia. Hemoglobin-AGE measurements might provide an index of long-term tissue modification by AGEs and prove useful in assessing the contribution of advanced glycosylation to a variety of diabetic, vascular, and age-related complications.[78]

Glycohemoglobin levels can be measured by ion-exchange column chromatography on Bio-Rex 70, affinity chromatography, HPLC, by electrophoresis, and colorimetrically. Electrospray ionization mass spectrometry to detect glycation of samples separated by boronate affinity and cation exchange chromatography has provided additional

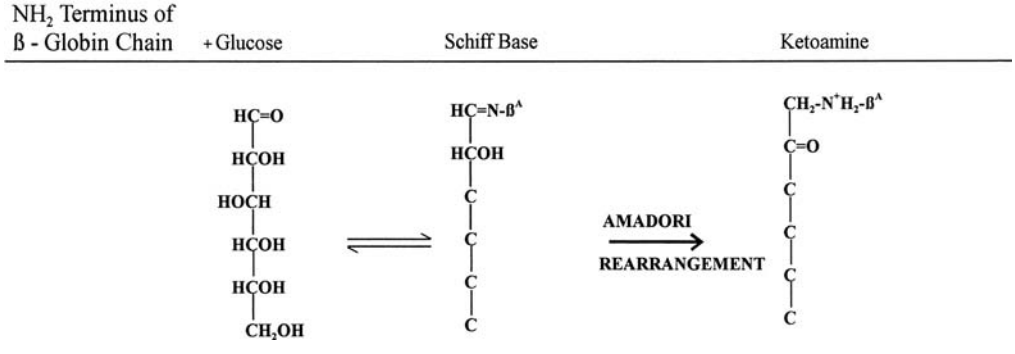

Figure 7.8. Mechanism of HbA1c formation.

insights.[79] Analyses of clinical samples were consistent with the curvilinear relationship between serum glucose and HbA1c. As glycation increased, the ratio of β- to α-globin chain glycation increased and the number of glycated sites on the β chain increased, although these were minor components. Several glycated species that cochromatographed with HbA1c on cation exchange chromatography, including species with both glycated α- and β-globin chains, nonglycated α- and glycated β-globin chains, and multiply glycated β-globin chains.

The P_{50} of stripped HbA and HbA1c is similar but as HbA1c has blocked N-terminal, it has reduced interaction with 2,3-BPG and a decreased P_{50}. The low-affinity conformation T-state of HbA1c is destabilized by the chemical modification per se and the Bohr effect is reduced compared with nonglycated HbA. The affinity of the T-state of HbA1c for 2,3-BPG is approximately 2.6-times lower than that of HbA, whereas the R-state is approximately 1.7-times lower.[80]

At the structural level, computer modeling studies showed that the two sugar moieties are asymmetrically disposed within the 2,3-BPG binding site. Calculations concerning the interaction with 2,3-BPG show that although in HbA the effector can assume two different stable orientations, in glycated hemoglobin only one orientation is possible. Together, these results show that glycation of the valine 1 residues of both β-globin chains do not impair the binding of 2,3-BPG but impose a different mode of binding by changing the internal geometry of the complex and the surface distribution of the positive electrostatic potential within the binding pocket.

When used to assess diabetic control, HbA1c levels can be affected by variant hemoglobins including elevated HbF.[81] Therefore, it has been suggested that in individual heterozygous for hemoglobin variants, laboratories either choose not to report HbA1c and propose another strategy for monitoring blood sugar levels or report HbA1c with the needed cautions.[82]

Other Glycated Hemoglobins: Like Hb A1c, components HbA1a1, HbA1a2, and HbA1b also contain a sugar moiety linked to the N terminus of the β-globin chain. Bio-Rex 70 chromatography in normal and diabetic patients detects the following minor hemoglobins: A1a1, A1a2, A1b1, A1b2, A1b3, A1d1, A1d2, and A1d3. Based on colorimetric assay, protein-bound ketoamine was present in all the minor hemoglobins, which was confirmed by chromatographic separation of hemoglobins after reduction with NaB_3H_4. All the minor hemoglobins, except HbA1a1, Hba2, and HbA1b1, were increased twofold in diabetics. HbA1d3, measures approximately 1.9% in normal individuals and approximately 3.2% in diabetics and has reduced O_2 affinity in the presence of 2,3-BPG. Glycation of hemoglobin with [^{14}C]glucose followed by separation of hemoglobins by two Bio-Rex 70 chromatographic methods indicated that the minor hemoglobin formed by glycation of the α-globin chain amino terminus was separable from HbA, whereas the minor hemoglobins formed by the glycation of ε-amino groups chromatographed with HbA.

Cord blood samples from women with preterm fetuses of gestational ages 30–36 weeks and from a control group of term fetuses of 40 weeks gestational age were analyzed for total glycated hemoglobin and the percentages of the minor hemoglobins F1a+b and F1c. The absolute levels and the increase due to red cell aging of glycohemoglobins F1a+b and Hb F1c were significantly reduced in the preterm samples compared with the term samples, suggesting decreased hemoglobin glycation in preterm fetus. The acetylated form of HbFIc also showed an increase with red cell aging indicating posttranslational enzymatic or nonenzymatic acetylation of HbF during the entire lifespan of red cells. As with glycohemoglobins, the acetylated HbF was also decreased in the preterm newborns. Both erythrocyte age and the time of gestation are factors that influence hemoglobin glycation. Minor components of Hb Barts are also acetylated and glycated.

The structure of HbA1b that forms less than 0.5% of total hemoglobin has been established and shown to be consistent with a ketoamine-linked pyruvic acid at the amino end of the β chain.[83]

Hemoglobin variants also have glycated minor components and those of HbS have been best studied. HbS1c and HbSo, a component formed by glycation of the ε-amino groups of lysine, made up 33% and 42%, respectively, of the total glycohemoglobin in individuals with sickle cell anemia, the remainder being glycated HbF and HbA_2. These modified HbS fractions had higher minimum gelling concentrations, suggesting that HbS polymerization was inhibited, perhaps because of interference with contact points in the polymer by glycated amino acid residues. Diabetics with sickle cell anemia had a twofold increase in glycohemoglobin but this increase is less than the increase in HbA1c seen in diabetics without sickle cell anemia, perhaps a result of the very short lifespan of sickle cells. A direct relationship is present between HbF concentration and the level of glycated hemoglobin in patients with sickle cell anemia, presumably due to the longer lifespan of cells containing high concentrations of HbF that permits additional time for the slow process of nonenzymatic glycation.

Other Minor Hemoglobins

Hemoglobin acetylation, in contrast to glycation, is usually an enzymatically driven process, although, at least in vitro, nonenzymatic acetylation has been reported. Additional discussion of hemoglobin and protein acetylation is provided in Chapter 24 in which acetylated mutant hemoglobins are discussed. Acetylation is more common in proteins where the N-terminal amino acid is alanine, serine, and to a lesser extent, glycine. Hemoglobin requires an unblocked N terminus to function normally, so that blocked N-terminal residues have been largely excluded

by selection. A blocked N-terminal glycine in HbF contributes to its decreased 2,3-BPG binding. Acetylation occurs early in the posttranslational period and involves the acetyltransferase-mediated catalytic transfer of the acetyl moiety from acetyl–coenzyme A to the hemoglobin. Acetylated HbF is called HbF_1. Whether or not there is any functional advantage or disadvantage of HbF_1 is unknown. Feline hemoglobin, in which the β1 residue is serine, is also acetylated and binds 2,3-BPG poorly.

Acetaldehyde, a metabolic product of ethanol, forms nonenzymatically mediated adducts with hemoglobin and approximately 15%–25% of the adducts are stable to dialysis. No current assay systems are available to detect acetaldehyde adducts in the blood of humans consuming alcohol. Acetaldehyde adducts separate chromatographically with HbA1a and HbA1b. The amount of stable hemoglobin adducts formed is proportional to the amount of acetaldehyde. Acetaldehyde adducts with hemoglobin involve primarily three different amino acid residues of the β-globin chain. The acetaldehyde possibly reacts with the ε-amino group of lysine and α-amino group of valine probably through an initial Schiff base. The secondary amines of glycated valine or glycated lysine residues are also proposed to be at the sites of reaction with acetaldehyde. Acetaldehyde adduct formation with tyrosine residues is not as well understood.

Urea is in equilibrium with cyanate, and when urea concentrations are high, as in uremia, irreversible covalent adducts of cyanate with the N-terminal amino groups of both α- and β-globin chains are present. Carbamylated hemoglobin levels of up to 4% have been found in individuals with untreated uremia but are unlikely to be functionally significant.

Hemoglobin can also be glutathionylated via S-glutathionylation of reactive cysteine residues. The levels of this minor hemoglobin, which has a high O_2 affinity and reduced cooperativity, are markedly increased in diabetic individuals with microangiopathy, perhaps reflecting oxidative tissue damage.[84]

SECTION TWO

PATHOPHYSIOLOGY OF HEMOGLOBIN AND ITS DISORDERS

Martin H. Steinberg

One convenient classification of hemoglobin disorders dichotomizes these conditions into mutations that either change the primary structure of globin, called hemoglobinopathies, or reduce the expression of globin genes, called thalassemia. Rarely, a single mutation affects both the structure and expression level of the affected gene, and these have been called thalassemic hemoglobinopathies. Although at the level of the abnormal erythrocyte, many hemoglobinopathies and thalassemias can have similar pathophysiological effects, and result in similar clinical features, such generalizations do not apply to all hemoglobin disorders. For example, only sickle hemoglobin (HbS) polymerizes, triggering many features of sickle cell disease, and extreme ineffective erythropoiesis is characteristic of β thalassemia major.

The next four chapters consider how hemoglobin disorders can perturb vascular biology, the erythrocyte membrane, nitric oxide biology, and the lifespan of the affected red cell. A final chapter brings up to date the animal models that permit certain detailed study of this pathobiology. All these chapters are new to this edition.

In sickle cell disease and thalassemia, chronic hypoxia and hemolysis require vascular tone and flow adaptations. In sickle cell disease, red cell deformability is sensitive to intravascular oxygen tension as deoxygenation results in HbS polymerization, erythrocyte sickling, and vasoocclusion. Vasoocclusive events in sickle cell disease result in reperfusion injury characterized by excessive oxidant generation, endothelial activation and dysfunction, and inflammation. Similarly, in thalassemia, red cell abnormalities caused by precipitation of excess globin chains and oxidative stress lead to hemolysis and reduced red cell deformability and contribute to vascular pathobiology. In Chapter 8, Kaul discusses factors that contribute to the vascular pathobiology of sickle cell disease and thalassemia, with special emphasis on blood rheology, its sensitivity to oxygen saturation, and cell heterogeneity in sickle cell disease and the adhesive interactions between sickle erythrocytes and the endothelium that mediate sickle vasoocclusion.

The erythrocyte membrane is a complex dynamic structure with multiple regulated functions. Cytoskeletal proteins maintain its structural integrity, which must simultaneously be flexible enough to deform in the microcirculation and sufficiently durable to resist high shear stresses in large vessels. Multiple ligands and receptors interact with the external surface of the membrane. Specific proteins maintain a highly ordered lipid structure, which in turn might modulate other membrane protein functions or cellular interactions. Multiple regulated transport systems control solute and water flux across the membrane to facilitate the transport of respiratory gases, provide metabolic substrates, and regulate cell volume.

Given the physiological interactions of hemoglobin with the erythrocyte membrane, it is perhaps not surprising that abnormal hemoglobins can elicit significant pathological effects on membrane structure and function. A significant source of membrane damage in hemoglobinopathies is the increased level of oxidant species produced by reactive sulfhydryls on unstable or denatured hemoglobin molecules, membrane bound heme, or free iron. Oxidation affects cytoskeletal function, increases membrane rigidity and fragility, and perturbs cation transport and volume regulation.

HbS polymerization produces major damage to the membrane. Polymer formation, in addition to increasing cellular rigidity and blood viscosity, results in formation of membrane spicules in which the cytoskeleton is dissociated from its membrane connections. Associated with this membrane disruption is externalization of phosphatidyl serine and an increase in cation permeability. Calcium influx results in activation of the Gardos pathway, which mediates selective potassium loss that results in cation depletion. Potassium-chloride cotransport is excessively active in the red cells of HbSC disease and sickle cell anemia and in other hemoglobinopathies and thalassemias, and leads to dehydrated, dense cells with high hemoglobin concentrations. In sickle erythrocytes, elevated hemoglobin concentration greatly potentiates the rate and extent of HbS polymer formation. Gallagher and Joiner, in Chapter 9, discuss structural and functional abnormalities of the erythrocyte membrane and their contributions to the pathophysiology of hemoglobin disorders.

One of the most notable advances in the field since the first edition of this book has been the greater understanding of the role of dysregulated nitric oxide biology in the vasculopathy associated with hemolytic anemia. Two new chapters address this issue. In Chapter 10, Leopold and Loscalzo discuss the role of nitric oxide as the key mediator of endothelial function and vascular tone, its modulation of the integrity of the endothelium, and interactions between circulating blood components and the vessel wall. In this

paradigm, endothelium-derived nitric oxide is released to the vascular smooth muscle cells where it activates soluble guanylyl cyclase to generate cyclic guanine monophosphate and modulate cation flux that in turn induces vasodilation and adjusts vascular tone.

Anemia is the most basic clinical characteristic of sickle cell disease and thalassemia. The lifespan of the erythrocyte in sickle cell disease is shortened to less than one-tenth of normal, and in severe β thalassemia, it can be even shorter. In Chapter 11, Kato and Gladwin discuss the mechanisms that give rise to the accelerated hemolysis characteristic of these disorders. Emerging data suggest that chronic intravascular hemolysis produces endothelial dysfunction and progressive vasculopathy due to nitric oxide scavenging and reduced bioavailability of this key vasodilator and antiinflammatory molecule. This in turn contributes to complications shared by many chronic hemolytic anemias that include pulmonary arterial hypertension and cutaneous leg ulceration. Understanding this pathophysiology also suggests new treatment approaches.

Transgenic mice are important adjuncts for the study of the pathophysiology and treatment of human hemoglobin disorders. Insights into human gene therapy, new therapeutics, and disease pathophysiology have come from studies of transgenic and knockout mice, more so for sickle cell disease than thalassemia. Many inbred strains with spontaneous and induced mutations, and engineered knockout and knockin lines are available. Transgenic mice provide both advantages and disadvantages for studying human disease. Different inbred mouse strains can have different physiological characteristics, complicating the interpretation of some experiments and making it wise to examine more than one transgenic line before drawing conclusions about the relevance of a result to the human disease. State-of-the-art animal models for the study of hemoglobin disorders are discussed by Fabry in Chapter 12.

Rheology and Vascular Pathobiology in Sickle Cell Disease and Thalassemia

Dhananjay K. Kaul

INTRODUCTION

Oxygen delivery and metabolite transfer occur in the exchange compartment of the microcirculation, processes affected by erythrocyte abnormalities and alterations in components of the vascular wall, with the latter influencing flow regulation at the arteriolar level. In sickle cell disease and thalassemia, red cell rheology is abnormal; there is hemolysis, anemia, and red cell and tissue oxidative stress. Chronic hypoxia and hemolysis, common to both conditions, necessitate vascular tone and flow adaptations. In sickle cell disease, red cell deformability is sensitive to intravascular O_2 tension as deoxygenation results in hemoglobin S (HbS) polymerization, erythrocyte sickling, and vasoocclusion. Vasoocclusive events in sickle cell disease result in reperfusion injury characterized by excessive oxidant generation, endothelial activation and dysfunction, and inflammation. Similarly, in thalassemia, red cell abnormalities caused by precipitation of excess globin chains and oxidative stress lead to hemolysis and reduced red cell deformability and contribute to vascular pathobiology. Therefore, the heterozygote advantage seen in carriers of both these diseases (Chapter 26) is balanced by the vasculopathy characteristic of the homozygote.[1] This chapter addresses the role of blood components and other factors that contribute to the vascular pathobiology of sickle cell disease and thalassemia.

SICKLE CELL DISEASE

Red Cell Rheology

Red cell rheology is the study of the cellular deformation under shear forces as encountered in the blood circulation. Pliability, or deformability, is a prominent feature of normal red cells, which enables them to traverse the microcirculation. The average diameter of normal human erythrocytes is approximately 8 μm. Their biconcave discoid shape provides a high surface area/volume ratio enabling their extensive deformation during passage through narrow-diameter capillaries. Red cell deformability is indispensable for it to perform its basic functions. Cell deformability is a major determining factor of microvascular flow, as it affects the rate of erythrocyte entry into capillaries, which influences the pressure drop across small vessels and pressure distribution in the vascular bed, impacting microcirculatory vascular resistance.

In sickle cell disease, under deoxygenated conditions, HbS polymerization (Chapter 6) results in the formation of rigid sickled cells that have markedly reduced deformability accompanied by increases in whole blood viscosity. Ham and Castle[2] propounded the hypothesis of deoxygenation-induced increased blood viscosity resulting in a "vicious circle" of sickling. Using ektacytometry, micropipettes, the rheoscope, and nucleopore filtration, reduced red cell deformability and membrane fragility have been shown to be major determinants of the blood rheological abnormalities and hemolysis in sickle cell disease.

Oxygen Tension: In the oxygenated state, rheological and hemodynamic abnormalities of sickle red cells are attributed to higher than normal mean corpuscular hemoglobin concentration (MCHC) and the presence of irreversibly sickled cells (ISCs).[3–6] Micropipette studies have revealed that oxygenated sickle erythrocytes show an increase in both static (extensional deformation) and dynamic (rate of recovery following extensional deformation) rigidities.[7] Bulk viscosity of whole sickle cell disease blood and the rigidity of individual sickle cells are significantly influenced by their state of dehydration or increased MCHC. The static rigidity of individual sickle cells increases with decreasing O_2 tension (pO_2).[8,9] Intravital studies have shown that the hemodynamic behavior of deoxygenated sickle cell blood is dependent on pO_2 and perfusion pressure.[10–12] A decline in microvascular red blood cell velocities (Vrbc) and wall shear rates occurs at a relatively high pO_2 level of 60 mm Hg. When pO_2 is lowered to 40 mm Hg, it induces sufficient rigidity and some sickling to account for the drastic reduction in Vrbc and wall shear rates at low perfusion pressure.[12] Deoxygenation might induce arteriolar dilation, which is insufficient to overcome increased capillary resistance to deoxygenated sickle cells.[13] An issue of potential physiological importance concerns the rate of deoxygenation of sickle erythrocytes cells and how this affects HbS polymer characteristics and rheology. When subjected to gradual deoxygenation, most sickle red cells assume typical sickle shapes. This is accompanied by a steady increase in the bulk viscosity of sickle red cell suspensions during deoxygenation.[14] In contrast, rapid deoxygenation causes a high rate of homogeneous nucleation and formation of independent polymer domains resulting in granular morphology, regardless of MCHC differences among heterogeneous sickle red cells.

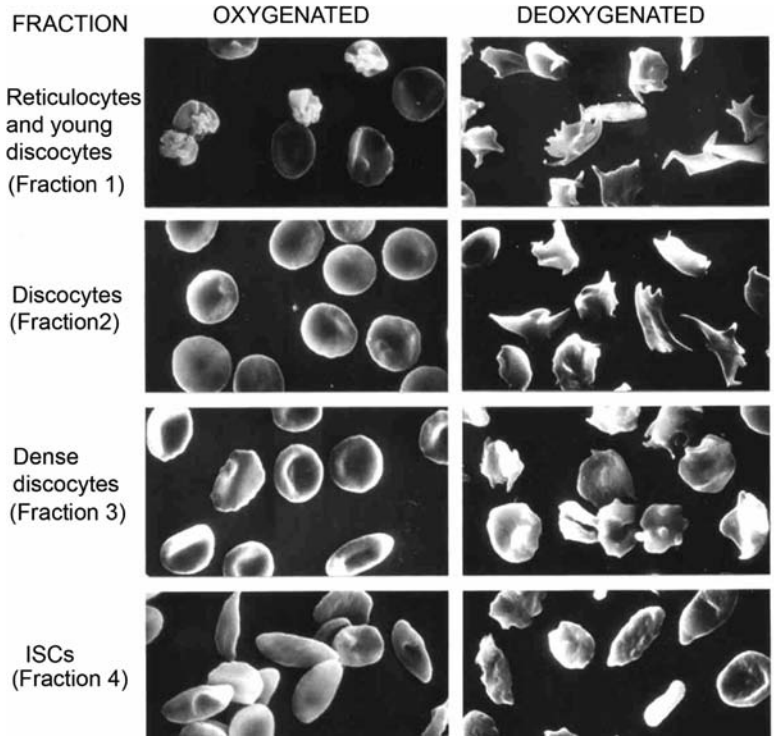

Figure 8.1. Density gradient separation of sickle cell blood reveals marked heterogeneity of red cells. Four distinct sickle red cell populations are identified. Fraction 1 is characterized by the presence of mostly reticulocytes; immature reticulocytes appear multilobulated. Fraction 2 consists of mainly discocytes that form the largest component of sickle blood and transform to typical sickled forms upon deoxygenation. Dense sickle red cells (e.g., dense discocytes and ISCs) seen in fractions 3 and 4 show minimal transformation with deoxygenation. (Modified from ref. 17.) (See color plate 8.1.)

The viscosity of rapidly deoxygenated sickle cell suspensions shows two distinct phases,[14] Following an initial rapid rise in viscosity to a peak value, in the second phase there is a significant time-dependent decrease in bulk viscosity. This phase is characterized by the appearance of elongated cells that are unlike typical sickled cells. Transmission electron microscopy shows that these cells develop long processes after prolonged deoxygenation that contain regions of aligned polymers in addition to regions of very small polymer domains or hemoglobin aggregates. This is in accordance with earlier kinetic, morphological, and ultrastructural analyses of rapidly deoxygenated sickle cells.[15] Prolonged deoxygenation would then result in elongated shape caused by growth of the aligned domains. The viscosity decrease is probably due to alignment of the elongated cells along the direction of the flow. Another study[16] concluded that it is the polymer fraction but not the cell shape that determines the filterability of deoxygenated sickle cells. This study, however, did not subject the cells to different rates of deoxygenation to produce distinct polymer domains. Thus, HbS polymer characteristics, as determined by the rate and duration of deoxygenation, could affect the microvascular flow dynamics of sickle red cells.

Sickle Red Cell Heterogeneity: Density gradient separation of sickle cell blood reveals marked heterogeneity. Red cell density is determined by MCHC. Sickle erythrocytes are bimodally distributed when centrifuged on density gradients. One major population comprised discocytic red cells with MCHC similar to normal red cells (fraction 2); the other major population was very dense (fraction 4) sickle cells and contained mainly rigid ISCs (Fig. 8.1). Light Fraction 1 cells contained a high percentage of reticulocytes. Fraction 3 was characterized by very dense and somewhat irregular shaped discocytes with high MCHC. In the gradient, the range of MCHC varied from approximately 30 g/dL for fraction 1 to more than 45 g/dL for fraction 4. Gradual deoxygenation of fraction 1 and 2 cells with low MCHC resulted in the formation of typical sickled cells and holly leaf forms; under the same deoxy conditions, hemoglobin in fraction 3 and 4 cells with high MCHC polymerized more rapidly but the cells had minimal shape changes.[17] The generation of dense sickle cells is mainly attributed to cell dehydration caused by abnormal membrane cation and water transport (Chapter 9). Homodynamic behavior of density-defined sickle erythrocytes populations, examined in an ex vivo microcirculatory preparation, showed that deoxygenation caused approximately a 10-fold increase in the vascular resistance of very dense sickle discocytes compared with oxygenated cells. The hemodynamic results indicated profound vasoocclusive behavior of dense sickle cells with deoxygenation. The observed differences in the hemodynamic behavior of deoxygenated sickle cell subpopulations reflect differences not only in the polymer characteristics but also in the extent of intracellular polymer. The abnormal viscoelastic behavior of individual deoxygenated sickle red cells correlates with the amount of intracellular polymer that is determined by MCHC.[9] Therefore, the microvascular flow of sickle cell blood will be determined by contributions from the distinct hemodynamic characteristics of heterogeneous sickle erythrocyte populations.

Factors Affecting Vascular Biology

Adhesion of sickle erythrocytes to vascular endothelial cells led to the recognition that vascular factors played an important role in the pathophysiology of sickle cell disease.[18,19] The study of vascular dysfunction in sickle cell disease has been facilitated by the discoveries of endothelial vasoactive molecules, especially nitric oxide (NO), elucidation of the role of oxidative stress, and identification of adhesion molecules expressed by activated endothelium that mediate increased red cell adhesion and inflammatory responses.

Oxidative Stress: Reperfusion injury and cell-free plasma heme are major elements in intravascular and endothelial oxidant generation (Chapter 11). The initiation, progression, and resolution of a vasoocclusive episode (Chapter 20) have features of reperfusion injury. Subclinical transient vasoocclusive events, caused by intravascular sickling and abnormal adhesion of red cells, are likely to be even more frequent than acute events recognized clinically. These "microcrises"[20] could inflict organ damage by chronic generation of reactive oxygen species (ROS). Reperfusion with the resupply of O_2 after a vasoocclusive event has a deleterious effect on vascular endothelium resulting in increased levels of superoxide ($O_2^{\cdot -}$) generated by xanthine oxidase (XO), nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase)[21,22] and "uncoupling" of endothelial nitric oxide synthase (eNOS).[23] Uncoupling is likely due to depletion of the substrate arginine and cofactor tetrahydrobiopterin (BH_4).[24] Thus, endothelium is an early and prominent, but not exclusive, target of reperfusion injury. Increased oxidant generation causes endothelial activation and dysfunction, altered responses of resistance vessels, and inflammatory effects in postcapillary venules, the site of blood cell–endothelium interactions.

Increased lipid peroxidation, and hydroxyl ($\cdot OH^-$) radical generation in transgenic sickle mice (NY1DD model; mild pathology) suggested an inflammatory state.[25] Elevated leukocyte and neutrophil counts in the peripheral circulation in transgenic sickle mice was consistent with the pro-inflammatory condition in human sickle cell disease.[26,27] Increased oxidative stress was later confirmed[28] in sickle cell disease patients and transgenic-knockout BERK mice (expressing exclusively human α- and β^S-globins; severe pathology; Chapter 12), where increased vascular $O_2^{\cdot -}$ production and elevated plasma XO activity was observed. Hypoxia/reoxygenation in NY1DD mice enhanced endothelial oxidant generation and heightened leukocyte-endothelium interactions compared with control mice. Because NY1DD mice have little hemolysis, these studies indicated that hypoxia-induced sickling was preceded by reoxygenation-induced endothelial activation, oxidant production, and leukocyte recruitment.[26,29,30]

Oxidative stress in sickle cell disease is not limited to vascular endothelium and erythrocytes. Although increased leukocyte counts in sickle cell disease and sickle transgenic mice models suggest a systemic effect of oxidative stress, direct evidence of oxidative stress in can be found in mice.[31] Homozygous sickle mice have peroxidation of membrane lipids and a depletion of antioxidants, including reduced glutathione (GSH), superoxide dismutase (SOD), catalase and glutathione peroxidase (GPx).[31] Lipid peroxidation is perhaps the most recognized biological effect of O_2 radicals that occurs when free radicals attack double bonds of unsaturated fatty acids producing peroxides. In sickle cell disease, depleted levels of antioxidants likely cause increased susceptibility to lipid peroxidation.[32,33] Lipid peroxidation causes damage to the cell membrane and membranes of cellular organelles like mitochondria. Among the best-characterized enzymatic pathways are SOD, catalase, and GPx. H_2O_2 is a potential source of $\cdot OH$, and two enzymatic oxidants, catalase and GPx, transform it to water. GPx is specific for GSH as a hydrogen donor but accepts peroxides as well as H_2O_2. During reperfusion, these endogenous defenses are likely to be ineffective as a result of overproduction of O_2 radicals. Additionally, during reperfusion, degradation and consumption of antioxidants by the release of ROS has been documented.[34] Failure to replenish antioxidants might exacerbate oxidative stress and contribute to hemolysis and multiple organ damage in sickle cell disease.

GSH levels in muscle, kidney, and liver are higher in BERK mice compared with NY1DD mice but are significantly lower when compared with wild-type controls.[31] This could represent a protective response to a greater oxidative stress caused by recurring ischemia-reperfusion events, increased amounts of inflammatory cytokines, and higher levels of protein nitration.[35] Induction of mitochondrial peroxynitrite ($ONOO^-$) can also induce GSH synthesis[36] and BERK mice have increased nitrotyrosine (nitration of tyrosine residues by $ONOO^-$) levels.[35] This might be a result of the initial higher production of NO followed by consumption of NO by O_2 radicals and plasma heme that leads to increased depletion of arginine.[37,38] In idiopathic pulmonary arterial hypertension, GSH content in bronchoalveolar lavage fluid is increased, probably as an adaptive response to increased oxidant generation in the inflamed lungs.[39] The reported reduction in cellular GSH in sickle cell disease could be in response to oxidative stress, vasoocclusion, and hemolysis.[40,41] Decreased GSH and glutamine have been associated with compromised red cell integrity, hemolysis, and reduced NO bioavailability, all factors that might contribute to the pathogenesis of pulmonary hypertension in sickle cell disease.[23,42] Arginine supplementation of BERK mice significantly elevated NO metabolites accompanied by enhanced GSH and reduced lipid peroxidation,[31] further suggesting a role for NO bioavailability in modulating oxidative stress.

Endothelial Activation: Endothelial injury and activation is a prominent feature of sickle cell disease.[43,118] This is likely to be the result of reperfusion injury and oxidative stress (Chapter 11). Even under normoxic conditions, transgenic sickle mice show endothelial expression of P-selectin[44] and greater leukocyte rolling compared with wild-type mice, indicating activated endothelium.[26] Greater leukocyte recruitment caused by transient reperfusion injury in transgenic sickle mice is ameliorated by antibodies to P-selectin.[26] Similarly, P-selectin knockout mice transplanted with bone marrow from BERK mice showed absence of an inflammatory response.[45]

Endothelial oxidant generation can lead to increased peroxidation and up-regulation of the redox-sensitive transcription factor nuclear factor (NF)-κB that can activate genes for intercellular adhesion molecule-1 (ICAM-1),

vascular cell adhesion molecule-1 (VCAM-1), and E-selectin.[46] Similarly, transgenic sickle mouse models show up-regulation of these markers of endothelial activation.[29,47,48] Another source of endothelial injury is ROS generated by sickle erythrocytes due to the presence of unstable HbS and spontaneous autoxidation of heme iron.[49] Furthermore, elevated levels of inflammatory cytokines such as tumor necrosis factor-α (TNFα), interleukin-1β, and platelet-activating factor (PAF) induce up-regulation of endothelial adhesion molecules like VCAM-1, E-selectin, and ICAM-1, probably via endothelial oxidant generation and activation of NF-κB.[50,51]

Sickle cell disease patients have increased numbers of circulating endothelial cells.[52,53] Endothelial damage and detachment are also present following reperfusion injury in other ischemic diseases.[54] The activated phenotype of circulating endothelial cells in sickle cell disease is suggested by increased expression of cell adhesion markers and up-regulation of αVβ3 integrin[53] that have a pivotal role in sickle cell–endothelium adhesion. These data suggest the endothelium in sickle cell disease is likely to be in a perpetually activated state. Inflammatory cytokines, oxidant generation, and up-regulation of endothelial adhesive molecules might influence not only adhesion of leukocytes and sickle red cells but also potentially influence platelet activation and aggregation.

Sickle Red Cell Adhesion

Among multiple pathologies, sickle erythrocyte–endothelial interaction has been implicated as a potential initiating mechanism in vasoocclusion. In the microcirculation, sickle red cell adhesion can potentially prolong capillary transit time, promote hypoxia, and initiate sickling as suggested by higher peripheral resistance following enhanced sickle red cell adhesion.[55] Sickle red cell adhesion involves contributions from erythrocyte, plasma, and microvascular elements. These include red cell heterogeneity, deformability and adhesion molecules, oxidant radical generation, endothelial activation, and multiple vascular adhesion molecules.

Static incubation assays showed that sickle red cells adhere abnormally to endothelial monolayers and suggests that this mechanism contributes to vasoocclusion.[18,56] Studies using a parallel plate flow chamber showed sickle cell adhesion under controlled flow conditions at a low shear stress (1 dyne/cm^2).[57] In contrast to greatest adhesion of most dense sickle cells in static assays, flow studies showed that the greatest adhesion was exhibited by cells from the least dense fraction, the reticulocytes. Similar results were found with respect to adhesion of ISCs, but irregular, deformable dense discocytes were more adhesive.[58] The reduced adhesivity of dense sickle red cells in shear flow conditions could be due in part to their inability to deform to establish sufficient areas of contact with endothelial cell surface. Controlled dehydration of deformable discocytes, using Nystatin-sucrose to increase their density, rendered them less adherent; rehydration of dense red cells increased their adhesivity.[59] Cell dehydration might also alter the conformation of the red cell surface receptors.

Using a more physiological ex vivo microcirculatory preparation, postcapillary venules were identified as the exclusive sites of sickle cell adhesion in the microcirculation (Fig. 8.2A-D)[60] Adhesion was inversely correlated with vessel diameter (Fig. 8.2D) where smaller-diameter immediate postcapillary venules showed maximal adhesion[60] and were frequent sites of vasoocclusion when a pro-adhesive stimulus was applied.[61] Maximal adhesion was observed at vessel bending and vascular junctions (Fig. 8.2C). The relationship between sickle red cell adhesion and the venular diameter was recently confirmed.[62] In the ex vivo experiments, selective fluorescent labeling allowed identification of a given density sickle red cell class in a defined mixture of two cell classes. When a bolus of defined mixture was infused, the resulting adhesion of sickle red cells was density-class dependent in the following order; reticulocytes and young discocytes > discocytes > dense discocytes and ISCs. Dense sickle red cells contributed maximally to microvascular obstruction, as shown by their selective trapping in postcapillary venules in which deformable light-density sickle red cells preferentially adhered.

Sickle cell adhesion has been confirmed using a variety of assay systems.[58,60,63,64] Studies using the cremaster muscle microcirculation of transgenic sickle mice expressing HbS and HbS-Antilles (S+S-Antilles) confirmed venules as the exclusive sites of red cell adhesion in vivo.[65] In contrast to S+S-Antilles mice, red cell adhesion is less obvious in BERK mice. In studies of C57BL mice transplanted with BERK marrow, adhesion was not observed, although transient interactions between leukocytes and red cells were noted.[45] In contrast to S+S-Antilles mice, BERK mice have fewer dense red cells and have erythrocyte features of β thalassemia, with microcytic red cells having reduced mean cell hemoglobin.[66] BERK mice, however, have erythrocytes that sickle, hemolyse and undergo oxidative stress. These mice are more suitable for studying the role of hemolysis and inflammation than sickle cell adhesion and illustrate the imperfection of sickle mice and that different sickle mouse strains must be used for understanding different features of this disease (Chapter 12).

Mechanisms of Sickle Red Cell Adhesion

Sickle erythrocytes adhere to endothelium by multiple mechanisms via adhesion molecules expressed on both sickle red cells and endothelium. Although repeated sickling–unsickling cycles result in red cell membrane damage and exposure of red cell membrane components like sulfated glycolipids and phosphatidylserine (PS) that might mediate adhesion, increased red cell destruction results

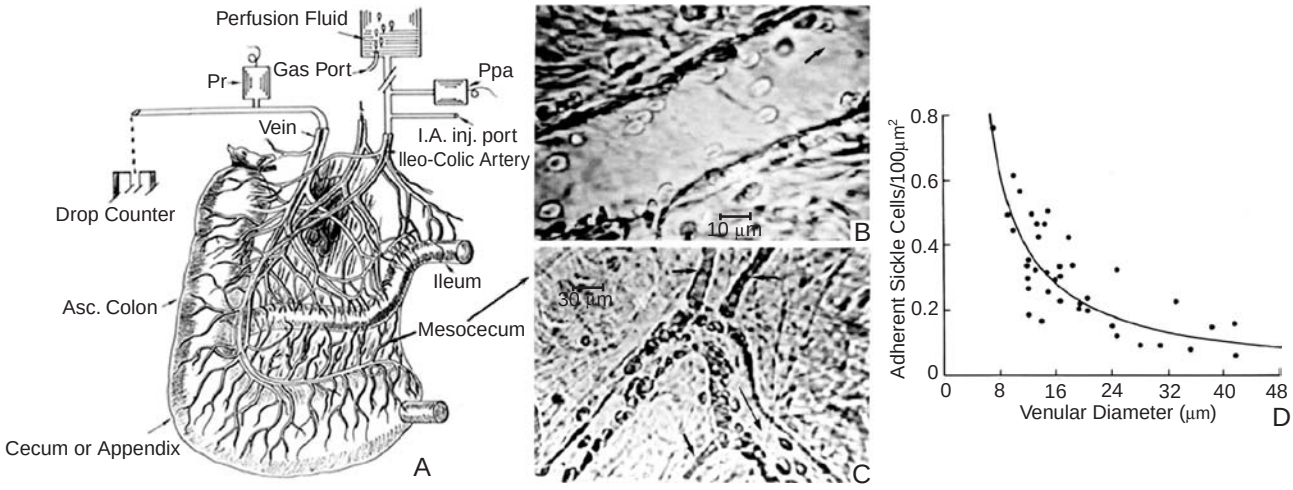

Figure 8.2. Adhesion of sickle red cells in venules of the ex vivo mesocecum vasculature infused with a bolus of human sickle red cells during perfusion with Ringers albumin. **(A)** Artificially perfused mesocecum preparation of the rat (Asc. Colon, ascending colon; I.A. inj. port, arterial injection port; Ppa, arterial perfusion pressure; and Pv, venous outflow pressure). **(B)** Adherent sickle red cells of discocyte morphology are seen deformed in the direction of the flow (arrow). **(C)** Increased adhesion of sickle red cells at venular bending and at junctions of small-diameter immediate postcapillary venules. In this instance, the immediate postcapillary venules are completely blocked (arrows). **(D)** The inverse relationship between vessel diameter and sickle red cell adhesion in venules of the ex vivo mesocecum vasculature. The regression fits the equation $y = aX^{-b}$, $r = -0.81$, $P < 0.001$). (Modified from ref. 60.) (See color plate 8.2.)

in excessive production of stress reticulocytes that display adhesion molecules.

The adhesion molecules implicated in sickle red cell adhesion are broadly categorized as 1) red cell receptors; 2) adhesive bridging proteins; 3) endothelial adhesion molecules; 4) extracellular matrix adhesion molecules (Fig. 8.3).

Red Cell Receptors: Two subcategories of receptors have been recognized in sickle erythrocytes. The first consists of receptors that are expressed on stress sickle reticulocytes. Two well-characterized receptors on reticulocytes are very-late-activation-antigen-4 (VLA-4/$\alpha_4\beta_1$) and CD36.[63,67,68] The integrin $\alpha_4\beta_1$ binds its endothelial ligand VCAM-1.

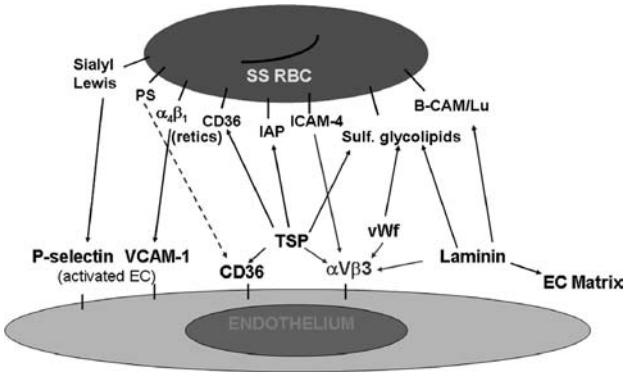

Figure 8.3. Schematic representation of adhesion molecules involved in sickle red cell–endothelium interactions. B-CAM/Lu = basal cell adhesion molecule/Lutheran; EC matrix = extracellular (subendothelial) matrix; IAP = integrin-associated protein; ICAM-4 = intercellular adhesion molecule-4; and Sulf. Glycolipids = sulfated glycolipids.

VCAM-1 is not constitutively expressed on endothelium but can be induced by cytokines or hypoxia.[67,69] Importantly, VCAM-1 interactions with $\alpha_4\beta_1$ are enhanced under hypoxic conditions, and this interaction might play an important role in sickle acute chest syndrome, which is characterized by infiltration and retention of sickle red cells into the lung microcirculation.[70,71] CD36 interacts with soluble thrombospondin (TSP), an adhesive bridging protein.[68] Plausibly, CD36-expressing reticulocytes could also interact with endothelial αVβ3 integrin receptor via soluble TSP. Exposed membrane sulfated glycolipids could facilitate sickle red cell interaction with von Willebrand factor (vWF), an endothelial ultra-large-molecular weight protein and TSP, contributing to sickle cell–endothelium adhesion.[72,73]

The second subcategory of receptors includes more recently described molecules that are activated by signal transduction. Activation of integrin-associated protein (IAP/CD47) on sickle erythrocytes can induce signal transduction to activate still unidentified red cell receptors for TSP.[74] A receptor, intercellular adhesion molecule-4 (ICAM-4 (Landsteiner–Weiner protein or CD 242) has been identified on sickle erythrocytes, which can mediate adhesion by binding endothelial αvβ3 integrin.[75] Activation of ICAM-4 by the physiological stress mediator epinephrine enhances sickle red cell adhesion. The epinephrine-induced activation of ICAM-4 involves a cyclic adenosine monophosphate–dependent signaling pathway, probably via stimulation of the red cell β-adrenergic receptor.[75] Previous studies have ascribed a role of cyclic adenosine monophosphate–dependent pathways in sickle

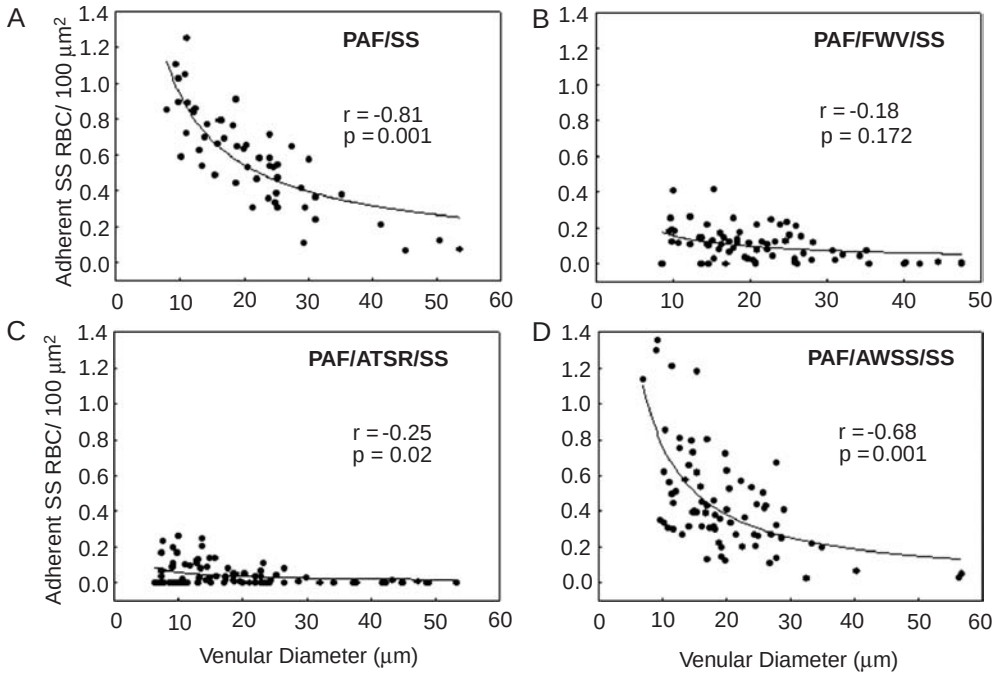

Figure 8.4. Regression plots for the number of adherent sickle red cells (SS RBC)/100 μm^2 relative to venular diameters in ex vivo preparations treated as follows: **(A)** PAF alone, **(B)** PAF and peptide FWV, **(C)** PAF and peptide ATSR, and **(D)** PAF and control peptide AWSS. The regression lines represent the multiplicative equation of the form $Y = aX^{-b}$ for the best fit. In preparations treated with PAF alone, adhesion of sickle erythrocytes showed a strong correlation with the venular diameter. Preparations treated with peptide FWV or ATSR showed a marked inhibition of sickle erythrocyte adhesion in venules of all diameters, with ATSR having the maximal inhibitory effect, especially in small-diameter venules, the sites of frequent blockage. In contrast, in the presence of the control peptide AWSS, the resulting adhesion was essentially similar to that observed in PAF-treated preparations. (Modified from ref. 61.)

red cell adhesion wherein epinephrine-induced activation of basal cell adhesion molecule/Lutheran (B-CAM/Lu) increased adhesion to immobilized laminin, an extracellular matrix molecule.[76] Although epinephrine can activate both B-CAM/Lu and ICAM-4 in sickle red cells, the latter is specifically involved in adhesion to endothelial cells, as antibodies to B-CAM/Lu and laminin are ineffective in the ICAM-4–mediated interactions.[75] Epinephrine enhances sickle cell adhesion to the extracellular matrix via B-CAM/LU and laminin and to endothelium via ICAM-4 and αVβ3, suggesting a role for physiological stress in vasoocclusion. Among the ICAM-4 family of adhesive proteins, ICAM-4 is unique in its expression on erythroid cells. ICAM-4 can bind diverse arrays of integrins including several αV integrins, β2 integrins expressed on leukocytes and α4β1 integrin,[77,78] suggesting multiple functions of this adhesion molecule. Although exposed PS might mediate adhesion,[79] the tenacity of this interaction has not been evaluated.

Adhesive Bridging Proteins: Adhesive proteins released by platelet and vascular endothelium are implicated in sickle red cell adhesion. Unusually large molecular weight forms of vWf and soluble TSP are known to enhance adhesion of sickle red cells to endothelium.[80,81] Soluble TSP is likely to contribute to adhesion of sickle red cells via its C-terminal cell-binding domain.[82] TSP and vWf, both present in platelets and endothelial cells, can be released into the local environment under appropriate stimulation.[83] Elevated levels of both these adhesive bridging proteins have been identified in the plasma of patients with sickle cell disease.[68,84,85] vWf and TSP can act as bridging proteins because they can bind specific red cell receptors and endothelial αVβ3 integrin. Inhibition of sickle erythrocyte adhesion to TSP by vWf involved the use of plasma vWf that lacked the extra-large molecular weight forms of vWf released by endothelial cells and were implicated in sickle red cell adhesion.[86]

Endothelial Adhesion Molecules: Among the most prominent endothelial adhesion molecules, in addition to TSP and vWf, are P-selectin, CD36, and integrin αVβ3. P-selectin is expressed in activated endothelial cells in transgenic mouse models of sickle cell disease. P-selectin might facilitate a weak adhesion via interaction with red cell sialyl Lewis moieties.[87] P-selectin–mediated transient interaction could affect local wall shear rates followed by a more tenacious adhesion via high affinity adhesion mechanisms. Antibodies to P-selectin can partially inhibit sickle red cell adhesion to human endothelial cells in a flow system.[88] Moreover, P-selectin–mediated sickle red cell adhesion was inhibited by unfractionated heparin. Heparin and other anionic polysaccharides can inhibit TSP-mediated adhesion of sickle cells in the ex vivo mesocecum preparation,

and in human endothelial cells under flow conditions,[72] suggesting that an inhibitory effect of anionic polysaccharides is not limited to P-selectin–mediated adhesion. An agonist peptide for murine protease–activated receptor-1 (PARS-1), which selectively activates mouse endothelial cells, but not platelets, resulted in flow stoppage of infused BERK sickle red cells in the microcirculation, an effect not observed in P-selectin knockout mice.[89] The contribution of leukocytes, however, was not confirmed. Moreover, the endothelial activation by murine protease–activated receptor-1 could concomitantly release vWF as both P-selectin and vWf are stored in endothelial Weibel–Palade bodies. Additional studies are needed to clarify the relative roles of P-selectin and extra-large forms of endothelial vWF in sickle red cell adhesion.

CD36, an 88-kD protein, is expressed by microvascular endothelial cells[90] in addition to platelets and sickle reticulocytes. CD36 has been implicated as a ligand to the exposed PS on sickle red cells.[79] Moreover, endothelial CD36 can interact with soluble TSP to promote TSP-mediated adhesion.

The vitronectin receptor, αVβ3 integrin, expressed on activated endothelium, is likely to play an important role in stable sickle red cell adhesion. αVβ3 integrin can interact with several adhesive bridging proteins (TSP, vWf, and possibly soluble laminin),[85,91,92] and also with ICAM-4 (a receptor for αVβ3) on sickle red cells.[75] Antibodies directed against this integrin can dramatically inhibit sickle red cell adhesion in the ex vivo mesocecum preparation[83] and to human endothelial cells.[75] Peptides (ATSR and FWV) based on αV-binding domains of ICAM-4 markedly decreased sickle cell adhesion and vasoocclusion in the PAF-treated ex vivo mesocecum vasculature under shear flow conditions[61] (Fig. 8.4A-D). PAF is a potent endothelial activating and inflammatory agent that is elevated in sickle cell disease.[93] The infused fluoresceinated ATSR peptide is colocalized with vascular endothelium and pretreatment with function-blocking antibody (7E3) to αVβ3 markedly inhibited this interaction (Fig. 8.5). These studies show that ICAM-4 on sickle red cells binds endothelium via αVβ3 and that this interaction contributes to vasoocclusion, suggesting that peptides or small molecules based on αV-binding domains of ICAM-4 might have a therapeutic potential. Moreover, small-molecule cyclic αVβ3 antagonists containing the integrin recognition motif RGD are potent inhibitors of sickle cell adhesion.[94] Because of its ability to bind several adhesive proteins, αVβ3 is a potential target in designing antiadhesive therapies.[95] In addition to direct interaction between red cell ICAM-4 and endothelial αVβ3 integrin, possible formation of tripartite complexes involving the red cell receptor, adhesive protein, and endothelial receptor with αVβ3 might contribute to sickle red cell adhesion (Fig. 8.6),

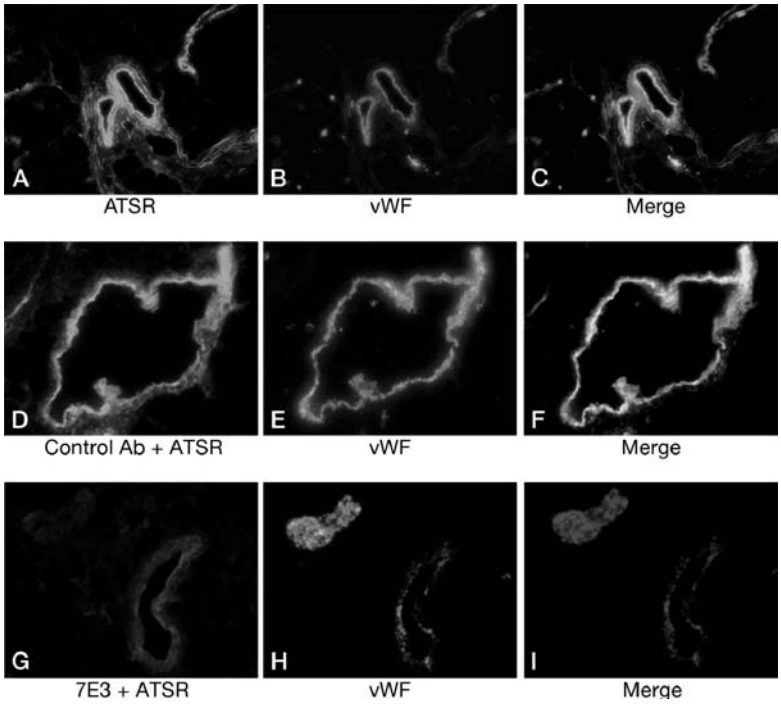

Figure 8.5. Top panel: Colocalization of fluoresceinated ATSR peptide with vascular endothelium of the ex vivo mesocecum preparation pretreated with PAF **(A–C)**. **(A)** The presence of the fluorescent peptide is shown in green. **(B)** Blood vessels were identified by a polyclonal primary antibody to vWF and a secondary TRITC-conjugated antibody (red). **(C)** Merged image signals showed colocalization (yellow) of ATSR with the endothelial lining. Middle panel: The effect of a control antibody OC125 **(D–F)** on the colocalization of fluoresceinated ATSR peptide with vascular endothelium of PAF-treated ex vivo preparation. **(D)** The presence of the fluorescent peptide is shown in green. **(E)** Blood vessels were identified by a polyclonal antibody to vWF as in **B** (red). **(F)** Merged image signals showed colocalization (yellow) of ATSR with the vessel wall. Bottom panel: The effect of 7E3 antibody to αVβ3 **(G–I)** on the colocalization of fluoresceinated ATSR peptide with vascular endothelium in PAF-treated ex vivo preparation. **(G)** In the presence of 7E3 antibody, there was a marked decrease in ATSR localization with the vessel wall. ATSR infusion resulted in weak green staining likely attributable to autofluorescence or a low level of binding of ATSR peptide. **(H)** Vessel was identified by immunofluorescent staining for vWF (red). **(I)** No colocalization of ATSR with vessel wall in the presence of 7E3. (Modified from ref. 61.) (See color plate 8.5.)

for example, CD36-TSP-αVβ3, IAP-TSP-αVβ3, sulfated glycolipids-TSP-αVβ3, and sulfated glycolipids-vWF-αVβ3.

Endothelial oxidant generation induced by elevated inflammatory stimuli and intermittent vasoocclusion events will cause endothelial activation and up-regulation of adhesion molecules, particularly αVβ3. PAF-induced endothelial oxidant generation resulted in markedly enhanced sickle red cell adhesion to vascular endothelium, which was abrogated by SOD and catalase.[55]

The Effect of Hydroxyurea and NO on Adhesion: One therapeutic approach to treat sickle cell disease is to increase fetal hemoglobin (HbF) concentration (Chapter 30).[96,97] An inverse relationship exists between CD36-positive reticulocytes and F cells[98] and patients with higher levels of F cells have fewer adherent cells. Hydroxyurea decreases red cell adhesion and down-regulates endothelial adhesion molecules such as sVCAM-1 and sICAM-1.[99,100] Hydroxyurea is an NO donor and by the activation of soluble guanylate cyclase (cGMP) might induce HbF expression.[101] NO generation by hydroxyurea could be a critical factor for its reported antiinflammatory action and down-regulation of endothelial adhesion molecules such as sVCAM-1 and sICAM-1.[99] Sickle cell adhesion to TNFα-treated endothelial monolayers is markedly inhibited by the NO donor DETA-NO.[102] The relative roles of HbF and NO in the therapeutic efficacy of hydroxyurea have yet to be clarified.

Extracellular Matrix Adhesion Molecules: Indirect evidence indicates the potential exposure of subendothelial matrix of the vascular intima where endothelial cell damage and detachment occurs, probably due to rheological insult and adhesion of sickle cells. Endothelial detachment is probably exemplified by the presence of circulating endothelial cells.[52,53] Matrix proteins, including TSP, vWf, and laminin have been implicated in sickle cell adhesion (Fig. 8.7). Such interactions could be relevant to the pathophysiology of this disease but might not represent a generalized phenomenon.

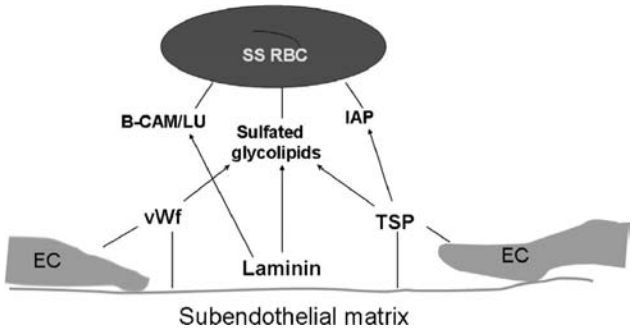

Figure 8.7. Schematic representation of matrix adhesive proteins involved in potential adhesion of sickle red cells to extracellular (subendothelial) matrix.

Pathophysiological Implications of Sickle Erythrocyte Adhesive Interactions

Sickle red cell adhesion in postcapillary venules increases microvascular transit times, induces hypoxia, and promotes HbS polymerization in the adherent and trapped cells, as shown by direct intravital microscopy and by increased peripheral resistance caused by sickle red cell adhesion.[55,61] It was proposed that sickle red cell adhesion–induced vasoocclusion is a two-step process in which preferential adhesion of deformable, light-density cells in postcapillary venules is followed by reduced effective lumen diameter and selective trapping of dense cells causing vessel blockage.[60,103] Dense cell trapping permits rapid HbS polymerization due to the high MCHC of these cells. Postcapillary obstruction might proceed to involve whole feeding capillary networks in a retrograde fashion.[104–107] The obstructive behavior of dense sickle red cells has also been shown in a perfused rat leg model[108] corroborating findings in the ex vivo mesocecum. That obstruction results in a disproportionate trapping of dense sickle red cells was suggested by the analysis of cells eluted in venous effluents under high perfusion pressure.[109] Selective trapping of dense cells might occur during the evolution of the acute painful episode (Chapter 20). Following an initial increase in the circulating dense cells at the onset of the acute painful event,[111] an observation explained by the sequestration of deformable light-density sickle red cells as they interact with endothelium, the highest density fraction of sickle erythrocytes disappears from the peripheral circulation during the course of the event. Together, these observations support the proposed two-step model of sickle vasoocclusion.[110]

Sickle Red Cell Adhesion and the Endothelial Response

Sickle cell adhesion and intravascular sickling are likely to contribute not only to endothelial damage and up-regulation of vasoactive molecules such as prostaglandins and endothelin-1 (ET-1)[112] but also to up-regulation of adhesion molecules involved in blood cell–endothelium interactions.[27] In vitro studies have shown that sickle cell contact and adhesion to cultured endothelial cells can inhibit endothelial DNA synthesis, increase ET-1 mRNA,[113] impair NO synthesis,[114] and stimulate arachidonic acid metabolism and prostacyclin release[115,116] and up-regulate expression of endothelial adhesion molecules.[46] Adhesion might promote release of hemoglobin and adenosine diphosphate. Damaged endothelium also releases adenosine diphosphate,[117] a potent platelet activator that causes aggregation. Although of potential importance, the significance of these observations remains to be validated in the context of pathophysiology of sickle cell disease.[46,118,119]

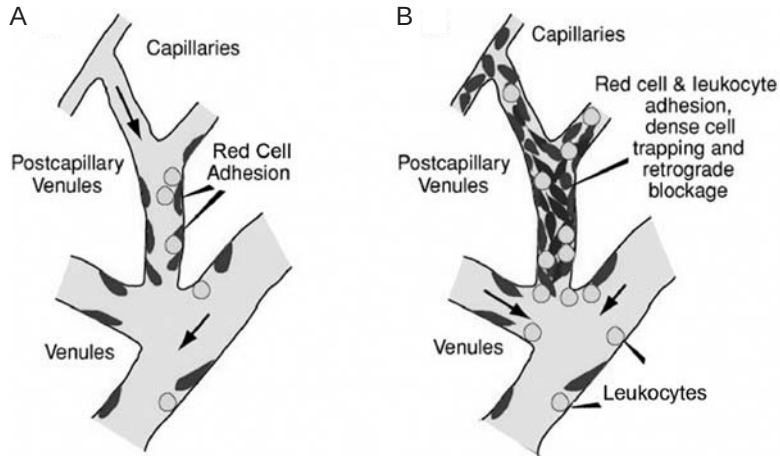

Figure 8.8. A model for vasoocclusion in sickle cell disease. **(A)** Adhesion of deformable sickle red cells and leukocytes (light colored) in postcapillary venules. **(B)** Adhesion of these cells is followed by reduction in local wall shear rates and selective trapping of dense sickle red cells, which could result in HbS polymerization in the trapped (dark red) and adhered sickle cells and obstruction of the affected vessels. (See color plate 8.8.)

Leukocytes and Vasoocclusion

Neutrophils are increased in the peripheral circulation of most patients with sickle cell anemia and could be an important factor modulating microvascular flow.[120,121] Because neutrophils are relatively large and less deformable than erythrocytes, an increase in their numbers, activation and recruitment to sites of injury will increase intravascular resistance and adversely affect microvascular flow.[122,123] Increases numbers of neutrophils might increase red cell transit time and impair O_2 delivery. In vivo studies have shown that microcirculatory flow is significantly influenced not only by sickle erythrocytes but also by increased leukocyte recruitment due to reperfusion injury and oxidant generation. In transgenic sickle mice, hypoxia/reoxygenation generated by transient occlusion might induce an inflammatory endothelial phenotype resulting in increased leukocyte–endothelium interactions.[26] When bone marrow from BERK mice was transplanted into C57BL mice, adherent leukocytes facilitated mechanical trapping of elongated sickled red cells in venules.[45] This log jamming of sickled red cells among adherent leukocytes was similar to the pattern of dense cell and ISC trapping among adherent sickle erythrocytes.[60] These observations suggest that both erythrocyte and leukocyte adhesion to endothelium can help entrap sickled or dense red cells, potentially initiating vasoocclusion (Fig. 8.8).

The results from C57BL mice that underwent BERK mouse bone marrow transplantation were used to further address the role of leukocytes in sickle vasoocclusion.[124] Pretreatment with intravenous human gamma globulin (IVIG) followed by an inflammatory stimulus by using TNFα caused a significant reduction in leukocyte recruitment and associated red cell trapping in recipient mice. Pretreating the BERK marrow recipient C57BL mice with TNFα followed by IVIG administration reversed TNFα-induced vasoocclusion.[125] These studies suggested a role for IVIG for treatment of acute painful episode, nevertheless, the underlying mechanism(s) of IVIG action are unresolved.

Vascular Function

Vascular tone adaptations in sickle cell disease are a response to hemolytic anemia, intravascular sickling, and vasoocclusive events, all of which can contribute to tissue hypoxia. Subclinical transient vasoocclusive events or "microcrises" triggered by intravascular sickling and cell adhesion not only contribute to an inflammatory state and local tissue hypoxia, but are likely to cause endothelial dysfunction as reported for other inflammatory diseases.[35] Chronic anemia is compensated for by hyperperfusion to maintain O_2 delivery.[126,127] Hyperperfusion is not limited to large conduit arteries but is also observed in the microcirculation of transgenic knockout sickle mice as a consequence of arteriolar dilation.[35] In sickle cell disease and transgenic knockout sickle mice, relatively reduced systemic blood pressure[35,128] is a likely consequence of the dilation of resistance arterioles. In patients, vasodilation and reduced blood pressure are associated with a 50%–60% decrease in the peripheral resistance.[126]

Vascular Tone Response to Red Cell Rheology: Abnormal rheology of sickle red cells might require appropriate adjustments in the vascular tone to facilitate their capillary passage. Increased intravascular pressure caused by less deformable sickle red cells could potentially trigger an oscillatory vasomotion pattern, or intermittent periodic flow, to facilitate microvascular passage of rheologically abnormal sickle cell blood.[129,130] Vasomotor response is depressed following postocclusive hyperemia.[130]

The effect of red cell rheology on vascular tone was studied in transgenic sickle mice exposed to different levels of oxygenation.[65] Experiments performed to determine the effect of local, transient hyperoxia revealed striking differences in the microvascular responses in control and

transgenic sickle mice. In S+S-Antilles transgenic sickle mice, Vrbc was significantly reduced under hypoxic conditions with pO_2 of 15–20 mm Hg, consistent with increased viscosity due to in vivo HbS polymer formation. During transient hyperoxia, an altered microvascular tone and response was observed. In control animals, O_2 caused approximately 70% arteriolar constriction, accompanied by 75% reduction in Vrbc. In contrast, in transgenic sickle mice, hyperoxia resulted in only an 8% decrease in the arteriolar diameter and a 70% increase in Vrbc. The altered response in transgenic mice to hyperoxia was probably due to an improved flow behavior of red cells as a consequence of HbS depolymerization and cell unsickling, although possibly intrinsic or acquired differences in the endothelial/vascular smooth muscle might also contribute to this response. This attenuated response to O_2 was later validated in patients who showed a considerably smaller decrease in the brachial artery diameter when exposed to 100% O_2.[127]

NO Bioavailability, Non-NO Vasodilators and Vascular Reactivity: Vascular function in sickle cell disease has been facilitated by recent studies of NO bioavailability.[23,26,28,38,131] Reduced NO bioavailability in patients and in transgenic sickle mice,[35,132,133] results in vascular tone adaptations and attenuated vascular responses to NO-mediated stimuli.

The biological functions of NO are discussed in detail in Chapters 10 and 11. NO has diverse biological functions and its altered metabolism is a feature of many diseases.[31,131,134–136] NO consumption by plasma hemoglobin and O_2 radicals potentially results in excess consumption of arginine substrate by eNOS to compensate for reduced NO availability. In both patients and sickle mouse models, the evidence shows depleted levels of L-arginine and NO metabolites (NOx).[37,137–142]

NO depletion attenuates vascular reactivity to NO-mediated vasodilators and NOS antagonists in transgenic sickle mice[35,143,144] and in patients with high plasma hemoglobin levels.[145,146] Impaired NO bioavailability is suggested by attenuated vascular reactivity in sickle mouse models to endothelium-dependent vasodilators like acetylcholine (ACh), and in particular to sodium nitroprusside (SNP), a NO donor.[28,35,143,144] Reduced flow-mediated vasodilation in sickle cell disease patients also suggests reduced bioavailability of NO.[133,146] Nevertheless, plethysmographic measurements of the forearm flow in patients show an increased blood flow greater or an enhanced vasodilatory response to ACh compared with normal individuals.[127,146] This response to ACh might imply up-regulation of non-NO vasodilators because ACh augments the release of NO, prostaglandins and endothelium hyperpolarizing factors.[146] Interestingly, responses to both ACh and SNP are reduced in men but not women with sickle cell disease,[146] suggesting sex differences in NO bioavailability.

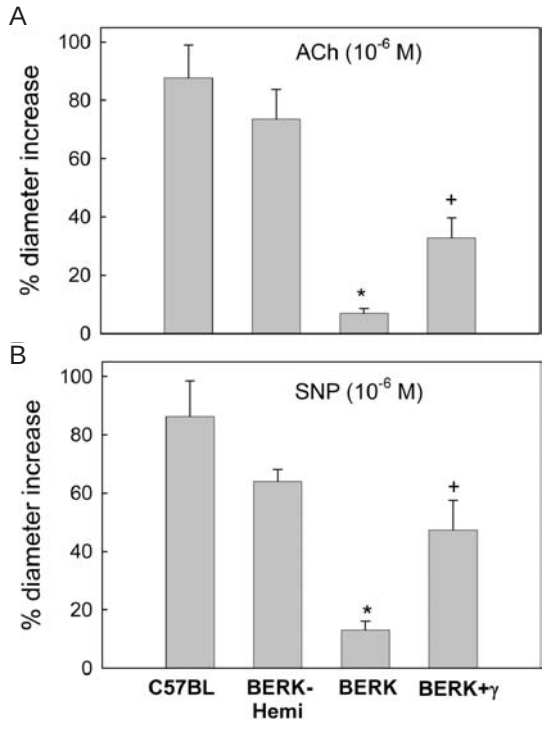

Figure 8.9. Arteriolar diameter (percentage of increase) responses to topical application of acetylcholine (ACh, 10^{-6} M) and sodium nitroprusside (SNP, 10^{-6} M) in C57BL, BERK-trait, BERK, and BERK+γ mice. Note the blunted response of arterioles in BERK mice to ACh **(A)** and SNP **(B)**. ACh and SNP caused significant increases in arteriolar diameters of BERK+γ mice as compared with that in BERK mice (~33% and ~50% increases, respectively). $^{*}P <$ 0.005–0.000001 compared with C57BL and BERK-trait mice. $^{+}P <$ 0.00–0.002 compared with the diameter increase in BERK mice. (Reproduced with permission from ref. 35.)

Because vascular resistance to blood flow is determined mainly by the vascular tone of arterioles, BERK mice were used to determine the role of NO and non-NO-related mechanisms in affecting the arteriolar tone.[35] Arteriolar responses to NO-mediated vasoactive stimuli such as ACh and SNP were attenuated in BERK mice compared with C57BL and hemizygous BERK (BERK-Hemi) controls (Fig. 8.9). N^G-nitro-L-arginine methyl ester (L-NAME) had no appreciable effect on blood pressure in these mice. Almost complete attenuation of arteriolar dilation to SNP, reflected inactivation and/or destruction of NO. As shown in Figure 8.10B, the arteriolar diameter response to SNP is strongly correlated with hemolytic rate. This observation is consistent with the ability of plasma heme to consume NO (Fig. 8.10A).[38] The greater plasma heme level in BERK mice caused blunted vessel diameter response. In contrast, the low plasma heme levels in control mice were associated with maximal arteriolar dilation. BERK-Hemi and BERK mice expressing 20% HbF that had intermediate levels of plasma heme showed improved vessel diameter response to SNP. Sickle cell disease patients have a diminished response to SNP.[38] The BERK model differs markedly from ischemic coronary artery disease, which is

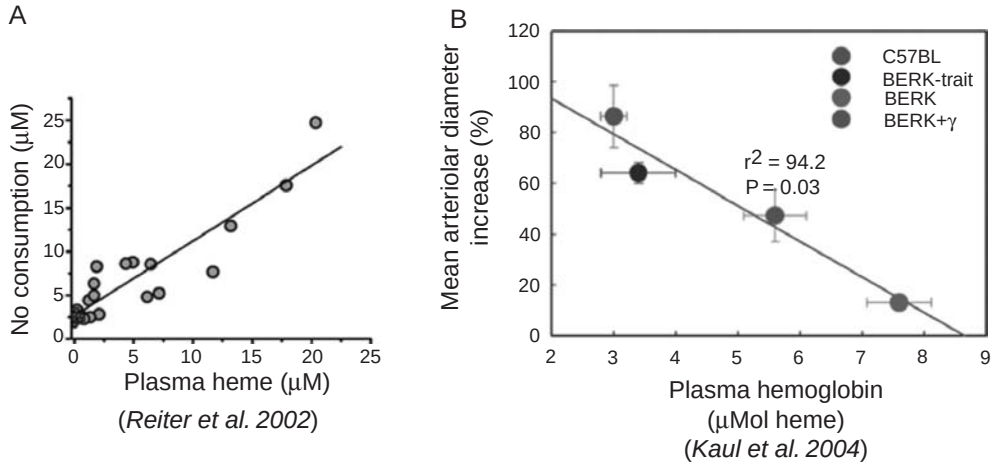

Figure 8.10. Plasma heme and its effect on NO consumption and microvascular response to sodium nitroprusside (SNP). **(A)** Heme concentration within plasma of sickle cell disease patients shows a significant correlation with NO consumption ($r = 0.9$, $P < 0.0001$). **(B)** Relationship between plasma heme levels and the arteriolar diameter response to SNP in the cremaster microcirculation of C57BL (control), BERK, BERK-trait, and BERK+γ mice. A strong correlation is observed between the percent arteriolar diameter increase in response to SNP and the extent of hemolysis (plasma heme). With a greater hemolysis in sickle (BERK) mice the diameter response was blunted. Low plasma heme levels in controls were associated with maximal arteriolar dilation, whereas BERK mice expressing 20% HbF showed a lower plasma heme and an improved diameter response compared with BERK mice. (**A** is reproduced from ref. 38 by permission, and **B** is based on the published data in ref. 61.)

characterized by blunted responses to L-N^G-monomethyl arginine but normal responses to SNP.[54]

BERK mice have more than a 2.5-fold increase in the plasma hemoglobin compared with control mice.[35] They have an increase in the endothelial-bound XO,[28] which might catalyze the increased generation of $O_2^{\cdot -}$ and H_2O_2, altering the vascular response to NO-mediated vasodilators. Increased $O_2^{\cdot -}$ generation will consume NO forming $ONOO^-$, resulting in the increased formation of nitrotyrosine.[35] Additional studies are needed to differentiate the relative contributions of oxidative stress and cell-free plasma hemoglobin in NO consumption and sickle vasculopathy.

With chronic hypoxia and hemolysis, induction of non-NO vasodilators such as prostaglandins and heme oxygenase-1 (HO-1) could compensate for reduced NO bioavailability.[131,146] HO-1, also a marker of hemolysis, catalyzes degradation of excess heme to produce carbon monoxide, a vasodilator. Also, elevated levels of cyclic guanosine monophosphate caused by HO-1 induction[144] in response to excess plasma heme could contribute to the blunted effect of SNP in BERK mice. The second non-NO vasodilator enzyme, cyclooxygenase-2 (COX-2), is induced under the conditions of chronic hypoxia and oxidative stress. $ONOO^-$ has been implicated in the induction of COX-2.[147] In BERK mice, reduced NO bioavailability and increased nitrotyrosine formation are associated with COX-2 induction in microvascular endothelium,[35] suggesting that the reported increase in prostaglandin E_2 levels in sickle cell disease[112] might be due to COX-2 activity. Moreover, COX-2 induction in BERK mice is associated with dilation of arteriolar resistance vessels, hyperperfusion, and hypotension as reported in sickle patients.[35,26,127] Activation of non-NO vasodilator mechanisms in the BERK model might compensate for NO deficiency and help maintain optimal O_2 delivery in the face of chronic anemia.

Depletion of the substrate arginine and cofactor BH_4 results in uncoupling of electron flow from L-arginine oxidation and NO production.[148] This uncoupling of eNOS leads to its inactivation and O_2 radical generation.[149,150] Increased inflammatory effects were seen when bone marrow from transgenic sickle mice was transplanted into eNOS overexpressing mice.[151] This was likely an effect caused by excessive $ONOO^-$ formation and BH_4 depletion. Enhanced nitrotyrosine formation in transgenic sickle mice (Fig. 8.11A)[35] has been supported by recent studies[23] that showed increased $ONOO^-$ formation was associated with impaired eNOS activity with a loss of eNOS dimerization (Fig. 8.11B and C). The role of BH_4 supplementation in microvascular tone and reactivity has not been examined, except for its role in leukocyte adhesion.[151] NO depletion also up-regulates endothelin-1, a potent vasoconstrictor whose levels are increased in sickle cell disease.

Altered Vascular Responses to Vasoconstrictors: Enhanced oxidative stress, particularly the formation of nitrotyrosine, might cause chronic vascular injury and impaired vascular reactivity. Nitrotyrosine infusion in rats attenuated the hemodynamic responses to epinephrine, norepinephrine, and angiotensin II,[152,153] which is comparable to the blunted blood pressure response to norepinephrine

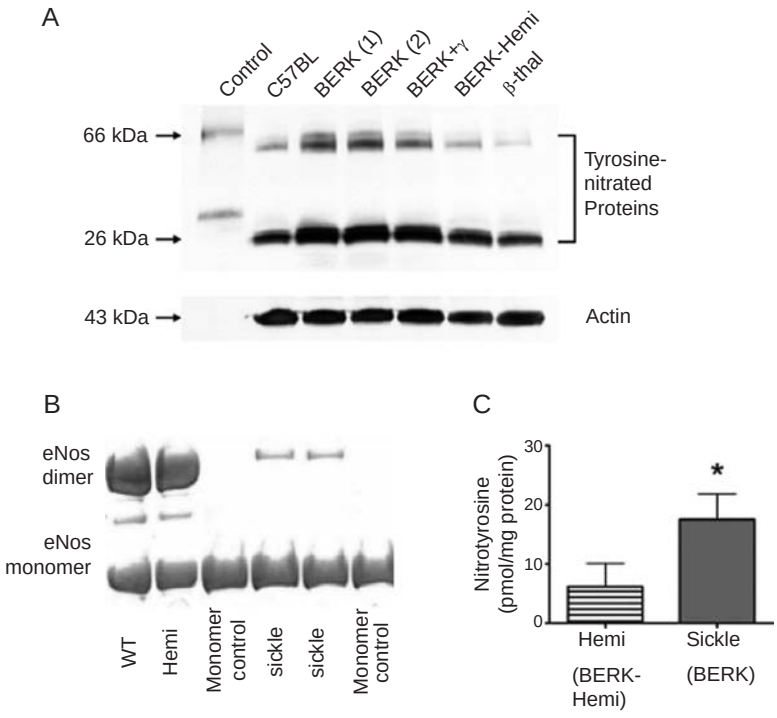

Figure 8.11. Elevated nitrotyrosine levels and endothelial nitric oxide synthase (eNOS) monomerization in BERK mice. **(A)** Western blot analysis of cremaster muscle lysates for the expression of nitrotyrosine. Two prominent bands of nitrated proteins (66 and 26 kD) were detected by the antibody to nitrotyrosine. BERK mice showed increased tyrosine nitration of both 66- and 26-kD proteins (i.e., average increase: fivefold and ~twofold, respectively), whereas the BERK+γ mouse showed a smaller increase compared with C57BL controls. The nitrotyrosine levels in BERK-trait and β thalassemia mice showed no increase as compared with C57BL controls. Control lane depicts positive nitrotyrosine controls provided by the antibody manufacturer. **(B)** Western blots of lung homogenates under nondenaturing conditions demonstrate 280-kD dimer (active form) and 140-kD eNOS monomer. Wild-type (WT) and hemizygous (Hemi) sickle mice had more eNOS dimer than monomer, but sickle mice show almost a complete lack of dimerized eNOS. Positive monomer controls show eNOS dissociated completely to monomeric form by boiling. **(C)** Lung nitrotyrosine, evidence of NO scavenging by superoxide, was elevated in sickle mice. (Figure **A** is reproduced with permission from ref. 61. Figures **B** and **C** are reproduced from ref. 23 by permission.)

in BERK mice.[35] An attenuated hemodynamic response to angiotensin II[154] in sickle patients could also involve a similar mechanism.

Hypercoagulability

Under normal conditions, vascular endothelium exerts a potent anticoagulant effect. Inhibition of coagulation by endothelium involves the expression of thrombomodulin that activates protein C; heparan sulfate that activates antithrombin III; annexin V that prevents binding of procoagulation factors such as PS; NO that has inhibitory effect on platelet activation and leukocyte adhesion; and prostacyclin, a vasodilator and an inhibitor of platelet aggregation. In sickle cell disease, inflammatory cytokines, hypoxia, sickle red cell–endothelium interaction, and perhaps apoptosis of injured endothelial cells can shift endothelium to a prothrombotic state. During acute painful episodes, there is excessive thrombin generation, platelet activation, and plasma fibrinolytic activity.[27] The expression of tissue factor, a trigger of coagulation, is abnormally increased in sickle monocytes and circulating endothelial cells.[27] Furthermore, procoagulant properties of sickle red cells are linked to externalization of PS, which is a consequence of repeated cycles of sickling and unsickling. PS exposure and thrombin generation are correlated in sickle patients.[155] Thrombotic events in large vessels of the brain are implicated in sickle cell strokes[156] and thrombi in the pulmonary vessels might be associated with acute chest syndrome and are often found in postmortem.

THALASSEMIA

Red Cell Rheology

An imbalance in globin chain synthesis is the major cause of red cell abnormalities in thalassemia and affects cell survival and deformability.[157,158] In α and β thalassemia, the relative excess of unpaired β- and α-globin chains, respectively, result in accumulation of excessive amounts of unpaired globin chains that precipitate, and by different mechanisms, damage the cell membrane and cause their premature destruction (Chapters 14 and 17). Globin chain inclusion bodies are "pitted" from erythrocytes by reticuloendothelial cells. Erythrocytes in β-thalassemia major are less deformable than normal cells.[159]

Analysis of cellular and membrane deformability characteristics has shown that red cells of both α and β thalassemia have excess surface area in relation to cell volume, increased membrane dynamic rigidity, and a decreased ability to undergo cellular deformation under hypertonic osmotic stress.[160] Nevertheless, when blood from thalassemia is analyzed on density gradients, erythrocytes of HbH disease, characterized by the presence of β_4 tetramers, appeared less dense than normal red cells. In contrast, erythrocytes from β thalassemia intermedia and major showed a much broader range of density distribution with cell populations showing both lower and higher densities than that observed for normal red cells.[160] Therefore, the presence of dense cells in β thalassemia indicates cellular dehydration owing to abnormal membrane transport. The membrane

rigidity of β thalassemia cells from nonsplenectomized and splenectomized patients showed a progressive increase with increasing cell density. The greater membrane rigidity in splenectomized patients is associated with increased pathological interactions of hemichromes with the membrane protein band 3,[161] and with ankyrin, spectrin, and protein 4.1 of the membrane skeleton.[162] Overall, the mechanical stability of α-thalassemia red cell membranes is normal or slightly decreased, and that of β thalassemia membranes is markedly decreased.[160] The membrane instability in β thalassemia was attributed to decreased binding of spectrin to protein 4.1.

The coexistence of α thalassemia with sickle cell disease has a salutary effect on MCHC, dense cell numbers and the erythrocyte deformability (Chapter 23).[163,164] The deformability of sickle cell anemia α thalassemia erythrocytes is inversely correlated with the number of α-globin genes.[164] Introduction of a β^S-globin gene into β thalassemic mice was associated with a significant improvement in red cell deformabilities.[165] This improvement, however, is probably due to a slight excess synthesis of α-globin chains in these mice, suggesting that a mild decrement in β-globin synthesis might have a beneficial effect on hemoglobin concentration in sickle cell anemia by normalizing red cell density distribution profiles; however, reduced anemia might promote the viscosity/vasoocclusion features of sickle cell anemia (Chapters 11 and 19).

Hypercoagulation

Hemostatic changes have been reported in patients with β thalassemia major and β thalassemia intermedia and HbH disease. An increased incidence of thromboembolic events, mainly in β thalassemia intermedia, and the occurrence of prothrombotic hemostatic anomalies in the majority of the patients suggest the existence of a hypercoagulable state.[166] Thalassemia is associated enhanced platelet and endothelial and monocyte activation.[158] Thalassemia red cells show increased expression of PS as in sickle cell disease[167] and patients have decreased levels of proteins C, S, and antithrombin III.[166]

Vascular Pathobiology

Pulmonary Hypertension: Pulmonary hypertension is a feature of β thalassemia and the same risk factors as in sickle cell disease are involved. These include platelet activation, hypercoagulability, and chronic hemolysis and reduced NO bioavailability.[168–170] Chronic hypoxia and lung injury caused by infections and iron deposition could also contribute to this complication.[171,172] In β thalassemia, the incidence of pulmonary hypertension is increased following splenectomy,[170] probably due to increased hypercoagulability consequent to erythrocyte PS exposure.[167] Plausibly, reduced NO bioavailability, chronic hypoxia, and hypercoagulability might act in concert or independently to cause elevation of pulmonary artery pressure. Pulmonary hypertension in hemolytic anemia is discussed in detail in Chapter 11.

Cardiac and Arterial Abnormalities: Chronic hemolysis, the release of iron from lysed red cells, blood transfusions, and the resulting iron overload in thalassemia leads to the formation of O_2 free radicals. Increased oxidative stress and lipid peroxidation can have detrimental effects on cell membranes. Moreover, in thalassemia, the iron-transport protein transferrin becomes saturated, causing a marked increase in nonheme- and non-transferrin-bound iron in the plasma (Chapter 29).[158] In β thalassemia major, iron overload constitutes the major cause of heart disease because unbound iron is readily taken up by cardiac monocytes, causing heart failure, structural alterations of arteries, and deleterious effects on endothelial function.[173,174] Iron overload might result in left ventricular systolic and diastolic dysfunction.[174] Alterations of arterial components with disruption of elastic tissue and calcification also occur in β thalassemia major. These arterial changes could translate functionally into altered arterial stiffness in vivo.[175] Arterial stiffness is related to vascular impedance and, in turn, to the afterload that is presented to left ventricle, resulting in decreased mechanical efficiency of the heart. Endothelial dysfunction and vasoconstriction might be promoted by reduced NO bioavailability, leading to diffuse elastic tissue injury.[174,176] Although right ventricular dysfunction is a prominent feature in β thalassemia intermedia, left ventricular impairment also develops consequent to an increased state of volume and pressure overload needed to maintain high cardiac output through a dilated and yet rigid vascular bed.[174] A uniform feature of β thalassemia intermedia patients is high cardiac output. Echocardiographic measurements in these patients show an almost two-fold increase in the cardiac output levels when compared with normal individuals.[176] β Thalassemia mice have significantly increased peripheral vascular resistance, suggesting that altered arteriolar diameters, endothelial dysfunction and abnormal rheology of red cells contribute significantly to the increased resistance.[177]

CONCLUSIONS

The presence of HbS in the sickle cell makes this disorder unique. Nevertheless, sickle cell disease and thalassemia share certain vascular abnormalities, although the majority of experimental work has focused on sickle cell disease. Some common features are a result of hemolysis and diminished NO bioavailability, reduced or absent splenic function, and damage to the erythrocyte membrane. The commonality of certain vascular abnormalities suggests that common approaches to treatment, for example, restoration of NO bioavailability or antiinflammatory agents, might be useful. These approaches are discussed in disease-specific chapters and in Chapter 31.

The Erythrocyte Membrane

Patrick G. Gallagher and Clinton H. Joiner

INTRODUCTION

Hemoglobinopathies, including the thalassemia syndromes and sickle cell disease, are complex disorders with protean manifestations. Their pathophysiology is influenced by environmental and genetic factors in addition to the pleiotropic effects of the globin gene mutations themselves. The erythrocyte membrane plays a critical role in these disorders because of the effects of its structural and functional perturbations and alterations in ion and water homeostasis regulated by membrane proteins.[1] The first portion of this chapter reviews the structural and functional characteristics of the erythrocyte membrane; this is followed by a review of the alterations in ion and water homeostasis observed in the erythrocytes of sickle cell disease and thalassemia.

MEMBRANE STRUCTURE AND FUNCTION

The erythrocyte membrane is a complex, multifunctional structure. Although providing a protective layer between hemoglobin and other intracellular components and the external environment, it provides the erythrocyte with the deformability and stability required to withstand its travels through the circulation. The erythrocyte is subjected to high sheer stress in the arterial system, dramatic changes in size in the microcirculation, and wide variations in tonicity, pH, and pO_2 as it travels throughout the body. It facilitates the transport of cations, anions, urea, water and other small molecules in and out of the cell, but denies entry to larger molecules, particularly if charged. A unique anucleate cell, the erythrocyte has a limited capacity for self-repair.

Membrane Structure

The erythrocyte membrane is composed of a lipid bilayer linked to an underlying cortical membrane skeleton.[2] Membrane proteins are classified as integral, penetrating or crossing the lipid bilayer and interacting with the hydrophobic lipid core, or peripheral, interacting with integral proteins or lipids at the membrane surface, but not penetrating the bilayer core. Integral membrane proteins of the erythrocyte include the glycophorins, the Rh proteins, transport proteins such as band 3, the sodium pump, Ca^{2+}–adenosine triphosphatase (ATPase) and Mg^{2+}-ATPase. Peripheral membrane proteins include the structural proteins of the spectrin-actin–based membrane skeleton.

Membrane Pathobiology

The membrane is in intimate contact with excess unpaired globin chains found in the thalassemia syndromes and sickle hemoglobin (HbS) in sickle cell disease, leading to membrane distortion by physical effects. Membrane proteins are also subjected to the toxic byproducts of the oxidative stress induced by the presence of excess unpaired globin, and hemoglobin, particularly that induced by the decompartmentalization of erythrocyte iron.[3]

Oxidant Stress. The normal erythrocyte is under continuous oxidative stress, with cyclic hemoglobin oxygenation and deoxygenation constantly generating oxidants in the form of reactive oxygen species. Because the mature, anucleate erythrocyte lacks the ability to synthesize proteins or lipids damaged by reactive oxygen species, it has many antioxidants, including superoxide dismutase, catalase, thiol species such as glutathione and peroxyredoxin, and vitamin E, to combat this ongoing oxidant stress.

Thalassemic and sickle erythrocyte are especially challenged by oxidants. The instability of reactive, heme-containing α- or β-globin chains and HbS, which is relatively unstable compared with normal HbA, leads to autooxidation,[4–7] generating additional peroxide and oxygen radicals. As a result, the erythrocyte's normal defenses against reactive oxidant species begins to be overwhelmed, and irreversible oxidative damage of both membrane and cytoplasmic proteins and lipids occurs.[8,9]

Excess globin chains and HbS precipitate on the inner membrane surface. This most likely is mediated by the formation of insoluble hemichromes that are oxidation products of methemoglobin. They prompt formation of reactive oxygen species and lead to the release of iron from heme in the form of highly reactive free, or molecular iron.[10] The interaction between HbS and phosphatidylserine (PS) present on the inner leaflet of the lipid bilayer also promotes the formation of methemoglobin, hemichromes, and the release of heme into the lipid phase.[11,12] In the presence of peroxidation byproducts, this process liberates free iron and causes additional lipid peroxidation. The rate of HbS oxidation becomes 3.4-fold faster in the presence of lipids, which corresponds to a doubling rate for the oxidation rate for HbS in solution (1.7-fold greater for HbS than HbA).[11]

Thalassemia and sickle erythrocytes constantly generate excessive amounts of superoxide, peroxide, and hydroxyl radicals. Furthermore, levels or activities of scavengers and enzymes involved in antioxidant defenses are perturbed,

with decreased levels of glutathione, vitamin C, glutathione reductase, possibly glutathione peroxidase and catalase,[13] decreased levels of plasma and erythrocyte vitamin E,[14] variable levels of superoxide dismutase,[13,15] and increased levels of glucose-6-phosphate dehydrogenase. Sickle erythrocytes also demonstrate decreased NADH redox potential, decreased hexose monophosphate shunt activity, and increased ATP catabolism, attributed to the ongoing need to regenerate intracellular glutathione.

Membrane-associated Iron. In living cells, iron is typically separated from lipids. Thus, the association of iron with the lipid bilayer would be expected to lead to significant pathological effects, particularly by iron-catalyzed lipid oxidation. In the hemoglobinopathies, membrane-associated iron plays a major role in erythrocyte pathobiology by its damaging oxidative effects.[12,16–18] On the cytoplasmic face of thalassemic and sickle erythrocyte membranes, abnormal membrane association of iron is compartmentalized into heme-derived iron, as heme-protein or as free heme, or non-heme-derived iron, as molecular free iron or as ferritin iron. Quantitatively, these erythrocyte membranes contain approximately three times more total heme (heme proteins plus free heme) than normal erythrocytes.[19]

The deposition of heme proteins is primarily in the form of hemichromes.[20,21] These heme proteins are associated with integral or membrane skeletal proteins, partially through disulfide bonding, with a fraction nonrandomly associated with membrane aggregates of the protein, band 3.[22–24] Normal erythrocytes exposed to oxidant stress also develop clusters of denatured hemoglobin and band 3.[25] Sickle membranes also contain free heme, at approximately 5% of total membrane heme.[26]

Nonheme-derived iron associates with the erythrocyte membrane as ferritin iron or as molecular iron (nonheme, nonferritin iron). Ferritin iron is present in small amounts and its significance is unknown. Molecular iron, which reacts rapidly with ferrozone and is removed from ghost membranes by high-affinity free iron chelators, is present in larger amounts than heme iron.[21,27] Membrane affinity for molecular iron is extremely high, predicting that binding sites on the membrane are able to maintain cytosolic free iron at a concentration below 10^{-20}.[16,28] Molecular iron is bioactive and accounts for most of the ability of these variant erythrocyte to generate highly reactive hydroxyl radicals.[29] It is likely that molecular iron plays an important role in promoting oxidation of hemoglobin to methemoglobin and deposition of denatured hemoglobin onto the red cell membrane. Thus, catalytic iron associated with the membrane can valence cycle between ferric and ferrous states, allowing it to participate in redox reactions.

Molecular iron is associated with the membrane either as a chelate with bilayer phospholipids, particularly PS, or nonrandomly associated with clusters of hemichrome and band 3 aggregates. The specific amounts of molecular iron associated with phospholipids or hemichromes are unknown. Interestingly, denatured hemoglobin on sickle erythrocyte membranes can be coated with phospholipids, suggesting that some membrane-associated molecular iron is associated with hemichromes because of the phospholipids that cover them.[30]

The amount of membrane-associated molecular iron is unrelated to systemic iron status; however, the removal of iron from the sickle membrane has several potential benefits for the erythrocyte and might have potential therapeutic benefit. The iron chelator deferiprone (L1) is effective in removing free iron from sickle and thalassemic erythrocytes (Chapter 29).[31,32] This has been attributed to the neutral charge of L1, allowing it to penetrate erythrocyte membranes. In contrast, the chelator deferoxime, which is charged, does not penetrate the membrane.[33] L1 therapy has also been associated with a significant reduction in the activity of the potassium-chloride (KCl) cotransporter (KCC), whose activity is abnormally increased as the result of oxidative damage present in homozygous β thalassemia erythrocytes.[34] Development of a safe, effective, and high-affinity iron chelator would be useful to reduce the membrane damage associated with the deposition of free iron in sickle erythrocytes.

The Membrane Skeleton

The membrane skeleton (Fig. 9.1) is composed of an intricately interwoven meshwork of proteins that interact with the lipid bilayer and integral membrane proteins. The major proteins of the membrane skeleton include spectrin, actin, ankyrin, protein 4.1R, and protein 4.2. Spectrin is the primary structural component of the membrane skeleton and its most abundant protein. Spectrin functions include provision of structural support for the lipid bilayer, maintenance of cellular shape, and regulation of lateral movement of integral membrane proteins. αβ-Spectrin heterodimers self-associate with other αβ-spectrin heterodimers to form tetramers, the functional spectrin subunit in the erythrocyte. Tetramers provide significant flexibility and structural support for the lipid bilayer, helping maintain cellular shape. Spectrin heterodimer–tetramer interconversion is a moderate affinity, temperature-dependent association that favors tetramer formation.

The membrane skeleton is linked to the plasma membrane by several interactions. These include binding of spectrin tetramers to ankyrin, which in turn binds to the integral protein band 3 and binding of spectrin to the "junctional complex," a multiprotein complex that includes actin, adducin, protein 4.1R, tropomyosin, tropomodulin, and dematin. Another membrane skeleton linkage to the plasma membrane is mediated via binding of a multiprotein complex containing the Rh proteins, the RH-associated glycoproteins, CD47, LW, glycophorin B, and protein 4.2 to ankyrin. Finally, direct interactions of several skeletal proteins with the anionic phospholipids provides another linkage of the membrane skeleton to the lipid bilayer.

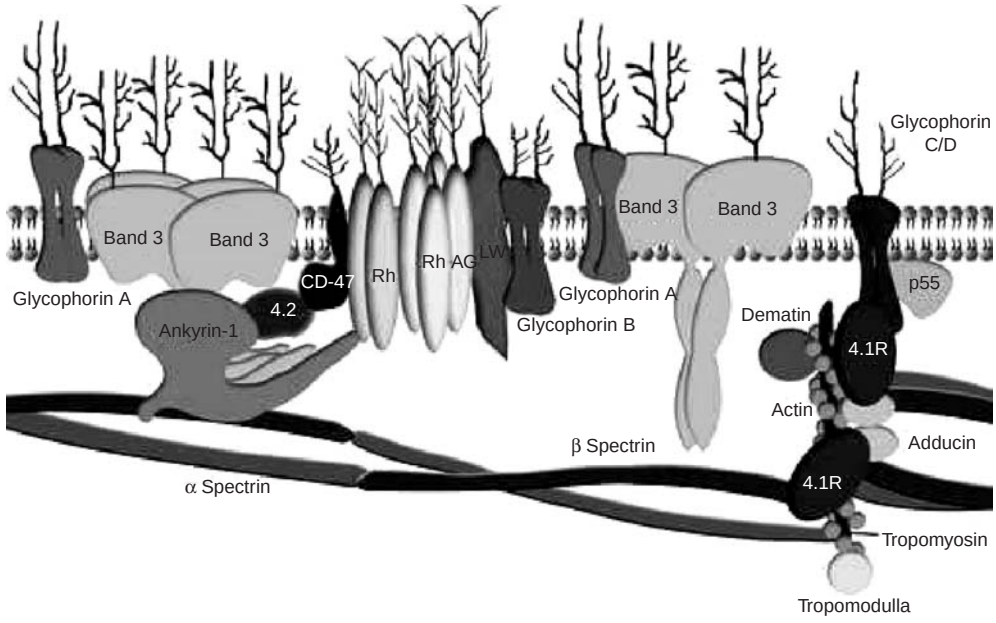

Figure 9.1. Schematic model of the red cell membrane. (Reprinted with permission from ref. 2.)

Membrane Skeleton in Thalassemia and in Sickle Erythrocytes. Numerous alterations in the membrane skeleton have been described in thalassemic and sickle erythrocytes. In thalassemic erythrocytes, alterations in the membrane skeleton vary depending on the type of thalassemia.[35–39] α Thalassemia erythrocyte membranes, isolated from patients with HbH disease (Chapter 14), have approximately a 50% decrease in high-affinity spectrin-binding sites, thought to be due to perturbed or aggregated ankyrin. β Thalassemia membranes, isolated from patients with β thalassemia intermedia, have abnormal protein 4.1R.[35,38] These findings are highly selective; protein 4.1R function is normal in α- thalassemia erythrocytes and spectrin binding is normal in β thalassemia erythrocytes. In both types of erythrocytes, spectrin function is normal.[40]

In normal erythrocytes, hemoglobin binds to the cytoplasmic surface of band 3, which is linked to the membrane skeleton via ankyrin,[41–44] HbS, especially its deoxy form, binds more avidly than HbA.[45–48] The precipitation of byproducts derived from excessive α- or β-globin chains or HbS on the inner surface of the membrane, followed by the associated oxidative damage leads to the formation of Heinz bodies. Denatured hemoglobin, the major constituent of Heinz bodies, binds to the cytoplasmic surface of band 3 with extremely high avidity, leading to aggregation of band 3 into clusters followed by binding of autologous immunoglobulin G and erythrocyte removal.[22–24,30,49,50] Sickle erythrocytes lack the typical large Heinz bodies associated with HbH molecules in α thalassemia or oxidant-challenged glucose-6-phosphate dehydrogenase–deficient erythrocytes. Instead there are smaller inclusions composed of hemichrome,[20] called by some "micro-Heinz bodies."

In the regions of sickle erythrocyte membrane associated with micro-Heinz bodies, protein topography and distribution are drastically altered, with aggregation and clustering of band 3, glycophorin and ankyrin.[22] As sickle erythrocytes dehydrate, there is progressive membrane protein redistribution, particularly near micro-Heinz bodies, leading to irregular, negatively charged clumps on the membrane surface. A similar process of band 3 aggregation and altered topography occurs in thalassemic red cell membranes.

Continuous polymerization of HbS with formation of long spicules can physically dissociate fragments of the lipid bilayer from the membrane skeleton.[51] This uncoupling of membrane from skeleton is most likely due to the growth of the sickle polymer though gaps in the membrane skeletal network. The membrane that comprises the spicule contains band 3, but not spectrin, which is limited to the body of the cell and the base of the spicule. The detachment of the lipid bilayer containing band 3 and possibly other integral membrane proteins from the skeleton likely facilitates membrane release from the erythrocyte as spectrin-poor vesicles (see later).

Other changes have been observed in membrane proteins in sickle cell disease. The lateral mobility of band 3 and glycophorin is abnormal, becoming increasingly and progressively more aggregated in erythrocytes of increasing density.[52] Ankyrin exhibits abnormal binding properties in sickle erythrocytes, both in binding band 3 and binding spectrin,[53,54] similar to defects observed in erythrocytes containing Heinz bodies due to unstable

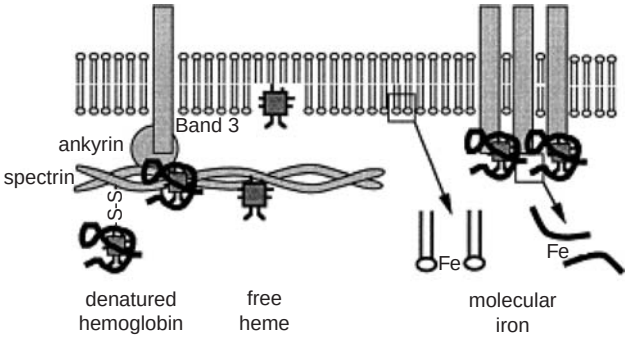

Figure 9.2. Pathological iron compartments on sickle red cell membranes. These compartments include (left to right): denatured hemoglobin associated by disulfide bonding or noncovalently, free heme associated with protein or lipid, and molecular iron associated with membrane aminophospholipid and with denatured hemoglobin. (Reprinted with permission from ref. 16.)

hemoglobinopathies (Chapter 24).[55] These changes could be induced by changes brought about by oxidation, for example the thiol redox status of spectrin, ankyrin, and protein 4.1R is abnormal in sickle erythrocytes,[56] or by direct deposition of denatured hemoglobin on the inner membrane. Functional abnormalities of protein 4.1R have been reported in sickle erythrocytes on one study[57] but are unconfirmed.[53] Oxidative changes of skeletal proteins might lead to loss of membrane flexibility.[58]

Membrane Loss and Vesiculation

Sickle erythrocytes shed part of their membrane as spectrin-deficient vesicles during cyclic oxygenation and deoxygenation.[59,60] These vesicles are likely derived from spicules that are apparently completely uncoupled from the underlying membrane skeleton.[51] This vesicular shedding is viewed by some as the ultimate stage in membrane deformation induced by erythrocyte sickling.

Some vesicles contain phosphoinositol-anchored membrane proteins,[60–62] leading to depletion in the residual erythrocytes of the complement regulatory proteins acetylcholinesterase and decay accelerating factor (CD55). It has been hypothesized that this leaves the erythrocyte susceptible to complement-mediated intravascular hemolysis,[63,64] facilitating erythrocyte recognition and removal by macrophages.[65]

Vesicles are also thought to play a role in the hypercoagulability of sickle cell disease.[66] Vesicles produced by erythrocyte shedding shorten in vitro clotting times[67,68] dramatically enhance generation of thrombin from the prothrombinase complex in vitro,[69] and bind protein S in vitro, possibly accounting for decreased protein S levels in vivo.[70]

Irreversibly Sickled Cells. Irreversibly sickled cells (ISCs) are elongated, pointed erythrocytes that are found in the well-oxygenated peripheral blood smears of most patients with sickle cell disease, especially individuals with sickle cell anemia (Chapter 19; Fig. 19.1). These dense, HbF-poor cells contain virtually no polymerized hemoglobin when they are fully oxygenated; they survive only a few days. ISCs maintain a deformed shape when exposed to oxygen or other factors that result in reversal of HbS polymerization;[71,72] they were one of the first indicators of membrane perturbation in sickle erythrocytes. The number of ISCs is greatest in the dense, dehydrated cell population and correlates well with hemolysis and spleen size, but not with the prevalence of vasoocclusive complications.[73,74] ISCs can be produced by ATP depletion, calcium accumulation, and oxy-deoxy cycling.[75–78]

The abnormal morphology of the ISC is maintained by irreversible deformation of the spectrin–actin membrane skeleton.[79] Spectrin dimer–tetramer self-association could play a role in this permanent deformation, by the dissociation of spectrin tetramers into dimers, which then reassociate into tetramers in a permanently deformed configuration.[80] It has also been proposed that the rigidity of the ISC is due to a defect in β-actin, which is brought about by oxidative changes that lead to formation of a disulfide bridge between two cysteine residues critical for actin function.[81,82] Diminished content of reduced glutathione and other crucial antioxidants in ISCs might play a role in facilitating oxidant damage and posttranslational modification of β-actin in sickle erythrocytes.[13,83,84]

Membrane Lipids

The human erythrocyte contains approximately 455 million lipid molecules within the lipid bilayer, where they comprise approximately half the weight of the plasma membrane. This bilayer is composed predominantly of phospholipids intercalated with unesterified cholesterol in nearly equimolar concentrations, and small amounts of glycolipids. The major membrane phospholipids are phosphatidyl choline (PC), phosphatidyl ethanolamine (PE), sphingomyelin (SM), and PS. Small quantities of phosphatidic acid, phosphatidyl inositol (PI) and lysophosphatidyl choline (lysoPC) are also found. Cholesterol is distributed unequally between the inner and outer monolayers,[85] and

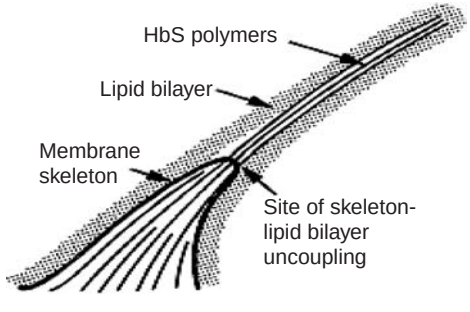

Figure 9.3. Model of the long spicule in the deoxygenated sickled cell. Hemoglobin S polymers penetrate the membrane skeleton, and uncouple the lipid bilayer from the skeleton. (Reprinted with permission from ref. 51.)

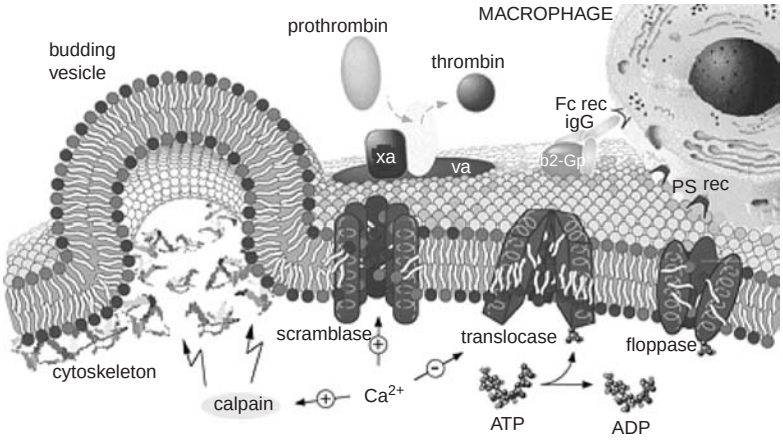

Figure 9.4. The regulation and physiology of membrane phospholipids asymmetry. This model describes how membrane phospholipids asymmetry is generated, maintained, and perturbed as a prerequisite to various PS-related pathophysiologies. Membrane lipid asymmetry is regulated by the cooperative activities of three transporters: 1) the ATP-dependent aminophospholipid-specific translocase, which rapidly transports PS and PE from the cell's outer-to-inner leaflet; 2) the ATP-dependent nonspecific lipid floppase, which slowly transports lipids from the cell's inner-to-outer leaflet; and 3) the Ca^{2+}-dependent nonspecific lipid scramblase, which allows lipids to move randomly between both leaflets. The model predicts that the translocases are targets for Ca^{2+} that directly regulates the transporter's activities. Elevated intracellular Ca^{2+} induces PS randomization across the cell's plasma membrane by providing a stimulus that positively and negatively regulates scramblase and translocase activities, respectively. At physiological Ca^{2+} concentrations, PS asymmetry is promoted because of an active translocase and floppase by inactive scramblase. Depending on the type of cell, elevated intracellular Ca^{2+} levels can be achieved by cellular stores. Increased cytosolic Ca^{2+} can also result in calpain activation, which facilitates membrane blebbing and the release of PS-expressing procoagulant microvesicles. The appearance of PS at the cell's outer leaflet promotes coagulation and thrombosis by providing a catalytic surface for the assembly of the prothrombinase and tenase (not shown) complexes and marks the cell as a pathological target for elimination by phagocytes. Recognition of the PS-expressing targets can occur by both antibody-dependent and direct receptor-mediated pathways. (Amino phospholipids are shown with dark polar head groups and choline phospholipids with lights polar head groups b2-Gp, B2-glycoprotein-1; rec, receptor). (Reprinted with permission from ref. 106.)

the phospholipids are also asymmetrically organized, with PC and SM, the choline phospholipids, primarily in the outer monolayer, with most of PE, all of PS, the amino phospholipids, and the phosphoinositides, in the inner monolayer.

Maintenance of Phospholipid Asymmetry. The asymmetrical distribution of membrane bilayer phospholipids, first recognized in erythrocytes,[86] is universal in eukaryotic cells. This asymmetrical distribution of phospholipids is a dynamic system involving a constant exchange between phospholipids of the two bilayer leaflets. Generated primarily by selective synthesis of lipids on one side of the membrane, a number of proteins participate in the maintenance or dissipation of this lipid gradient.[87,88] "Flippases," or aminophospholipid translocases, move phospholipids, particularly PS, from the outer to the inner monolayer using Mg^{++}-ATP, keeping them sequestered from the cell surface, and "floppases" do the opposite against a concentration gradient in an energy-dependent manner. "Scramblases" are bidirectional, ATP-independent transporters that move phospholipids bidirectionally down their concentration gradients in an energy-independent manner. The precise identity of all the proteins maintaining phospholipid asymmetry in the erythrocyte is still unclear.[87] Moreover, despite exhaustive searching, the identity of the PS receptor has not yet been discovered in any biological system.[89] A recent study demonstrated the existence of a novel functional adhesion receptor for PS on the microendothelium upregulated by hypoxia, cytokines, and heme.[90]

Membrane Lipid Alterations. Mature erythrocytes are unable to synthesize fatty acids, phospholipids or cholesterol; thus exchange pathways account for lipid modifications. Cholesterol is rapidly exchanged with unesterified cholesterol from plasma lipoproteins in the circulation. PC and SM are slowly exchanged with plasma lipids, whereas PS and PE do not participate in lipid exchange. Another potential lipid renewal pathway, fatty acid acylation, is an ATP-dependent process in which fatty acids combine with lysophosphatides to remake the native phospholipids, renewing damaged or lost fatty acid side chains. The composition of red cell phospholipids is quite distinct from that of plasma phospholipids, suggesting that specific pathways exist in red cells to remodel phospholipids to optimize their function. Dietary changes have only a minimal effect on the composition of erythrocyte membrane phospholipids. The inability of the erythrocyte from individuals with sickle cell disease and thalassemia to maintain normal lipid composition and repair or renew oxidized lipids, particularly fatty acids, during periods of oxidative stress, a process essential for erythrocyte survival, leads to a variety of changes in membrane structure and function.[91]

Loss of Phospholipid Asymmetry. Maintenance of phospholipid asymmetry, particularly localization of PS and phosphoinositides to the inner monolayer, has important functional consequences.[92] Typically, PS is exposed when a signal for activation of a specific biological process, such as blood clotting or cell recognition and removal, is required. In thalassemia and sickle cell disease,[93–97] outward exposure of PS in subpopulations of erythrocytes leads to activation of blood clotting, increased cellular destruction, increased adhesion to endothelial and mononuclear phagocytic cells[1,98,99] and other effects. In sickle cell disease, morphological sickling upon deoxygenation results in exposure of external PS, especially in membrane spicules.[94] In some cells, PS exposure persists after reoxygenation. These PS-exposing cells are in the densest and very lightest or reticulocyte-rich erythrocyte fractions[100–102] with the number of PS-exposing cells varying among patients, changing during time in individual patients, and

decreasing after transfusion.[95] Normal and sickle reticulocytes both exhibit a moderate degree of externalized PS, and the reticulocytosis of sickle cell disease complicates so some degree the interpretation of studies on PS exposure. Unlike mature erythrocytes, however, some "mature" sickle erythrocytes have moderate PS exposure, and a subset of the dense, ISC-rich population shows much higher degrees of PS exposure than that seen in reticulocytes.[101]

PS-exposing surfaces propagate the proteolytic reactions that result in thrombin formation and activation of fibrinolysis by conversion of prothrombin to thrombin by providing docking sites for assembly of coagulation factors on their surfaces.[103,104] Exposure of PS also participates in feedback inhibition of thrombin formation via activation of the protein C pathway. These PS-exposing surfaces also can promote anticoagulation by providing a catalytic surface for factor Va inactivation by activated protein C.[105,106]

In sickle cell disease, the number of circulating erythrocytes with exposed PS has been correlated with the risk of stroke.[107] It has been suggested that other coagulation abnormalities observed in thalassemia and sickle cell disease, including decreased protein C and S activity and increased anti-PS antibodies, might be caused by circulation of PS-exposing erythrocytes.[108–110] In support of this hypothesis, the number of PS-exposing sickle erythrocytes correlated with plasma 1.2 (F1.2), d-dimer, and plasmin–antiplasmin complexes, but not the number of PS-positive platelets in pediatric sickle cell disease patients, suggesting that sickle erythrocytes and not platelets are responsible for the hemostatic activation.[111] High levels of HbF are associated with decreased erythrocyte PS exposure and decreased levels of thrombin generation and microvesicle formation.[112] Splenectomized HbE–β thalassemia patients exhibit significant levels of circulating plasma thrombin–antithrombin III complex associated with increased numbers of PS-exposing erythrocytes (Chapter 18).[113]

PS-exposure has been thought to be a signal for recognition by and attachment of these cells by macrophages of the reticuloendothelial system, marking them for destruction.[114,115] This mechanism of erythrocyte removal, shown in a murine model of sickle cell disease, is thought by some to contribute to the reduced red blood cell survival observed in sickle cell disease and the thalassemias.[91,108] In vivo studies using autologous, biotin-labeled sickle cells are not consistent with rapid removal of PS-exposing erythrocytes.[101]

PS exposure has other effects on sickle erythrocytes. Increased PS and PE exposure has been associated with activation of the alternative complement pathway.[116] Highly PS-positive sickle erythrocytes, including the densest sickle cells, cause an increase in endothelial cell tissue factor expression in vitro, not due to erythrocyte–endothelial interactions, but rather to increased levels of cell-free hemoglobin due to hemolysis (Chapter 11). Finally, PS-exposing erythrocytes can become targets for phospholipases. For example, secretory phospholipase A_2 ($sPLA_2$) will hydrolyze lipids of PS-exposing but not normal erythrocytes,[117] generating lysophospholipids and free fatty acids. In the presence of sPLA2, PS-exposing erythrocytes generate lysophosphatidic acid, which effects vascular integrity.[117] sPLA2 levels appear to predict impeding acute chest syndrome in sickle cell disease,[118] which would potentially allow intervention to prevent or ameliorate this devastating condition.[119] Strategies to bind PS or inhibit sPLA2 activity could prove to be therapeutic targets in sickle cell and other diseases.[91]

Although initially attributed to oxidative damage to the membrane, oxidative damage per se is not the cause of increased PS-exposure in sickle erythrocytes.[120] Repeated cycles of sickling and unsickling associated with HbS polymerization and depolymerization with resulting changes to the erythrocyte membrane likely contributes to the production of terminal spicules and vesicles with increased PS exposure.[60] In normal erythrocytes, neither "flippase" nor "floppase" activity is influenced by cellular oxygenation. Deoxygenation of sickle erythrocytes, however, is associated with increased PS and PE exposure and decrease in "flippase" activity,[121] particularly in PS-exposing erythrocytes.[100] Decreased "flippase" activity has been attributed to oxidative stress and sulfhydryl modifications. Deoxygenation of sickle cells results in both exposure of PS and the disruption of the membrane skeleton in membrane spicules, suggesting a role of skeletal proteins in the maintenance of phospholipid asymmetry.

"Flippase" inactivation alone, however, will not precipitate PS exposure. Activation of the "scramblase" is also required via increased levels of cytosolic calcium and/or enhanced calcium influx.[120] Not surprisingly, sulfhydryl modifications of the "scramblase" leads to increased PS exposure and a lower calcium requirement for scrambling,[122] leading to the suggestion that oxidative modifications of sulfhydryl groups in both the "flippase" and "scramblase" contribute to increased PS exposure by sickle erythrocytes.

Phosphoinositides. Phospholipids with a phosphoinositol-containing polar head group, which may be mono- (PIP or PI-4-monophosphate) or biphosphorylated (PIP2 or PI-4,5-biphosphate), make up the phosphoinositides. Comprising only approximately 2.5% of membrane phospholipids, they have significant biological activity, including a role in maintenance of erythrocyte red cell shape and deformability. Some membrane proteins, including proteins involved in complement regulation, are anchored to the red cell membrane through a phosphoinositol lipid domain.[123] This allows these proteins to move laterally in the membrane, preventing complement-mediated membrane damage. Phosphoinositol-anchored proteins are lost through the release of lipid-enriched vesicles from the cell during the membrane remodeling that accompanies reticulocyte maturation or cell aging. This process of vesiculation and loss of complement regulatory proteins is accelerated in sickle cell anemia by repeated cycles of

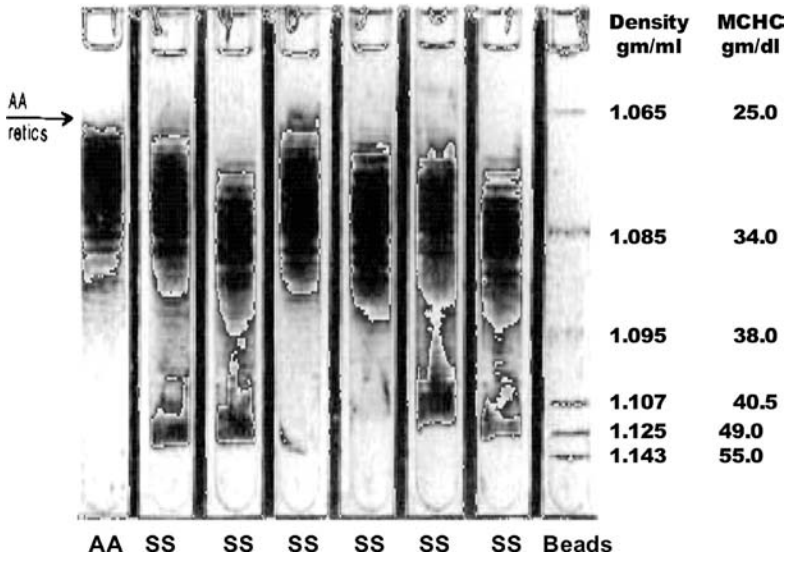

Figure 9.5. Dense erythrocytes in sickle cell blood. Whole blood samples on continuous density gradients reveal a range of densities for normal blood (AA). Sickle cell anemia (SS) blood contains a broader distribution with more low-density cells, mostly reticulocytes, and variable numbers of dehydrated cells with extremely high hemoglobin. (From ref. 148.)

sickling, making these cells sensitive to complement-mediated lysis.[64]

ALTERATIONS IN CATION CONTENT AND CELLULAR HYDRATION

The critical cellular function of maintaining cell volume is accomplished by regulation of water content. Because water is at osmotic equilibrium in most cells, cellular hydration state is a function of the content of cations (Na^+, K^+, Ca^{2+}, and Mg^{2+}) and anions (Cl^-, HCO_3^-, 2,3-BPG, hemoglobin). In red cells, hemoglobin content, which is similar in sickle and normal cells, is determined by synthesis during erythroid differentiation, and monovalent anion content is fixed by Donnan effects. Thus, cation content is the major variable determinant of cell volume and is subject to regulation by several specialized transport systems. Substantial volume reduction occurs after release of normal reticulocytes from the marrow: within approximately 2 days, cell volume drops from 115 to 85 fL and cell hemoglobin concentration (CHC) increases from 26–28 to 32–34 g/dL. Thereafter, cell volume and hemoglobin concentration remain remarkably stable over the cell's 100–120 day lifespan.

In sickle cells, dysregulation of cell volume is evident in the presence of dehydrated cells with high CHC. This abnormal hydration state is an important factor in the pathogenesis of sickle cell disease, because the polymerization of HbS is exquisitely dependent on its cellular concentration (Chapter 6).[124] Increased CHC resulting from erythrocyte dehydration markedly enhances the tendency of HbS to polymerize, reducing delay time for polymerization and resulting in the persistence of the polymer in the oxygenated state.[124–126] Dehydrated sickle cells also exhibit increased adhesion to endothelial cells, leukocytes, and other sickle erythrocytes, promoting endothelial damage and facilitating vaso-occlusion.[98,127–129] Experimental evidence for enhanced adherence of dense cells to endothelium is dependent on assay conditions, particularly shear stress (Chapter 8) In addition, dehydration directly impairs the rheological integrity of sickle cells, reducing deformability and increasing fragility.[130–133]

A distinguishing feature of sickle cell disease is the heterogeneity in the volume and water content of erythrocytes (Fig. 9.5).[72,134] In addition to large numbers of reticulocytes and young red cells with increased volume and normal to low CHC, the blood of patients with sickle cell disease contains dense, dehydrated erythrocytes and reticulocytes. The number of dehydrated cells with high CHC can be estimated by flow cytometry as the number or percentage of cells with CHC more than 41 g/dL or by centrifugation on density gradients (density > 1.1100).[134–137] This dense cell population is rich in ISCs. Early work established that the cation content of sickle erythrocytes was abnormal and was perturbed by deoxygenation.[138–140] Later studies established that the dense, ISC-rich fraction of sickle cells was due to severe potassium depletion, with a lesser variable degree of sodium loading.[141,142] More recently, the presence of overhydrated, sodium-loaded cells has been found in sickle cell disease.[143–145] These low-density cells with low CHC are older than most other sickle erythrocytes, appear to be derived from dehydrated cells, exhibit greater oxidative damage than other sickle cells or normal cells, and have very short in vivo survival.[143,145–147] High cation permeability of these cells[144] supports the idea that they represent a population of end-stage cells with damaged membranes undergoing swelling that culminates in intravascular hemolysis. Such osmotic lysis may be a source of free plasma hemoglobin contributing to the perturbations of nitric oxide metabolism that foster endothelial cell dysfunction and inflammation (Chapter 11).

The fraction of dense, dehydrated sickle cell ranges from 0% to 40% and varies among patients and over time in each patient. The number of dense cells decreases during pain episodes,[148–151] suggesting their selective removal during vasoocclusion. Dense cells are more susceptible to hemolysis,[130] and dense cell numbers correlate with the degree of hemolysis.[74] Coincident α thalassemia is associated with reduced numbers of dense sickle cells and milder hemolytic disease.[152–154] Individuals with the greatest numbers of dense cells appear to have the fewest pain episodes,[134,152–157] a paradox that might be explained by

the selective destruction of dense cells during vasoocclusive episodes.

Because of the importance of cellular dehydration in sickle cell disease pathophysiology, understanding the mechanisms of dehydration has potential for stimulating new therapeutic approaches to the disease. Proof of principle of this approach has been provided by several studies in humans and mouse models using specific inhibitors for cation transport pathways involved in sickle cell dehydration (Chapter 31).[158–163] Four major transport mechanisms have been implicated in the dehydration of sickle erythrocytes.

Deoxygenation-induced Cation Leak, Sodium–Potassium ATPase, Cell Sodium, and Sodium/Hydrogen Exchange in Sickle Erythrocytes

Deoxygenation-induced Cation Permeability. Seminal studies established that deoxygenation of sickle cells was associated with potassium loss and sodium gain and that increased permeability took place through a diffusional pathway and was accompanied by stimulation of the sodium–potassium pump.[138–140] The deoxygenation-induced increase in cation permeability of sickle cells has been amply confirmed[75,164–166] and extensively characterized.[167–172] Deoxy sodium influx and potassium efflux are activated when oxygen tension drops below 40–50 mm Hg (Fig. 9.6), correlating with deoxygenation of HbS and cell sickling.[171,173] Cation flux via the activated deoxygenation-induced pathway is dependent on external and internal pH, reaching maximal values at pH 6.9–7.0.[171] The deoxygenation-induced pathway is not selective among the alkali metal cations lithium, sodium, potassium, rubidium or cesium, and also permits passage of calcium and magnesium.[174–176] Deoxygenation does not, however, increase membrane permeability to organic cations such as tetramethyl- or tetraethyl-ammonium,[171,177] or sugars such as erythritol, arabinose, or mannitol,[177] reflecting a selectivity for metal cations. The basal permeability of the erythrocyte membrane to anions is roughly three orders of magnitude higher than that for cations, so that the permeability of the deoxygenation-induced pathway to anions cannot be assessed with accuracy.[170] These properties are suggestive of ion movement via a diffusion pathway, with restriction to monovalent or divalent cations. Under conditions of very low osmotic strength, deoxygenation induces an increase in sucrose permeability,[178] but its relationship to the sickling-induced cation pathway is not clear.

Inward transport of sodium and outward transport of potassium are balanced in deoxygenated sickle cells and do not lead directly to cell dehydration (Fig. 9.6);[166–168,179] however, the presence of external calcium and other divalent cations inhibits sodium influx more that potassium efflux, resulting in an imbalance between the two fluxes and a net potassium loss.[172,179] No evidence of Gardos channel activation was found in these experiments, indicating that the net potassium loss was indeed mediated by the deoxygenation-induced pathway. Interestingly, this effect was enhanced by the presence of heparin, suggesting modulation by a receptor–ligand interaction.[179]

The sodium–potassium pump might also play a role in sickle cell dehydration. Early work in normal human red cells indicated that activation of the pump in conditions of high sodium content lead to cell dehydration.[180] In vitro evidence for erythrocyte dehydration mediated by activation of the sodium–potassium pump has been provided for deoxygenated sickle cells and for red cells in hereditary xerocytosis that exhibit a balanced cation leak.[167] In deoxygenated sickle cells, increased cell sodium, even though initially balanced by potassium loss, stimulates the sodium–potassium pump to effect net cation loss due to its 3 Na_{out}/2 K_{in} stoichiometry. The integrated red cell model, discussed later, predicts that this mechanism cannot fully account for the extreme potassium depletion of sickle cells[181] because its contribution diminishes as the potassium gradient dissipates.

The activation of deoxygenation-induced permeability pathway is associated with morphological sickling[171,173] and can be impeded by agents that interfere with HbS polymerization.[182,183] High cation fluxes are associated with deoxygenation under conditions producing marked morphological changes and extensive spicule formation, such as gradual deoxygenation, alkaline pH, low hemoglobin concentrations, and reticulocyte deoxygenation.[171,173,179] This suggests that activation of this pathway is triggered by spicule formation, which is associated with disruption of spectrin–band 3 associations and perturbation of phospholipid and cholesterol domains.[51,69,184] A relationship between deoxygenation-induced cation pathway and the nonselective cation leak induced by shear stress and membrane deformation is suggested by their similar physiological and pharmacological characteristics.[185] The nature of these associations and the identification of the deoxygenation-induced pathway deserve further study.

Deoxygenation-induced fluxes of sodium, potassium, and calcium are reduced by the anion exchange inhibitor diisothiocyanostilbene disulfonate (DIDS) without affected morphological sickling.[169,175,177] Dipyridamole, an anion transport inhibitor, also blocks deoxygenation-induced cations fluxes in vitro, although other anion transport blockers are ineffective.[176] DIDS-sensitive cation fluxes, presumably mediated by the anion exchanger, can be elicited in normal red cells by incubation in low chloride media.[186] Single amino acid substitution in the anion exchange protein associated with stomatocytosis syndromes has been shown to be associated with increased erythrocyte cation permeability, sensitive to DIDS and dipyridamole; expression of these mutant anion exchangers in xenopus oocytes conferred increased cation permeability with similar inhibitor sensitivity.[187] These findings

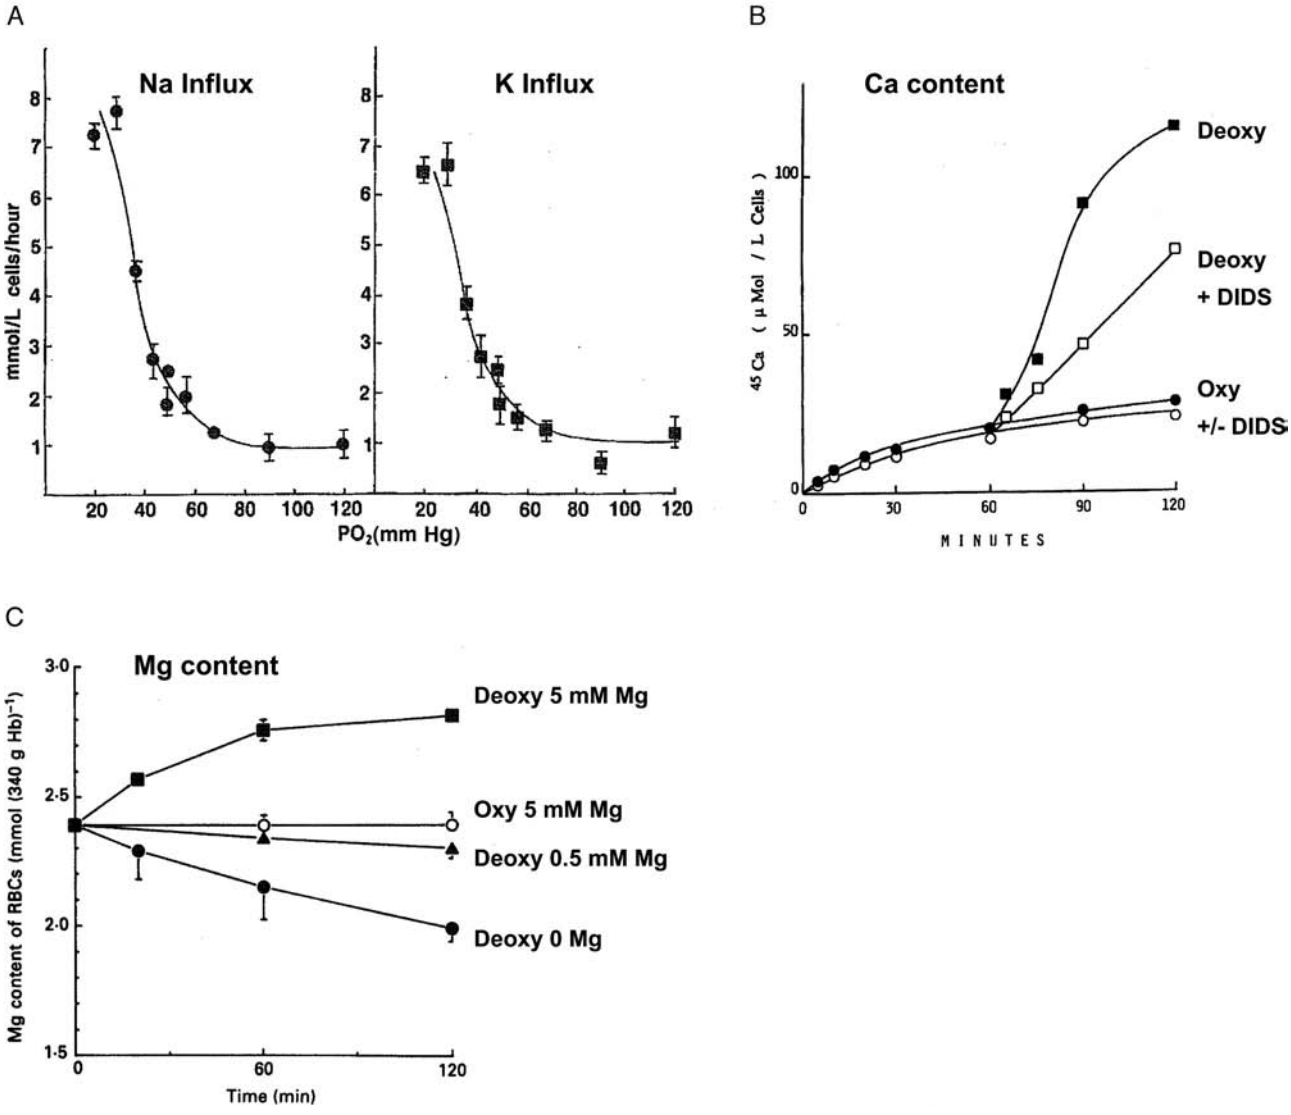

Figure 9.6. Deoxygenation-induced permeability increase to mono- and divalent cations in sickle red cells. **(A)** Sodium and potassium influx as a function of pO_2. Increased permeability below 40 mm Hg corresponds to morphological sickling. (from ref. 168, used with permission) **(B)** Ca permeability, assessed as ^{45}Ca content of cells containing the chelator quin2 to minimize efflux. Increased cellular calcium uptake in deoxygenated sickle cells (■) compared with oxygenated cells (●); DIDS partially inhibits calcium uptake in deoxygenated (□), but not oxygenated cells (○). (from ref. 175, used with permission) **(C)**. Changes in cellular magnesium content upon deoxygenation in sickle cell incubated in high external Mg (5 mmol ■), normal Mg (0.5 mmol ▲) or no Mg (5 mmol EDTA ●). Oxygenated cells (○) had stable Mg contents under all conditions. (Used with permission from ref. 174.). Normal red cells exhibit minimal changes in cation permeability upon deoxygenation.

support the notion that the anion exchange protein, at least in some altered states, could mediate deoxygenation-induced fluxes in sickle erythrocytes. Regardless of the mechanism, pharmacological inhibition of deoxygenation-induced cation movements provides a potential avenue for therapeutic intervention to improve sickle cell hydration (see Chapter 31).

Alterations in Cation Permeability by Shear Stress and Oxidation in Sickle Erythrocytes. Marked mechanical deformation of normal cells leads to a reversible increase in cation permeability.[188–191] In the absence of external calcium, the pathway mediates equivalent sodium and potassium movement,[189,190] but in the presence of calcium, potassium loss is accelerated by activation of the calcium-dependent Gardos pathway,[192] suggesting that the pathway also mediates calcium influx. Cation fluxes induced by mechanical stress are chloride-independent. The pathway is activated in sickle erythrocytes at lower shear stress than normal cells,[193] perhaps as a consequence of the oxidant damage to the membrane. When normal cells are mildly oxidized with t-butyl hydroperoxide, the leak is increased and activated at lower shear stress.[188,189] Under

hypotonic conditions that induce cell swelling, the deformation-induced leak is increased, with potassium loss in excess of sodium gain, and is partially inhibited by bromide.[185] Interestingly, deoxygenation-induced cation leaks in sickle cells was also reduced by bromide.[185] Mechanically induced cation fluxes are partially blocked by DIDS, independently from the drug's effect on anion permeability.[185,194] Thus, the mechanically induced cation leak and the deoxygenation-induced pathway share a number of physiological and pharmacological characteristics, including an apparent origin in membrane deformation. It is conceivable that they represent the same mechanism and that the abnormal oxidation state of the sickle membrane increases the deoxygenation-induced cation leak in sickle erythrocytes.

Sodium Permeability and Cell Sodium Content in Sickle Erythrocytes. The potassium depletion responsible for sickle erythrocyte dehydration is associated with variable degrees of sodium loading, especially marked in high-density cell populations rich in ISCs,[195] which could result from increased sodium permeability or decreased activity of the sodium–potassium pump. Pump activity is abnormally decreased in dehydrated sickle cells, although ATPase activity in membranes derived from these cells is not,[142] suggesting that there is abnormal downregulation of sodium–potassium pump activity in dense cells. One possible inhibitory factor might be the increased magnesium to phosphate ratio in these cells; when this ratio was normalized in vitro, the activity of the sodium–potassium pump was restored to normal.[174]

Increase sodium permeability could also contribute to high cell sodium content of dense cells. Several sodium influx pathways have been identified, including Na/H exchange,[196] NaKCl cotransport,[197] Na/Mg exchange,[198] but assessment of their activities and contribution to net sodium influx has been variable. Earlier estimates of very high Na/H exchange rates in sickle erythrocytes[196] have not been reproduced,[199] and the sodium permeability in the dense cell population does not appear abnormally elevated. Sodium/hydrogen exchange is not stimulated by deoxygenation, indicating that the increase in intracellular calcium associated with deoxygenation is not sufficient to activate phosphokinase C and stimulate the Na/H exchanger. Likewise, there are no data to suggest that reduction in a sodium influx pathway contributes to dehydration in any sickle cell population.

The presence of a subpopulation of extremely sodium loaded cells in the least dense fraction of sickle blood was revealed by the failure of these cells to undergo dehydration upon exposure to the potassium ionophore valinomycin.[143] These cells are older sickle cells that arise from the dense cell population[145,146] and might represent a terminal stage on their way to osmotic lysis (see below). Some of the sodium loading apparent in both the high- and low-density population of sickle cells could be due to this subpopulation of sodium loaded cells.

Cell Calcium and Calcium-activated Potassium Channel (Gardos Pathway) in Sickle Erythrocytes

Cell Calcium and Calcium Pump Activity. Early studies indicated very high cell calcium in sickle cells, ranging from 110 to 300 μmol/L cells,[200,201] two orders of magnitude higher than in normal cells (0.9–2.8 μmol/L cells).[202] Free ionized cytoplasmic calcium measured by a variety of techniques, such as ionophore-induced equilibration of intracellular chelator and ^{45}Ca, calcium-sensitive fluorescent dyes, fura-2 or benz-2, and nuclear magnetic resonance, ranges from 11 to 30 nmol/L and is similar in sickle and normal erythrocytes.[175,203–205] This apparent discrepancy was explained by the demonstration of compartmentation of calcium in sickle erythrocytes into cytoplasmic vesicles, first demonstrated by electron probe x-ray analysis of cryosections.[206–208] These vesicles are derived from the plasma membrane and contain integral membrane proteins, including the Ca-ATPase, in an inside-out configuration. The Ca-ATPase pumps calcium from the cytoplasm into these vesicles, creating a very high intravesicular calcium concentration.[206,207] Most of the calcium contained in sickle erythrocytes is sequestered into vesicles.

Deoxygenation of sickle, but not normal, red cells increases the permeability of the membrane to calcium, resulting in enhanced calcium influx (Fig. 9.6).[175,176,209,210] The effects on cellular ionized calcium are complex and heterogeneous within a population of cells, depending on the balance between the influx rate in an individual cell and its capacity to extrude calcium via the Ca–ATPase pump. Deoxygenation enhanced calcium influx rate in sickle cells is increased five fold, and reduced calcium pump activity by as much as 28%.[210] The net effect produced a threefold increase in cellular ionized calcium level from 10 to 30 nmol in the discocyte fraction. Although these levels do not rise to the 40-nmol concentration estimated as the threshold for activation of the Gardos channel,[211] it was suggested that cellular heterogeneity could account for higher calcium levels in certain cell populations. Indeed, sickling-induced permeability changes were greatest in reticulocytes,[179] which are known to exhibit the most dramatic morphological changes upon deoxygenation and to deform at higher oxygen tensions, despite their relatively low CHC.[212] It was later shown that the deoxygenation-induced permeability change occurred in a subset of cells (see later).[213] The deoxygenation-induced fluxes of calcium, sodium and potassium have similar pharmacological sensitivity to DIDS and dipyridamole, suggesting mediation by a common pathway.[169,175,176]

Calcium-activated Potassium Channel (Gardos Pathway). In 1958, the Hungarian physiologist, Gyorgy Gárdos, described calcium-dependent potassium efflux from ATP-depleted red cells.[214] These fluxes are now known to be mediated by a specific type of potassium channel activated by increased cytoplasmic calcium and known by several designations. Small (or intermediate) conductance

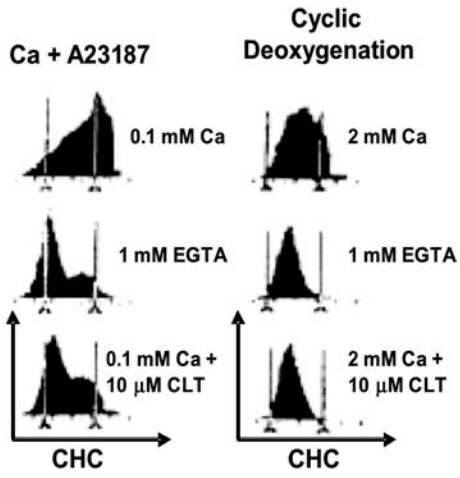

Figure 9.7. Dehydration of sickle cells via the Gardos pathway. Frequency distributions of cellular hemoglobin concentrations (CHC) were measured by Bayer Advia automated cell counter; normal range of 28–41 g/dL is shown vertical markers. In vitro activation of the Gardos pathway by incubation of sickle cells in the presence of external calcium plus ionophore A23187 induces shift to higher CHC (upper left), which is blocked by chelation of calcium or by the Gardos channel inhibitor, clotrimazole (CLT). Cyclic deoxygenation (3 hours, 1 min O_2, 4 min N_2) also produces a calcium-dependent (upper right) shift to higher CHC, absent in EGTA and inhibited by CLT. (Modified from ref. 239.)

calcium-activated potassium channel, IK1, SK4, all describe the product of the *KCCN4* gene,[215–217] which codes for a protein of 428 amino acids with six transmembrane domains and a pore region with the canonical GYGD sequence that determines K^+ selectivity in numerous potassium channels.[218] mRNA for *KCNN4*, but not *KCNN3*, increases during erythroid differentiation and is present in reticulocytes; protein is detected by *KCNN4* protein antibodies in mature erythrocyte membranes.[215] The peptide toxin charbydotoxin (ChTx) is a specific inhibitor of the human red cell Gardos channel.[219,220] Binding studies with ^{125}I-ChTx demonstrated that normal human erythrocytes possess approximately 150 of these channels per cell.[221] Upon uniform, maximal activation of Gardos channels via controlled ionophore-induced permeabilization of red cells to calcium, rapid, but remarkably uniform dehydration of both sickle and normal erythrocytes occurs.[222] These results suggest a uniform distribution of channels among erythrocytes and are consistent with estimates of several hundred channels per cell.

Generation of dense ISCs under conditions of ATP depletion was dependent on external calcium and an outwardly directed potassium gradient.[75] When sickle cells are deoxygenated under conditions in which ATP levels are maintained, calcium-dependent formation of dense, dehydrated cells was observed (Fig. 9.7).[76,158,223–226] Sickle erythrocyte dehydration produced by rapid in vitro deoxygenation–oxygenation cycles that mimicked in vivo circulatory times was predominantly calcium dependent, suggesting it was predominantly mediated by the Gardos channel.[227] The integrated red cell model[181,228] has examined the different modalities of dehydration for reticulocytes and provided theoretical and indirect experimental evidence for a calcium dependent process based on transient activation of the Gardos pathway upon deoxygenation.[179] Nevertheless, although Gardos channel potassium fluxes can be readily elicited in red cells in vitro, calcium-dependent potassium fluxes blocked by the specific Gardos channel inhibitors have been difficult to demonstrate directly upon deoxygenation of sickle cells.

An elegant set of experiments helps to explain this apparent paradox. When sickle discocytes were deoxygenated, only 10%–40% became dense, and thus had evidence for calcium permeabilization and Gardos channel activation upon deoxygenation. The process was rapid and transient, and the resultant dense cell fraction did not increase with prolonged deoxygenation. If those dehydrated cells were removed, however, and the procedure was repeated, a similar fraction of cells became dense. These studies suggest that the activation of the sickling-induced permeability pathway that permits calcium influx in deoxygenated sickle cell is a stochastic process affecting a small fraction of cells during each deoxygenation event. Thus Gardos-mediated potassium efflux is rapid and transient in only a few cells upon a given deoxygenation. This explains why oxy–deoxy cycling has generally been more effective than continuous deoxygenation in eliciting calcium-dependent density shifts in sickle cells and why Gardos potassium fluxes have been difficult to measure directly in vitro.

Modulation of Gardos Channel Activity in Sickle Cell Disease. Gardos channel activity is subject to regulation in vitro by cytokines and lipid mediators of inflammation known to be elevated in persons with sickle cell disease as a result of the inflammatory vasculopathy associated with oxidative stress, endothelial cell damage and leukocyte activation (Chapters 8, 10, and 11). In murine erythrocytes, endothelin-1 (ET-1), a cytokine released from endothelial cells under oxidative or other stresses, increases both the internal calcium affinity and the V_{max} of the Gardos channel. Pharmacological studies indicated that this effect was mediated by the ET-1 receptor B and involved activation of protein kinase C.[229] Treatment of SAD sickle mice (Chapter 12) with a specific inhibitor of the ET-1 receptor B but not A, reduced sickle cell dehydration in vivo and Gardos channel fluxes measured ex vivo.[161] The ability of ET-1 to augment Gardos channel activity was also demonstrated in human sickle cells in vitro. The increase in sickle cell density produced by oxy/deoxy cycling in vitro was enhanced by ET-1,[230] indicating increased activation of the Gardos channel via sickling-induced calcium influx. In addition, two inflammatory cytokines – interleukin-10 and RANTES (Regulated upon Activation, Normal T lymphocyte Expressed and Secreted) – and the inflammatory

phospholipid mediator, platelet activating factor, had similar effects on Gardos channel activity in sickle cells.

Other lipid mediators could augment Gardos channel activity by enhancing calcium influx. Treatment of normal erythrocytes with subnanomolar concentrations of prostaglandin E2 (PGE_2) activated the Gardos channel in vitro in approximately 15% of cells, producing reduced cell volume and osmotic resistance,[231] apparently as a result of an increase in calcium uptake by PGE_2, which has been demonstrated independently.[232] Lysophosphatidic acid, a lipid mediator released from activated platelets, stimulates calcium uptake, detected by fluorescent dyes, in approximately 25% of red cells, as does activation of protein kinase C by phorbol esters and diacylglycerol. Calcium influx stimulated by lysophosphatidic and protein kinase C are both inhibited by ω-agatoxin-TK, suggesting mediation by a P-type calcium channel and are modulated by inhibitors of tyrosine kinases (TK), but in subtly different ways, indicating that multiple signaling pathways might be involved.[233,234]

The modulation of Gardos channel activity by inflammatory cytokines and other mediators could be particularly relevant in sickle cell disease. Endothelial cells are stimulated to produce endothelin by interactions with sickle cells and activated leukocytes. Plasma levels of ET-1 and PGE_2 are abnormally elevated in patients with sickle cell disease in the "steady state"[235–237] and increase further with acute chest syndrome or other vasoocclusive events.[236,238] It is possible that local levels of ET-1 and/or PGE_2 in the microcirculation are even higher and potentiate Gardos channel activity of sickle cells during vasoocclusive or adhesive interactions. Such receptor ligand interactions could be exploited pharmacologically, as several specific blockers, such as ET-1 receptor antagonists, have been found to have clinical benefit in other disorders.

Direct blockade of the Gardos channel is possible using the imidazole antimycotic clotrimazole and its derivatives, which acts by binding to the external pore of the channel (Chapter 31).[239] Early studies indicated the ability of clotrimazole to reduce the number of dense cells in sickle cell patients.[158] More recently, compounds lacking the imidazole ring have been shown to be effective Gardos channel blockers.[240] One of these, senicapoc, has been tested in phase II and phase III clinical trials in sickle cell disease. Patients treated with a daily oral dose of senicapoc exhibited fewer dense cells, increased hemoglobin levels, reduced reticulocyte counts, lower bilirubin and lactate dehydrogenase levels, which was consistent with reduced hemolysis,[163] and a predictable outcome of the mitigation of cellular dehydration. A phase III (ClinTrials.gov/, NCT00102791) study of senicapoc was recently terminated, as it was unlikely that its chosen endpoint, a reduction in pain episodes, could be reached. Nevertheless, given that vasoocclusion and hemolysis represent different aspects of sickle cell pathology, that dense cell numbers are most closely associated with hemolysis, and that hemolysis appears to be associated with long-term complications, such as pulmonary hypertension, a drug such as senicapoc that reduces hemolysis might ultimately have important long-term benefit in sickle cell disease.

In summary, the ionized calcium level in red cells in vivo is a dynamic balance between calcium influx and the compensatory capacity of the calcium pump and is normally maintained well below the threshold for activation of the Gardos pathway. Calcium influx can increase, especially in sickle cells, by a variety of mechanisms – triggering of the deoxygenation-induced pathway by sickling, modulation of calcium channels by cytokines or inflammatory mediators, or activation of stretch-induced cation channels by circulatory shear stress. Such influx events appear to produce calcium transients in red cells sufficient to activate the Gardos pathway. Compromise of the capacity of the calcium pump by physiological regulation or pathological damage would make such calcium transients greater in magnitude and/or more prolonged, increasing the probability of potassium channel activation and enhancing its adverse effects on cell volume. Modulation of the kinetic properties of the Gardos channel by inflammatory mediators might also enhance potassium loss in some cells. A substantial body of data now exists to support the occurrence of such events in vivo, at least in some populations of sickle erythrocytes. The quantitative integration of these events and their pathophysiological modulation in vivo remains a fruitful area of study.

Potassium Chloride Cotransport in Sickle Erythrocytes

KCC was first described in red cells as a chloride-dependent potassium efflux stimulated by the sulfhydryl alkylating agent N-ethylmaleimide.[241,242] Other activators of KCC in vitro include cell swelling, acid pH, urea, sulfhydryl oxidation, reduced cellular magnesium, and hyperbaric conditions.[243–246] The activity of KCC is maximal in normal reticulocytes and young cells and is progressively reduced to negligible values in mature and dense normal red cells.[197,247–250] Early reports established that sickle cell disease blood samples had high KCC activity (Fig. 9.8),[197,251,252] although the quantitative comparison to normal cells is complicated by the presence of large number of reticulocytes and young cells in patient blood.

KCC activity is highest in the least dense sickle cells, which contain most of the reticulocytes, and is least active in the dense cell fractions.[197,252,253] The relative importance of activating stimuli for KCC and volume regulation in vivo is not known. Even reticulocyte rich fractions of sickle erythrocytes have minimal KCC activity in the absence of stimulation, and reticulocyte volume and CHC are stable upon in vitro incubation under these conditions.[254] KCC fluxes are inversely proportional to whole blood MCHC over the range from 24 to 34 g/dL, but the relative activation of KCC in sickle and normal cells is indistinguishable

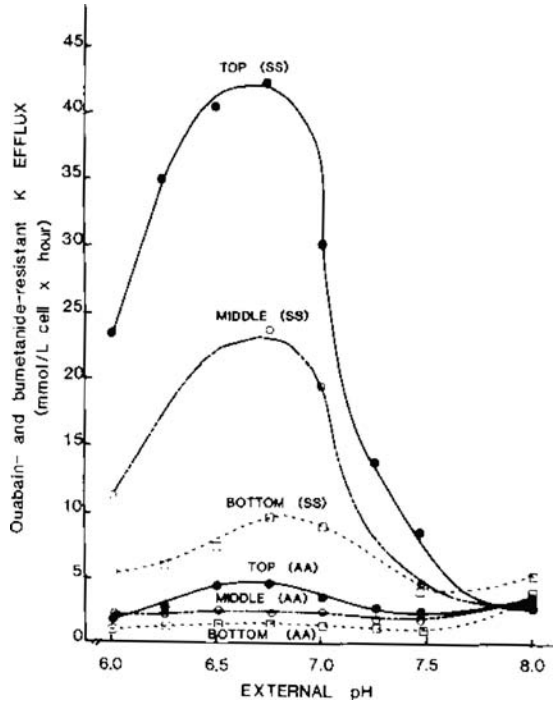

Figure 9.8. High levels KCl cotransport activity in sickle cells. High rate of acid-stimulated potassium efflux in various density fractions reflects high activity of KCC in sickle cell disease blood. The highest activity is in the "top" density fraction containing the most reticulocytes, but other density fractions contain more reticulocytes than normal blood. Given that KCC activity declines with reticulocyte maturation, higher reticulocyte counts in sickle cell blood and the absence of older sickle cells means that cell age must be taken into account in any comparison of flux rates between sickle and normal erythrocytes, even in density fractionated cells. (From ref. 252.)

(Fig. 9.9). KCC activation by acid pH is exaggerated in sickle cells compared with normal cells (Fig. 9.9), so that if acidic conditions occur in the circulation, sickle cells would be more vulnerable to KCC-mediation dehydration than normal cells. Likewise, sickle cells are more sensitive to KCC activation by urea than normal cells (Fig. 9.9), showing activation at lower concentrations, well within those found in the medulla of the kidney. The heightened sensitivity of KCC in sickle cells to activation by acid pH and urea is due at least in part to reversible sulfhydryl oxidation, as suggested by its normalization on treatment by the sulfhydryl agent dithiothreitol. This raises the possibility of the therapeutic potential of reducing agents, such as N-acetyl cysteine, which has been shown to block in vitro dehydration of sickle cells,[255] and, in a limited trial, to improve sickle cell hydration.[256]

Activation of KCC results in potassium, chloride and water loss, with reduction in cell volume and increase in CHC.[252–254,257–260] This can be demonstrated in the phthalate density profile of sickle cell disease blood,[257] but changes in normal erythrocytes with low reticulocyte counts are minimal. Measurement of the rapid reduction in reticulocyte CHC upon activation of KCC permits direct comparison of sickle and normal cells, as shown in Figure 9.9. Whether activated by swelling, acid pH, or urea, sickle cells exhibit more extensive volume reduction than normal cells, achieving in each case a higher CHC. Swelling-induced volume regulation is not altered by sulfhydryl-reducing agents, but abnormal sickle cell volume reduction triggered by acid pH and urea is partially normalized by dithiothreitol.[254,261] Thus the CHC 'set point' for KCC-mediated volume regulation appears to be abnormal in sickle cells and could result in part from their abnormal oxidation state.[3,262,263]

Deoxygenation of sickle erythrocytes produces complex changes in KCC activity. In normal human cells, and in fish and horse cells, KCC activity stimulated by urea, acid pH, or cell swelling is inhibited as pO_2 falls.[264,265] In sickle cells, activity initially declines with deoxygenation, but begins to increase again at approximately 40 mm Hg, with the onset of sickling; blockade of sickling with dimethyl adipimidate abolishes this effect.[182] Nevertheless, activated KCC fluxes in fully deoxygenated cells are lower than in oxygenated cells, so that the overall effect of deoxygenation on activated KCC in sickle cells appears inhibitory. Part of this inhibition, although probably not all, results from the increase in cellular free magnesium concentration associated with binding of 2,3-BPG to deoxyhemoglobin.[249] In sickle cells suspended in isotonic media at normal pH, in which KCC activity is minimal at high pO_2, deoxygenation activates KCC, especially if deoxygenation-induced increase in ionized magnesium is prevented by use of divalent cation ionophores.[266] This behavior might explain other observations that cycles of oxygenation and deoxygenation produced chloride-dependent potassium loss and shifts toward higher density in sickle cells, especially reticulocytes. It has been suggested that on deoxygenation, changes in phosphorylation activate KCC, but the activity is masked by the increase in cellular magnesium, which is known to inhibit KCC. On reoxygenation, magnesium levels are restored to normal more rapidly than the changes in phosphorylation are reversed, providing a brief pulse of KCC activity that produces cumulative dehydration upon repeated cycling. If this mechanism occurs in vivo, cyclic deoxygenation in the circulation might be responsible for activation of KCC and dehydration of sickle cells, especially in reticulocytes which can linger in the venous circulation due to abnormal adhesive interactions.[127]

Cellular Magnesium and KCC in Sickle Cells. Although total erythrocyte magnesium content is reduced, especially in dense sickle cells, during deoxygenation the binding of 2,3-BPG, a major chelator of magnesium, to deoxy hemoglobin results in a large increase in free magnesium concentration. Cell sickling increases membrane permeability to magnesium and the transient outwardly directed magnesium gradient during deoxygenation produces magnesium efflux, resulting in reduced total magnesium content in sickle erythrocytes.[174] Human erythrocytes also

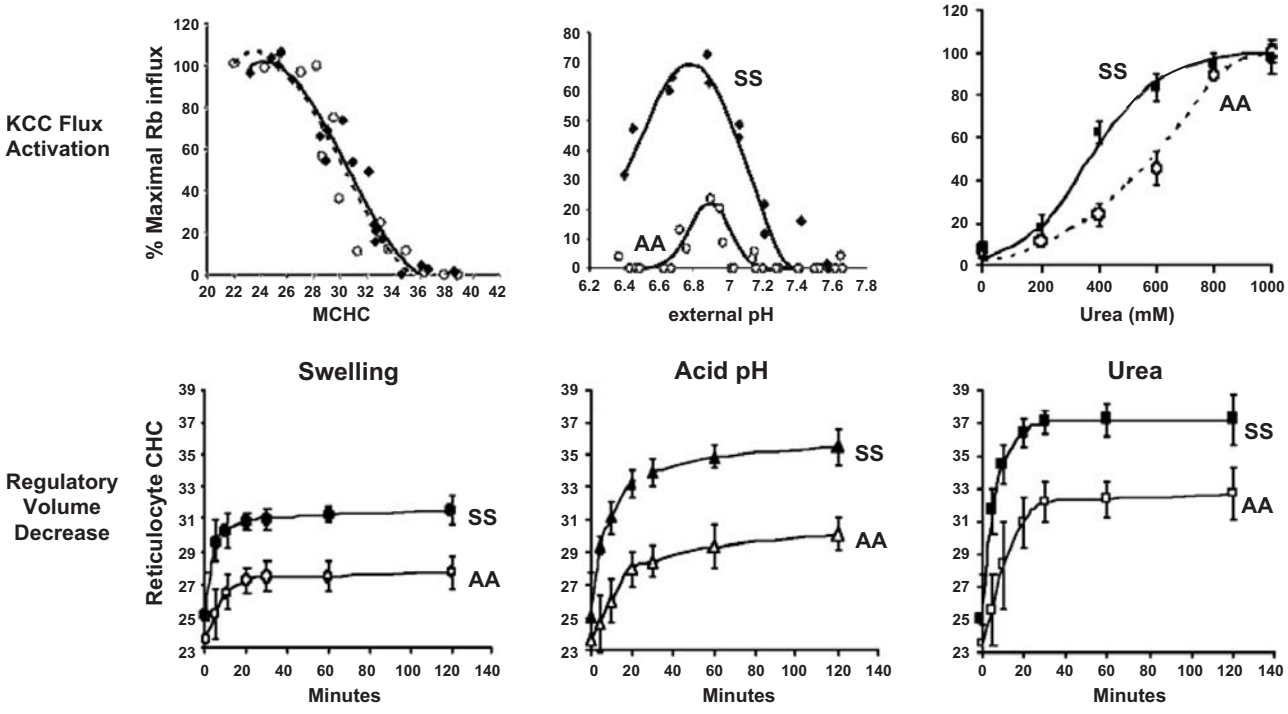

Figure 9.9. Abnormal regulation of KCC in sickle reticulocytes. Upper panels show activation of KCC-mediated fluxes as a function of initial MCHC (cell swelling), external pH, and urea concentration in normal (AA; open symbols) and sickle (SS; filled symbols) red cells. Fluxes are expressed as a percentage of the maximal volume stimulated flux to normalize for differences in the age distribution of the cells. Although SS proportionate activation by cell swelling is "normal," response to acid pH is exaggerated, and activation by urea occurs at lower concentrations than in AA cells. (From refs. 254, 260.) Lower panels depict regulatory volume decrease, reflected as an increase in reticulocyte CHC with time upon activation of KCC. Reticulocyte CHC was measured by Advia cell counter. Regardless of how KCC is activated, the final MCHC achieved is higher in SS than in AA reticulocytes (From CH Joiner, unpublished data.)

possess a specific sodium–magnesium exchanges system, whose activity produces slow loss of magnesium from the erythrocyte.[267] Sickle erythrocytes exhibit markedly increased activity of the sodium–magnesium exchanger, which could theoretically contribute to their reduced total magnesium content.

Magnesium depletion of sickle cells is pathophysiologically relevant in view of the sensitivity of KCC to cellular magnesium. KCC is stimulated by the reduced levels of cellular magnesium found in sickle erythrocytes.[159,174,268,269] The inhibition of KCC by increasing cellular magnesium content provides a new potential opportunity for preventing dehydration in thalassemic[270,271] and sickle erythrocytes.[160,272] Oral magnesium supplementation corrects the deficit in cellular magnesium in sickle cells, inhibits KCC cotransport, and reduces cell dehydration.[160,272] Small pilot studies of magnesium supplementation demonstrate that oral magnesium supplementation can improve sickle cell hydration and decrease dense cell numbers, and phase I and II trials are in progress in sickle cell anemia and in HbSC disease (NCT00143572, NCT00532883). Large-scale trials have not been reported. Interestingly, magnesium supplements also reduced the activity of the sodium–magnesium exchanger in sickle cells (Chapter 31).[160]

Molecular Basis for KCC. KCC is mediated by members of the cation-chloride cotransporter (SLC12) family,[273,274] which includes the thiazide-sensitive NaCl cotransporters, the bumetanide-sensitive Na-K-Cl cotransporter and the volume-sensitive KCCs. These electroneutral transporters play three important physiological roles: transepithelial movement of solute, maintenance of intracellular ion concentrations (especially chloride) in electrically excitable cells, and regulation of cell volume. In erythrocytes, the KCC mediates the volume reduction and resultant increase in CHC that accompanies reticulocyte maturation.[244,245,275,276]

The prototype KCC (KCC1, *SLC12A4*)[277] is expressed in most tissues. Three other KCC genes code for additional isoforms with more limited tissue distributions. The neuronal-specific KCC2 (*SLC12A5*) appears to function primarily as a regulator of chloride concentrations in neurons.[278,279] KCC3 (*SLC12A6*) is expressed predominantly in kidney, lung, skeletal muscle, and brain, with a unique splicing isoform present in kidney.[280–283] KCC4 (*SLC12A7*) is highly expressed in heart, kidney, and pancreas.[282,284]

The functional characteristics of the four isoforms are generally similar, although anion selective is subtly different and KCC1, KCC3, and KCC4 respond to hypotonic stimuli, whereas KCC2 does not.

Human, sheep, and mouse red cell membranes contain both KCC1 and KCC3.[285–288] In mouse cells, deletion of the KCC1 gene has little effect on KCC activity or cell volume; deletion of KCC3 results in a reduction of KCC activity, associated with an increase in KCC1 expression. Dual deletion abolishes KCC activity and results in overhydration of red cells with normal hemoglobin and mitigation of the dehydrated red cell phenotype found in the SAD mouse (Chapter 12).[287] These data suggest that KCC3 is the predominant KCC transporter in mouse red cells. Human erythroid cells also express KCC4[288,289] in addition to KCC1 and KCC3. The relative contribution of each of these transporters to KCC activity in human cells is unknown. It is possible that they interact with each other to modulate activity, as has been shown with artificially truncated KCC constructs,[290] naturally occurring splicing isoforms of the sodium-potassium-chloride cotransporter (NKCC),[291] and interactions between KCC and NKCC.[292]

Recent reports reveal that KCC isoforms interact differently with various regulatory kinases.[293,294] Differences in the relative expression of KCC isoforms between sickle and normal red cells could conceivably produce increased KCC activity and/or abnormal regulation of KCC activity in sickle cells (Fig. 9.9). Interindividual differences in KCC isoform expression could also be a source of genetic variation that affects the phenotype of sickle cell disease (Chapter 27).

Activation of KCC is associated with a serine/threonine dephosphorylation event, as protein phosphatase inhibitors such as okadaic acid and calyculin A block activation. Membrane stretch or shape change is not a signal transduction mechanism for KCC activation.[295] Rather, studies of activation/inactivation kinetics in response to volume changes have suggested that cell swelling inhibits the putative inactivating protein kinase, shifting the kinase/phosphatase equilibrium toward dephosphorylation and activating the transporter.[296–299] Perhaps changes in cellular hemoglobin concentration associated with swelling produce dramatic alteration in the activity of cellular enzymes through macromolecular crowding effects in the nonideal thermodynamic conditions of concentrated protein solutions as present in erythrocytes (Chapter 6).[300]

The ubiquitous and promiscuous protein phosphatases 1 and 2A (PP1, PP2A) activate KCC and might function redundantly.[269,301–304] Neither the phosphorylation sites on KCC nor the inhibitory kinase in red cells have been identified. In KCC1, threonine phosphorylation sites on the N terminus have been shown to be altered in response to changes in cell volume and to modulate the activity of the transporter.[305] Several ST kinases have been shown to interact with NKCC1, including the stress-related kinase SPAK (STE20-related-proline-alanine-rich kinase, also known as PASK), OSR1 (oxidative stress response kinase), and the WNK (with-no-lysine) kinases. Using a yeast two-hybrid system, SPAK and OSR1 have been shown to interact with KCC3, but not KCC1 or KCC4,[293] although SPAK was unable to modulate KCC3 activity[294] when coexpressed in xenopus oocytes. Coexpression of WNK 4 with KCC1, KCC3, or KCC4 resulted in inhibition of hypotonic activation of these transporters, whereas coexpression of a kinase-inactive mutant WNK4 activated KCC3 although not KCC1 and KCC4, under isotonic conditions. Interestingly, although inactivated SPAK was not able to activate KCC3 alone, it enhanced the activation of KCC3 by inactivated WNK4, suggesting interaction of these kinases, as has been shown in the regulation of NKCC1.[306] The behavior of the WNK4 kinase in these in vitro systems is consistent with that expected from the putative swelling-inhibited kinase responsible for modulating KCC activity in red cells, but this identity remains to be demonstrated. Identification of the regulatory sites of KCC and the associated kinases would be an important step in delineating its dysregulation in sickle cell disease.

The activities of PP1 and PP2A are themselves regulated by TKs. TK inhibitors such as staurosporine and celerythine activate KCC, probably by maintaining PP1/PP2A in the dephosphorylated, active state. Mice with genetic knockout of two src tyrosine kinases, fgr and hck, have constitutively activated KCC and exhibit dehydrated erythrocytes,[307] elimination of either kinase alone was not sufficient to produce this phenotype, suggesting redundant function of the src kinases. Interestingly these animals do not show the normal decline in KCC activity with red cell aging, which could be explained by age-associated reduction in the paired TK. Deoxygenation alters protein phosphorylation state of the erythrocyte membrane, decreasing phosphorylation of several high abundance membrane proteins.[308] Deoxygenation increased the activity of the syk kinase, and inhibitors of *syk* blocked the stimulation of KCC that accompanied deoxygenation. Activity of the src kinase expressed in human cells (lyn) was not changed by deoxygenation and lyn inhibitors did not alter the deoxystimulation of KCC.[309] Thus, src-family TKs are negative regulators of KCC activity, probably via effects on the activating phosphatases, and syk-family TKs appear to be positive regulators. This complex pattern of regulation probably explains why some TK inhibitors stimulate and others inhibit KCC.[310,311]

MULTITRACK MODEL OF SICKLE CELL VOLUME REGULATION PATHOBIOLOGY

Cell heterogeneity is a hallmark of sickle cell disease,[134] with high numbers of dense cells and many low-density reticulocytes. In general, low-density sickle cells have high KCC activity and dehydrated cells exhibit low activity.[249,252] Even if fractionated by age or density, sickle cells exhibit considerable heterogeneity. Some reticulocytes are found in the dense cell fraction, suggest very rapid dehydration in the circulation, or, fast-track dehydration. Within the

low-density fraction containing most of the sickle reticulocytes is a pool of cells exhibiting enhanced capacity to dehydrate via KCC.[179] A similar fraction of reticulocytes/young cells was found with decreased F cell content.[258] Transferrin receptor–positive sickle reticulocytes present in the dense cell fraction had greater KCC activity than sickle reticulocytes which had normal hydration in vivo;[253] both studies demonstrated that KCC activity did not correlate with HbF content.[259]

Sickle erythrocyte maturation and density changes have been followed in vivo by using biotin-labeled erythrocytes.[146,312,313] After ex vivo labeling and reinfusion, biotin-labeled cells exhibit increased density and dehydration within the first week, with loss of the least dense fractions and relative increases in high-density populations. This suggests that density changes in vivo occur soon after release of young cells into the circulation, supporting the notion of rapid dehydration. Sickle cells surviving longer than 1 week in the circulation, which account for 50%–66% of the population, are all strikingly dehydrated, with densities exceeding the densest normal cells.[312]

The low HbF content of dense reticulocytes suggests a sickling-induced mechanism for fast-track dehydration.[179,181] This model envisions initial dehydration of a population of reticulocytes via activation of the Gardos channel by calcium influx through the sickling-induced pathway. Incremental dehydration would result in a slight intracellular acidification, which in turn would activate KCC in susceptible cells. Mathematical modeling of this mechanism predicts rapid volume collapse after cycles of deoxygenation.[181] Reticulocyte heterogeneity in susceptibility to KCC activation by intracellular acidification could account for a subset of rapidly dehydrating cells. This notion is supported by the increased susceptibility of KCC activation to acid pH in sickle cells compared with normal cells.[179,254] An alternative model for fast-track dehydration is that reticulocytes reach a state of intermediate dehydration via KCC activity, with heterogeneity derived from cellular differences in KCC capacity, function, or regulation. Reticulocytes with CHC thus increased would be “set up” for sickling, calcium permeabilization via the sickling-induced pathway, Gardos channel activation and subsequent severe dehydration.[226] This model is supported by the finding that formation of transferrin receptor–positive cells of intermediate density, which are dehydrated compared with normal reticulocytes, is not dependent on HbF concentration.[259] Presently, the data do distinguish between these two models of initial dehydration through sickling-induced Gardos activation followed by KCC activation compared with dehydration by abnormal KCC activation potentiating sickling-induced Gardos activation.

The lifespan of sickle erythrocytes that contain little or no HbF is approximately 2 weeks, compared with 6–8 weeks for F cells,[312] confirming the selective survival of F cells inferred from the number of F cells and F reticulocytes in the circulation (Chapter 7).[314] Unexpectedly high levels of HbF, either naturally occurring or induced by hydroxyurea, were found to be associated with shortened survival times of non-F cells.[313] The survival of dense sickle cells in vivo is extremely short, with 50% survival times ranging from 40 to 60 hours for dehydrated non-F cells and 120–330 hours for dense F cells.[146] Their fragility and selective involvement in vascular occlusion and hemolysis, plus their rapid clearance during vasoocclusive episodes, supported the notion that dense sickle cells represented an end-stage in the life of sickle cells. That model has recently expanded to accommodate the existence of significant numbers of low-density, potassium-depleted, and sodium-loaded sickle erythrocytes resistant to dehydration by in vitro treatment with valinomycin, as discussed previously. The majority of low-density sickle cells that were older as assessed by biotin labeling were in fact, valinomycin-resistant, sodium-loaded cells. Such low-density cells arose spontaneously in vitro upon incubation of dense sickle erythrocytes under oxygenated conditions, and this process was accelerated by cyclic deoxygenation.[145] The steady-state in vivo levels of valinomycin-resistant cells in sickle blood is approximately 3%–10%.[143] Together with their short survival, this suggests that a significant proportion of sickle cells pass through this phase of sodium loading and over hydration prior to their destruction.

A new model of the sickle cell “hydration” cycle thus includes pathological rehydration following pathological dehydration. The potassium loss that produces initial dense cell production deprives the cell of the ability to offset cation uptake driven by Donnan forces. Progressive sodium loading would then ensue, by virtue either of the deoxygenation-induced permeability increase or in response to dehydration, as has been shown experimentally under other conditions. Provided that the combination of sodium influx and potassium efflux exceeded the capacity for compensation by the sodium pump, the cell would be destined to swell to the point of osmotic lysis. This process of osmotic volume regulatory failure could contribute to intravascular hemolysis in sickle cell disease, now appreciated as an important aspect of the pathophysiology in light of the perturbations in nitric oxide metabolism brought about by free hemoglobin in the plasma (Chapter 11).[315]

Pharmacological Inhibition of Sickle Cell Dehydration

The pathological dehydration of sickle cells and its contribution to hemolysis and vasoocclusion raised the possibility of a therapeutic benefit from improving sickle cell hydration.[316] Attempts to rehydrate cells by infusions of hypotonic fluids or treatment with antidiuretic hormone proved impractical.[317] More recently, drugs targeting specific pathways contributing to dehydration have undergone preliminary testing and some are discussed in Chapter 31. A trial of dipyridamole, an inhibitor of the deoxygenation-induced cation leak,[176] is currently underway (NCT00276146).

Cation Transport and Volume Regulation in Other Hemoglobinopathies and Thalassemia

Specific and nonspecific interactions of hemoglobin with components of the red cell membrane can have important functional effects, which can be pathological when abnormal hemoglobins are involved. HbC is capable of powerful stimulation of KCC, resulting in excessive volume reduction of erythrocytes to produce elevated MCHC.[252,318–321] The pathological consequences of elevated MCHC could contribute to crystal formation in the case of HbC disease (Chapter 21). Dehydration is particularly significant in HbSC disease, in which cellular dehydration produces conditions that permit sickling, even thought the participation of HbC in polymer formation is no greater than HbA.[319] An argument has been made that KCC stimulation is specifically related to mutations around the sixth amino acid position of *HBB*, as HbS and HbC. Hb Siriraj (*HBB* glu7lys) and Hb San Jose (*HBB* glu7gly) produce slight elevations in KCC activity in heterozygotes, which were not observed in heterozygotes with HbO Arab or HbD (Chapter 23).[320] Other studies, however, showed marked KCC stimulation and dehydration of both mature red cells and reticulocytes in homozygotes with HbO Arab and compound heterozygote with HbS and HbO Arab.[322]

In thalassemia, both hemoglobin content and abnormal cation transport affect cell volume. Although the responsible mechanisms are poorly understood, total hemoglobin content is an important determinant of cell volume so any condition that reduces hemoglobin synthesis produces microcytic, hypochromic erythrocytes. Indeed, the red cell "phenotype" in α thalassemia, where one or two α-globin genes are deleted (Chapters 13 and 14) is virtually indistinguishable from that in iron deficiency. MCHC in these conditions and in HbH disease is slightly less than in normal erythrocytes.

In contrast, despite their reduced hemoglobin content, β-thalassemia erythrocytes, especially those of β-thalassemia intermedia (Chapter 17), exhibit a substantial population of dense erythrocytes (Fig. 9.10).[36] This elevated hemoglobin concentration results in increased cellular viscosity, which contributes to increased dynamic rigidity. KCC is increased in both β and α thalassemia erythrocytes, in proportion to the severity of disease. Swelling-induced KCC activity is substantially increased in both types of thalassemia.[323] Although high reticulocyte counts might contribute to some of the elevation of KCC activity in these samples, several lines of evidence suggest that pathological activation might also occur. In vitro treatment of thalassemia red cells with dithiothreitol markedly reduced KCC activity, suggesting KCC activation by oxidative stress, consistent with the presence of hemichromes and other oxidant products in membrane. This connection is strengthened by the finding that treatment of patients with the iron chelator L1, which reduced iron content of red cell membranes, also lowered KCC activity and improved cellular potassium content.[324] Like sickle cells, β thalassemia red cells are depleted of cellular magnesium, and oral supplementation with magnesium pidolate has been shown to restore cellular magnesium, reduce KCC activity, and improve cellular potassium content.[271] Although these findings support a link between abnormal KCC regulation and cellular dehydration in thalassemia, erythrocytes, especially in HbH disease, show quantitatively similar increases in KCC activity, with no increase in cellular hemoglobin concentration (Fig. 9.10).

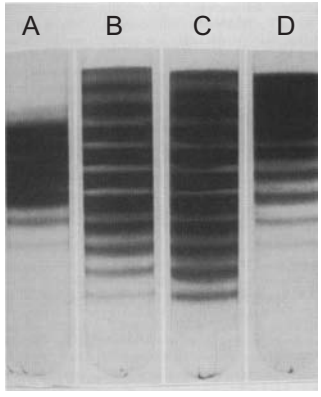

Figure 9.10. Density gradient analysis of thalassemic erythrocytes on discontinuous Stractan gradients. Density range 1.065–1.130 g/mL in 0.0045 g/mL increments. **(A)** Normal red blood cells. **(B)** β thalassemia intermedia, unsplenectomized. **(C)** β thalassemia intermedia, splenectomized. **(D)** HbH disease. (From ref. 36.)

Whether mechanisms other than KCC contribute to dehydration of β thalassemia red cells is unknown. Calcium content of β thalassemia red cells is elevated, but most is sequestered in intracellular vesicles or retained organelles, and cytoplasmic calcium levels appear to be normal, as do active and passive calcium fluxes.[325,326] In contrast, in a mouse model of β thalassemia, treatment of animals with the Gardos channel blocker, clotrimazole, resulted in fewer dense cells, higher MCHC, and higher potassium content, but no change in hemoglobin or reticulocyte count.[327] This suggested that the Gardos pathway plays a role in cellular dehydration in β thalassemia red cells, but that dehydration does not shorten red cell survival. As yet there are no experimental data to support the hypothetical possibility of K channel activation via increase calcium influx due to shear stress on the mechanically unstable thalassemic membrane.

SUMMARY

The erythrocyte membrane is a complex dynamic structure with multiple regulated functions. Cytoskeletal proteins maintain the structural integrity of a membrane that must simultaneously be flexible enough to deform in the microcirculation and durable enough to resist high shear stresses in large vessels. Multiple ligands and receptors interact with the external surface of the membrane, and some of these interactions trigger signaling cascades that regulate cell function. Specific proteins maintain a highly ordered lipid structure, which in turn, might modulate other membrane

protein functions or cellular interactions. Multiple regulated transport systems control solute and water fluxes across the membrane to facilitate the transport of respiratory gases, provide metabolic substrates, and regulate cell volume. Substantial energy is required to detoxify oxidant molecules that arise as an occupational hazard of the erythrocyte's major tasks, the transport of oxygen.

Given the physiological interactions of hemoglobin with the erythrocyte membrane, it is perhaps not surprising that abnormal hemoglobins can elicit significant pathological effects on membrane structure and function. A significant source of membrane damage in hemoglobinopathies is the increased level of oxidant species produced by reactive sulfhydryl on unstable or denatured hemoglobin molecules, membrane bound heme, or free iron. Oxidation affects cytoskeletal function, leads to externalization of PS, increases membrane rigidity and fragility, and perturbs cation transport and volume regulation.

HbS polymerization elicits major perturbations of membrane structure and function. Polymer formation, in addition to increasing cellular rigidity and blood viscosity, results in formation of membrane spicules in which the cytoskeleton is dissociated from its membrane connections. Associated with this membrane disruption is externalization of PS and an increase in cation permeability via a nonselective cation pathway. Calcium influx via this deoxygenation-induced pathway results in activation of the Gardos pathway, which mediates selective potassium loss that results in cation depletion. KCC, normally involved in establishing reticulocyte hemoglobin concentration, is excessively active in the red cells of certain hemoglobinopathies and thalassemias, and leads to dehydrated, dense cells with high hemoglobin concentrations. In cells containing HbS, elevated hemoglobin concentrations greatly potentiates the rate and extent of polymer formation.

The pleiotropic effects of abnormal hemoglobins on erythrocyte membrane structure and function contribute to the pathophysiology of sickle cell disease and thalassemia. Strategies targeting specific membrane pathology offer novel avenues to develop new therapy for these diseases.

The Biology of Vascular Nitric Oxide

Jane A. Leopold and Joseph Loscalzo

The role of nitric oxide (NO) as the key mediator of endothelial function and vascular tone was initially recognized by Furchgott and Zawadski[1] over two decades ago when they discovered that an intact endothelium was required for acetylcholine-stimulated vasodilation. From these studies, they determined that the endothelium released a potent vasodilator substance that they termed endothelium-derived relaxing factor;[1] several years later, this factor was identified as NO.[2,3] Since that time, NO has been shown to modulate a host of functions that maintain the integrity of the endothelium as well as regulate interactions between circulating blood components and the vessel wall. Through its chemical reactions with a variety of species, including heme iron, NO is uniquely positioned to regulate these vascular homeostatic processes.

Endothelium-derived NO serves as a paracrine regulator of vascular function. NO is released to the vascular smooth muscle cells where it activates soluble guanylyl cyclase to generate cyclic guanosine monophosphate (cGMP) and modulate cation flux which, in turn, induce vasodilation and adjust vascular tone accordingly.[4,5] NO is also released to the bloodstream where it encounters erythrocytes, platelets, and plasma components. Here, the metabolic fate of NO is determined by a complex series of reactions that both consume and preserve stores of bioavailable NO. Owing to the relative abundance of erythrocytes compared with other circulating cell types, interactions between NO and redox-active hemoglobin achieve biological significance. In this chapter, we will discuss NO synthesis and biological chemistry, with particular focus on NO reactions with hemoglobin as well as the physiological relevance of NO-hemoglobin derivatives. In addition, we will detail the importance of NO for endothelial, vascular smooth muscle, and platelet homeostatic functions.

THE BIOLOCHEMISTRY, GENETICS, AND VASCULAR CELL BIOLOGY OF NITRIC OXIDE

Nitric Oxide Synthesis

NO is synthesized in numerous cell types and tissues by NO synthases (NOS). NOSs exists as two main isoform classes: the constitutive enzyme identified in the endothelium (eNOS or NOS3) and neuronal cells (nNOS or NOS1) and the inducible enzyme (iNOS or NOS2) found in smooth muscle cells, neutrophils, and macrophages (as well as many other cell types) following exposure to inflammatory cytokines or bacterial endotoxin.[6] NO is generated via the five-electron oxidation of L-arginine to form L-citrulline and stoichiometric amounts of NO.[3] This reaction requires molecular O_2 and nicotinamide adenine dinucleotide phosphate as cosubstrates and flavin adenine dinucleotide, flavin mononucleotide, and tetrahydrobiopterin as cofactors to facilitate electron transfer to the NOS heme moiety.[7] Each of the NOS isoforms possesses specific structural and functional characteristics that determine the degree to which cofactors regulate enzyme activity and NO production. Comparison of the amino acid sequences reveals that there is 50%–55% homology among NOS isoforms with the greatest conservation between sequences for the two main catalytic domains.[8]

All NOS isoforms are under the regulatory control of Ca^{2+} and calmodulin for effective electron transfer between the reductase and oxygenase domains of the enzyme; however, the affinity of NOS for the Ca^{2+}–calmodulin complex differs among isoforms and accounts, in part, for the difference in regulation of NO production. In endothelial cells, eNOS is membrane-bound within caveoli and binds calmodulin in a strongly Ca^{2+}-dependent manner that is reversible.[9] Following stimulation with agonists such as acetylcholine or bradykinin, inositol 1,4,5-trisphosphate production is increased to promote the release of intracellular Ca^{2+} stores.[10] This transient increase in intracellular Ca^{2+} enhances the formation of a Ca^{2+}–calmodulin complex, which, in turn, activates eNOS to facilitate dissociation from caveolin-1.[11] Once activated, eNOS generates continuously low levels of NO until Ca^{2+} stores are depleted.[9,12] Although eNOS is constitutively expressed, it is now recognized that expression may be differentially regulated under physiological and pathophysiological conditions and is subject to both posttranscriptional and posttranslational modification.[6] In contrast, iNOS binds calmodulin in states of low intracellular Ca^{2+}, is regulated at the transcriptional level, and, therefore, requires several hours to effect a physiological response.[13] Concentrations of NO (per mole of enzyme per minute) generated by iNOS are substantially greater than those achieved by eNOS,[14] are potentially cytotoxic, and indicate that iNOS may play an integral role in both the immune response and apoptosis.[15,16]

In the vascular endothelium, a number of signaling molecules as well as hemodynamic forces modulate eNOS expression to influence NO production. For example, transforming growth factor-β1, lysophosphatidylcholine, hydrogen peroxide, tumor necrosis factor–α (TNFα), oxidized low-density lipoprotein, laminar shear stress, and hypoxia all mediate eNOS expression by regulating gene transcription. In addition, TNFα, lipopolysaccharide, oxidized low-density lipoprotein, hydroxymethylglutaryl coenzyme A reductase inhibitors (statins), thrombin, and hydrogen peroxide have been shown to regulate eNOS expression by influencing mRNA degradation.[17]

NO production may be influenced further by a number of polymorphisms of the eNOS gene that have been identified and evaluated to determine the consequences for eNOS activity and association with vascular disease. Among these polymorphisms, a single nucleotide polymorphism in the promoter region (−786T/C) and in exon 7 resulting in the conversion of glutamate to aspartate at position 298 (Glu298Asp) and a variable number of tandem repeats in intron 4 (b/a) have been the most extensively studied. In a meta-analysis of 26 studies that examined these three polymorphisms, homozygosity for the Asp298 (odds ratio = 1.31; 95% confidence interval = 1.13−1.51) or the intron-4a allele (odds ratio = 1.34; 95% confidence interval = 1.03−1.75) was associated with an increased risk of ischemic heart disease, whereas no association was demonstrated for the −786C allele.[18]

Despite these findings, individual studies examining the functional significance of the Glu298Asp polymorphism have yielded conflicting results. Select studies of subjects homozygous for Asp298 demonstrate impaired endothelium-dependent brachial artery flow–mediated dilation, suggesting decreased bioavailable NO,[19] whereas other studies fail to make this association.[20–22] Although direct measures of eNOS activity and NO production were not determined in these studies, in vitro studies performed in primary human endothelial cells with the Glu298Asp polymorphism revealed enhanced eNOS protein cleavage, implying that this polymorphism should be associated with decreased NO production.[23]

A second polymorphism that has been studied is located in the promoter region and results from a T-to-C substitution, which may influence eNOS transcriptional activity, although this effect has not yet been confirmed in vivo. In contrast to what was found in the meta-analysis,[18] individuals with the −786C promoter polymorphism had impaired endothelium-dependent vascular reactivity[24] that was associated with a significant increase in death from cardiovascular causes at the end of a 2,000-day follow-up period.[25]

Interestingly, among the hemoglobinopathies, eNOS polymorphisms have been associated with disease status only in individuals with sickle cell disease.[26] In African-American women with sickle cell disease, the presence of the −786C promoter polymorphism was significantly associated with acute chest syndrome (relative risk = 8.7; 95% confidence interval = 1.76–42.92).[27] A mechanism to explain this association has not yet been elucidated; however, the −786T/C polymorphism adversely influences erythrocyte deformability.[28]

Bioreactivity of Nitric Oxide

NO, as a free radical, is only modestly reactive compared with other biological free radicals (i.e., it can diffuse over micron rather than Ångstrom distances before encountering another coreactant). NO may exist in one of three closely related redox forms, each with discrete properties and reactivities: $NO^{\bullet}$, NO^{+} (nitrosonium, formed by single-electron oxidation of $NO^{\bullet}$), and NO^{-} (nitroxyl, formed by single-electron reduction of $NO^{\bullet}$).[29] These NO species react further with O_2-derived free radicals, redox metals, and thiols to generate NO compounds that have unique biological effects (Fig. 10.1).[30] For example, the reaction of NO with the heme iron of guanylyl cyclase results in enzyme activation, whereas the reaction of NO derivatives (NO^{+}, N_2O_3, or $ONOO^{-}$) with –SH (or $–S^{-}$ derivatives)-containing low-molecular-weight molecules and proteins generates *S*-nitrosothiols, a stable reservoir of bioavailable NO.[31] In plasma, *S*-nitroso-albumin serves as an NO adduct and limits the inactivation of NO by reactive oxygen species.[29] NO also forms *N*-nitroso adducts with amine moieties and nitrosyl adducts with heme groups to yield *N*-nitrosamines and nitrosylheme, respectively.[32,33] Human plasma contains an approximately fivefold higher concentration of *N*-nitrosamine species (32.3 +/− 5.0 nmol/L) than *S*-nitrosothiols (7.2 +/− 1.1 nmol/L);[34] however, functional studies in animal models studies suggest that *S*-nitrosothiols are biologically more active by an order of magnitude compared to *N*-nitrosamine species.[35] Dinitrosyl iron complexes also possess biological activity, inhibiting platelet aggregation and decreasing vascular tone in experimental models.[36,37]

In an O_2-rich environment, NO can be oxidized to nitrite (NO_2^{-}) and nitrate (NO_3^{-}), stable end products of its metabolism.[30] Although nitrite has been reported to have no intrinsic vasodilator activity,[38] nitrite does serve as a physiologically important source of NO, which is released in the circulation through the nitrite reductase activity of hemoglobin (*vide infra*).[39] Under ischemic conditions, where the pH is in the acidic range, nitrite may be reduced directly to NO through a nonenzymatic mechanism.[40] NO may also interact with reactive oxygen species, including superoxide, hydrogen peroxide, and lipid peroxyl radicals, formed during normal cellular metabolism or states of increased oxidant stress. In this manner, bioavailable NO is inactivated through the formation of peroxynitrite ($ONOO^{-}$), nitrous acid (HNO_2), and lipid peroxynitrites (LOONO), respectively.[30]

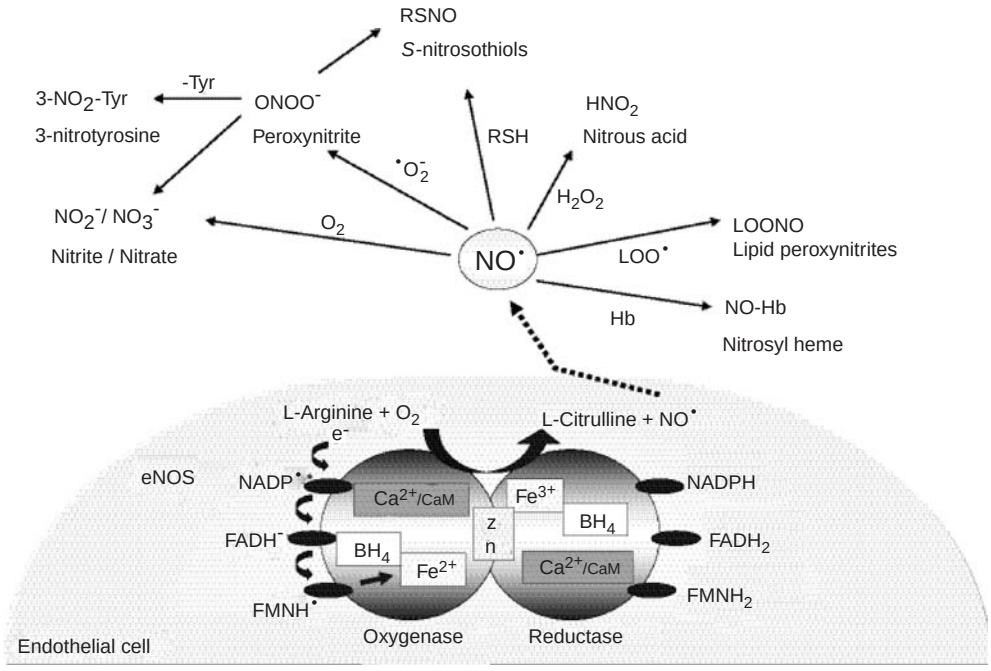

Figure 10.1. Biological source and reactions of nitric oxide. Nitric oxide (NO•) is synthesized in endothelial cells by the endothelial isoform of nitric oxide synthase (eNOS) via the five-electron oxidation reaction of L-arginine to L-citrulline. eNOS is activated by Ca^{2+}/calmodulin (Ca^{2+}/CaM) and the reaction requires molecular O_2 and NADPH as cosubstrates and flavin adenine dinucleotide ($FADH^+$), flavin mononucleotide ($FMNH^+$), and tetrahydrobiopterin (BH_4) as cofactors to facilitate electron transfer to the NOS heme moiety. Once generated, NO• diffuses into the interstitium and the bloodstream where it reacts with molecular O_2, superoxide anion ($•O_2^-$), R-SH groups, hydrogen peroxide (H_2O_2), lipid oxides (LOO•), and hemoglobin (Hb) to generate NO species – some of which have biological activity. (See color plate 10.1.)

Bioreactivity of Nitric Oxide with Hemoglobin

NO can also bind to transition metals within heme groups, including myoglobin and hemoglobin itself. Endothelial-derived NO diffuses readily from the endothelial cell into the blood pool, where it first encounters platelets, which are enriched in the blood lamina nearest to the endothelial monolayer, and then erythrocytes, in which it can react with hemoglobin (Fig. 10.2). The reaction of NO with hemoglobin was first carefully characterized by Drabkin and Austin,[41] who recorded the absorption spectrum of nitrosyl-hemoglobin under anaerobic (i.e., deoxygenated) conditions:

$$\mathrm{Hb(II) + NO \rightarrow Hb(II)NO} \qquad (10.1)$$

This reaction occurs with a second-order rate constant of $2–6 \times 10^7$ M/s,[42,43] and an extremely slow off-rate of approximately $10^{-3}–10^{-5}$ s.[44,45] This slow off-rate renders the bound NO effectively irreversibly complexed to deoxygenated hemoglobin. Under normal conditions in circulating whole blood, there is a large pool of oxyhemoglobin with which NO also readily reacts to form methemoglobin [Hb(III)] and nitrate:

$$\mathrm{Hb(II)O_2 + NO \rightarrow Hb(III) + NO_3^-} \qquad (10.2)$$

The second-order rate constant for this reaction is $6–8 \times 10^7$ M/s,[46,47] leading to an estimated half-life in the erythrocyte of approximately 0.5 μs. The kinetics of the reaction of NO with deoxyhemoglobin and with oxyhemoglobin suggests that the erythrocyte should serve as an highly efficient sink for NO; however, if this were the case, erythrocytic hemoglobin would significantly limit NO's bioavailability for vascular smooth muscle cell and platelet homeostatic functions. This is best explained by the finding that erythrocytic hemoglobin is far less efficient than cell-free hemoglobin at scavenging NO, owing to the time required for NO to diffuse from the endothelial cell to the erythrocyte (accounted for by the erythrocyte-free zone nearest the endothelial monolayer and by the unstirred fluid layer surrounding the erythrocyte).[48] Furthermore, the erythrocyte membrane provides a physical diffusion barrier that effectively compartmentalizes hemoglobin and limits its access to the endothelial monolayer or vascular interstitium.[49,50] As shown in ex vivo studies performed in the absence of flow, 1,000 times more erythrocyte-encapsulated hemoglobin is required to inactivate NO compared with cell-free hemoglobin.[51]

Nitrite has recently been recognized as a reservoir of bioactive NO in mammals. Under ischemic or acidic conditions, nitrite can be reduced to NO directly or enzymatically via xanthine oxidase.[52,53] Recent data suggest that nitrite is

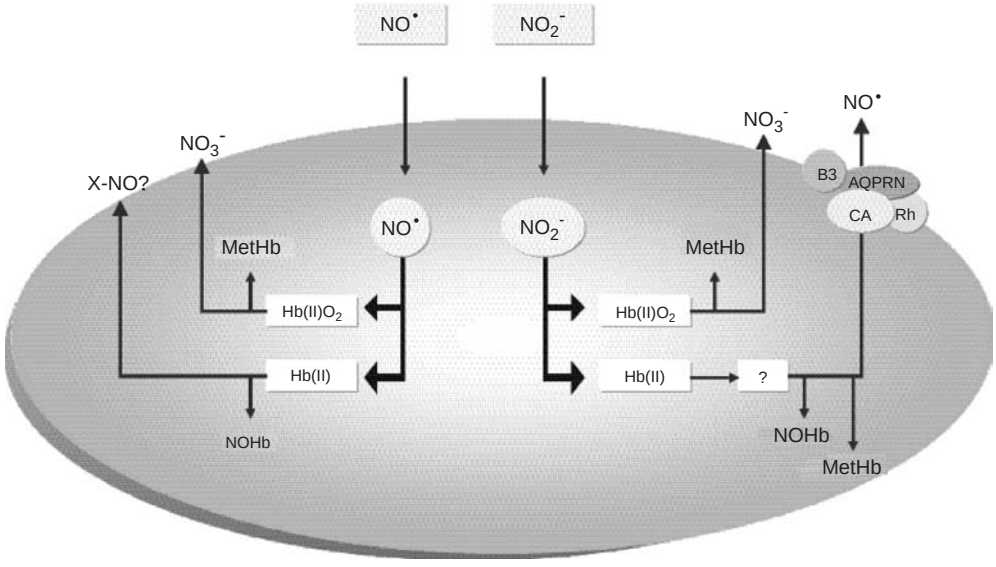

Figure 10.2. Reactions between NO and hemoglobin in erythrocytes. Nitric oxide (NO•), synthesized by the endothelium, or nitrite (NO_2^-) circulating in plasma, diffuses into the erythrocyte where it reacts with oxyhemoglobin [Hb(II)O_2] to yield methemoglobin (MetHb) and nitrate (NO_3^-), or with deoxyhemoglobin [Hb(II)] to generate nitrosylhemoglobin (NOHb) and NO adducts (X-NO). Nitrite also diffuses into the erythrocyte and reacts with deoxyhemoglobin and, via a possible intermediate species (?), produces nitrosylhemoglobin and methemoglobin. Once formed, NO• and NO• adducts are thought to exit the cell through a functional metabolon that is composed of oxy- and deoxyhemoglobin, Rh channels (Rh), aquaporin (AQPRN), band-3 complex (B3), and carbonic anhydrase (CA). These channels theoretically may transport NO• through the erythrocyte membrane. (See color plate 10.2.)

reduced by deoxygenated hemoglobin and that this reaction yields bioactive NO and methemoglobin.[39,54] In this construct, hemoglobin can be viewed as a nitrite reductase that mediates hypoxic vasodilation and in this way contributes to homeostatic regulation of tissue perfusion and O_2 delivery.[50] The reactions involved in this process are:

$$\mathrm{HONO} + 2\mathrm{Hb(II)} \rightarrow \mathrm{Hb(III)} + \mathrm{Hb(II)NO} + \mathrm{OH}^- \quad (10.3)$$

$$\mathrm{Hb(II)NO} \rightarrow \mathrm{Hb(II)} + \mathrm{NO} \quad (10.4)$$

Hb(II)NO can also transfer NO to glutathione to yield *S*-nitrosoglutathione. These reactions are further complicated by hemoglobin allostery, as indicated by their sigmoidal (rather than pseudo-first-order) kinetics when nitrite is in excess over hemoglobin,[55] and derives from the fact that the relaxed- (R-) state hemoglobin reduces nitrite faster than does tense- (T-) state hemoglobin. This allosteric dependence of the reaction coupled with its stoichiometry leads to accelerated kinetics as hemoglobin is converted from the R- to T-state during the reaction.[56] Consistent with an allosteric mechanism, hemoglobin-mediated nitrite reduction proceeds most rapidly at the hemoglobin P_{50} (where only half the hemoglobin is O_2 bound). At the P_{50}, the reduced rate of the reaction caused by fewer deoxygenated hemes being present than at zero O_2 is compensated for by the presence of more deoxygenated hemes in R-state hemoglobin tetramers.[56] Recent data suggest that NO dissociation from hemoglobin (Eq. 10.4) alone cannot account for an exportable pool of NO within the erythrocyte that can manifest bioactivity.[57] Either compartmentalization or a reaction intermediate (an S-nitrosothiol?) may provide a physiological explanation for the phenomenon, but neither mechanism has been proven to date.

Another hypothesis that has been advanced to explain the role of erythrocytic hemoglobin in NO bioactivity is that of *S*-nitrosation of its β-93 cysteinyl residue to form *S*-nitrosohemoglobin (SNO-Hb).[58] According to this view, NO binds allosterically to a deoxyheme moiety on a partially oxygenated hemoglobin tetramer, and is then transferred to the cysteinyl residue upon transition from the T- to the R-state with reoxygenation. Upon deoxygenation, the process is reversed with release of NO (possibly transferred to a protein or thiol-carrier), according to the following reaction mechanism:

$$\mathrm{Hb(II)NO} + \mathrm{O_2} \rightarrow \mathrm{Hb(II)O_2^{cys93}SNO} \quad (10.5)$$

$$\mathrm{Hb(II)O_2^{cys93}SNO} \rightarrow \mathrm{Hb(II)} + \mathrm{O_2} + \mathrm{NO} \quad (10.6)$$

or

$$\mathrm{Hb(II)O_2^{cys93}SNO} + \mathrm{GSH} \rightarrow \mathrm{Hb(II)} + \mathrm{O_2} + \mathrm{GSNO} \quad (10.7)$$

Based on this hypothesis, NO is then exported from the cell as an "X-NO." The identity of the X-NO species and the mechanism of export have not been elucidated. Although this hypothesis received much attention when first proposed, it remains controversial, owing largely to published experimental data that reveal the preferential (if not exclusive) binding of NO to deoxygenated heme groups on

R-state hemoglobin,[59,60] an inability to detect cyclic transfer of NO from the heme group to the β-93 cysteinyl residue and vice versa,[61] and failure to determine the O_2 dependency of SNO-Hb instability in the presence of erythrocyte concentrations of glutathione (i.e., the S-NO linkage decays independent of O_2 tension in the presence of millimolar concentrations of glutathione). Most important, the high intracellular concentration of glutathione would limit the stability of the β-93 S-NO bond.[62] Thus, it is our opinion that the preponderance of data support the nitrite reductase hypothesis as the principal mechanism for the generation of bioactive NO by erythrocytes.

Nitrite Reductase Activity of Hemoglobin

Nitrite, a stable end-product formed by the oxidation of NO, is generated and/or accumulates in the blood, measurements of which in human plasma isolated from healthy volunteers demonstrate levels of approximately 0.20 ± 0.02 μmol/L.[34] Although nitrite itself does not possess intrinsic vasodilator properties at physiological concentrations, it may be considered an important vasodilator substance via its reduction to NO by the nitrite reductase activity of hemoglobin.

Evidence to support the role of hemoglobin-mediated nitrite reduction as a physiological source of NO was first demonstrated when Gladwin and colleagues[59] observed a plasma gradient of nitrite across vascular beds of human subjects under basal conditions and following the inhalation of NO gas. They next infused nitrite into the forearm brachial artery at near physiological levels (0.9–2.5 μmol/L) and noted an increase in blood flow as measured by strain gauge plethysmography.[39] When subjects were pretreated with L-N^G-monomethyl arginine citrate to inhibit eNOS and endogenous NO synthesis, infusion of near physiological levels of nitrite resulted in an increase in forearm blood flow during exercise. Nitrite infusion was associated with a detectable increase in erythrocyte Hb(II)NO that formed rapidly indicating that nitrite was being reduced to NO during one artery-to-vein transit in a manner that was inversely proportional to oxyhemoglobin saturation.[39] When NO gas production was measured by chemiluminescence, the rate of NO production following the addition of nitrite to erythrocytes was significantly greater when hemoglobin was in a deoxygenated than oxygenated state. The ability to measure NO gas production in this system demonstrated further that some fraction of the released NO escaped autocapture by free heme groups and that NO generation is augmented under anaerobic conditions, consistent with a nitrite–deoxyhemoglobin reaction.[39]

The bioactivity of NO generated by the reaction between nitrite and hemoglobin was confirmed in a rat aortic ring bioassay where it was demonstrated that this reaction was, indeed, responsible for the observed vasodilation. In these studies, the aortic rings were found to relax spontaneously only at very low O_2 tensions (10–15 mm Hg); however, in the presence of nitrite (0.5–2 μmol/L) and erythrocytes, the vessel tension–O_2 threshold curve was left-shifted to higher O_2 tensions (~40 mm Hg). This effect was mediated by the nitrite reductase activity of deoxygenated hemoglobin as oxygenated hemoglobin had no effect on vasodilation, even in the presence of excess nitrite. Together, these studies demonstrate that hemoglobin serves as a nitrite reductase under hypoxic conditions to release NO from nitrite and effect vasodilation.[50]

Nitric Oxide Export from Erythrocytes

Although the aforementioned studies convincingly demonstrate a role for hemoglobin as an effective nitrite reductase to generate bioavailable NO from nitrite, the mechanism by which NO is exported from the erythrocyte remains to be determined. As noted, the half-life of NO in the erythrocyte is estimated to be approximately 5 μs, suggesting that it is unlikely that NO itself freely diffuses across the erythrocyte membrane.[63] One proposed mechanism for NO export suggests that erythrocyte membrane proteins comprise a potential nitrite reductase metabolon containing deoxyhemoglobin and methemoglobin, anion exchange protein, carbonic anhydrase, aquaporin, and Rh channels that reside within the erythrocyte lipid raft, a caveola homolog. This metabolon would facilitate NO export by localizing nitrite, proton, and deoxyheme with highly hydrophobic channels at the membrane complex. Another proposed mechanism suggests that the reaction of nitrite with deoxyhemoglobin yields an intermediate species that could be stabilized by and transported through the red blood cell membrane (via lipid raft, Rh channels, or aquaporin); candidate species include *S*-nitrosothiols, nitrogen dioxide, peroxynitrite, and nitrated lipids.[63,64] Measurements obtained in simulation studies support the existence of a NO intermediate species. Here, when the rate of NO formation was as high as 100 nM/s, the maximal NO concentration in blood was less than 0.012 nM in the setting of erythrocyte membrane permeability to NO of 4.5 cm/s at a hematocrit of 45%. Thus, it is unlikely that NO is exported directly from the erythrocyte because the resident plasma concentration would be too low to have physiological effects.[65] At present, it remains to be determined which systems of export and candidate intermediate signaling molecule(s) are operative.

NITRIC OXIDE–DEPENDENT REGULATION OF TISSUE OXYGEN LEVELS

Nitric Oxide and Hemoglobin–Oxygen Affinity

By virtue of its reaction(s) with hemoglobin, it has been suggested that NO directly influences hemoglobin–O_2 affinity; however, it is difficult to predict a priori the effect of NO binding on net hemoglobin–O_2 affinity owing to the different hemoglobin species present at any given time that react

with NO. For example, NO oxidizes oxyhemoglobin to form methemoglobin, which increases O_2 affinity,[66] although the reaction of NO with deoxyhemoglobin yields nitrosylhemoglobin, which has a markedly decreased affinity for O_2.[67] It has also been reported that when NO reacts with the β-Cys93 residue to form SNO-Hb, its O_2 affinity increases compared to underivatized hemoglobin.[68] As such, the overall net effect of NO on hemoglobin–O_2 affinity may result, in part, from the relative abundance of each of these NO-hemoglobin derivatives.

Despite the recognized differences in hemoglobin–O_2 affinity of these NO-hemoglobin products, evidence indicates that the reaction of NO and hemoglobin may not, in fact, significantly influence hemoglobin–O_2 affinity by a mechanism other than by increasing methemoglobin formation. In a study that examined the effect of NO gas (80 ppm) inhalation for 2 hours on hemoglobin–O_2 affinity, inhaled NO did not alter hemoglobin–O_2 affinity in normal subjects, and methemoglobin levels rose to only 1%, suggesting that the level of NO bound to hemoglobin was too low to influence overall O_2 affinity.[69] In vitro studies that exposed erythrocytes to NO gas (80 ppm) or the NO donors diethylamine NONOate and *S*-nitrosocysteine reported similar findings. Here, exposure to NO did not affect hemoglobin–O_2 affinity per se, but a significant rise in methemoglobin formation was detected that was associated with a leftward shift in the P_{50}.[70] These observations, therefore, imply that low concentrations of NO do not alter the hemoglobin–O_2 affinity of erythrocytes directly, and perceived changes likely result from an increase in methemoglobin formation and loss of cooperativity (Hill coefficient).[70,71]

Tissue Oxygen Consumption

The interaction between NO and O_2 is of physiological importance: NO has been shown to regulate tissue O_2 consumption and, conversely, O_2 levels may determine the rate of NO catabolism. Endothelium-derived NO limits tissue O_2 consumption, an effect that is independent of the rate of O_2 delivery and associated with a decrease in both intravascular and tissue pO_2 as well as a rightward shift in the hemoglobin–O_2 dissociation curve.[72]

Other studies have confirmed that endothelium-derived NO modulates tissue oxygenation by decreasing vessel wall O_2 consumption. Although it has been shown that the pO_2 drops in arterioles, the observed decreases were too great to be explained by diffusion alone suggesting active consumption of O_2 by the vessel wall. In a series of studies performed in vivo to examine the O_2 consumption rate of arteriolar walls in rat cremaster muscle, inhibition of NO synthesis with N^G-nitro-L-arginine methyl ester (L-NAME) resulted in a 42% increase in vessel wall O_2 consumption. In contrast, enhancement of flow-mediated NO release resulted in a 34% decrease in O_2 consumption by the vessel wall.[73] One explanation for these findings is that O_2 consumption by the arteriole wall is, in part, dependent upon vascular tone; vasoconstriction increases vessel wall O_2 consumption whereas vasodilation has the opposite effect.[74,75] Further study of this model during NO-dependent and NO-independent vasodilation revealed that the NO-mediated reduction in O_2 consumption resulted principally from a decrease in the mechanical work of vascular smooth muscle cells.[76]

Although the aforementioned studies demonstrate that NO regulates tissue and vessel wall O_2 consumption, it has also been demonstrated that O_2 determines vascular NO catabolism. Under normoxic conditions, rat aortas incubated in a solution injected with NO at constant O_2 tension demonstrated a 50% increase in NO consumption as compared to what was observed in the absence of the vessel. Furthermore, aorta NO consumption declined as the O_2 concentration was decreased to mimic hypoxic conditions, suggesting that mitochondria may be involved in the vessel wall interaction between O_2 and NO. This may result from the direct reaction of NO with O_2 in the mitochondrial membrane or with cytochrome *c* oxidase. In support of this theory, increased aorta NO consumption under anaerobic conditions was inhibited by the cytochrome *c* oxidase inhibitor sodium cyanide. These studies imply that decreased aorta NO catabolism that occurs under low O_2 concentrations may preserve bioavailable NO levels to promote vasodilation. In contrast, increased NO consumption observed under anaerobic conditions suggests that this phenomenon may limit formation or accumulation of toxic NO metabolites in the vessel wall.[77]

HYPOXIC VASODILATION

NO plays an integral role in hypoxic vasodilation, a physiological response that regulates blood flow to deliver O_2 and meet tissue metabolic demands. It has been hypothesized that this response results from a feedback mechanism that signals alterations in O_2 or pH levels resulting from a discordance between the basal delivery rate of O_2 and tissue O_2 consumption.[78] To ensure tissue O_2 demands in the setting of perceived hypoxia, vasodilator substances such as NO are released to increase blood flow and, thereby, maintain tissue oxygenation. In mammalian systems, hypoxic vasodilation occurs concomitant with the desaturation of hemoglobin from 60% to 40% corresponding to partial pressures of O_2 from 40 to 20 mm Hg.[64]

Interestingly, in skeletal muscle tissue O_2 extraction occurs mainly in resistance arterioles implying that hypoxic sensing takes place in the vasculature at a location proximal to the arterioles and arteriolar capillaries.[79] In this vascular bed, erythrocytes, which traverse the artery-to-arteriole-to-capillary in approximately 10 s, form a column of moving blood such that the hemoglobin and O_2 concentrations remain relatively constant at any given

location within an arteriole.[64] As such, it is likely that there is one anatomical site within the microcirculation that contains the greatest number of R_3 tetramers with maximal nitrite reductase activity. It is at this anatomical location that hemoglobin-mediated nitrite reduction to release NO will be maximal in response to tissue O_2 consumption and metabolic demands, and hypoxic vasodilation will ensue.[64] In contrast, in the heart and brain, tissue O_2 is delivered via the capillary bed through a mechanism that involves retrograde signaling. Here, it is believed that the capillaries or venous circulation provide the vasodilator signal.[80,81] One proposed mechanism to explain vasodilation in these vascular beds involves the diffusional shunting of NO from veins to an adjacent arteriole. In fact, when cotransport of NO and O_2 in a paired arteriole-venule surrounded by capillary-perfused tissue was modeled, it was found that the capillary bed connecting the arteriole and venule facilitates the release of O_2 from the vessel pair to the surrounding tissue. In this model, decreasing the distance between the arteriole and venule resulted in a higher local NO concentration in the venule than in the arteriole wall, suggesting that transvalvular diffusional shunting of NO is plausible.[82]

Although the identity of the O_2 sensor and released vasodilator has not yet been confirmed definitively, evidence suggests that hemoglobin serves as the O_2 sensor and, owing to its nitrite reductase properties, reduces nitrite to release NO, the vasodilator. Hemoglobin is well poised to serve as the O_2 sensor; the O_2-linked allosteric structural transition from the R-state to the T-state may function to signal for release of NO from the erythrocyte.[83] NO as the candidate vasodilator agent to regulate hypoxic vasodilation is intuitively sound. NO is a paracrine-signaling molecule synthesized by the endothelium and released into the bloodstream where it reacts at a nearly diffusion-limited rate (10^7 M/s) with both oxy- and deoxyhemoglobin to yield methemoglobin/nitrite and iron-nitrosyl-hemoglobin, respectively. Although these reactions limit the half-life of NO in blood ($\sim$5 μs half-life in blood) as well as the diffusion distance ($<$2 μs in lysed blood),[50,84] from a biochemical perspective, the pool of circulating NO may be stabilized in blood by the formation of NO-modified proteins, peptides, and lipids or by oxidation to nitrite.[64] Nitrite, in turn, serves as a source of bioavailable NO under hypoxic or ischemic conditions.[85–88]

HOMEOSTATIC FUNCTIONS OF NO IN THE VASCULATURE

In addition to its reaction with erythrocytes, NO released to the vessel wall diffuses readily across biological membranes to modulate endothelial and vascular smooth muscle physiological functions. In this manner, NO is a key determinant of vascular tone, vascular permeability, and cell proliferation. Moreover, NO released to the erythrocyte-free zone nearest the endothelial monolayer encounters platelets and, as such, modulates platelet activation, adhesion, and aggregation. The key mechanisms by which NO regulates these processes to maintain normal endothelial cell and vessel wall phenotype are discussed later.

Vascular Tone

Continuous, low levels of NO released by the endothelium initiate relaxation of the underlying vascular smooth muscle cells and, thereby, determine vascular tone. The importance of NO in maintaining vascular tone is demonstrated in disease states characterized by decreased or increased bioavailable NO; inhibition of vascular NO synthesis by pharmacological agents or targeted gene disruption promotes vasoconstriction and hypertension, whereas overproduction of NO, as occurs in septic shock, leads to profound vasodilation and hypotension.[89–92]

Under basal conditions, endothelium-derived NO production is stimulated in response to a number of physiological biochemical factors including thrombin, adenosine diphosphate, serotonin, acetylcholine, and bradykinin, as well as physical forces, such as shear stress and cyclic strain. In addition, NO is generated in response to changes in O_2 tension (as discussed previously) and, thereby, autoregulates blood flow in both large vessels and the microcirculation. In this manner, NO is a determinant of both the state of vascular relaxation and the distribution of blood flow among multiple vascular beds concurrently.[93,94]

NO diffuses readily from the endothelium to adjacent vascular smooth muscle cells and binds to the heme-containing enzyme soluble guanylyl cyclase (Fig. 10.3).[95] Among heme-containing proteins, guanylyl cyclase is of interest because it selectively binds NO in preference to O_2, despite a greater affinity of heme for O_2 and higher concentrations of O_2 than NO in eukaryotic cells. This phenomenon has been resolved by the recent discovery that guanylyl cyclase lacks a distal pocket tyrosine or alternative hydrogen donor to bind O_2 and, therefore, selectively binds NO to activate the enzyme.[96] Once NO activates soluble guanylyl cyclase in vascular smooth muscle cells, there is an increase in cytosolic cGMP, and several signaling pathways converge to decrease intracellular Ca^{2+} stores and initiate vascular smooth muscle relaxation. For example, voltage-gated Ca^{2+} channels are inhibited to decrease intracellular Ca^{2+} flux, whereas protein kinase G I, which phosphorylates Ca^{2+}-dependent potassium channels, 1,4,5 inositol triphosphate receptor–associated cGMP kinase substrate, and phospholamban, is activated.[5,97,98] Phospholamban, in turn, activates sarcoplasmic reticulum adenosine triphosphatase to sequester Ca^{2+} in the sarcoplasmic reticulum and decrease further intracellular Ca^{2+} flux and limit formation of the Ca^{2+}-calmodulin-myosin light chain complex.[4] Activation of protein kinase G I also regulates myosin light chain phosphorylation state. Phosphorylation of myosin light chain at Ser19 by myosin light

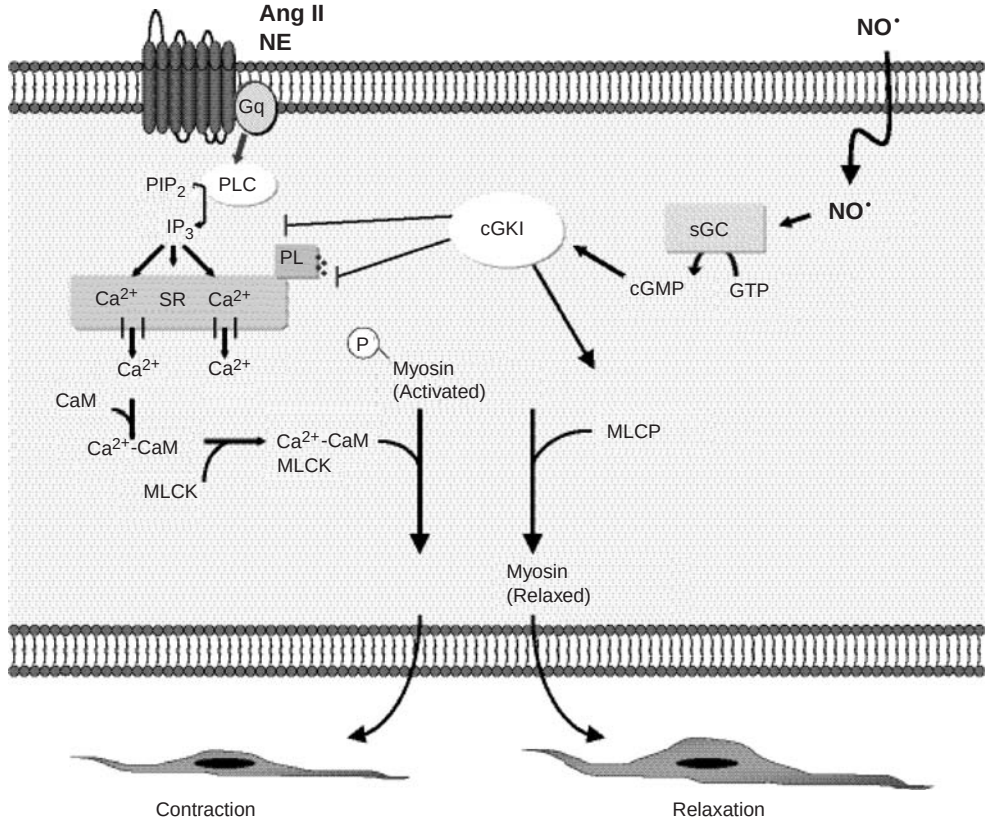

Figure 10.3. NO and vascular smooth muscle relaxation. NO•, synthesized by the endothelium, diffuses into the vascular smooth muscle cytosol and reacts with the heme iron of soluble guanylyl cyclase (sGC). This activates the enzyme, which in turn generates cGMP. As cGMP levels rise, cGMP-dependent kinase I (cGKI) is activated to inhibit inositol 1,4,5, trisphosphate (IP_3)-mediated release of Ca^{2+} from the sarcoplasmic reticulum (SR). cGKI activates phospholamban (PL), which facilitates this process by stimulating Ca^{2+} sequestration by the SR. This effect in turn also limits the ability of the Ca^{2+}-calmodulin (CaM)-myosin-light chain kinase (MLCK) complex to phosphorylate myosin and initiate contraction. cGKI also promotes vascular smooth muscle relaxation by stimulating myosin-light chain phosphatase (MLCP) to dephosphorylate myosin. (See color plate 10.3.)

chain kinase is required for actin activation of actomyosin ATPase and cross-bridge cycling.[99] Although there is no definitive evidence that protein kinase G I phosphorylates myosin light chain kinase directly to modulate its activity, protein kinase G I stimulates myosin light chain phosphatase, which dephosphorylates myosin and initiates vascular smooth muscle relaxation.[100]

Vascular Permeability

Traditionally, it is believed that NO is necessary to maintain endothelial barrier function and limit vascular permeability; however, a number of studies have challenged this tenet and provided compelling evidence to demonstrate that physiological levels of NO may actually increase microvascular permeability. The concept that NO is required to maintain endothelial barrier integrity is supported by electron microscopy analysis of vascular beds that demonstrated interendothelial junction opening and increased transendothelial transport of albumin in the setting of eNOS inhibition.[101] Moreover, when eNOS knockout mice were studied, open interendothelial junctions were observed in capillaries and venules, and there was enhanced leakage of a tracer agent indicating increased vascular permeability.[102] Conversely, other studies suggested that endothelium-derived NO is permissive for increased vascular permeability. NO donors have been shown to facilitate leakage of water and macromolecules across the endothelium, whereas eNOS inhibitors limit the edemagenic response to carrageenan and inflammatory mediators, including histamine, platelet-activating factor (PAF), and cytokines.[101,103] A number of theories have been advanced to explain these conflicting results, including differences in the agonists and models studied, methodology used to asses vascular permeability, heterogeneity of the microvascular beds, and the concomitant effect of NO as a vasodilator to increase local blood flow and, therefore, hydrostatic pressure.[101]

One potentially unifying explanation for these seemingly discordant observations suggests that vascular permeability and vasodilator agents differentially influence intracellular eNOS trafficking. This hypothesis was validated in ECV-304 (an immortalized endothelial cell line) cells stimulated with acetylcholine, which induces

vasodilation with minimal effect on vascular permeability, or PAF, which promotes interendothelial junction opening with limited effect on vasodilation. In unstimulated cells, eNOS resides in association with caveolae and lipid rafts in the plasma membrane, where caveolin-1 binds eNOS to inhibit its activity.[103] In ECV-304 cells that were stably transfected with eNOS-GFP, acetylcholine stimulated translocation of eNOS from the caveolae to the Golgi network. In contrast, PAF administration resulted in translocation of eNOS to the cell cytosol. In the cytosol, eNOS was localized near mitogen-activated protein kinase, myosin light chain kinase, protein kinase C, and protein kinase G, all signaling molecules that are modulated by NO to enhance cytoskeletal contraction and cell junction disassembly.[104] A second mechanism by which eNOS translocation may influence endothelial cell permeability is by directly destabilizing the structural integrity of the endothelium.[105] As such, these findings suggest that PAF initiates an edemagenic response by trafficking eNOS to the cell cytosol to induce cytoskeletal conformational changes, whereas acetylcholine-mediated translocation to the Golgi apparatus localizes eNOS to a signaling cascade that favors vasodilation.

Endothelial Cell Proliferation, Migration, and Angiogenesis

Angiogenesis, a form of postnatal neovascularization in which new vessels are derived from preexisting blood vessels in response to tissue ischemia, is dependent on the coordinated processes of endothelial cell proliferation, migration, and tube formation. Experimental evidence confirms the central role of NO in these angiogenic processes. For example, augmentation of eNOS-generated NO production improved neovascularization in a rabbit hind limb ischemia model, whereas, in contrast, eNOS knockout mice demonstrate a limited angiogenic response to surgically induced hind limb ischemia compared with wild-type mice.[106] Furthermore, a number of proangiogenic factors, including vascular endothelial growth factor(s), platelet-derived growth factor(s), angiopoietins, and sphingosine-1-phosphate, all stimulate angiogenesis by increasing NO production.[107]

NO facilitates angiogenesis, in part, by enhancing endothelial cell proliferation. eNOS expression and activity are increased in proliferating cell cultures and reach a peak level at confluence, whereas gene transfer of eNOS promotes endothelial cell proliferation.[108,109] Other studies have shown that eNOS mRNA levels are fourfold higher and eNOS mRNA half-life is three times longer in proliferating compared with quiescent cells.[110] NO also stimulates endothelial cell migration, an effect that may be due to activation of podokinesis.[107] NO increases dissolution of the extracellular matrix via upregulation of urokinase-type plasminogen activator to initiate matrix metalloproteinase activation and dissolution of the extracellular matrix.[111] NO generated by the NO donor diethylamine NONOate has been shown to increase endothelial cell chemotaxis in a cGMP-dependent manner. Interestingly, the effect of NO on chemotaxis was found to be dependent upon the presence of a spatial NO subnanomolar gradient as well as the absolute magnitude of NO exposure per unit time to increase endothelial cell mobilization.[112]

Vascular endothelial growth factor (VEGF), one of the most potent angiogenic factors known, stimulates angiogenesis by increasing eNOS activity and NO production via PI3-kinase-Akt–mediated phosphorylation of eNOS, induction of Ca^{2+} flux, and the recruitment of heat shock protein 90.[113] VEGF has also been shown to increase eNOS expression and NO synthesis in endothelial cells and isolated rabbit thoracic aortic strips. In a tube formation assay, endothelial cells stimulated with VEGF transform from a monolayer to capillary tube–like structures concomitant with an increase in NO production. In contrast, when VEGF-stimulated cells are pretreated with L-NAME, capillary tube formation does not occur.[107]

Evidence suggests that soluble guanylyl cyclase may be an important downstream mediator of NO in angiogenic processes. In a chick chorioallantoic membrane angiogenesis assay, inhibition of endogenous guanylyl cyclase limited angiogenesis, whereas activation of guanylyl cyclase increased neovascularization. In cultured endothelial cells, pharmacologic activation, or gene transfer, of guanylyl cyclase increased endothelial cell proliferation, migration, and tube formation that was associated with extracellular signal–regulated kinase 1/2 and p38 MAPK signaling.[114] Interestingly, sildenafil, which inhibits cGMP-specific phosphodiesterase 5 to increase cGMP levels, also promotes endothelial cell proliferation, migration, and endothelial tube formation in a similar manner.[114]

Apoptosis

As an adjunct to angiogenesis, NO has been shown to have opposing, dose-dependent effects on endothelial cell apoptosis: low physiological concentrations of NO are cytoprotective, whereas markedly elevated levels of NO induce apoptosis.[115] Physiological levels of NO prevent endothelial cell apoptosis by the cGMP-dependent inhibition of cytochrome *c* release from mitochondria and downstream caspase activation, the cGMP-independent increase of bcl-2 expression, and the inactivation of caspases through *S*-nitrosation reactions.[116] The apoptosis-inducing effects of pathophysiologically elevated levels of NO in endothelial cells are cGMP-independent and include direct DNA damage by NO or peroxynitrite, activation of JNK/SAPK signaling pathways to stimulate caspases, and increased intracellular ceramide levels that induce the release of cytochrome *c*.[116]

Statins, which have been shown to promote angiogenesis via activation of eNOS, were also reported to initiate endothelial cell apoptosis owing to a concentration-dependent effect of these agents. For example, low doses of atorvastatin (0.01–0.1 μmol/L) were shown to enhance endothelial cell migration and tube formation, whereas

higher concentrations (>0.1 μmol/L) stimulated endothelial cell apoptosis. These findings were attributed to the influence of statins on eNOS expression; low doses of statins did not influence eNOS expression whereas higher doses markedly increased eNOS expression and NO generation.[117]

NO has also been shown to modulate endothelial cell senescence, recognized as the limited ability of cells to proliferate in vitro accompanied by phenotypic changes in morphology, gene expression, and function. As such, cellular senescence is believed to contribute to the pathogenesis of vascular disease. Endothelial cell senescence, measured as senescence-associated β-galactosidase and telomerase activity, is inhibited in cells treated with the NO donor diethylamine NONOate or gene transfer of eNOS. In contrast, in cells treated with L-NAME, transfection with eNOS had no effect, indicating that endothelium-derived NO was essential to maintain the proliferating phenotype.[118]

Vascular Smooth Muscle Cell Proliferation

In contrast to its stimulatory effects on endothelial cell proliferation, endothelium-derived NO inhibits vascular smooth muscle cell proliferation to maintain the normal architecture of the vascular wall and preserve the vessel lumen. When the endothelium is injured, as occurs in vascular disease states such as atherosclerosis or mechanical disruption by angioplasty, the resultant decrease in bioavailable NO is permissive for vascular smooth muscle cell phenotype transition from a contractile state to a dedifferentiated synthetic phenotype. Once this phenotype transition occurs, vascular smooth muscle cells proliferate, migrate, and elaborate extracellular matrix proteins to fashion the neointima and thereby narrow the vessel lumen.

NO maintains a constant inhibition of vascular smooth muscle cell proliferation via cGMP-dependent and -independent signaling pathways. NO increases cAMP levels in a cGMP-dependent manner to activate protein kinase A and decrease intracellular Ca^{2+} stores; increased levels of intracellular Ca^{2+} have been shown to promote vascular smooth muscle proliferation.[119] Protein kinase A activation limits cell proliferation further by inhibiting Raf-1 activation of mitogen-activated protein kinase signaling cascades to decrease DNA synthesis, and studies performed in eNOS-transfected vascular smooth muscle cells demonstrate increased expression of the cyclin-dependent kinase inhibitor $p21^{waf1/Cip1}$, which inhibits proliferation.[120,121] Recently, it has been shown that cyclic nucleotide phosphodiesterases (PDE), which catalyze the hydrolysis of cGMP to 5′GMP, participate in the regulation of vascular smooth muscle cell proliferation. In quiescent cells in the contractile state, PDE1A is primarily localized in the cytoplasm of the cell, whereas in synthetic vascular smooth muscle cells PDE1A is translocated to the nucleus. The functional significance of PDE1A nuclear translocation was elucidated using siRNA to decrease PDE1A expression; increased cGMP levels were associated with $p27^{kip1}$ upregulation, cyclin D1 downregulation, and p53 activation to decrease proliferation and promote apoptosis.[122]

Similarly, NO inhibits vascular smooth muscle cell proliferation via a number of mechanisms that are cGMP-independent. For example, NO mediates two distinct cell cycle arrests; an immediate cGMP-independent block in S-phase followed by a shift back in the cell cycle from G_1–S to a quiescent G_0-like state.[123] NO also decreases the activity of arginase and ornithine decarboxylases, resulting in reduced formation of polyamines that are required for DNA synthesis and increased expression of $p21^{waf1/Cip1}$.[124,125] NO further increases $p21^{waf1/Cip1}$ expression by inhibition of the small GTPase RhoA by *S*-nitrosation.[126] Together, the divergent signaling pathways regulated by NO that converge to inhibit vascular smooth muscle cell proliferation highlight the importance of NO in maintaining the vascular smooth muscle cell contractile phenotype.

Platelet Adhesion and Aggregation

NO synthesized by the endothelium as well as by platelets importantly limits platelet adhesion, aggregation, and recruitment (Fig. 10.4). Although the formation of a hemostatic plug by platelets is a physiological response to vessel wall damage, platelet hyperreactivity, as occurs in NO-deficient states, results in pathophysiological arterial thrombosis. Under basal conditions, platelets remain in an inactive state that is regulated by NO, prostacyclin, and ecto-AD(T)Pase (CD39).[127] In the bloodstream, platelets circulate in the erythrocyte-free low-shear boundary near the endothelial surface and are in optimal position to be affected by endothelium-derived NO.[128] Platelets are also exposed to NO via a circulating pool of *S*-nitrosothiols; however, here, NO uptake is in part dependent on protein disulfide isomerase activity for *S*-nitrosothiol metabolism and transmembrane NO transfer.[129]

Once NO reaches the platelet cytosol, it activates soluble guanylyl cyclase to increase cGMP levels resulting in a decrease in intracellular Ca^{2+} flux and inhibition of platelet activation.[130] In resting platelets, intracellular Ca^{2+} levels are maintained between 50 and 100 nM by the collaborative actions of the cGMP-responsive sarcoplasmic reticulum ATPase and plasma membrane Ca^{2+} ATPase pumps.[131,132] NO also inhibits inositol-1,4,5-trisphosphate–induced intracellular Ca^{2+} release by stimulating cyclic GMP-dependent kinase to phosphorylate the inositol-1,4,5-trisphosphate receptor-associated cGMP kinase substrate (IRAG). IRAG is expressed in platelets and phosphorylated at Ser664 and Ser677 to negatively regulate inositol-1,4,5-trisphosphate-induced intracellular Ca^{2+} flux.[133] NO-dependent regulation of the intracellular Ca^{2+} flux limits the conformational change to the active state of the heterodimeric fibrinogen-binding integrin glycoprotein IIb/IIIa as well as decreases the number (by 50%) and

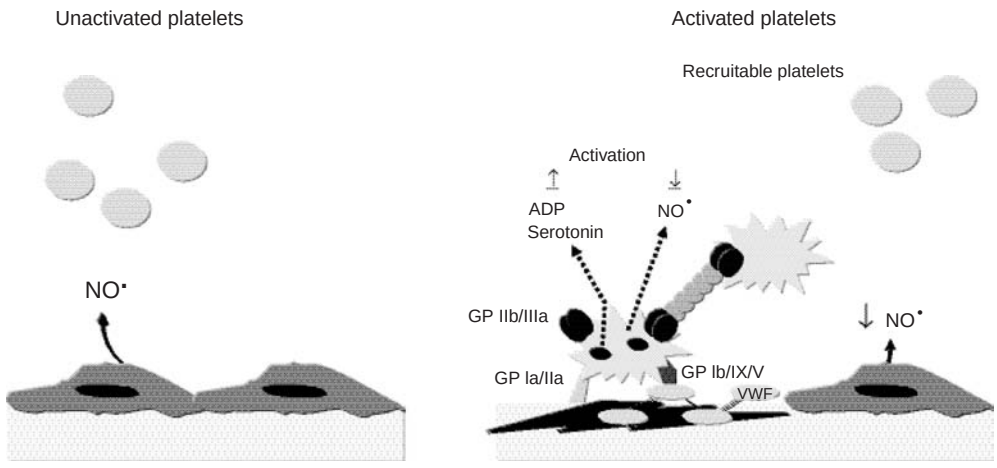

Figure 10.4. NO and platelet activation. Under basal conditions, the vascular endothelium elaborates NO• to maintain a nonthrombogenic surface. In contrast, when the endothelium is disrupted and NO• levels are decreased, platelets become activated and adhere to collagen via the cell surface receptor glycoprotein Ib/IIa (GP Ia/IIa) and glycoprotein Ib/IX/V (GP Ib/IX/V) that binds to the interstitium by von Willebrand factor (VWF). These activated platelets undergo shape change and release adenosine diphosphate (ADP) and serotonin to recruit and activate additional circulating platelets to the growing thrombus, and increase expression of the conformationally active fibrinogen receptor, glycoprotein IIb/IIIa (GP IIb/IIIa) to increase platelet aggregation and thrombus formation; the concomitant release of NO limits platelet aggregation. Platelet-derived NO limits recruitment of platelets to the growing platelet-rich hemostatic plug (or thrombus). (See color plate 10.4.)

the affinity (2.7-fold increase in K_d) of fibrinogen binding sites on the platelet surface.[134,135]

Another key component of platelet activation that is inhibited by NO is the exocytosis of platelet granules, which release mediators that modulate platelet interactions with the endothelium. Exocytosis is regulated, in part, by N-ethylmaleimide-sensitive factor (NSF), an ATPase that promotes disassembly of soluble NSF attachment protein–receptor complexes. In human platelets, it has been shown that NO inhibits exocytosis of dense, lysosomal, and α-granules by *S*-nitrosation of NSF. Furthermore, platelets isolated from an $eNOS^{-/-}$ mouse model demonstrate increased exocytosis in vivo.[136] In fact, it is this mechanism that may explain the observation that eNOS-deficient mice do not demonstrate enhanced thrombosis in vivo. In these mice, it was shown that fibrinolysis is enhanced owing to the lack of NO-dependent inhibition of the release of endothelial Weibel–Palade body storage granule contents, which include von Willebrand factor, P-selectin, and tissue plasminogen activator.[137,138]

NO donors have also been shown to inhibit platelet adhesion by interfering with the interaction between von Willebrand factor and glycoprotein IIb/IIIa.[139] In fact, an *S*-nitrosated derivative of the recombinant von Willebrand factor fragment, AR545C, has been shown to decrease platelet adhesion in both in vitro and in vivo studies. Furthermore, poly-*S*-nitrosated bovine serum albumin, an NO-releasing protein that increases platelet cGMP levels, has also been shown to limit platelet adhesion to collagen.[140]

In addition to the effects of endothelium-derived NO on platelet function, human platelets and megakaryoblastic cells express eNOS and synthesize NO.[141,142] NO release has been measured in resting platelets and reported to be approximately 11.2 pmol NO min/10^8 cells, suggesting that the amount of NO generated and released by platelets approaches that of endothelial cells.[143] Based on these observations, it is therefore important to note the relative contribution of endothelium-derived as compared to platelet-derived NO to platelet activation and aggregation. To examine this phenomenon, platelets were isolated from eNOS knockout mice or wild-type mice, and transfused into a thrombocytopenic eNOS knockout mouse model. In mice transfused with eNOS knockout platelets, bleeding time was decreased significantly compared to what was observed in mice transfused with wild-type platelets (Δ bleeding time $= 24.6 \pm 9$ s vs. 3.4 ± 5 s; $P < 0.04$), indicating that platelet-derived NO contributes significantly to limit platelet recruitment and thrombus formation.[144]

The importance of platelet-generated NO has also demonstrated in studies of patients with clinical atherothrombotic vascular disease. In 87 patients with symptomatic coronary artery disease referred for coronary angiography, platelets isolated from patients with acute coronary syndromes generated significantly less NO than those isolated from patients with stable angina (0.26 ± 0.05 pmol/10^8 platelets vs. 1.78 ± 0.36 pmol/10^8 platelets, $P = 0.0001$).[144] This finding suggests that platelet-derived NO, in addition to endothelium-derived NO, importantly modulates platelet function and thereby affects vascular disease risk.

Leukocyte Adhesion

Endothelium-derived NO also prevents leukocyte adhesion to the endothelium and transmigration into the vessel wall. NO donors, or endogenous NO, limit(s) leukocyte

adherence to the endothelium, whereas inhibition of eNOS results in increased adhesion and emigration from the bloodstream.[145] Following exposure to cytokines such as interleukin (IL)-1β or TNFα, the endothelium is activated and expresses endothelial-leukocyte adhesion molecules including vascular cell adhesion molecule-1, E-selectin, P-selectin, and intercellular adhesion molecule-1.[146] In addition, activated endothelial cells produce leukocyte chemoattractants (chemokines), such as IL-8 and monocyte chemotactic protein-1. In this manner, activated endothelium both recruits and traps circulating leukocytes. NO regulates leukocyte chemotaxis by inhibiting expression of adhesion molecules and synthesis of chemoattractant proteins.[146,147] NO also inhibits exocytosis of Weibel–Palade bodies and release of P-selectin through *S*-nitrosylation of NSF.[148] NO limits leukocyte recruitment and adhesion further by decreasing the synthesis of IL-1β, TNFα, IL-6, and interferon-γ in lymphocytes and monocytes. These effects are mediated, in part, by *S*-nitrosation of transcription factors, including NF-KB/IkB and JAK/STAT, to inhibit upregulation of adhesion molecule expression.[149]

CONCLUSION

NO, a paracrine mediator of vascular homeostasis, is synthesized by the endothelium and released continuously to the vascular interstitium to regulate basal vascular tone. NO also diffuses into the bloodstream where it undergoes a complex series of reactions and may be oxidized to nitrite and nitrate, or react with redox metals and thiols to yield NO compounds, including dinitrosyl iron, *N*-nitrosamines, and *S*-nitrosothiols that have unique biological effects. Notably, NO also reacts with erythrocyte deoxy- and oxyhemoglobin to generate nitrosyl-hemoglobin or methemoglobin and nitrite, respectively. Moreover, owing to the nitrite reductase activity of hemoglobin, NO is released in the vasculature response to tissue ischemia and, thereby, modulates tissue O_2 consumption and hypoxic vasodilation. Endothelium-derived NO is also a key determinant of vascular permeability, endothelial and vascular smooth muscle cell proliferation and apoptosis, platelet adhesion and aggregation, as well as leukocyte recruitment and adhesion. As such, NO serves as an integral mediator of vessel wall integrity and vascular homoeostasis.

Mechanisms and Clinical Complications of Hemolysis in Sickle Cell Disease and Thalassemia

Gregory J. Kato and Mark T. Gladwin

OVERVIEW OF HEMOLYSIS IN SICKLE CELL DISEASE AND THALASSEMIA

Anemia is the most basic clinical characteristic of sickle cell disease and thalassemia. In sickle cell disease, the polymerization of sickle hemoglobin (HbS) causes profound changes in the integrity and viability of the erythrocyte, leading to both extravascular and intravascular hemolysis. The lifespan of the erythrocyte in sickle cell disease is often shortened to less than one-tenth of normal. In β-thalassemia intermedia and major, but not in sickle cell disease, a substantial portion of the hemolysis occurs in the intramedullary space before the developing erythrocytes can even exit the bone marrow, referred to as ineffective erythropoiesis. In either case, erythropoiesis is markedly increased, but insufficient to compensate completely for the accelerated hemolysis, resulting in chronic anemia. This chapter examines the mechanisms that give rise to the accelerated hemolysis characteristic of these hemoglobinopathies and considers emerging data suggesting that chronic intravascular hemolysis produces endothelial dysfunction and a progressive vasculopathy. The latter mechanism of disease contributes to a clinical subphenotype of complications shared by many of the hemolytic anemias, including pulmonary arterial hypertension, cutaneous leg ulceration, priapism, and perhaps stroke. The mechanisms and consequences of hemolysis differ by two main anatomical compartments: extravascular hemolysis, which primarily involves phagocytosis by macrophages in the reticuloendothelial system, and intravascular hemolysis, which occurs within the blood vessel lumen.

Approximately two-thirds of hemolysis in sickle cell disease is extravascular and one-third intravascular.[1] Extravascular hemolysis occurs primarily through mechanisms involving cell surface phosphatidylserine exposure, adherent immunoglobulin G (IgG) and splenic entrapment of rigid red cells. Intravascular hemolysis decompartmentalizes the red cell contents into blood plasma, releasing hemoglobin, arginase-1, erythroid isoforms of lactate dehydrogenase (LDH), and other intraerythrocytic enzymes. In sickle cell disease, the development of irreversibly sickled cells (ISCs), and oxidative injury to red cell membrane proteins and lipids are believed to contribute to intravascular hemolysis (Chapter 9).

Irreversibly Sickled Cells

Aging sickle erythrocytes become increasingly dense and noncompliant.[2] Dehydration of the red cell (Chapter 9) involves leakage of intracellular potassium and sodium, and dysfunction of K:Cl cotransport and calcium-dependent potassium transport. This loss of solute and water increases the mean corpuscular hemoglobin concentration (MCHC), which promotes HbS polymerization (Chapter 6) (Fig. 11.1).[3] This effect can be inhibited by the coinheritance of α thalassemia which decreases the MCHC, or increased fetal hemoglobin (HbF) levels, which inhibits HbS polymerization.[4] Cycles of polymerization and depolymerization give rise to ISCs.[5]

ISCs cells are rigid and prone to being removed from the circulation by physical entrapment in the microvasculature, including peripheral blood vessels and the spleen, where presumably the lysis occurs.[6] The ISC has a short survival and its numbers reflect the hemolytic rate.[7,8] In fact, the severity of hemolysis correlates with the extent of HbS polymerization, as estimated from the MCHC and the relative proportion of hemoglobin fractions.[9,10] Following red cell dehydration and polymerization of HbS, the formation of ISCs involves oxidation of erythrocyte components, and loss of aminophospholipid asymmetry, with subsequent binding of IgG or complement.

Oxidation of Erythrocyte Proteins and Lipids

In sickle erythrocytes, oxygen radicals are formed at rates twice that of control erythrocytes, and membrane-bound hemichrome (oxidized hemoglobin precipitates) greatly enhances superoxide and peroxide-driven hydroxyl radical generation (Fig. 11.1).[11] Data from many laboratories suggest that in sickle cell disease the red cell is exposed to high levels of superoxide produced by intravascular enzymes such as xanthine oxidase,[12] nicotinamide adenine dinucleotide phosphate (NADPH) oxidase[13] and uncoupled nitric oxide (NO) synthase.[14] Signs of oxidative injury are seen in the cytoplasm and membrane of the red cell, in association with membrane bound iron.[15,16] The sickle erythrocyte membrane has reduced abundance of reduced sulfhydryl groups and increased lipid peroxidation.[17–21] Cytoskeletal proteins, particularly protein 4.1, are also oxidized.[22,23] These oxidative changes in the red cell cytoskeleton appear to contribute to the development of ISCs

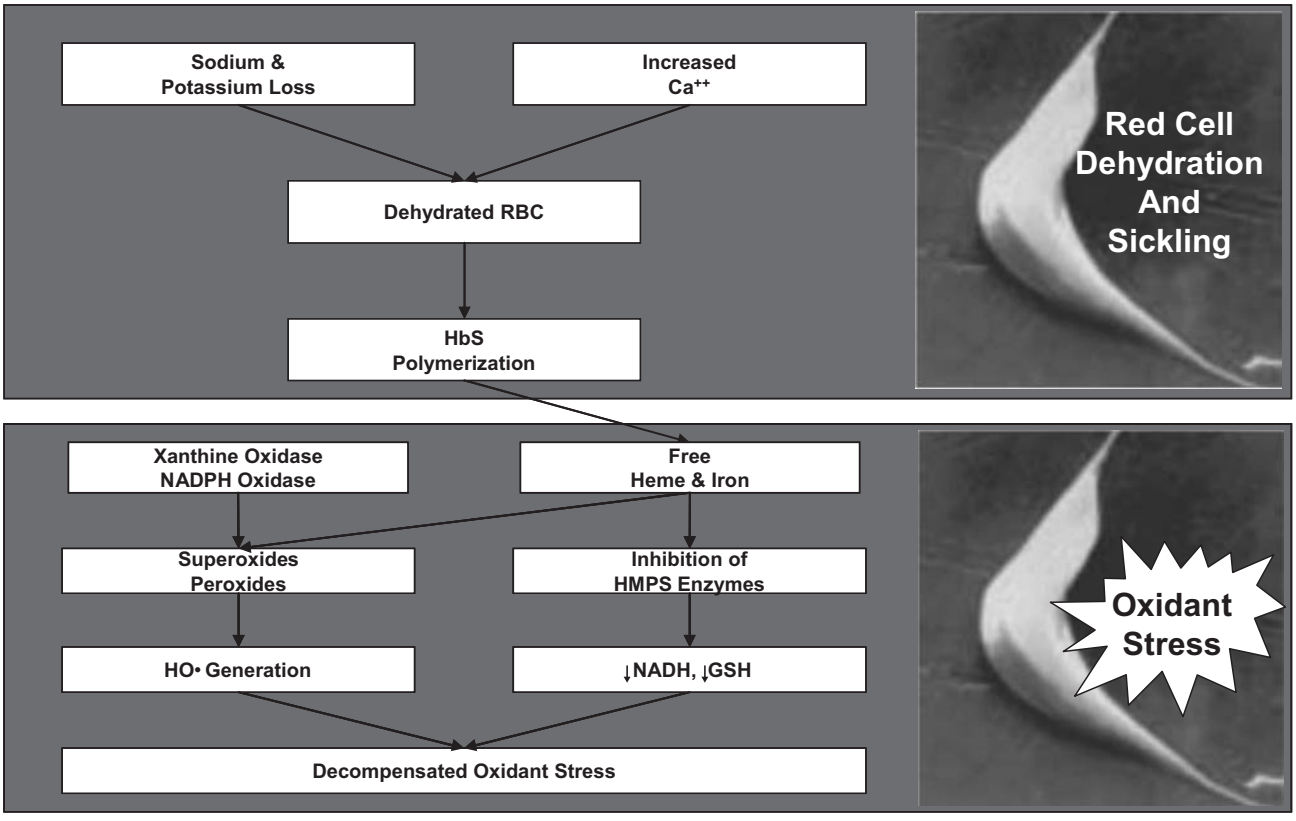

Figure 11.1. Factors leading to sickling and oxidant stress in erythrocytes in sickle cell disease. Solute loss and increased intracellular calcium promote red cell dehydration, which raises the intracellular concentration of sickle hemoglobin. This promotes polymerization of sickle hemoglobin, which is associated with generation of increased levels of oxidant species and depletion of cellular antioxidants, leading to a heightened state of oxidative stress. Each of these steps is described in the text, although the exact sequence of these events is somewhat speculative. (See color plate 11.1.)

(Fig. 11.2),[24] as the red cell membrane ghosts and the cytoskeletons of ISCs remain deformed after removal of hemoglobin.[24,25] Oxidation-induced defects in β-actin and spectrin appear to slow the dissociation of their ternary complex with protein 4.1. In ISCs, formation of a disulfide bridge is favored in β-actin involving cysteines at the 284 and 373 positions.[24]

The intense oxidative stress places high demands on metabolic pathways that provide compensatory reducing capacity in the red cell, such as the hexose monophosphate shunt, which produces NADH and reduced glutathione (Fig. 11.1).[26,27] The enzymes in these pathways are inhibited by the excess free heme present in sickle[11] and thalassemic red cells.[28] As glutathione becomes oxidized, identified by a high ratio of oxidized to reduced glutathione or as a low level of total glutathione,[11,29–31] cysteine residues in α-spectrin become glutathiolated.[24] This blocks the normal ubiquitin-conjugating and ligating activity of α-spectrin, impairing its autoubiquitination in sickle erythrocytes.[32,33] The lack of ubiquitination prevents normal dissociation of α-spectrin and protein 4.1, diminishing erythrocyte cytoskeletal flexibility and contributing to the rigid shape of the ISC.[34]

Consistent with a role for oxidative stress in ISC formation, the reducing agent N-acetylcysteine in vitro can convert ISCs into biconcave discs.[35] A pilot trial of N-acetylcysteine in 16 patients with sickle cell disease did not, however, produce a significant change in the hemoglobin level or reticulocyte count, despite achieving higher erythrocyte glutathione levels and a lower percentage of ISCs at the highest dose tested.[36] This suggests that the mechanisms of hemolysis are not solely related to erythrocyte shape. Some investigators have found deficiency of the naturally occurring antioxidant vitamin E in patients with sickle cell disease or thalassemia,[37–39] although this has been inconsistent.[40] Pilot studies have suggested that vitamin E supplementation may reduce hemolysis in sickle cell disease.[41,42] Future approaches will likely attempt to inhibit extracellular sources of reactive oxygen species, including xanthine oxidase, NADPH oxidase, and uncoupled endothelial NO synthase.

Membrane Phospholipid Asymmetry

In erythrocytes and other cell types, active mechanisms maintain asymmetry of membrane phospholipids. Over

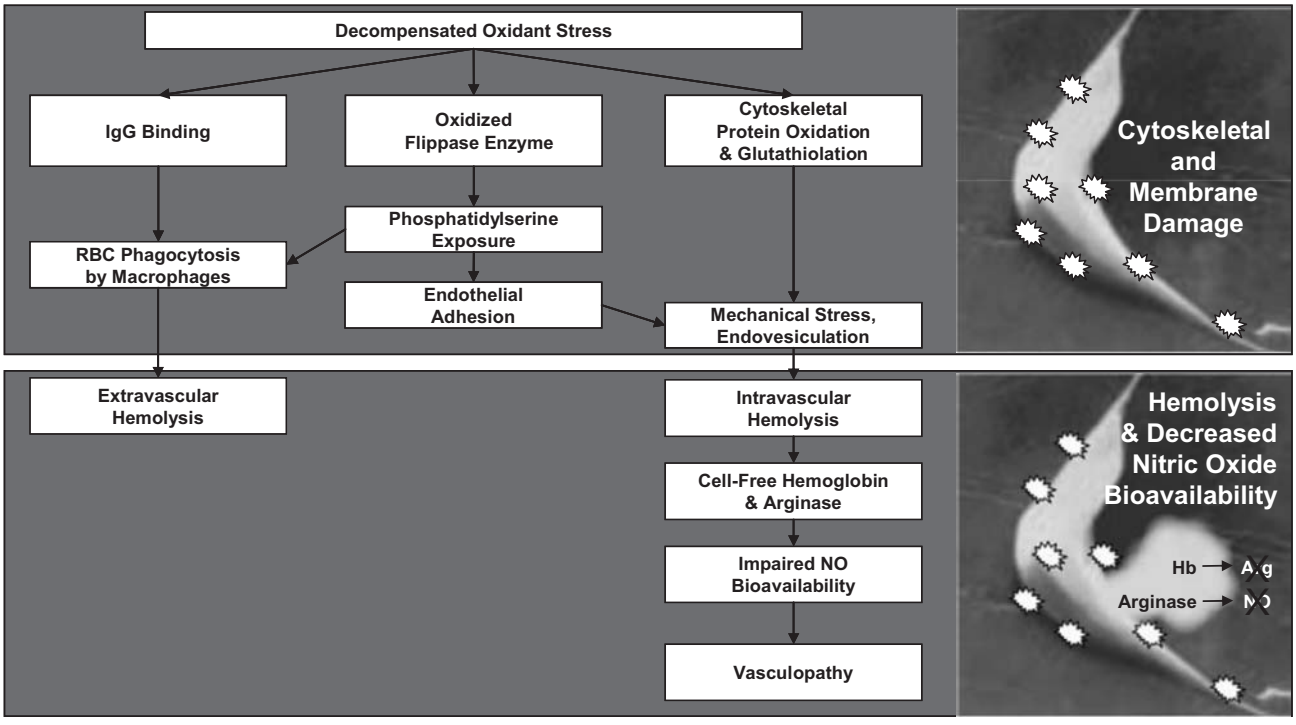

Figure 11.2. Factors promoting hemolysis in sickle cell disease. Decompensated oxidative stress in the sickle erythrocyte is associated with multiple lesions in its cytoskeleton and membrane. These lesions are responsible for binding of immunoglobulin to the membrane, promoting Fc receptor–mediated endocytosis of the damaged red cell by reticuloendothelial macrophages, considered extravascular hemolysis. Oxidative damage to the flippase enzyme is proposed to cause externalization of phosphatidylserine and phosphatidylethanolamine that also stimulate uptake of the red cell by macrophages, in addition to adhesion to endothelium. Oxidative damage and glutathiolation of the cytoskeleton can trigger endovesiculation of the membrane and release of membrane microparticles, and mechanical fragility of the damaged red cell. These latter events tend to produce intravascular hemolysis, resulting in the decompartmentalization of erythrocyte contents into plasma. (See color plate 11.2.)

75% of cellular phosphatidylcholine and sphingomyelin normally are maintained in the outer leaflet of the red cell membrane, whereas more than 80% of total phosphatidylserine and phosphatidylethanolamine are maintained in the inner leaflet (Chapter 9). This is accomplished by adenosinetriphosphate (ATP)–dependent aminophospholipid translocase, or flipase, which actively transports phosphatidylserine and phosphatidylethanolamine from the outer to the inner monolayer. Flippase can become dysfunctional with hypoxia-induced sickling (Fig. 11.2).[43,44] The mechanism of flippase inactivation in murine sickle cells involves its oxidation,[45] although this has not been confirmed in human sickle cells.[46] Inactivation of flipase permits phosphatidylserine exposure on the outer leaflet of the red cell membrane.[47]

Phosphatidylserine and phosphatidylethanolamine also are transported actively to the outer leaflet by activation of a Ca^{2+}-dependent scramblase. With increased Ca^{2+} flux, this scramblase can become activated, resulting in abundant phosphatidylserine exposure on the red cell surface in sickle cell disease and β thalassemia.[48] Thus Ca^{2+} flux and accumulated oxidant stress may both play a role in red cell aging and destruction, mediated though phosphatidylserine exposure.[49]

Cytoskeletal abnormalities in sickled cells, particularly spiculation, also appear to promote localized membrane phospholipid asymmetry.[50–52] Similar localized phospholipid asymmetry occurs at sites of Heinz bodies.[53] Reticuloendothelial system macrophages bind to and engulf these phosphatidylserine-externalized red cells, contributing to extravascular hemolysis (Fig. 11.2).[45,54] Phosphatidylserine exposure also induces binding of red cells to endothelial cells,[55–57] likely leading to sequestration of phosphatidylserine-exposing cells in peripheral blood vessels. Other mechanisms also induce adhesion of young sickled cells to endothelial cells. Immobilization of ISCs in flowing blood onto vascular endothelium may lead to increased shear stress and intravascular hemolysis (Chapter 8).

Fragility of ISCs to Mechanical and Shear Stress

The numbers of circulating ISCs decreases during the latter stages of vasoocclusive crisis, suggesting that the rigid, adhesive red cells might become sequestered in the microvasculature.[58,59] ISCs are also implicated in intravascular hemolysis during mechanical membrane fragmentation. Repeated cycles of sickling in vitro generate

dehydrated red cells with membrane spiculation apparent on electron microscopy, which appear to give rise to spectrin-free, hemoglobin-containing microparticles.[60,61] Increased mechanical fragility of sickle erythrocytes has been documented in vitro by increased lysis with application of shear stress, and confirmed in vivo with the increased shear stress due to exercise-induced increase in blood flow.[62] Cell fractionation experiments indicate that the dense, dehydrated sickle erythrocytes are the most sensitive to mechanical or shear-induced hemolysis[62–66] and that rehydration restores resistance to shear stress, except in the densest red cells.[62] The membrane structure of ISCs is weakened and may contribute to intravascular fragmentation (Fig. 11.2).[67] Mechanical stress also induces hemoglobin denaturation and loss of hemin, which contributes to oxidative stress.[68] ISCs may be the most sensitive circulating red cells to this mechanical lysis induced by shear stress.

Adherent Immunoglobulin G

A subpopulation of erythrocytes in sickle cell disease binds IgG.[20,69–71] Cyclic oxygenation-deoxygenation, or oxidant stress in sickle cell disease, indicated by malondialdehyde production stimulates binding of IgG to the red cell surface.[20,72] Part or all of this effect may be related to Heinz bodies, oxidatively denatured hemoglobin, which generates a hemichrome that cross-links the major red cell membrane spanning protein, band-3.[73] A cryptic antigen exposed on the clustered band-3 complexes on the erythrocyte surface is recognized and bound by specific IgG antibodies, which in turn bind avidly to the Fc receptors on reticuloendothelial system macrophages.[74,75] This culminates in phagocytosis and lysis of the antibody-coated sickle erythrocytes by macrophages, a normal consequence of aging of red cells that is accelerated in sickle cells (Fig. 11.2).[72] This Fc receptor–mediated mechanism is a second significant contributor to oxidant stress-related, extravascular hemolysis in sickle cell disease.

Complement-mediated Hemolysis

Sickle cells are particularly sensitive to attack by complement-inducing intravascular hemolysis. Similar to erythrocytes in paroxysmal nocturnal hemoglobinuria, sickle cells show a defect in activity of the membrane attack complex, C5b-9.[76] This occurs due to increased binding of complement C5b-7 and C9 to sickle cells, particularly to the densest cells. This binding leads to C5b-9-mediated lysis initiated by C5b-6, especially on ISCs. Because it has been found that anionic lipids on the surface of the red cell can induce binding of C5b-6,[77] it is possible this binding occurs via the increased phosphatidylserine exposure that has been described on the outer membrane of the sickle and thalassemic erythrocyte.[45,78–84]

Clinical Consequences of Extravascular Hemolysis

Chronic extravascular hemolytic anemias in general are associated with the gradual development of splenomegaly that occurs frequently in patients with β-thalassemia intermedia and major. Although most adults and older children with sickle cell anemia have functional asplenia and splenic atrophy due to chronic subclinical splenic infarction, there are cases of sickle cell disease in which splenomegaly is present. These include young children homozygous for the HbS gene and patients with clinically milder sickling syndromes such as HbSC disease and HbS-β^+ thalassemia.[85,86] Patients with splenomegaly and sickle cell disease or β thalassemia often are more anemic than similar patients without splenomegaly, presumably due to chronic hypersplenism.[87,88] In some of these cases, chronic hypersplenism has been documented by improvement in anemia following splenectomy.[89,90]

CLEARANCE OF HEMOGLOBIN

Extracellular hemoglobin is toxic to vascular health, and humans have developed multiple redundant pathways to facilitate its rapid clearance.[91] During intravascular hemolysis, large amounts of hemoglobin are released from the lysed red cells into plasma. During extravascular hemolysis, the red cell is engulfed by a reticuloendothelial macrophage, and hemoglobin is degraded directly in the macrophage, releasing small amounts of hemoglobin into plasma. Upon its dilution into plasma, the hemoglobin tetramers decompose into αβ dimers. Dimeric hemoglobin rapidly forms complexes with the soluble plasma protein haptoglobin, the principal hemoglobin scavenging protein, which prevents hemoglobin from crossing the glomerular membrane. Upon formation of the complex, haptoglobin displays a previously hidden binding site for its cognate receptor on macrophages, CD163, the hemoglobin scavenger receptor (Fig. 11.3).[92] This high-affinity binding promotes endocytosis of the CD163-haptoglobin-hemoglobin complex, where it is degraded, disposing of the hemoglobin and along with it, haptoglobin, which is not recycled. Even with the lower-grade hemolysis seen in HbSC disease, serum haptoglobin levels are low. During the robust hemolysis of sickle cell anemia or β-thalassemia intermedia, haptoglobin is completely depleted from plasma. Thus, an undetectable plasma haptoglobin clinically signifies high-level hemolysis and pathophysiologically indicates that the primary, rapid mechanism for hemoglobin clearance has become saturated. The binding capacity of haptoglobin to hemoglobin is reported to be 0.07–0.15 g/dL, depending on different genetic variants of haptoglobin.

Hemopexin plays a complementary role, clearing plasma of free heme. Plasma hemoglobin that becomes oxidized to methemoglobin is prone to lose the oxidized heme

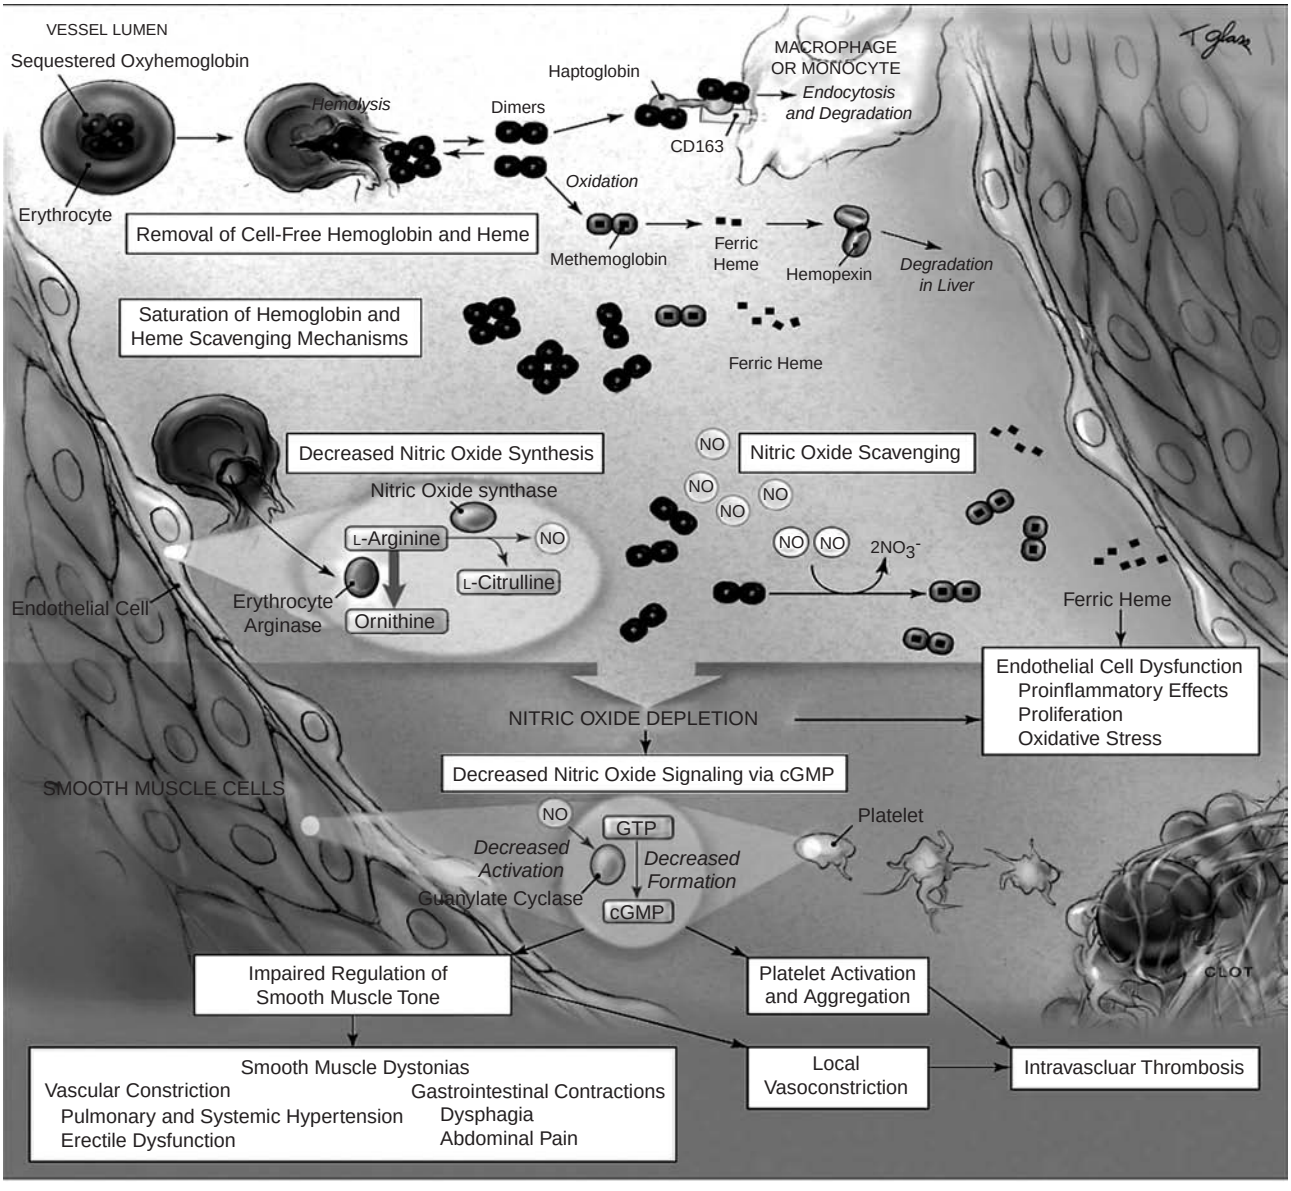

Figure 11.3. Pathophysiological consequences of intravascular hemolysis. Decompartmentalization of red cell contents results in ectopic localization of hemoglobin and arginase into plasma. Hemoglobin is rapidly bound to haptoglobin, and this complex binds to CD163 on macrophages, resulting in endocytosis and clearance of the whole complex. If the utilization of haptoglobin exceeds its replacement by hepatic synthesis, plasma cell–free hemoglobin accumulates, which stoichiometrically inactivates NO. Plasma cell–free arginase converts plasma arginine to ornithine, reducing availability of arginine, the obligate substrate for NOS. Depletion of NO results in pulmonary vasoconstriction, platelet activation, smooth muscle dystonias, and reduced antioxidant capacity. (Reproduced with permission of the publisher from ref. 110.)

porphyrin ring, known as hemin. Free heme is capable of inserting into cell membranes and producing hydroxyl and nitrogen dioxide radicals via Fenton and peroxidase chemistry, respectively, and a specific clearance pathway exists to avoid this oxidative insult. Hemin is bound by another β-globulin plasma glycoprotein, hemopexin, and the complex is slowly cleared by hepatic parenchymal cells. After saturation of hemopexin, free hemin is adsorbed to albumin as the brown pigment methemalbumin. Depletion of plasma hemopexin is another indicator of hemolysis.

Disposal of plasma hemoglobin via the haptoglobin–CD163 pathway activates a program that helps to counteract the adverse effects of plasma hemoglobin on vascular homeostasis. Binding of hemoglobin-haptoglobin to CD163 activates the antiinflammatory cytokine interleukin-10 and the heme oxygenase-1 heme catabolic enzyme, which also has antioxidant activities (Fig. 11.3).[93]

Heme oxygenase-1 breaks down heme into biliverdin, free iron, and carbon monoxide. Carbon monoxide induces vasodilatory, antioxidant, antiinflammatory, and antiproliferative responses.[94–96] Biliverdin is converted by biliverdin reductase to bilirubin, which also has antioxidant properties.[97] Carbon monoxide, produced in the body solely through the heme oxygenase reaction and eliminated via the lungs, may be monitored in exhaled breath as an indicator of the rate of heme turnover.[98]

The hemoglobin scavenging activity of haptoglobin is supplemented by the haptoglobin-related protein (Hpr). This plasma protein also binds to plasma hemoglobin with high affinity, but this complex does not bind to CD163. Instead, the hemoglobin–Hpr complex is directed to specialized high-density lipoprotein particles called HDL3 OR TLF-1, which contain apolipoprotein A-I, L-I, and others.[99] Whether this sequestration protects the vascular system against the toxic effects of plasma hemoglobin is unknown. Unlike haptoglobin, Hpr is not depleted from plasma of patients with sickle cell disease or other forms of intravascular hemolysis.[100] It is not known whether hemoglobin–Hpr complexes in HDL particles are capable of scavenging NO.

High-grade intravascular hemolysis may saturate the capacity of the haptoglobin-hemopexin-Hpr system, forcing hemoglobin clearance through alternative mechanisms. The relatively small size of αβ globin dimers allows their penetration of the glomerulus into filtrate.[91] Hemoglobinuria results when the maximal tubular reabsorption rate of 1.4 mg/min is exceeded.[101] Hemoglobin reabsorbed into renal tubular cells is degraded, generating bilirubin and iron. Iron stored in ferritin in the renal tubular cells can accumulate to high levels, generating insoluble hemosiderin.[102,103] The hemosiderin-laden renal epithelial cells are eventually sloughed into urine, where they may be identified in urinary sediment by Prussian blue staining and are indicative of high-grade chronic intravascular hemolysis. Such hemolytic rates are common in paroxysmal nocturnal hemoglobinuria, and may occur in sickle cell disease. In states of haptoglobin depletion, plasma hemoglobin also undergoes endocytosis by hepatic macrophages via direct binding to CD163.[92] There is also indirect evidence of similar activity in macrophages of neovascularized atherosclerotic lesions. This might suggest a protective role for this pathway in the development of proliferative vasculopathy related to cases of chronic intravascular hemolysis or to intraplaque hemorrhage.

CLINICAL CONSEQUENCES OF INTRAVASCULAR HEMOLYSIS

When the rate of intravascular hemolysis exceeds the capacity of the hemoglobin scavenging mechanisms, hemoglobin and other red cell constituents accumulate in plasma compartment. Several of these constituents are toxic to vascular health, and a clinical vasculopathy syndrome has been identified in sickle cell disease, thalassemia, and other hemolytic anemias.

Hemolysis-associated Vascular Dysfunction: A Unique State of NO Resistance in Hemolytic Diseases

NO is a free radical molecule produced in endothelium by the endothelial NO synthase enzyme, via the oxygen-dependent five-electron oxidation of L-arginine to citrulline.[104–106] Once produced, NO diffuses as a paracrine-signaling molecule to adjacent smooth muscle where it binds avidly to the heme moiety of soluble guanylate cyclase. This activates the enzyme which in turn converts guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP), activating cGMP-dependent protein kinases, which ultimately leads to Ca^{2+} sequestration and relaxation of the perivascular smooth muscle to produce vasodilation (Chapter 10).

NO-dependent vasodilation can be stimulated by shear stress and direct activation of muscarinic receptors by agonists such as acetylcholine. Vascular NO production is also tonic and controls approximately 25% of our resting blood flow.[107,108] This steady-state vascular NO flux promotes general vascular homeostasis and health. NO tonically down-regulates transcription of endothelial adhesion molecules such as VCAM-1, ICAM-1, P-selectin and E-selectin[109] and inhibits platelet activation, tissue factor expression and thrombin generation.[110] NO modulates the expression of endothelin receptors (promoting a vasodilator effect by increasing endothelial endothelin receptor B expression) and decreases expression of endothelin-1, a potent mitogen and vasoconstrictor.[111,112] Finally, NO reacts in a nearly diffusion limited reaction with the superoxide radical, critically modulating vascular redox balance. All these pathways, normally inhibited by NO, are pathologically activated in sickle cell disease and perhaps other hemolytic anemias.

The concentration of NO available for the activation of soluble guanylate cyclase depends on the rate of production from endothelial NO synthase and the extent of scavenging reactions with superoxide and hemoglobin (or other high affinity heme-globins such as myoglobin).[113] NO reacts with oxy- and deoxy-hemoglobin at the near diffusion limit (10^7 Ms) to produce methemoglobin and nitrate or iron-nitrosyl-hemoglobin, respectively (Equations 11.1 and 11.2).[114,115] NO will react even faster with superoxide (at the diffusion limit, $10^{9–10}$ Ms), formed by the enzymes xanthine oxidase, NADPH oxidase, uncoupled NO synthase, as well as by hemoglobin autooxidation ($HbFe^{+2}\text{-}O_2 \rightarrow HbFe^{+3} + O_2{\cdot}^-$), to form peroxynitrite (Equation 11.3).[106] Although the reaction of NO with superoxide is approximately 100 times faster than that with hemoglobin, the concentration of hemoglobin in the plasma of patients with sickle cell disease (approximate mean concentrations of 4 μM[116]) is approximately more than 100 times that of superoxide, suggesting that

both pathways have the potential to limit NO bioavailability in vivo.

$$NO + HbFe^{+2}\text{-}O_2\ [\text{oxyhemoglobin}] \rightarrow HbFe^{+3}\ [\text{methemoglobin}] + NO_3^-\ [\text{nitrate}] \quad (11.1)$$

$$NO + HbFe^{+2}\ [\text{deoxyhemoglobin}] \rightarrow HbFe^{+2}\text{-}NO\ [\text{iron-nitrosyl-hemoglobin}] \quad (11.2)$$

$$NO + O_2^{\bullet -}\ [\text{superoxide}] \rightarrow ONOO^-\ [\text{peroxynitrite}] \quad (11.3)$$

Because mammals do not possess nitrate reductase enzymes and the off-rate of NO from iron-nitrosyl-hemoglobin is so slow, these three reactions represent irreversible scavenging reactions. Indeed, the half-life of NO in a free (i.e., not encapsulated by a red cell membrane) solution of 10 mM oxyhemoglobin (the concentration of hemoglobin in whole blood) is estimated to be 1 μs and this NO could only diffuse 1 μm.[117] Based on the kinetics of these reactions (nearly diffusion limited) and the concentration of intravascular hemoglobin in red blood cells (10 mM concentration in heme in whole blood), theoretical calculations suggest that the diffusion radius of NO from endothelium would be severely limited.[117] This effect is only slightly diminished by the fact that the smooth muscle cells are on one side of the endothelium and the blood is on the other.[105] Because the net flux of NO is always defined by the three dimensional spatial gradient in its concentration, the presence of hemoglobin on one side of the endothelium decreases the concentration on the other side. Conceptually, one can appreciate that NO diffusion is random from its source of production, so that a particular NO molecule can diffuse luminally and then back abluminally; if a trap is present on one side, any molecule that diffuses in that direction is eliminated and the concentration of NO on the other side will thus diminish. Indeed, recent modeling studies reveal that as little as one micromolar cell-free intraluminal hemoglobin in plasma will dramatically reduce NO concentrations that reach smooth muscle.[118] This effect is magnified in hemolytic anemia, where the total level of NO scavenging by the red cells is reduced as the red cell mass decreases, so that the relative contribution of NO scavenging by the plasma hemoglobin compartment increases.[118]

These chemical reactions create a paradox in vascular biology: How can NO be the endothelium derived relaxing factor if the massive concentrations of intravascular hemoglobin should scavenge it and limit its ability to diffuse from endothelium to smooth muscle? This paradox has been largely solved by the understanding that there are major diffusional barriers for NO between the source of production, endothelial NO synthases, and hemoglobin in the red blood cell (Fig. 11.4).[113] There exist several major diffusional barriers for NO in the unstirred layer around the erythrocyte,[119,120] in the cell free zone that forms along the endothelium in laminar flowing blood,[121–123] and possibly in the red cell submembrane, formed from the protein lattice of actin, spectrin, methemoglobin, hemichromes, band-3, and other components of the inner membrane scaffolding.[124–126] These three major diffusional barriers reduce the reaction of NO with intracellular hemoglobin by approximately 300–1,000 fold and allow sufficient NO diffusion for paracrine signaling from endothelium to smooth muscle. For example, with a cell-free zone of 5 micrometers, the lifetime of NO would increase from 1 microsecond to approximately 7.5 ms before it reached the red cell rich zone and would be scavenged; thus the lifetime of NO increases by a factor of almost 10,000 in this situation.[117]

Understanding this balance between NO production, diffusion to smooth muscle, and scavenging reactions with intracellular hemoglobin helps explain the clear toxicity observed in the clinical development of the stroma-free hemoglobin-based blood substitutes (recently reviewed[110] and illustrated in Figure 11.4). The infusion of cell free hemoglobin solutions into normal volunteers and patients immediately disrupts the NO diffusion barriers and produces dose-dependent vasoconstriction (systemic and pulmonary hypertension),[127–136] smooth muscle dystonias (gastroparesis, esophageal spasm and abdominal and chest pain),[127,128,130,133,137] platelet activation,[138–141] and death.[142,143] The toxicity of cell free hemoglobin solutions has resulted in serious morbidity (myocardial infarction) and excess mortality in most clinical trials of blood substitutes in at-risk patients.[110]

In sickle cell disease, thalassemia, malaria and other acquired, iatrogenic, infectious and hereditary hemolytic conditions, intravascular hemolysis similarly disrupts the NO diffusional barriers created by the red cell membrane that limit NO reactions with hemoglobin, and the cell-free plasma hemoglobin destroys NO at a rate 1,000-fold faster than intraerythrocytic hemoglobin.[110,113,116,144] As a result of hemolysis, hemoglobin is released into plasma where it reacts with and destroys NO, resulting in abnormally high rates of NO consumption and produces a state of resistance to NO bioactivity. Consequently, smooth muscle guanylyl cyclase is not activated and vasodilation is impaired. In support of this mechanism, plasma from patients with sickle cell disease contains cell-free ferrous oxyhemoglobin, which stoichiometrically consumes micromolar quantities of NO and abrogates forearm blood flow responses to NO donor infusions.[116]

This NO resistance syndrome is a unique form of vascular dysfunction. In coronary artery disease and its risk factors, diabetes, obesity, hypertension, smoking, increasing age, and hyperlipidemia, NO production is reduced. This is clinically characterized by the demonstration that infusions of the competitive NO synthase inhibitor, L-NMMA, into the brachial artery or coronary arteries exhibits a blunted vasoconstrictor response, suggesting that tonic NO synthase activity is impaired.[107,145] However, in these patients with the metabolic syndrome, the infusion of sodium

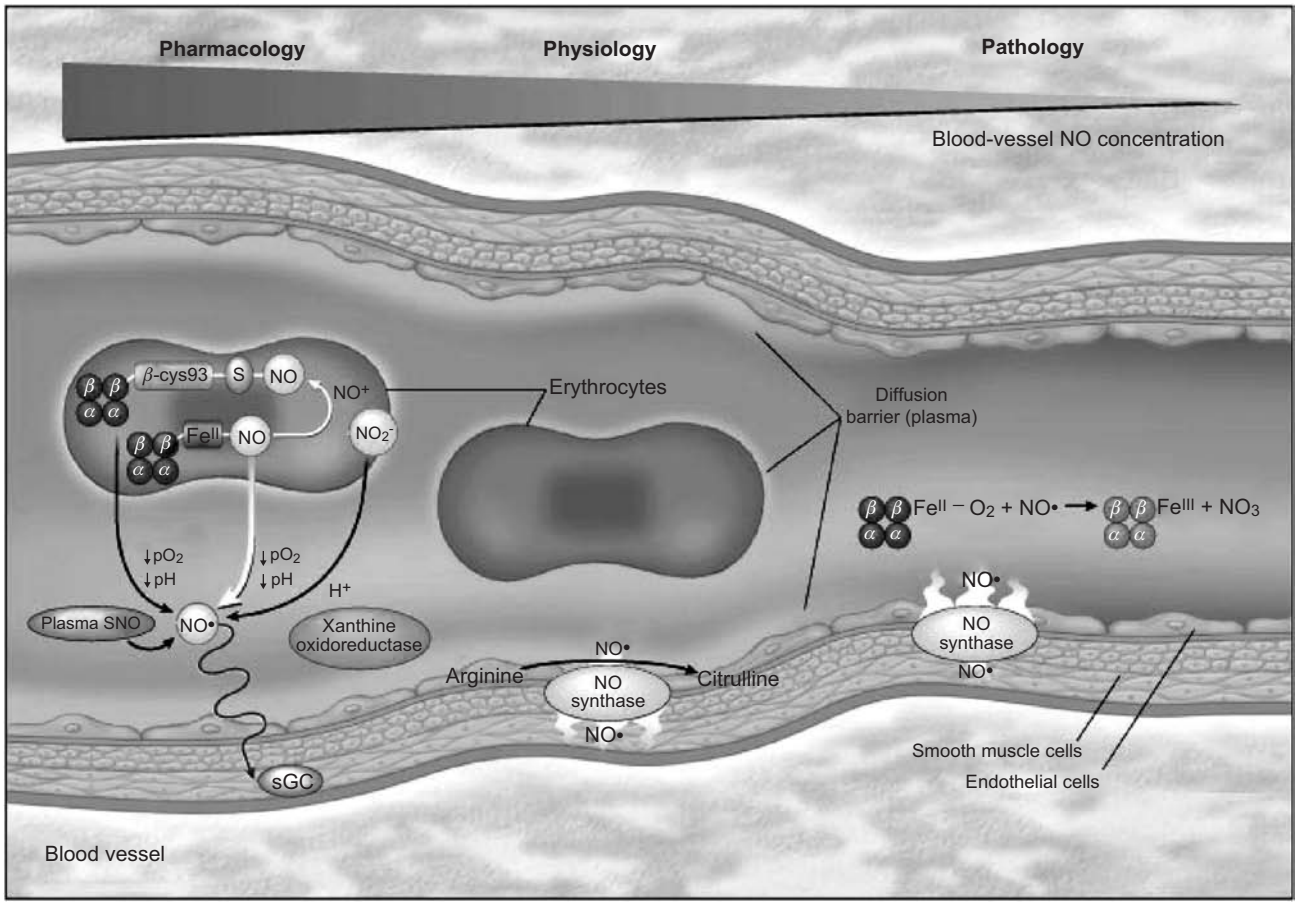

Figure 11.4. Role of diffusion barriers in intact red cells and plasma cell–free hemoglobin. Intact red cells carry a reservoir of NO in the form of nitrite. Nitrite can be reduced by deoxyhemoglobin to NO, although it remains to be determined how NO escapes from the erythrocyte. Xanthine oxidoreductase may also have the potential to perform this reaction. S-nitroso-hemoglobin has also been proposed as another erythrocyte storage form of NO. NO is produced principally by NOS from arginine and binds to soluble guanylyl cyclase in vascular smooth muscle cells, producing tonic vasodilation. Diffusion barriers to consumption of NO by intact erythrocyte hemoglobin are provided by the cell-free zone along the endothelium associated with laminar flow of blood, and by the unstirred layer surrounding the red cell. (Reproduced with permission from ref. 113.)

nitroprusside or nitroglycerin, NO donor medications, produces normal vasodilation effects and are used as controls to show that the vessels are capable of vasodilation. In striking contrast, in patients with sickle cell disease with high hemolytic rates and high plasma hemoglobin levels, the vasodilatory effect to L-NMMA and the NO donor sodium nitroprusside are both blunted. This unique state of resistance to NO-dependent vasodilation[146] has been recapitulated in numerous mouse and human studies (Fig. 11.5).

- In patients with sickle cell disease and high plasma hemoglobin concentrations the blood flow responses to infusions of the NO synthase inhibitor L-NMMA are blunted and blood flow responses to the NO donor sodium nitroprusside are nearly abolished.[116,147] This effect appears to be more pronounced in males, consistent with estrogenic effects on NO synthase expression and activity.
- Endothelium-dependent, NO-dependent blood flow is impaired in patients with sickle cell disease, when measured by flow-mediated vasodilation. The responses to the exogenous NO donor, nitroglycerin are impaired, compared with control subjects with non-hemolytic anemia.[148]
- A similar state of resistance to exogenous NO (the NO donor NONOate or sodium nitroprusside) in different transgenic mouse models of sickle cell disease has also been described.[149,150] NO resistance was highly correlated with plasma hemoglobin levels suggesting that NO resistance in this model was linked to hemolytic rate and oxidant stress.[151]
- NO is inhibited in the vasculature of transgenic sickle cell mice with sickle cell disease by a diffusion-limited reaction with superoxide produced from xanthine oxidase on endothelium.[12,152] Increased xanthine oxidase expression in the lung of the transgenic mouse has also been reported to scavenge NO in this vascular system.[153]

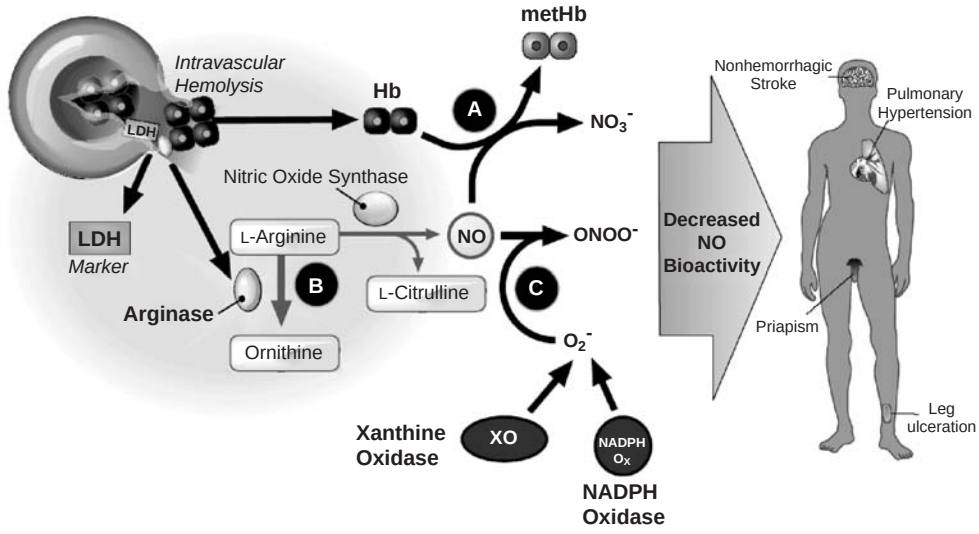

Figure 11.5. Intravascular hemolysis and decreased NO bioactivity. Arginine is converted by NOS to NO plus citrulline. Intravascular hemolysis releases cell-free hemoglobin into blood plasma, where it stoichiometrically can react with NO (reaction A), producing methemoglobin and inert nitrate. In addition, erythrocyte arginase released into plasma catabolizes plasma arginine (reaction B), reducing its availability to NOS. In reactions not directly related to hemolysis, increased xanthine oxidase and NADPH oxidase activities found in sickle cell disease produce oxygen radicals, which can react with and further deplete NO, producing highly oxidative peroxynitrites (reaction C). Consequent decreased NO bioactivity contributes to the clinical risk of pulmonary hypertension, nonhemorrhagic stroke, priapism, and leg ulceration. (Reproduced with permission of the publisher from ref. 183.)

Recent studies have suggested a role for vascular NADPH oxidase in enhanced superoxide mediated NO scavenging in the sickle cell cerebral vasculature.[154]

- Sickle cell transgenic mice develop spontaneous pulmonary hypertension associated with a global impairment in both the production of NO (from uncoupled eNOS) and from NO inactivation by plasma hemoglobin and superoxide.[155] Both pulmonary and systemic impairment in the vasodilatory responses to inhaled NO, sodium nitroprusside, NONOates and even phosphodiesterase-5 inhibitors were observed. A similar state of NO resistance developed in an alloimmunized intravascular hemolysis mouse model.[156]
- In a canine model of acute intravascular hypotonic water hemolysis,[157] pulmonary and systemic vasoconstriction was associated with the degree of hemoglobinemia and the development of resistance to the NO donor sodium nitroprusside.

Similar effects of hemolysis on NO bioavailability and endothelial function have been considered in paroxysmal nocturnal hemoglobinuria,[110] in primate models of thrombotic thrombocytopenic purpura,[158] and have recently been described in animal models of malaria.[159,160] In the latter malaria studies, the degree of hemoglobinemia, which reduced systemic NO bioavailability, was even more closely linked to risk of death than the severity of parasitemia.

Arginasemia Limitations on NOS Substrate Bioavailability

In addition to release of hemoglobin from the red cell into plasma, hemolysis releases erythrocyte arginase, which converts L-arginine, the substrate for NO synthesis, to ornithine (Figs. 11.4 and 11.5).[161–163] Arginase activities in the plasma of patients correlated significantly with cell-free plasma hemoglobin and was increased in the plasma and red cells of patients with sickle cell disease (Fig. 11.6). Consistent with this observation, the arginine:ornithine ratio decreased significantly as plasma arginase activity rose. Low arginine:ornithine ratios were found in patients with sickle cell disease and comorbid pulmonary hypertension and were associated with increasing mortality.[163,164]

Hemolysis, Coagulation and the Spleen

Intravascular hemolysis has the potential to drive a procoagulant state. Platelet activation is profoundly inhibited by NO and such NO-dependent inhibition may in turn be blocked by plasma hemoglobin-mediated NO scavenging.[139,141,165,166] Activation of platelets in sickle cell disease correlated with pulmonary artery pressures and indices of hemolysis. In vitro experiments suggested that cell-free hemoglobin could directly activate platelets and inhibit the modulatory effects of NO on platelet activation.[141] High hemolytic rate, reflected by reticulocytosis, was also associated with hemoglobin desaturation (ventilation/perfusion inhomogeneity) and adhesion molecule

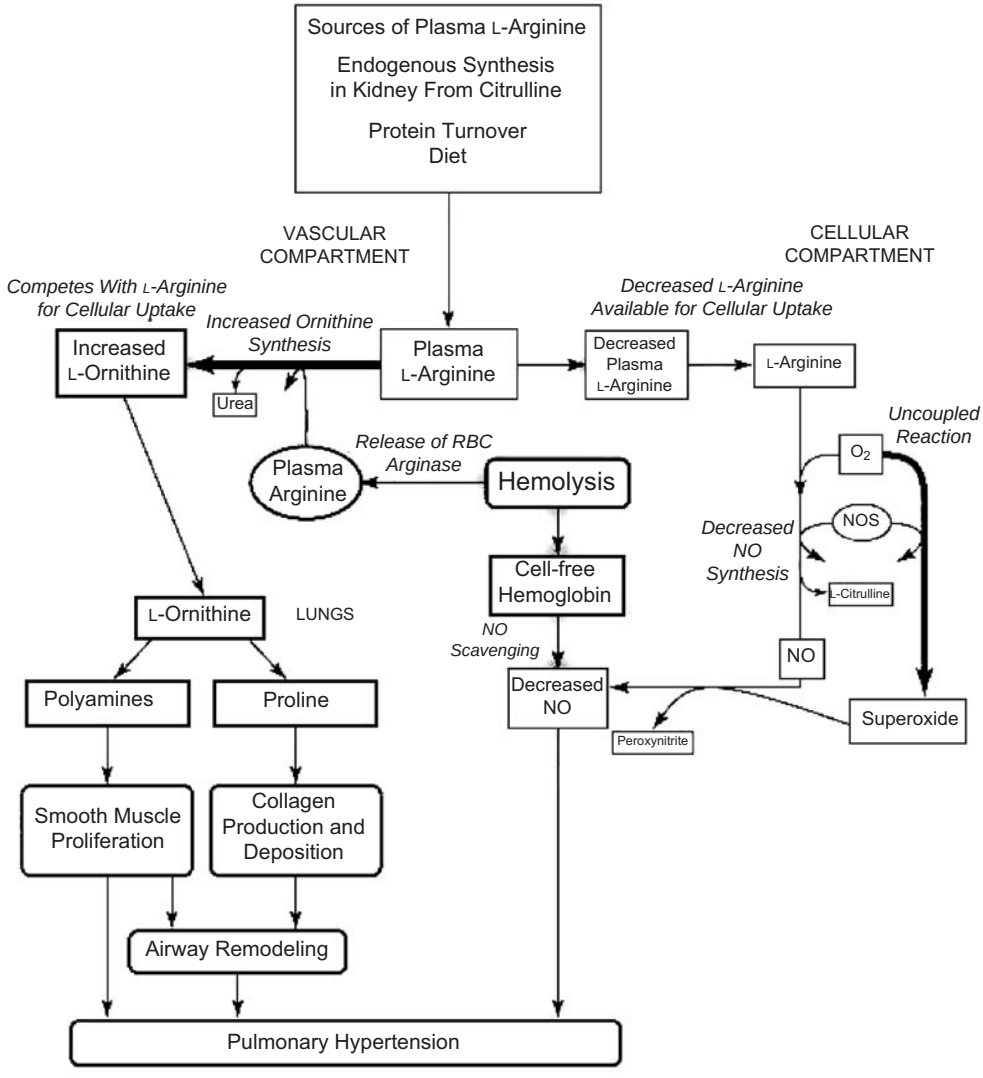

Figure 11.6. Alterations in arginine metabolism in sickle cell disease and thalassemia. Plasma L-arginine is derived from synthesis in the kidney, from protein turnover, and from dietary sources. Intravascular hemolysis results in ectopic localization of erythrocyte arginase into blood plasma, where it can convert L-arginine into L-ornithine, reducing the availability of L-arginine as a substrate for NO synthesis. Under such conditions of limiting substrate, the subunits of NO synthase can become uncoupled, producing superoxides that can react with NO to form peroxynitrites. Excess production of ornithine has been proposed to provide substrate for production of polyamines and proline. Polyamines can fuel DNA production and cell proliferation, and proline can stimulate collagen production. These processes are proposed along with decreased NO bioavailability to contribute to pulmonary hypertension in patients with chronic intravascular hemolysis. (Reproduced with permission of the publisher from ref. 163.)

expression;[167,168] it is possible that such a hypoxic state can induce hypoxia-inducing factor-1 (HIF-1) dependent factors such as erythropoietin, vascular endothelial growth factor (VEGF), and endothelin-1.

Splenectomy has been reported to be a risk factor for the development of pulmonary hypertension, particularly in patients with hemolytic disorders.[169–173] Perhaps the loss of splenic function increases the circulation of platelet derived mediators and that senescent and abnormal erythrocytes in the circulation trigger platelet activation, promoting pulmonary microthrombosis and red cell adhesion to the endothelium.[169] A role for intensification of intravascular hemolysis by splenectomy has also been suggested by the demonstration of significantly higher plasma hemoglobin and erythrocyte-derived microvesicles levels patients with β-thalassemia intermedia who have undergone splenectomy, compared with those who have not.[174] It is likely that splenic reticuloendothelial cells subserve a critical function in the removal of senescent and damaged erythrocytes and that following surgical or autosplenectomy, the rate of intravascular hemolysis increases, resulting in increased plasma hemoglobin and NO scavenging, and increased circulating red cells with phosphatidylserine exposed on their membranes. Consistent with such a mechanism, the

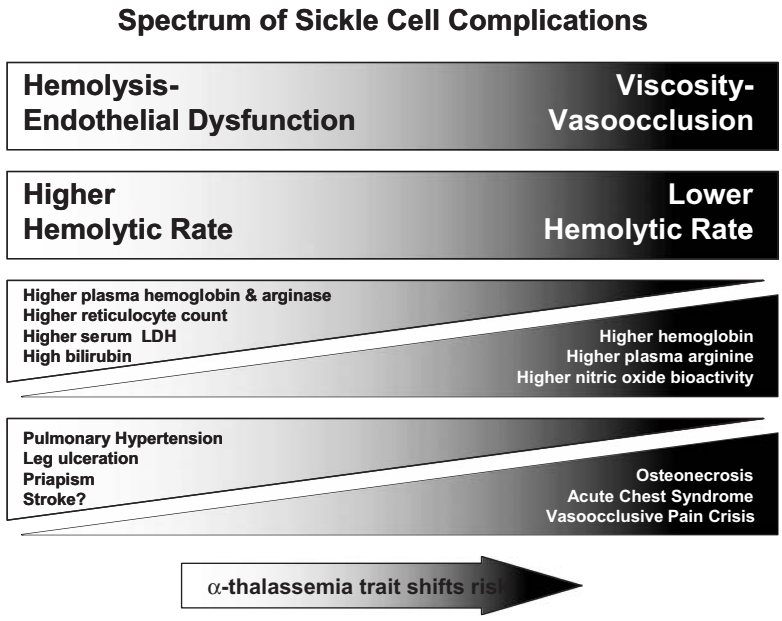

Figure 11.7. Spectrum of sickle cell subphenotypes affected by hemolytic rate. The viscosity-vasoocclusion subphenotype is associated with a lower hemolytic rate, marked by a higher hemoglobin level, and low plasma hemoglobin, lactate dehydrogenase, bilirubin, and arginase levels. Patients with these features have a higher incidence of vasoocclusive pain crisis, the acute chest syndrome, and osteonecrosis. In contrast, patients with the hemolysis-endothelial dysfunction subphenotype exhibit markers of high hemolytic rate, including low hemoglobin level, high plasma hemoglobin, LDH, bilirubin, and arginase, culminating in low NO bioavailability and high prevalence of pulmonary hypertension, leg ulceration, priapism, and stroke. Coinheritance of α thalassemia trait with sickle cell disease reduces the hemolytic rate, reducing the risk of hemolysis-associated complications and increasing the risk of viscosity-related complications. (Adapted with permission from ref. 183.)

experimental intravenous injection of hemolysate promotes the formation of platelet-rich thrombi in the pulmonary vascular bed of rabbits after ligation of the splenic artery, without any thrombus formation in the animals without splenic artery ligation.[175,176]

HEMOLYTIC ANEMIA-ASSOCIATED CLINICAL SUBPHENOTYPES

Recent epidemiological reexamination of the clinical complications of sickle cell disease suggests that the clinical manifestations of sickle cell disease may fall into two partially overlapping subphenotypes (Fig. 11.7). The first subphenotype encompasses the more classic manifestations of the disease: vasoocclusive crisis, acute chest syndrome and osteonecrosis. These morbidities are epidemiologically associated with high steady-state white blood cell counts, high steady-state hemoglobin levels and low HbF concentrations.[177] These complications are largely mediated by microvascular obstruction by sickle erythrocytes and the pathogenesis characterized by ischemia-reperfusion injury, adhesion, infarction and inflammation.[178,179] The second subphenotype encompasses clinical complications shared by other hemolytic anemias and includes pulmonary arterial hypertension, systemic systolic arterial hypertension, cutaneous leg ulceration, priapism, sudden death and possibly stroke.[116,164,180–182] Consistent with this formulation, coinheritance of α thalassemia, which reduces hemolytic rate in sickle cell disease, reduces the risk of leg ulceration, priapism and stroke, and increases the risk of vasoocclusive pain crisis, acute chest syndrome, and osteonecrosis as hemolysis is reduced and blood viscosity increases.[183]

Pulmonary hypertension is an increasingly recognized complication of chronic hereditary and acquired hemolytic anemias, including sickle cell disease,[164,184–192] β thalassemia (in particular β-thalassemia intermedia and inadequately transfused and chelated patients with β-thalassemia major),[169,193–201] paroxysmal nocturnal hemoglobinuria,[202–204] hereditary spherocytosis and stomatocytosis,[205–211] microangiopathic hemolytic anemias,[212,212–218] pyruvate kinase deficiency,[219] red cell alloimmune–mediated hemolytic anemia,[220] unstable hemoglobin variants,[221] and possibly malaria.[222–224] Additionally, certain conditions are associated with both intravascular hemolysis and risk of pulmonary hypertension, such as schistosomiasis,[225,226] iatrogenic hemolysis from mechanical heart valves,[227,228] left ventricular assist devices, and cardiopulmonary bypass procedures.[93,229–232] These studies are consistent with growing appreciation for a distinct syndrome of hemolysis-associated pulmonary hypertension.

Priapism and Hemolytic Anemia

Priapism has been reported in patients with sickle cell disease, β-thalassemia intermedia, red cell enzymopathy, unstable hemoglobin disorders, and other hemolytic anemias.[233–241] In one study, patients with a history of priapism had evidence of increased hemolytic rate and were five-fold more likely to have pulmonary hypertension, supporting a mechanistic and epidemiological link between these complications.[164] Further analysis of this cohort based on stratum of hemolysis defined by relative levels of LDH confirmed an association between the intensity of hemolysis and the prevalence of priapism, cutaneous leg ulceration, and pulmonary hypertension.[181] In a case-control analysis of data from the Comprehensive Study of Sickle Cell Disease (CSSCD), priapism was associated with laboratory markers of high hemolytic rate and

Table 11.1. Laboratory characteristics of cases with priapism and controls in a population of patients with sickle cell disease

	Case subjects n = 273	Control subjects n = 979	*P*
Age at last follow-up, y ± SD	26.2 ± 12.28	22.8 ± 12.72	.001
Hemoglobin, g/dL	8.64 ± 0.13	9.51 ± 0.07	<.001
HbF, g/dL	0.44 ± 0.04	0.50 ± 0.02	.309
Bilirubin, mg/dL	3.52 ± 0.13	2.92 ± 0.07	<.001
Urea nitrogen (BUN), mg/dL	9.49 ± 0.39	10.09 ± 0.20	.178
Mean corpuscular volume, μm^3	89.82 ± 0.48	87.18 ± 0.25	<.001
LDH, U/L	526.19 ± 13.08	459.23 ± 6.92	<.001
Reticulocytes	11.67 ± 0.35	9.37 ± 0.18	<.001
AST, U/L	50.34 ± 1.44	45.78 ± 0.76	.005
ALT, U/L	36.70 ± 2.96	35.18 ± 1.55	.649
WBC count, $\times 10^9$/L	11.62 ± 0.20	10.18 ± 0.10	<.0001

With the exception of age at last follow-up (presented as mean ± SD), the means shown in the table are age-adjusted and presented as mean ± standard error. HbF indicates fetal hemoglobin; BUN, blood urea nitrogen; LDH, lactic dehydrogenase; RBC, red blood cell; AST, aspartate aminotransferase; ALT, alanine aminotransferase; and WBC, white blood cell. (Adapted from ref. 258.)

leukocytosis (Table 11.1).[180,242] Genetic polymorphism in Klotho (*KL*), a gene that regulates NO bioavailability, was also linked to priapism.[242] Additionally, priapism is less common in patients with HbSC disease and HbS-β^+-thalassemia, and is less prevalent among ethnically distinct subpopulations of sickle cell disease characterized by high expression of HbF and lower hemolytic rates.[243]

From a mechanistic standpoint, recent transgenic and knock out mouse studies have revealed increased priapic activity in the double *nos3* and *nos1* null mouse and in the sickle cell mouse,[244] consistent with a paradoxical role for NO deficiency in the mechanism of priapism. NO deficiency in these models produced a secondary severe down-regulation of phosphodiesterase-5, resulting in episodic surges in vascular smooth muscle cGMP and dysregulated penile blood flow.

Cutaneous Leg Ulceration and Hemolytic Anemia

Cutaneous leg ulceration has also been associated with hemolytic anemias including sickle cell disease, thalassemia, and spherocytosis.[245–257] Consistent with this shared complication of hemolytic anemias, patients with a history of leg ulcers had the highest rates of hemolysis (Table 11.2).[181,258]

Stroke and Hemolytic Anemia

Although less clearly linked to hemolytic rate, there are a number of pathological and clinical features of stroke in children with sickle cell disease that suggest a parallel pathobiology with the vasculopathy of pulmonary hypertension.[259] Stroke and pulmonary hypertension have many epidemiological risk factors in common, including history of prior stroke, systolic hypertension, low transcutaneous oxygen saturation, and severe anemia.[177,260–263] Both have histopathological evidence of large vessel arterial disease, featuring smooth muscle hyperplasia with overlying endothelial damage, fibrosis, and thrombosis in situ. HbF expression has not proven protective in either condition. Although the potential role of NO resistance and hemolysis in cerebrovascular disease remains to be investigated in sickle cell disease and thalassemia, recent studies suggest that chronic transfusion reduces plasma cell-free hemoglobin levels and stroke incidence in children with sickle cell disease at risk for stroke[264] and LDH has been associated with increased transcranial Doppler blood flow, a predictor of stroke.

Pulmonary Arterial Hypertension in Sickle Cell Disease and Thalassemia

Echocardiographic studies have reported that approximately 30% of screened adult patients with sickle cell

Table 11.2. Association of sickle cell leg ulcers with hemolysis

disease develop mild-to-severe pulmonary hypertension in adulthood (defined by systolic pulmonary artery pressures (sPAP) ≥ 35 mm Hg).[186,187,192,265] In 9%–20% of patients the pulmonary hypertension is more severe (defined by sPAP ≥ 45 mm Hg.[164,192] Recent autopsy studies suggest that up to 75% of sickle cell patients have histological evidence of pulmonary arterial hypertension at the time of death.[189,266] Similarly, retrospective studies have demonstrated that 40%–50% of patients with β-thalassemia intermedia,[267] and 10%–75% of patients with β thalassemia major have echocardiographic evidence of pulmonary hypertension.[196,198,268,269] More recent studies suggest that pulmonary hypertension may be more common in patients with β-thalassemia intermedia and hemoglobin E–β thalassemia than in patients with β thalassemia major,[172,270,271] probably because most β thalassemia major patients receive sufficient blood transfusions to reduce hemolysis.

The NIH pulmonary hypertension screening study in patients with sickle cell disease enrolled 195 adult patients with sickle cell disease who were screened with transthoracic Doppler echocardiograms.[164] To avoid the more subjective estimation of central venous pressure in this study, pulmonary hypertension was prospectively defined by a specific tricuspid regurgitant Doppler jet velocity value (TRJ) ≥ 2.5 m/s and moderate-to-severe pulmonary hypertension defined by a TRJ ≥ 3.0 m/s. Right heart catheterization was performed in consenting patients with TRJ ≥ 2.8 m/s. Using these definitions, 32% of patients with sickle cell disease had elevated pulmonary artery systolic pressures and 9% had moderately-to-severely elevated pressures.

Two other prospective studies of the prevalence of pulmonary hypertension in sickle cell adult patients have found comparable results. In a screening study of 60 patients at a comprehensive sickle cell treatment center, the prevalence of pulmonary hypertension was 30%.[272] Another study of 125 patients with sickle cell disease found an overall prevalence of 32%.[273]

Pathogenesis of Pulmonary Hypertension

In the NIH pulmonary hypertension screening study, all markers of hemolytic anemia, including low hemoglobin concentration and hematocrit, high LDH, and high aspartate aminotransferase, but not alanine aminotransferase levels, were associated with elevated pulmonary pressures.[164] Increasing age was also associated with a high TRJ. Multiple logistic regression analysis identified a history of renal or cardiovascular complications, increased systemic systolic blood pressure, LDH, elevated alkaline phosphatase, and low transferrin levels as independent predictors of pulmonary hypertension. A history of priapism was an independent risk factor. These associated risk factors for pulmonary hypertension suggest that pulmonary hypertension represents one element of the systemic vasculopathy seen in some patients with sickle cell disease (systemic hypertension, renal failure and priapism) and is mechanistically linked to hemolytic rate, iron overload and cholestatic hepatic dysfunction. Interestingly, the development of pulmonary hypertension was not associated with markers of inflammation, HbF or platelet counts.[164] The associations with LDH and renal insufficiency have been confirmed but a protective effect of HbF and an inverse relationship to systolic blood pressure were also noted.[274,275]

Prognosis of Patients with Sickle Cell Disease and Pulmonary Hypertension

Patients with sickle cell disease and pulmonary hypertension have a significantly increased mortality rate compared with patients without pulmonary hypertension. Sutton and colleagues reported a 40% mortality rate at 22 months with an odds ratio for death of 7.86 (95% confidence interval [CI] 2.63–23.4).[186] Powars and colleagues reported a mean 2.5-year survival in sickle cell patients with chronic lung disease with pulmonary hypertension.[185] Castro and colleagues similarly reported a 50% 2-year mortality rate in patients with sickle cell disease with pulmonary hypertension confirmed by right heart catheterization.[190]

Consistent with retrospective studies indicating that pulmonary hypertension is associated with a higher mortality, in the NIH screening study, a measured TRJ of at least 2.5 m/s, as compared with a velocity of less than 2.5 m/s, was associated with a marked increased risk of death (RR 10.1; 95% CI, 2.2–47; $P < 0.001$) and remained so after adjustment for other possible risk factors in proportional hazards regression analysis. The 18 month mortality was 16% for patients with a TRJ velocity of greater than or equal to 2.5 m/s and was less than 2% in patients without pulmonary hypertension. Follow-up data from this cohort continues to demonstrate that pulmonary hypertension is a strong independent risk factor for mortality (RR 7.4, 95% CI 2.4–22.6, $P < 0.001$) with 40 month mortality rate of approximately 40%. These follow-up data show that survival can be stratified by pulmonary pressure severity with the highest risk of death with a TRJ ≥ 3.0 m/s and an intermediate risk in those with TRJ 2.5–2.9 m/s. Ataga and colleagues have also found a high mortality rate in the patients with TRJ ≥ 2.5 m/s with a relative risk for death of 9.24 (95% CI 1.2–73.3; $P = 0.01$).[275] In addition, De Castro and colleagues reported a remarkably similar 17% mortality rate for patients with pulmonary hypertension over 2 years compared with approximately 2% for subjects without pulmonary hypertension.[273] Taken together, the retrospective[185,186,190] and prospective studies[164,272,275] suggest that that pulmonary hypertension is the greatest risk factor for death facing the aging population of patients with sickle cell disease and possibly other patients with chronic high-grade intravascular hemolysis.

Pulmonary Hypertension in Children with Sickle Cell Disease

Case reports have described children with sickle cell disease and symptomatic, clinically significant pulmonary hypertension.[276] However, it is likely that the actual prevalence of such cases among children is lower than among adults. In an attempt to estimate this prevalence, a number of small retrospective and prospective echocardiographic screening studies among children with sickle cell disease have been published or presented (Table 11.3).[277] Although the study design and results have varied widely, when the study results are summed together, the pediatric results have showed some striking parallels to the results from the adults. Three prospective screening studies comprising a total of 530 adults have indicated a 38% prevalence of a TRJ ≥ 2.5 m/s, and 14% prevalence of TRJ ≥ 3 m/s. Twelve studies in children have screened a total of 756 patients, showing an overall 26% prevalence of a TRJ ≥ 2.5 m/s, and approximately 4% prevalence of TRJ ≥ 3 m/s. Five of 12 pediatric studies have reported statistically significant associations of low hemoglobin and high reticulocyte levels with the high TRJ.[278–281] Four of the 12 have found associations with high serum LDH levels[279,281,282] and three with high bilirubin levels.[279,282,283] It is impressive that these markers of hemolytic severity recurrently have reached statistical significance, because the statistical power to find such associations has been limited by the average pediatric study size of only 50 patients. Furthermore, when such associations have been found in the pediatric studies, they have been consistent with the results of the three larger adult studies.[192,265,273]

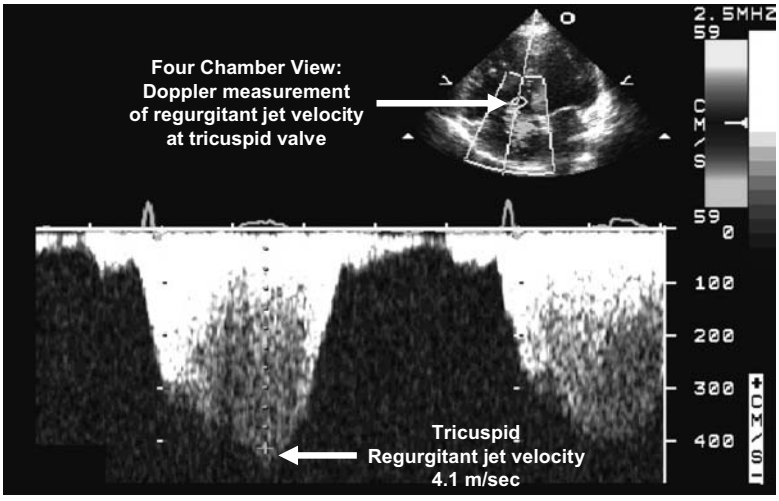

Figure 11.8. Doppler echocardiographic screening for pulmonary hypertension. Above, a four-chamber view of the heart of a patient with sickle cell disease, with the cursor over the tricuspid valve. Below, the downward displacement indicates retrograde flow across the tricuspid valve during systole. The degree of downward displacement is proportional to the tricuspid regurgitant jet velocity, in this case, 410 cm/s, or 4.1 m/s, suggestive of severe pulmonary hypertension.

These preliminary data are consistent with a tentative model in which more severe hemolysis impairs NO bioavailability, causing initially reversible pulmonary vasoconstriction. Over years, this and other factors may contribute to vascular proliferative changes that worsen the pulmonary pressures with an incompletely reversible phenotype. Further progression likely involves more severe proliferative changes, accompanied by pulmonary thrombosis in situ, and the development of the characteristic plexogenic vascular changes of severe pulmonary hypertension. Hypothetically, early detection and treatment of pulmonary hypertension at more reversible stages might improve later prognosis, analogous to such approaches to presymptomatic detection and treatment of systemic hypertension in the general population. Before such strategies can be recommended routinely in children with sickle cell disease, large prospective studies with longitudinal clinical follow up are needed to more accurately determine the prevalence and prognosis of a high TRJ in this age group, with right heart catheterization validation in more severe cases. In the meantime, an individualized approach is required for diagnosis and management of pediatric cases of high TRJ.

Diagnosis, Evaluation and Therapy of Pulmonary Hypertension in Sickle Cell Disease

Doppler echocardiography provides essential information such as non-invasive estimation of pulmonary artery systolic pressure (via calculation of the TRJ), valvular function and right and left ventricular systolic and diastolic function. The use of echocardiography to estimate pulmonary artery systolic pressures has been validated in patients with sickle cell disease, and non-invasive assessment correlates well with the measurement of pulmonary arterial pressures by right heart catheterization.[284] The velocity of regurgitant blood across the tricuspid valve during systole is measured, and the pulmonary artery systolic pressure is calculated using the modified Bernoulli's equation ($4 * \text{TRJ}^2$ plus central venous pressure estimate; method described in detail in Ref. 164). To avoid the more subjective estimation of central venous pressures, pulmonary hypertension can be defined by a specific TRJ $\geq$ 2.5 m/s and moderate-to-severe pulmonary hypertension defined by a TRJ $\geq$ 3.0 m/s (Fig. 11.8). More severe disease is also suggested by evidence of right ventricular failure, such as paradoxical septal motion, a flattened interventricular septum, a dilated right ventricle and atrium, and a pericardial effusion.

Because the differential diagnosis for an elevated TRJ includes left heart failure, it is important to evaluate by echocardiogram indications of left ventricular systolic dysfunction (observed in 2% of patients cohort) and diastolic dysfunction (observed in 18% of patients of patients with sickle cell disease),[285] either of which may be found alone or in combination with pulmonary arterial hypertension.[286] Diastolic dysfunction produces elevations in end-diastolic filling pressures which increase pulmonary venous and pulmonary artery pressures.[286] The presence of diastolic dysfunction can be assessed by echocardiography (tissue Doppler or conventional assessment of the E/A ratio) and a combination of both pulmonary hypertension estimated by high TRJ and diastolic dysfunction is present in 11% of sickle cell patients. The presence of both pulmonary hypertension and diastolic dysfunction is a particularly poor prognostic sign, associated with a relative risk of death of 12.0 (95% CI 3.8–38.1; $P < 0.01$).[285]

Pulmonary artery pressure increases in sickle cell patients after mild exercise and with vasoocclusive painful crisis.[287] Exercise echocardiograms, with assessment of pulmonary pressures might be useful to evaluate patients with significant exertional dyspnea and normal TRJ velocities. Although the criteria for an abnormal response to exercise are not well established, in healthy nontrained men TRJ velocity increases from an average baseline of 1.72 m/s to an average of 2.46 m/s at mid-level exercise and to 2.27 at peak exercise (240 W).[288]

Treatment suggestions: In the absence of clinical guidelines and placebo-controlled therapeutic trials for the evaluation and treatment of pulmonary hypertension in the sickle cell population, and because we do not yet know if an elevated pulmonary pressure is a direct cause of death or a risk factor for multiorgan disease and generalized

sickle cell vasculopathy, for patients with mild pulmonary hypertension (TRJ 2.5–2.9 m/s) we recommend intensification of sickle cell–specific therapy.

- Hydroxyurea treatment at the maximum tolerated dose as defined by the Multicenter Study of Hydroxyurea, with erythropoietin therapy considered if reticulocytopenia limits hydroxyurea therapy.[289]
- Regular transfusions can be considered for patients with poor responses to hydroxyurea and accompanied by chelation therapy as needed. The TRJ has declined in some patients with institution of these treatment measures, especially in children and young adults, although this has not been carefully studied.
- Consultation with a pulmonologist or cardiologist experienced in pulmonary hypertension, the latter especially if the echocardiogram shows evidence of left or right ventricular dysfunction should be considered.
- Identify and treat risk factors associated with pulmonary hypertension such as rest, exercise and nocturnal hypoxemia, sleep apnea, pulmonary thromboembolic disease, left ventricular systolic and diastolic dysfunction, severe anemia and iron overload.

In addition to the above measures, patients with TRJ $\geq$ 3 m/s should undergo:

- Right heart catheterization to assess left ventricular diastolic and systolic function.
- A CT-pulmonary angiogram, V/Q scan, and or pulmonary angiogram to exclude chronic thromboembolic pulmonary hypertension.
- Consider systemic anticoagulation (improves outcomes in patients with primary pulmonary hypertension and in situ thrombosis (no data are available in patients with sickle cell disease).
- Consider specific therapy with selective pulmonary vasodilator and remodeling drugs, particularly if the patient has symptomatic dyspnea on exertion that has progressed in recent months or years. Drugs that are FDA-approved for primary pulmonary hypertension include bosentan and various forms of prostaglandin therapy; none of which have been comprehensively investigated for sickle cell pulmonary hypertension. Phase I-II data with sildenafil, which has recently gained FDA approval for pulmonary hypertension under the trade name Revatio®, suggests efficacy.[290] A multicenter trial of sildenafil for hemolysis-associated pulmonary hypertension has now been initiated but the results are not yet available. Appropriate consultation and right heart catheterization is recommended at baseline and repeated annually for patients on such therapy. More detailed management recommendations are available in recently published reviews.[291,292]

Animal Models of Hemoglobinopathies and Thalassemia

Mary Fabry

INTRODUCTION

Transgenic mice are important adjuncts for the study of the pathophysiology and treatment of human hemoglobin disorders. Many inbred strains with spontaneous and induced mutations and engineered knockout and knockin lines are available (Table 12.1). Transgenic mice have both advantages and disadvantages for studying human disease. Most available mice are of mixed or poorly characterized genetic backgrounds and must be bred onto another inbred strain to obtain sustainable lines and consistent physiology. The choice of genetic background or the presence of a mixed background can affect both hematology and physiology.

Different inbred mouse strains, and male and female mice, can have different physiological characteristics, complicating the interpretation of some experiments. Mice have a higher plasma osmolarity than man[1] and the 2,3-BPG content of mouse red cells is twice that of human erythrocytes. Inbred strains have five common α-globin chains and three common β-globin chains.[2] The common C57BL/6 strain has only a single α- and β-globin chain; other strains can have two α- or two β-globin chains. When these are combined with human globin transgenes, many homotetramers due to the presence of interspecies αβ dimers result, some of which form tetramers with low oxygen affinity that will affect polymer formation and pathophysiology.[3] These are some examples of factors likely to alter sickle cell mouse pathophysiology when compared with human.

THE TECHNOLOGY OF TRANSGENIC AND KNOCKOUT MICE

In the early 1980s cloned DNA was introduced into fertilized mouse embryos. Following the discovery of a locus control region (LCR) 5′ to the β-globin gene cluster (Chapter 5), investigators linked the LCR to various globin gene constructs and achieved erythroid expression in transgenic animals.[4–9] The process of producing transgenic mice from constructs injected into fertilized mouse embryos is illustrated in Figure 12.1.[10]

Knockout or knockin technology is a means of deleting endogenous genes or introducing new genes into a genome by homologous recombination (Fig. 12.2). Homologous sequences flanking the gene of interest are isolated and inserted into a targeting construct that contains selectable markers, in the illustration, neomycin resistance and herpes virus thymidine kinase, driven by a promoter. This targeting vector is transfected into a line of embryonic stem cells (ESCs) that are selected by exposure to neomycin and ganciclovir. Colonies are picked, expanded, and analyzed by Southern blot analysis for fragments of the predicted size. Cells with the mutated β-globin gene are then injected into blastocysts to generate chimeric animals that are screened for the mutation and bred to detect animals with germ line mutations (Fig. 12.3).

THALASSEMIC MICE

Mouse models of thalassemia with either deletions or knockouts of the α- and β-globin genes have been studied. A nonlethal deletion of the β^{major}-globin gene (Hbb^{th-1}) in a mouse with so-called diffuse hemoglobin, which can be bred to homozygosity, was detected by electrophoretic screening.[11] The excess of mouse β^{minor} in this model might be a general response to anemia or a more specific response to the deletion that generated the thalassemia. Mice homozygous for the β^{major} deletion have a high reticulocyte count, anemia, microcytosis, low mean corpuscular hemoglobin (MCH) and a low mean corpuscular hemoglobin concentration (MCHC). Their broad distribution of red cell densities looks much like the density distribution obtained for human patients with β-thalassemia intermedia.

Three different deletions in the α-globin chain have been described that lead to α thalassemia.[12] These deletions are sufficiently large so that they are lethal when homozygous, even in the presence of a rescuing human transgene. In the heterozygotes, the α:β globin chain synthesis chain ratio is approximately 0.75, and hence the induced thalassemia is relatively mild. If a single α-globin gene deletion is bred into mice homozygous for the β^{major} deletion, much of the red cell pathology is corrected; reticulocyte counts decrease from approximately 20% to 5% and red cell density is normalized, an observation akin to that observed when human β and α thalassemia coexist (Chapters 13, 14, 16, and 17). This is due to correction of the imbalance of α and β globin chains that is responsible for thalassemia pathology.

Mouse models have been advocated as models for human thalassemia[11,13–17] and mice with deletional thalassemia have been used to study treatments with erythropoietin, clotrimazole, and hydroxyurea.[18]

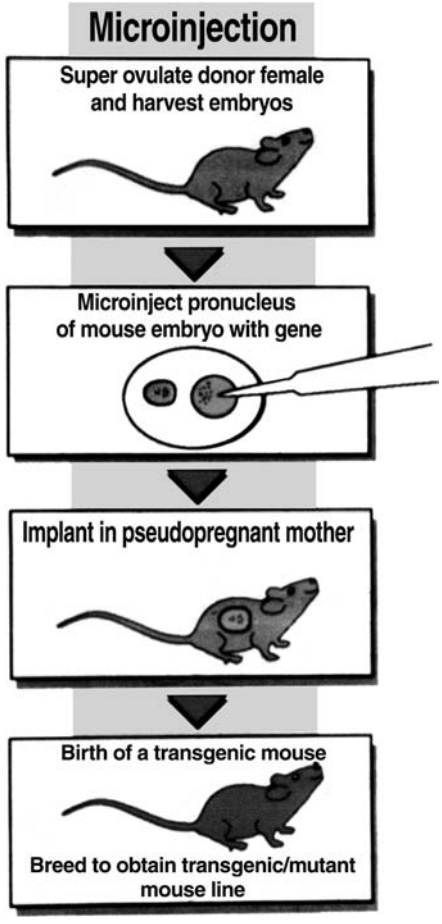

Figure 12.1. Creation of a transgenic mouse by injection of a construct into the pronucleus of a fertilized mouse egg. The injected eggs are then implanted into pseudopregnant females and the resulting pups are screened for the presence of the transgene. Pups positive for the transgene are bred to determine if the transgene is present in the germ line.

A disruption of the β^{major}-chain was generated by inserting a bacterial gene into the second exon of the mouse β^{major} gene.[19] This resulted in a more severe form of thalassemia than the previously described β^{major}deletion and is lethal in homozygotes despite the continued production of β^{minor}-globin. When bred into mice expressing the human β-globin gene, the percentage of human β-globin chain is higher than that obtained with the β^{major} deletion.[20] The reduced severity of the deletion model when compared with the disruption model might be due to the ability of the remaining β^{minor} gene to interact directly with the LCR without competition from the missing β^{major} gene. In contrast to the deletion, with a disrupted gene, not only is the β^{major} promoter intact, but, the inserted *tk* promoter

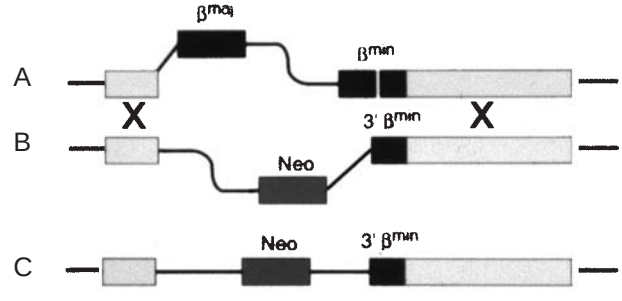

Figure 12.2. Targeted insertional deletion of the mouse β-globin genes. Line A is a simplified representation of the β-globin locus in the diffuse mouse, which makes two β-globins: β^{major} and β^{minor}. Line B represents the replacement vector, which has an area of homology on the 5′ side, a Neo fragment capable of conferring resistance to G418, which also contains thymidine kinase genes driven by a promoter, and another area of homology corresponding to a portion of the β^{minor} gene and extending beyond it. Line C shows the result of a crossover that contains the Neo fragment and an inactive remnant of the β^{minor} gene.

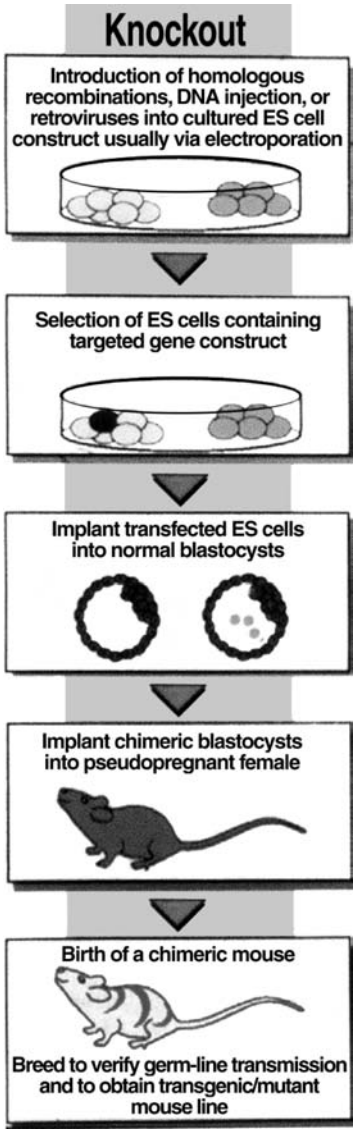

Figure 12.3. Creation of a knockout mouse by using ESC technology. The targeting vector is introduced into ESCs, which are then selected by exposure to neomycin and ganciclovir. The selected cells are implanted into normal blastocysts that are then implanted into pseudopregnant females. The resulting pups are then screened and bred to verify transmission of the mutated genes into the germ line.

driving the *neo* gene is present possibly resulting in further competition for the LCR and reduced transcription of the β^{minor} globin gene. A similar hypothesis has been proposed to account for the higher levels of HbA_2 and HbF when the β-globin gene promoter is deleted in some types of human β thalassemia (Chapters 16 and 17). Full β-globin gene knockout mice are available.[20–22] Full knockout of the α-globin gene cluster has also been generated[23] making possible transgenic mice with exclusively human hemoglobins. The knockouts are lethal in the homozygous state unless rescued by a transgene. In homozygotes, without a rescuing transgene, the α knockout mouse has a condition similar to human hydrops fetalis.[23]

MODELS FOR SICKLE CELL DISEASE

The complex pathophysiology of sickle cell disease (Chapters 8–11) and its modulation by many genetic, epistatic, and environmental elements (Chapter 27) make it unlikely that a single animal model will adequately represent all aspects of the disease; nonetheless, animal models have already made significant contributions to sickle cell pathophysiology and treatment.

Sickle Transgenic Mice

Early transgenic models of sickle cell disease had little pathology and the first models expressing moderately high levels of both human α- and β^S-globin chains were reported in 1990.[24–28] Subsequently, many different lines of mice with variable degrees of severity became available allowing more detailed studies of pathology (Tables 12.1 and 12.2). These strains included: mice expressing the "super β^S" HbS-Antilles (Chapters 22 and 23), which failed to exhibit the expected level of pathology in part because of low human α-globin expression;[29] the SAD mouse expressing the β^S mutation and two additional "super" β^S mutations, HbS-Antilles and HbD-Punjab (Chapter 23).[30] The enhanced effects on polymer formation of mice expressing the "super" β^S globins are due to reduction in oxygen affinity, which shifts the conformation of the hemoglobin to the T-state and favors polymer formation, and reduced solubility, which suggests that new contact sites in the polymer have been created.

The first report of the SAD mouse described mice with no deletions and a mouse with a single β^{major} deletion. The former had 19% of all β-globin as β-SAD and is used most often for study. Expression of HbS was increased in mice expressing both human α- and β^S-globins by breeding in a homozygous mouse β-globin gene deletion and, in some cases, addition of a heterozygous α-globin gene deletion.[29,31,32] Another model still in use is mice expressing human α-, β^S-, and $\beta^{S\text{-Antilles}}$, which balanced the high human α-globin gene expression of the β^S line against the low human α-globin gene expression of the $\beta^{S\text{-Antilles}}$ line; these mice are known as S+S-Antilles mice. A further model contains mouse high oxygen affinity globins and HbS-Antilles. Deoxygenation produced sickled cells and intracellular polymer formation.[33–38]

Many transgenic sickle cell mice have no anemia or very mild anemia. Hematological findings in sickle mice are shown in Table 12.2. The SAD mouse and the S+S-Antilles mouse have a modest reduction of packed cell volume, most evident neonatally. As sickle vasoocclusion appears to have association with high PCV, the absence of anemia in these models might be pathophysiologically important.

The most recent stage of creating mouse models of human sickle cell disease has been the creation of mice expressing exclusively human hemoglobins.[39,40] Available

lines incorporate the mouse α-globin gene knockout and the mouse β-globin gene knockout and transgenes expressing human α-, β-, and γ-globin genes.[21,23] Six different lines expressing HbS and varying levels of human HbF have been described. One of the most frequently utilized models is the BERK mouse. Although these mice have many useful similarities to human sickle cell disease including anemia, reticulocytosis, loss of urine concentrating ability, and tissue damage, many of these mice had features of β thalassemia, with a very low MCH and low MCHC. Most of the transgenic sickle mice previously described had elevated MCHC, a feature attributed to deoxygenation-induced potassium efflux.[41] Very low MCHC in these full knockout mice is coupled with low MCH. This combination will reduce both the rate and extent of HbS polymer formation and be protective against sickling-related pathology. It will also confound attempts to evaluate the effect of introducing antisickling globins into these mice because their introduction will correct the low MCH and raise the MCHC, which will have a strong propolymerization effect due to the increase in hemoglobin concentration; at the same time, the antisickling globin will interfere with polymer formation making evaluation of efficacy in treatment studies difficult.[42]

NY1KO mice express exclusively human hemoglobins and incorporate three different human γ-globin gene–expressing lines that express different levels of HbF.[43–46] Mice with the least adult HbF expression (more than 3%, NY1KO-γL) were the most severe; those with intermediate HbF (20%, NY1KO-γM) were less severe; and those with the highest HbF (40%, NY1KO-γH) were least severe.[44] The increase in HbF was correlated with progressive increase in PCV (from 22% to 34% to 40%) and progressive decrease in reticulocyte count (from 60% to 30% to 13%). Lifespan was also strongly correlated with HbF levels and increased as HbF increased.[45] These results suggest that pathology in NY1KO mice is strongly driven by HbS polymerization. The γ-globin gene–expressing lines have much higher expression of HbF expression during the fetal and neonatal period.[46]

All of the knockout sickle mice described are the product of hundreds of matings and once a successful line has been established it has been possible to propagate it. In contrast, a recently described line expressing exclusively HbC[47] was fully knocked-out in a relatively small number of matings, which implies that mouse red cells tolerate the presence of exclusively human hemoglobins relatively well. One possible explanation for this contrast is that the many matings of the HbS mice are required to find an epistatic ameliorating feature that allows each line to survive. This speculation can only be validated by extensive analysis of the existing lines.

Because mice expressing a sickle transgene with a full knockout of both mouse α- and β-globins are difficult to breed and are physiologically fragile, mice that are hemizygous for the mouse β-globin knockout are used for both breeding and sometimes experimentation, either as controls or as experimental animals. These mice are sometimes called BERK trait or sickle trait mice, but they are better referred to as BERK hemi or some other neutral appellation. These mice segregate into two populations, those with one copy of the BERK transgene (that expresses human α and human β^S) and those with two copies of the BERK transgene.[48] As expected those with two copies of the BERK transgene had higher expression of β^S (~30% vs. 15% for a single copy), but unexpectedly the pathophysiology of mice with a single transgene was more severe. Perhaps this was due to the abnormally high P_{50} of approximately 60 mm Hg compared with 40 mm Hg for a C57BL/6 control.

The BERK β-hemizygous mouse and the SAD mouse share the properties of a relatively low level of polymerizing hemoglobin and a very low oxygen affinity. Red cells from the BERK β-hemizygous mouse were used to induce endothelial inflammation in lung by producing reactive oxygen species leading to cytosolic Ca^{2+} increase and P-selectin-dependent leukocyte recruitment.[49] Adding catalase to the infusion blocked the effects of red cell released reactive oxygen species. The rationale for using red cells from these mice was that hypoxia dramatically increases the rate of hemoglobin autoxidation[50,51] and results in increased production of superoxide and hydrogen peroxide that can leak from erythrocytes.[52] Low oxygen affinity and presence of unstable HbS would be expected to increase these effects in BERK β-hemizygous red cells; therefore, one would predict that these mice would have a stronger oxidative stress component in their pathology than that attributable to hemoglobin polymerization alone.[53]

Two other lines of mice expressing exclusively human hemoglobins have been described.[54,55] Mice created with a β-globin YAC (yeast artificial chromosome) also exhibited β thalassemic characteristics; however, the percentage of live births was increased from less than 2% to approximately 35% by placing the mothers in a high oxygen environment after day 10 of gestation and keeping the pups in this environment until weaning. A knockin mouse has been used to demonstrate correction of sickle cell disease by homologous recombination.[56]

Erythrocytes of Transgenic Mice

Human erythrocytes live approximately 120 days whereas mouse red cells live approximately 40 days. Therefore, the baseline reticulocyte count in human blood is much lower than in mice. The oxygen affinity of murine hemoglobins is lower than that of human hemoglobins. Human red cells with HbA have a P_{50} of approximately 25 mm Hg, whereas C57BL/6 mouse red cells have a P_{50} of approximately 40 mm Hg. Mice do not have a high oxygen affinity HbF to cope with the low oxygen fetal environment. Instead, the red cells of fetal mice do not upregulate 2,3-BPG levels, which decreases oxygen affinity, until after birth and adult levels are not reached until approximately age 3 weeks.[57] Adult mouse red cells have much higher levels of 2,3-BPG than human red cells and mouse red cells that express exclusively human hemoglobin have even more elevated levels of 2,3-BPG, which reduces the P_{50} from that found in humans. For example the P_{50} of HbA in a fully knocked-out line expressing only human globins is 33 mm Hg due to the high level of 2,3-BPG. Polymer formation is enhanced by elevated levels of 2,3-BPG and the severity of pathology induced by HbS in mice might be due in part to 2,3-BPG elevation.[58]

MCHC plays a crucial role in the pathophysiology of sickle cell disease because the delay time for polymer formation is inversely proportional to the 30th power of the concentration of deoxyHbS and the extent of polymer formation is directly proportional to the concentration of HbS. Two features of mouse erythrocytes would be expected to increase the pathology caused by introduced HbS: elevated MCHC due to the higher plasma osmolarity of mice and elevated red cell 2,3-BPG content.

Transgenic mice offered a unique opportunity to study the mechanisms of cation transport in sickle cell disease. Deoxy potassium efflux, unique to human sickle cells, is also found in the red cells of transgenic mice expressing high levels of HbS.[41,59] The calcium-stimulated potassium channel (Gardos channel) is similar in mouse and the human red cells.[60] This property has been used to demonstrate the beneficial effects on red cell density of inhibition of the potassium channel by clotrimazole. Hypoxia leads to the formation of dense cells in both NY1DD[31] and SAD[61] mice due to the deoxy-stimulated potassium efflux of potassium via the Gardos channel, and dense cell formation was used to evaluate the use of clotrimazole and its derivatives as inhibitors.[62,63] Arginine supplementation of NY1DD mice and S+S-Antilles mice reduced red cell density by reduction of Gardos channel activity[64] that is in part coupled to the observed reduction of endothelin.[65–67] Endothelin receptor antagonists also reduce erythrocyte dehydration in the SAD mouse (Chapters 9 and 31).[68]

The characteristics of K-Cl cotransport in the mouse red cell are more controversial with differences in mouse and human red cells.[69] These include, lack of inhibition by NO_3^-,[70] lack of sensitivity to [(dihydroindenyl)oxy] alkanoic acid (DIOA), a long delay time for activation, lack of volume-sensitive activation, and a large isotonic flux.[69] These differences imply that the mouse erythrocyte may be an imperfect model for cation transport in sickle cell disease.

When the mice expressing exclusively human HbC, HbS and HbF were tested, sensitivity to NO_3^- and DIOA were restored, strongly suggesting interaction of the K-Cl cotransporter or its modulators with both human and murine hemoglobin.[71] The SAD mouse has been used to show that Mg^{2+} supplementation inhibits K-Cl cotransport.[72] The mouse K-Cl cotransporter is similar to that of human.[73–75] Three *KCC* genes were found to be expressed in normal and sickle human red cells and splicing variants were also evident.[77] In SAD mice *kcc1* and *kcc3* were knocked out and *kcc1* (−/−) mice had normal transport, *kcc3* (−/−) mice had reduced transport but only in the double knockout *kcc1:kcc3* mice was K-Cl cotransport completely abolished and erythrocyte properties normalized.[77]

Signs of oxidative damage have also been noted in erythrocytes of transgenic sickle mice and might also contribute to mouse red cell pathology.[78,79] Alterations in phosphatidylserine exposure are associated with shortened red cell survival.[80] Red cell characteristics of sickle transgenic mice and the utility of these models for developing therapies for prevention of dehydration of sickle cells has been reviewed.[81–84]

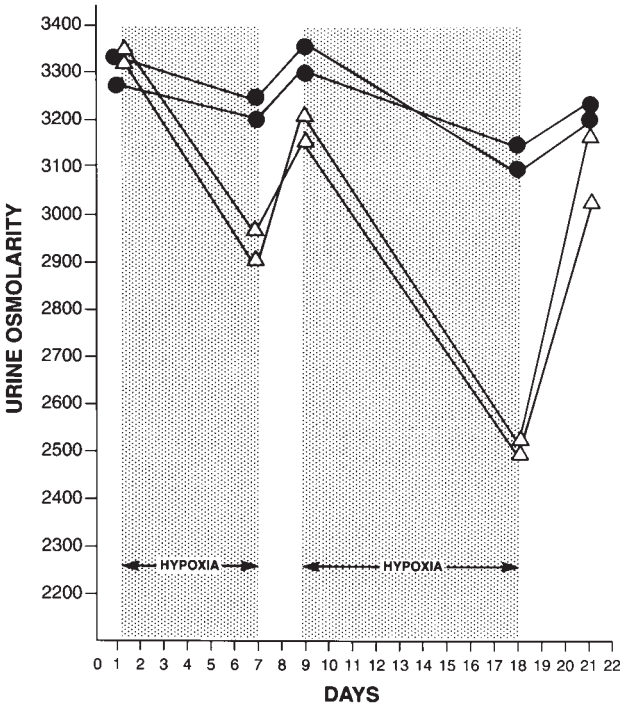

Figure 12.4. Urine-concentrating ability of mice expressing the $\alpha^{H}\beta^{S}$ transgene that are homozygous for the mouse β^{major} deletion. The mice were maintained under hypoxic conditions during the periods indicated and urine-concentrating ability was measured after 24 hours of water deprivation. Transgenic animals are indicated by open triangles and control C57BL/6 mice by filled circles. Note that significant but incomplete recovery occurred after 2 days at room air.

Organ Pathology in Sickle Mice

Kidney. The kidney in sickle transgenic mice has several abnormalities including glomerular sclerosis, increased blood urea nitrogen, and proteinuria in the SAD mouse.[30,85] Mice expressing human α- and β^{S}-globin on a homozygous deletional background (NY1DD) have an enhanced glomerular filtration rate and a urine-concentrating defect when exposed to hypoxia[31] (Fig. 12.4); S+S-Antilles mice have a severe and spontaneous urine-concentrating defect[86] and elevated levels of the nitric oxide synthases (NOSs) eNOS and iNOS that increase further with hypoxia. This might explain their elevated glomerular filtration rate.

When L-arginine is depleted, the production of nitric oxide (NO) from NOS falls, accompanied by increased production of O_2^- and peroxynitrite. A cytotoxic effect of peroxynitrite on tubular cells was evident by nitrotyrosine staining and release of lactate dehydrogenase.[87] In studies of control and sickle mice, using an antibody directed against nitrotyrosine, elevated levels colocalized with elevated iNOS in renal tubular epithelial cells. Moderate degrees of renal tubular cell apoptosis was also seen in transgenic sickle mice exposed to hypoxia.[88] Arginine, the precursor of NO, is depleted in the plasma of sickle cell disease patients[89] and other possible symptoms of dysregulated NOS activity such as low systemic blood pressure have been found in both human sickle cell disease patients[90–92] and in transgenic mice expressing HbS and HbS-Antilles (Chapters 10 and 11).[93] Magnetic resonance imaging of two sickle transgenic mouse models showed the presence of high levels of deoxyhemoglobin in the renal medulla of sickle mice under room air conditions.[94] The medulla is generally regarded as the most hypoxic region of the kidney[95] and polymer formation in this area would be expected to result in a urine-concentrating defect. Micromagnetic resonance imaging has also been used to detect renal cysts in a mouse model of sickle cell disease.[96] Inhibition of NOS was found to ameliorate renal damage in sickle transgenic mice,[97] as expected if elevated levels of NOS resulted in superoxide and peroxynitrite production. S+S-Antilles mice also have evidence of oxidative stress, increased plasma creatinine, and elevated heme oxygenase activity.[98] Gene expression studies using kidneys of S+S-Antilles mice showed up-regulation of the genes for arginase II, Na/K adenosine triphosphatase, renin-1, and alkaline phosphatase-2.[99] Up-regulation of arginase II could contribute to arginine depletion.[64] These mice were sensitive to ischemia/reperfusion injury after clamping the renal artery. Animals had 28% mortality after 22.5 minutes of clamping, and increase in the murine homolog of C-reactive protein,[100] and caspase-3 with congestion of lungs and heart.[101] The observation of increased caspase-3 activity is consistent with apoptosis in the kidneys of these mice.[88]

Renal function in BERK hemizygous mice showed that approximately half had mild to moderate abnormalities including glomerulonephritis, and elevated levels of iNOS, nitrotyrosine, and vascular cell adhesion molecule–1.[102] This could be due to the presence of sickle hemoglobin and/or the low oxygen affinity of this model and the naturally low pO_2 of the kidney. When SAD mice were exposed to 8% oxygen for 18 hours, ultrasound imaging revealed decreased renal blood flow velocity; histology showed congestion in peritubular capillaries and glomerular abnormalities with trapped sickle red cells that the authors suggested caused reduced flow.[103]

Retina. NY1DD sickle transgenic mice display preretinal neovascularization with many of the features of the retina in sickle cell disease (Chapters 19 and 21). Found in approximately 30% of transgenic mice aged more than 1 year, the abnormalities include drop-out of retinal vessels, structures reminiscent of black sunbursts that are due to invasion of pigmented epithelial cells from the choroid, and loss of photoreceptors in regions where the underlying choroid has been destroyed, forecasting the subsequent observations in human sickle retinopathy (Fig. 12.5).[104–106]

Microcirculation. In vivo adhesion of sickle cells to the endothelium[107,108] (Chapter 8) was first observed in the cremaster muscle preparation of the S+S-Antilles mouse.[109] Reduced red cell velocity and blood flow in the S+S-Antilles mouse was present when the cremaster muscle was suffused with a solution equilibrated with room air. When the gas used to equilibrate the suffusate contained increased oxygen, red cell velocity increased, blood flow

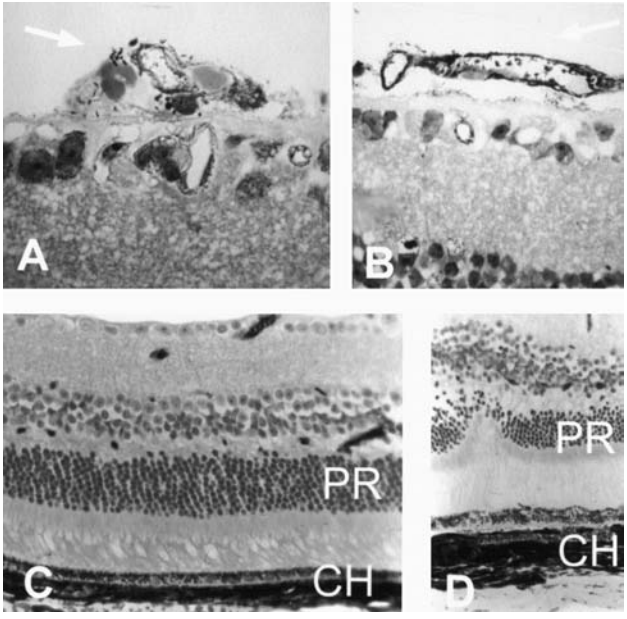

Figure 12.5. Examples of retinopathy in sickle transgenic mice expressing the $\alpha^{H}\beta^{S}$ transgene and homozygous for the β^{major} deletion. **(A** and **B)** Preretinal neovascularization indicated by arrows. **(C)** Normal retina indicating choroid (CH) and photoreceptor (PR) layers. **(D)** Pathological retina showing dilated obstructed CH with a disrupted PR layer above it. (See color plate 12.5.)

increased, and the vessel diameter was maintained. In contrast, in C57BL/6 mice, a change to suffusion with oxygen-equilibrated solutions resulted in decreased flow and vasoconstriction. Perhaps in the transgenic mouse, with equilibration with room air, there is HbS polymer formation that increases viscosity and reduces flow; oxygenation reverses this condition. This does not explain the failure to observe vasoconstriction under these conditions and has lead to the speculation that vascular response is blunted in sickle transgenic mice, a condition long suspected in humans with sickle cell disease and supported in studies outlined in Chapter 11. This observation lead to examination of other aspects of the vascular response in the S+S-Antilles mouse and it was found that these mice had constitutively low blood pressure and that vessel diameter did not respond to administration of acetylcholine, an endothelium-dependent vasodilator, or sodium nitroprusside, an NO donor. Nevertheless, N^{G}-nitro-L-arginine-methyl-ester, a nonselective inhibitor of NOS did cause a significant increase in blood pressure in both sickle and control mice.[110] It was concluded that increased NOS/NO activity resulted in hypotension and altered microvascular response to NO-mediated vasodilators in the S+S-Antilles mouse. Loss of vascular tone probably has both advantages and disadvantages. Vasodilation or lack of vasoconstriction might minimize the chance for blockage by nondeformable cells, but at the cost of over-exposure of tissues to oxygen with the consequent risk of oxidative damage. Intravital microscopy studies of the BERK knockout mouse showed that hyperoxia increased flow in contrast to the decreased flow observed in controls.[111] Hypoxia/reoxygenation of NY1DD mice resulted in elevated peroxide production in sickle transgenic animals but not controls with increased adherent and emigrated leukocytes, an effect blocked by P-selectin infusion.[112] In one sickle knockout line[40] oxygen radical inhibition of NO-dependent vascular function was due to increased vessel wall xanthine oxidase.[113] In C57BL/6 mice transplanted with BERK and BERK hemizygous bone marrow, adherent leukocytes recruited sickle cells.[114] Transplanted double-knockout mice for P- and E-selectins were protected from sickle vasoocclusion, leading to the suggestion that drugs targeting sickle erythrocyte–leukocyte or leukocyte–endothelial interactions might have a role in treating sickle cell disease. In BERK mice and C57BL/6 mice transplanted with BERK bone marrow, administration of tumor necrosis factor–α to simulate a sickle cell vasoocclusive event was rescued by commercial intravenous immunoglobulin.[115] Two criteria were used to evaluate outcome: survival time and the number of adherent leukocytes. The authors concluded that immunoglobulin was protective, and this agent is presently being evaluated in a clinical trial (ClinicalTrials.gov, NCT00644865).

Bone marrow from BERK β-hemizygous mice was transplanted into eNOS-overproducing and eNOS-deficient mice to study the effect of superoxide on leukocyte and platelet adhesion in cerebral venules. It was observed that eNOS overexpression enhanced and eNOS deficiency decreased adhesion. Sepiapterin, which enhances production of the cofactor of eNOS, tetrahydrobiopterin, and polyethylene glycol–superoxide dismutase had similar effects.[116] It was concluded that an imbalance of NO and superoxide contribute to the proinflammatory and prothrombogenic phenotype of these mice. Arginine significantly reduced expression of non-NO vasodilators COX-2 and heme oxygenase in BERK mice.[117] Reduced COX-2 expression correlated with reduced PGE2 levels. Response to the NO donor sodium nitroprusside was strongly correlated with the hemolytic rate and nitrotyrosine formation suggesting that improved microvascular function was a response to reduced hemolysis.

Liver. The liver in sickle mice shows infarcts that increase when mice are hypoxic[118] and occur with a greater frequency, as judged by both histology[34] and elevated levels of the serum enzyme alanine transaminase, in the more severe mouse models. Liver pathology has also been described in full knockout mice[39,40] and might be a source of arginase that results in arginine depletion in S+S-Antilles mice.[64] Elevated levels of iNOS and eNOS have been found in livers of transgenic sickle mice and have been attributed to hypoxic damage or the effect of shear stress due to the effectively higher viscosity of sickle blood and possibly damage by adhesion of red cells.[118] Extramedullary hematopoiesis has been detected in the liver of knockout transgenic sickle mice[40] and in mice expressing exclusively HbC.[119] Opioid metabolism was found to be altered in the hepatic microsomal fraction of BERK hemizygous mice and it was proposed that similar changes in sickle cell disease patients might alter clearance of this drug.[120]

Spleen. Splenic enlargement, fibrosis, and expansion of the erythropoietic red pulp was noted even in sickle transgenic mice with a relatively mild phenotype and was more pronounced in more severe strains.[30,32,34] A significant proportion of the total red cell mass is found in the spleen in these animals and might be partially responsible for their low hematocrit. Reduced spleen size has been used as an end point in gene therapy proof-of-principle using transgenic mouse models.[121–124]

Lung. The lung in transgenic and knock-out sickle mice with more severe pathology shows congestion, thickened septa fibrosis, and thrombosis.[39,42,44,85] Inhaled NO protected the SAD mouse from hypoxia/reoxygenation damage;[125] the mechanism of NO protection might be conversion of plasma free hemoglobin that can scavenge NO to inactive methemoglobin.[126] When hypoxia was used to induce acute lung injury in BERK sickle transgenic mice and BERK hemizygous mice,[127] under normoxic conditions xanthine oxidase, nitrotyrosine, and cyclic guanosine monophosphate were elevated in the sickle mice and hypoxia increased xanthine oxidase and nitrotyrosine and decreased cGMP. BERK mice challenged with endotoxin[128] had a higher increase in mortality and increased airway tone with cytokines found in serum and bronchoalveolar lavage. It was suggested that a subclinical proinflammatory state existed that resulted in an enhanced response to a proinflammatory challenge.

Polynitroxyl albumin has been proposed as an antioxidant and scavenger of reactive oxygen species and has been used to attenuate lung capillary leak.[129] A similar compound, S-nitrosoalbumin, was studied[130] in an acute hypoxia, SAD transgenic model to see if it protected against lung injury. Treatment resulted in reduced levels of interleukin (IL)-6 and IL-1β and hypoxia-induced increased granulocytosis.

Pulmonary hypertension is present in BERK mice and C57BL/6 mice transplanted with BERK bone marrow.[131] Mice expressing exclusively HbS suffered from pulmonary hypertension, pulmonary, and systemic endothelial dysfunction that was the result of reduced response to NO, NO donors, and impaired NOS activity. Similar effects were found in mice with immune-mediated hemolysis. In SAD mice used[132] to study the effect of peritonitis on lung NO production, control C57BL/6 mice, but not SAD mice, had an increase in eNOS and iNOS mRNA and proteins and an increase in exhaled NO leading to the conclusion that SAD mice have a defect in lung NO production and bioavailability that results in acute systemic and lung complications.

More severe pulmonary pathology was induced in SAD mice by exposure to 8% oxygen for 7 days.[133] Hypoxia increased neutrophils in bronchoalveolar lavage fluid and peripheral circulation, increased IL-1β, IL-6, and tumor necrosis factor–α, and upregulated genes for endothelin-1, cyclooxygenase-2, angiotensin-converting enzyme, and IL-1β. Hypoxia also increased *pde4* gene expression. A phosphodiesterase inhibitor prevented hypoxia-induced *pde4* up-regulation and prevented pulmonary arterial hypertension. In another publication, hypoxic erythrocytes from control C57BL/6 and BERK and hemizygous knockout mice induced endothelial inflammation in lung by producing reactive oxygen species leading to cytosolic Ca^{2+} increase, and P-selectin-dependent leukocyte recruitment.[49] Catalase blocked the effects of red cell–released oxidant radicals.

Brain. The brain in transgenic sickle mice is relatively unexplored. Occasional red neurons and rare pyknotic neurons were observed in S+S-Antilles mice.[34] The red neurons may be indicative of hypoxic episodes secondary to vasoocclusion. When perfusion and oxygenation in the brains of C57BL/6, S+S-Antilles, and BERK mice was studied, increased deoxyhemoglobin was correlated with reduced perfusion.[134] Although hyperoxia caused cerebral blood flow to decrease in control C57BL/6 mice, this resulted in increased blood flow in sickle transgenic mice, perhaps an effect of melting of sickle polymer found under room air conditions and/or loss of brain autoregulation.

Cerebral venules were studied in BERK β-hemizygous mice transplanted onto P-selectin knockout mice. Platelet and leukocyte adhesion was elevated in both unstimulated and posthypoxic sickle mice, suggesting both an inflammatory and prothrombogenic phenotype. In BERK β-hemizygous mice transplanted onto gp91phox NADPH-deficient mice and onto superoxide dismutase–overexpressing mice, strong platelet–endothelial and leukocyte–endothelial adhesion that was blunted by the iron chelator desferrioxamine, but not by the xanthine oxidase inhibitor allopurinol, was found. It was concluded that superoxide and catalytically active iron contributed to the proinflammatory and prothrombogenic responses.[135,136]

Other Hemoglobinopathies

Other nonsickle, human globin transgenes have been introduced into the mouse. These include *HBA*,[7,137] *HBG*,[43,138] *HBD* and the β^C-globin gene.[119] Some have been bred onto full knockout backgrounds. For example, a mouse expressing human α- and β^A-globin chains was bred onto a full knockout background.[137] This mouse has features of β thalassemia with a low MCHC that can be corrected by introducing the γ-globin gene. A mouse expressing exclusively human HbC has many features of human HbC disease (Chapter 21) including dehydrated, high MCHC red cells, high K-Cl cotransport, circulating intracellular crystals of HbC, which increase when the mice are splenectomized and folded red cells. More recently a mouse expressing HbE has been generated that has many of the features of HbE disease, without thalassemia.[140]

SUMMARY

Sickle cell transgenic mice, however imperfect as models, have made significant contributions to understanding the pathophysiology of sickle cell disease. Yet, the quest for a more perfect mouse is reasonable, as animal models allow the possibility of detecting early results of new therapies

and understanding complex physiological interactions that cannot be confidently predicted or verified in human studies. Mouse physiology has some features mentioned previously that might make the physiological consequences of sickle cell disease even more severe than they are in humans and it might not be possible to make a viable mouse with exclusively HbS, low levels of HbF in adults, and a normal MCHC.

Some hematological features of transgenic mice confound analysis in terms of disease severity, the ameliorating effects of natural human γ-globin chains or other antisickling hemoglobins and the applicability of results to gene therapy in humans. Although many transgenic lines have high expression of human HbF during the fetal period, 2,3-BPG production is delayed until just after birth. Many lines of transgenic mice express their human hemoglobins in a pancellular mode. F cells do occur in some mouse lines, which can both enhance the verisimilitude of the model and complicate data analysis because the percentage of γ-globin chains in whole blood is a balance between the synthesis of γ-globin and selective destruction of non-F cells. The amount of hemoglobin in whole blood due to transgene expression might not be constant during the lifetime of the mouse. Gene expression, the site of erythropoiesis, hemoglobin assembly, and selective red cell destruction can all play roles in this outcome. It is important to be aware of these features and transgene expression should be measured as a function of mouse age. Production of human hemoglobin in mouse red cells appears to require extremely high levels of mRNA and globin chain synthesis and the concentration of globin protein from the transgene should be measured before reaching conclusions about hemoglobin gene expression in transgenic mice.[141] Currently, the best way to demonstrate that the effect of antisickling globin chains in a sickle cell mouse model is due to inhibition of HbS polymer formation is by producing a similar mouse that expresses β^A-globin chains at a comparable level. The β^A chains will dilute the concentration of HbS but will not reduce polymer formation as effectively as HbF (Chapters 5–7). Similarly, antisickling hemoglobins intended for use in gene therapy need to be compared with γ-globin chains expressed at a similar level to validate their antisickling properties. A major obstacle to comparing the "same" mouse with β^A- or γ-globin chains is that every transgene is inserted in a different location in the chromosome and with a different copy number and potentially with a different level of expression at different ages in the mouse. This limitation can now be overcome with new technology based on site-specific recombination that eliminates position and variable copy number effects.[142,143]

Hematological severity might not equate to physiological severity. The full knockout HbC mouse has nearly the same level of hematological severity as some of the full sickle knockout mice. That is, the hematocrit and reticulocyte counts are nearly the same; however, homozygous HbC disease in human is trivial clinically (Chapter 21). The physiological impact of HbC is much milder in mice than suggested by the hematology alone, as these mice were bred to a full knockout with a very small number of matings and both male and female HbC mice can breed. Many matings are required to produce full knockout mice with HbS both with and without human γ-globin gene expression and female mice with high levels of β^S-globin uncommonly survive pregnancy and give birth to viable pups. In evaluating antisickling hemoglobins physiological parameters should be evaluated along with strictly hematological parameters.

The current generation of mice expressing exclusively human hemoglobin is technologically state of the art, and yet they too have imperfections. Most of the full knockouts have low MCHC, a condition not associated with human sickle cell disease. Low MCHC might be a necessary compensation to ameliorate the induced pathology and allow survival. Regulation of globin chain synthesis balance is imperfectly understood and in most transgenic lines chain balance is the result of chance as the mechanisms responsible for balanced globin synthesis are probably circumvented by transgene insertion. When chain balance is not achieved in mice expressing HbS, and the mice suffer from a thalassemic phenotype, the pathology observed will be a combination of HbS polymer–related damage and oxidative damage. Even in the absence of globin chain imbalance, low MCHC can confound the interpretation of results in experiments where breeding in an anti-sickling hemoglobin might alter red cell MCHC by ameliorating β thalassemia and affecting polymer formation or other MCHC-related pathology.

A single model does not "fit all," and it is wise to examine more than one transgenic line before drawing conclusions about the relevance of a result to the human disease. One might look for features that are consistent over several different mouse models. Recent reviews of transgenic sickle mice are available and deal with such issues as their roles in evaluating gene therapy, drug discovery and sickle vasculopathy.[146–153]

Reference Resources

A number of useful Internet sites can be accessed to find characteristics of mutant hemoglobins, inbred mouse strains, and associated literature.

SECTION THREE

α THALASSEMIA

Douglas R. Higgs

At all stages of development, human hemoglobin is made up of two α-like and two β-like globin chains. In embryonic life the ζ and ε genes are fully active, producing embryonic hemoglobin ($\zeta_2\epsilon_2$). Between 6 and 8 weeks of gestation there is a switch in expression so that the α- and γ-globin genes become fully expressed, producing fetal hemoglobin ($\alpha_2\gamma_2$). Finally, at around the time of birth there is a further switch from γ- to β-globin expression so that in adult red cells HbA ($\alpha_2\beta_2$) predominates.

In α thalassemia, the synthesis of α-globin chains is downregulated so that in fetal life there is anemia and the excess γ-globin chains form soluble tetramers (γ_4) called Hb Bart's. In adult life, α thalassemia also causes anemia but, because by this time the γ to β switch is complete, the excess non–α chains assemble into β_4 tetramers, called HbH. The degree of anemia and the amounts of the abnormal hemoglobins (Bart's and H) produced broadly reflect the degree to which α-globin synthesis has been downregulated.

We now know that normal individuals have four α-globin genes, arranged as linked pairs of genes at the tip of each copy of chromosome 16, written in shorthand as αα/αα. α Thalassemia most commonly results from the deletion of one (-α) or both (--) α genes from chromosome 16. Carriers of α thalassemia (-α/αα and --/αα) have mild hypochromic microcytic anemia and may produce detectable amounts of Hb Bart's at birth. In addition, occasional cells containing HbH may be detected in adults with the --/αα genotype, although hemoglobin electrophoresis is unremarkable. In all other respects carriers of α thalassemia are entirely normal and the most important consideration, from a clinical and hematological point of view, is to ensure that such patients do not become misdiagnosed and inappropriately treated for iron-deficiency anemia.

α Thalassemia is probably the most common disease-causing mutation affecting humankind. There is good circumstantial evidence that α thalassemia has attained such high frequencies by virtue of its selective advantage in areas where Falciparum malaria is or has been endemic. In tropical and subtropical regions of the world the carrier frequency of the mildest type of α thalassemia (-α) is very high and may be present in more than 90% of individuals in such populations. In southeast Asia and the Mediterranean basin the more severe defect (--) is also present at high frequencies (up to 10%). In these areas various combinations of alleles are seen. Homozygotes for the -α/ haplotype (-α/-α) have a mild hypochromic microcytic anemia. Compound heterozygotes (--/-α) have a hemolytic anemia producing large amounts of Hb Bart's at birth and similar levels of HbH in adult life, a condition known as HbH disease. Homozygotes for the --/ haplotype (--/--) have a lethal condition referred to as the Hb Bart's hydrops fetalis syndrome. As predicted from the distribution of the --/ haplotype, HbH disease and the Hb Bart's Hydrops Fetalis syndrome are mainly found in individuals of southeast Asian and Mediterranean origins.

Within the "malaria belt" there has been selection for a very wide range of hemoglobin variants and different types of α and β thalassemia. The major hemoglobinopathies include the HbS mutation and HbE. Coinheritance of α thalassemia has an important influence on the hematology and clinical manifestations of these common β-chain abnormalities and β thalassemia.

The molecular basis of α thalassemia is now understood in great detail. Normally, the α-like genes are arranged along chromosome 16 in the order in which they are expressed in development (telomere-ζ2-α2-α1-centromere). Furthermore, we now know that the cluster lies in a telomeric, gene-rich region of the genome, surrounded by widely expressed genes. Full expression of the α-like genes is critically dependent on the presence of a regulatory element (called HS-40), which lies 40 kb upstream of the cluster (toward the telomere). As many as 50 deletions removing one (-α/) or both (--) genes have been characterized and of these six ($-\alpha^{3.7}$/, $-\alpha^{4.2}$/, $--^{SEA/}$, $--^{MED}$/, $-(\alpha)^{20.5}$/ and $--^{FIL}$/) represent by far the most common causes of α thalassemia worldwide. In addition, many different point mutations affecting the structural genes have been identified, these cause the less common nondeletional forms of α thalassemia ($\alpha^T\alpha$/). This information has allowed researchers and hematologists to establish logical and robust screening programs for identifying patients with α thalassemia. This in turn allows clinicians to provide accurate genetic counseling and prenatal diagnosis for the severe syndromes of α thalassemia, including Hb Bart's Hydrops Fetalis and transfusion-dependent forms of HbH disease.

In addition to these common forms of α thalassemia there are many rare and unusual molecular defects that have been identified. These are important because they provide an explanation for patients with hitherto undiagnosed anemia, and they help us to understand how the α cluster is normally regulated in vivo. Rarely, α thalassemia is caused by deletions that remove the α-globin regulatory element (HS-40). In general these mutations have been

observed outside of the "malaria belt," indicating that they are sporadic genetic events that have not been selected during evolution. These natural deletions first indicated the existence of this unexpected form of long-range control of α-globin expression.

There are also two rare forms of α thalassemia that are found in association with a variety of developmental abnormalities, and in particular with mental retardation (so-called α thalassemia with mental retardation, ATR syndromes). The first group of patients has large (>1 Mb) deletions from the tip of chromosome 16 including the α-globin genes (ATR-16). These usually result from chromosome truncations or translocations and in fact this syndrome provided the first examples in human genetics of subcytogenetic chromosomal translocations, which are now known to underlie many cases of unexplained mental retardation. The second group of patients is now known to have mutations in a *trans*-acting factor (called ATRX) encoded on the X-chromosome (ATR-X syndrome). These patients have α thalassemia with profound mental retardation, facial abnormalities, and urogenital anomalies. In this case it is thought that the X-encoded factor regulates expression of many genes, the α genes being but one target.

Finally, there is a rare and unexplained form of α thalassemia that is seen as an acquired mutation in patients with myelodysplasia, hence called the ATMDS syndrome. These patients inherit a normal complement of α genes (αα/αα) but later in life develop myelodysplasia and presumably acquire a clonal genetic abnormality during the course of their disease. It is interesting that the majority of these patients are elderly males who at some stage of their disease have abnormal erythropoiesis. It has recently been shown that these patients have acquired mutations in the *ATRX* gene.

In the following chapters we will review the epidemiology, molecular pathology, pathophysiology, and clinical syndromes of α thalassemia in detail.

13

The Molecular Basis of α Thalassemia

Douglas R. Higgs

INTRODUCTION

Before describing the various ways in which α-globin expression may be downregulated in patients with α thalassemia, it is worth briefly reviewing the normal structure of the human α-globin cluster and how the genes are expressed throughout erythroid differentiation and development.

The α-globin cluster is located in a gene dense region of the genome close to the telomere of chromosome 16 (16p13.3). The genes are arranged along the chromosome in the order, telomere-ζ-ψζ-α^D-ψα1-α2-α1-θ-centromere (Fig. 13.1). Upstream of the α cluster there are four highly conserved, noncoding sequences multispecies conserved sequences called MCS-R1–R4[1] that are thought to be important in the regulation of the α-like globin genes. They correspond to previously identified erythroid-specific DNase I hypersensitive sites (DHS) referred to as HS-48, HS-40, HS-33, and HS-10,[2] the coordinates referring to their positions (kb) with respect to the ζ-globin mRNA cap site. Of these elements, only MCS-R2 (HS-40) has been shown to be essential for α globin expression (summarized in Higgs et al.[3]). The role(s) of the other MCS sequences are as yet unclear.

It has been shown that as progenitors commit to the erythroid lineage and differentiate to form mature red cells, a subset of the key erythroid transcription factors and cofactors (Chapter 4) progressively bind the upstream elements and the promoters of the α-like globin genes.[4–6] Finally, RNA polymerase II is recruited to both the upstream regions and the globin promoters as transcription starts in early and intermediate erythroblasts.[4,5] At the same time, it has been shown[5] that the upstream elements and promoters of the globin genes physically interact, forming a chromatin loop (Fig. 13.2).

Both ζ- and α-globins are expressed in primitive erythroblasts[7] emanating from the yolk sac (up to 6–7 weeks of gestation in human). It has been shown in mouse that as such cells mature there is a switch from ζ– to α-globin expression[8] and it seems likely that a similar maturational switch occurs in human[9] (E. E. Bouhassira, personal communication, 2006). Definitive line erythroblasts in the liver almost exclusively synthesize α-globin (from 6 weeks onward)[7] Very small amounts of ζ-mRNA are present throughout fetal life (for example, see ref. 10) and ζ-globin (as Hb Portland) can be detected in the cord bloods of nonthalassemic newborn (for example, see ref. 11). Using sensitive mRNA assays, low levels of θ-transcripts are detected in yolk sac, fetal liver,[12] adult blood,[13] and bone marrow[14] Similarly, very low levels of α^D (also called μ) mRNA can be detected in cord blood, adult blood and bone marrow[15] but proteins corresponding to θ and α^D have not yet been identified.

α–Globin transcription starts in basophilic erythroblasts and reaches a maximum in intermediate (polychromatophilic) erythroblasts and subsequently switches off as the erythroid cell matures.[16] Despite this, translation of globin mRNA continues for 2–3 days in reticulocytes from which the nucleus has been extruded. Continued globin synthesis, in these transcriptionally inert red cells, is critical for normal red cell production and is made possible by the long half life (>24 hours) of globin mRNA. This in turn depends on an RNA binding complex called the α-globin poly(C) binding protein (αCP). This is thought to stabilize α-globin mRNA by controlling deadenylation of its polyA tail and protecting the RNA from an erythroid enriched endoribonuclease (ErEN[17]).

Although the protein products of the α2- and α1-genes are identical, two methods exploiting the sequence divergence in their 3′ noncoding regions have enabled the relative amounts of α2- and α1-mRNA to be determined in reticulocytes.[18–20] This shows that in fetal and adult life the steady-state level of α2-mRNA predominates over α1-mRNA by approximately 3:1, probably as a result of differences at the level of transcription of the two genes. This may result from a competition between the α2 and α1 gene for access to the upstream MCS elements, which the α2 gene wins because of its relative proximity to HS-40. It is also possible, but less likely, that the α2 and α1 mRNAs may be made in similar amounts but have different stabilities.

It is still not clear whether the protein resulting from α2mRNA translation outweighs that from α1mRNA translation. Assessment of the ribosome loading of α2- and α1-mRNA has shown that they have identical translational profiles and therefore should be produced with equal efficiencies predicting a dominant role for the α2-globin locus.[21] It follows that, in heterozygotes, naturally occurring structural mutations of the α2 gene should represent approximately 37% of the peripheral blood hemoglobin and α1 mutants approximately 13%. Two studies addressing this point come to different conclusions. In the first,[22] it was found that α2 variants represented 24%–40% whereas α1 variants represented 11%–23%, suggesting a predominant role for the α2 gene at both mRNA and protein levels.

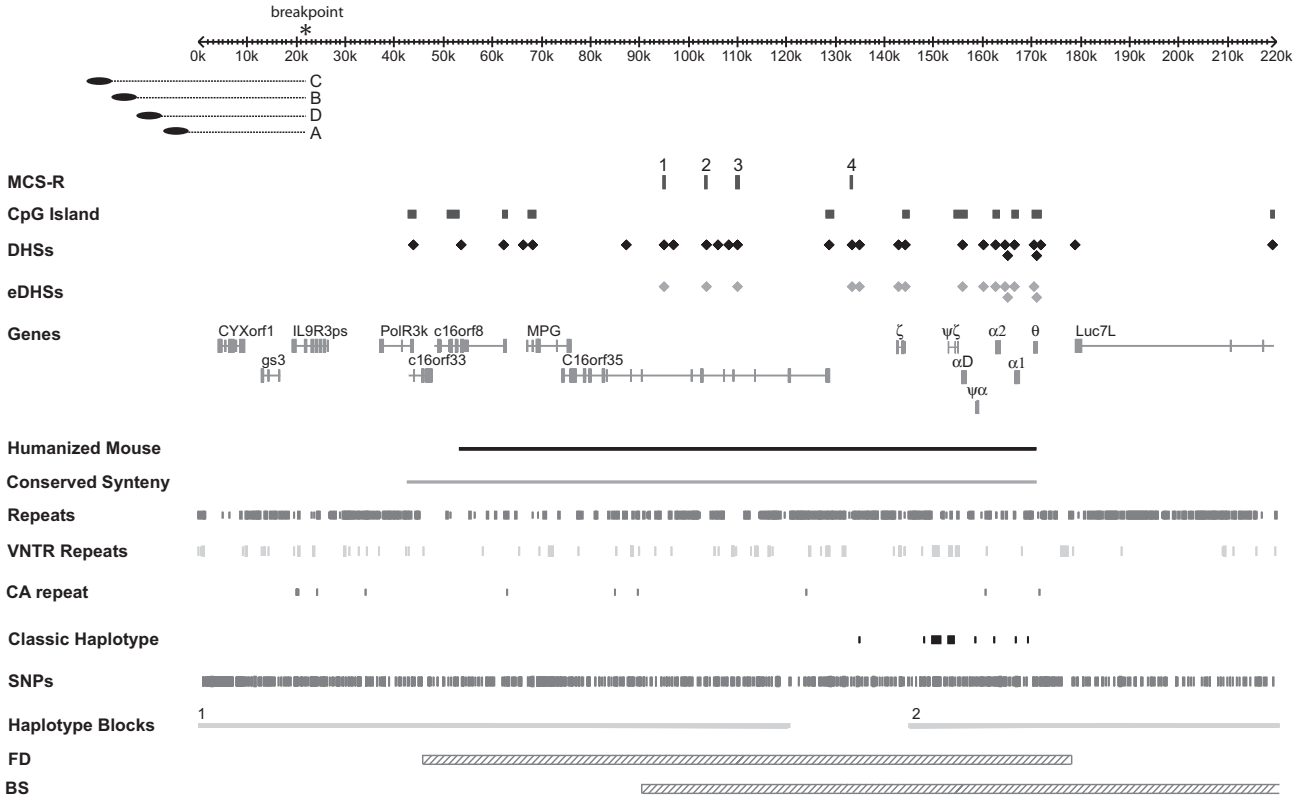

Figure 13.1. The normal α-cluster located at 16p13.3. The annotated genes extending from the 16p telomere (left) are shown. The polymorphic subtelomeric regions (A, B, C, and D) are shown, and the point of divergence between different subtelomeric regions is marked with an asterisk (breakpoint). Below the scale, the positions of multispecies conserved sequences (MCS-R1–4), CpG islands, all DNase I hypersensitive sites (DHSs) and erythroid specific sites (eDHS) are shown. Below the genes are shown the segment of DNA replaced in the "humanized mouse,"[27] the region of conserved synteny[1] and various repeat sequences (including VNTRs and CA repeats). Below this, the positions of the polymorphisms used to score the "classic haplotype"[48] SNPs and extended haplotype blocks (1 and 2) are shown. At the bottom are the two duplications of the α cluster described in ref. 26.

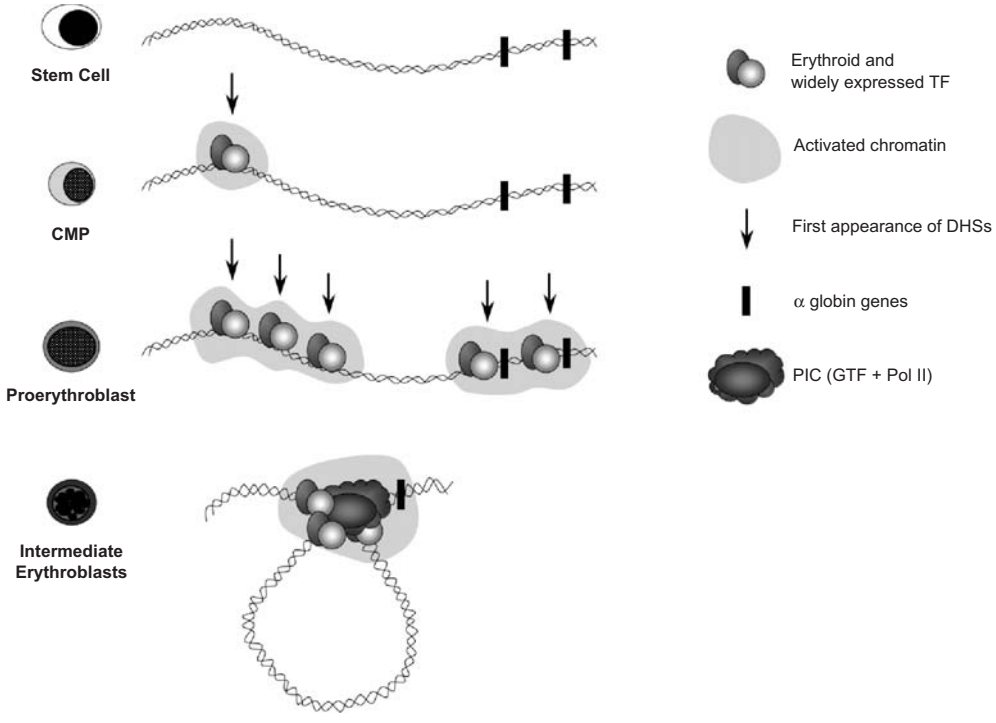

Figure 13.2. A summary of the events leading to α-globin gene activation during erythropoiesis with a key to the events (on the right). At the time the preinitiation complex (PIC) is recruited, the upstream elements form a loop via their interaction with the globin gene promoters.

Table 13.1. α-Globin variants associated with deletional forms of α-thalassemia

Variant		Haplotype	Population(s)	Reference
Hb Evanston	α^{14} Trp→Arg	$-\alpha^{3.7}$	Black	166, 167
Hb Hasharon	α^{47} Asp→His	$-\alpha^{3.7}$ and αα	Mediterranean, Ashkenazi Jews	22, 168–172
Hb G Philadelphia	α^{68} Asn→Lys	$-\alpha^{3.7}$ and αα	Algerian, Mediterranean, Black, Melanesian	22, 168, 173–177
Hb Q (Mahidol)	α^{74} Asp→His	$-\alpha^{4.2}$	Southeast Asian	178, 179
Hb Duan	α^{75} Asp→Ala	$-\alpha^{4.2}$	Chinese	180
Hb Stanleyville II	α^{78} Asn→Lys	$-\alpha^{3.7}$	Black	181
Hb Nigeria	α^{81} Ser→Lys	Not determined	Black	182
Hb J Capetown	α^{92} Arg→Gln	$-\alpha^{3.7I}$	South African	183
Hb J Tongariki	α^{115} Ala→Asp	$-\alpha^{3.7II}$	Melanesian	77, 184

In contrast, a more extensive survey of α globin variants by Molchanova et al.[20] found that in heterozygotes the average proportion of stable variants resulting from α2 mutants (23.5%) was only slightly higher than from α1 mutations (19.7%), suggesting a less efficient translation of the α2 mRNA and a more equal contribution from the two genes at the protein level. Further work is still needed to resolve this issue because it is of importance for understanding the pathophysiology of the nondeletional forms of α thalassemia (see later).

VARIANTS OF THE GLOBIN CLUSTER THAT DO NOT CAUSE THALASSEMIA

Before considering mutations of the α cluster that cause α thalassemia we will briefly review variants that occur in the nonthalassemic population. Some of these are relatively common and provide useful genetic markers for the α cluster and the 16p telomere. In addition, they illustrate some of the chromosomal rearrangements and DNA sequence changes that have taken place during the evolution of this multigene family. Furthermore, some mutants help to differentiate between regions of the gene cluster that are important for expression in vivo and those that may be irrelevant.

Chromosomal Rearrangements Involving 16p13.3

Rarely, chromosomal translocations involving 16p13.3 place the α-globin locus at the tip of another chromosome, as seen, for example, in some relatives of patients with the ATR-16 syndrome (see Chapter 15). To date we know of 16 individuals with such balanced translocations and none of them has α thalassemia. Fifteen were summarized in Table 13.1 in the previous edition of this book (see web site) and one additional case (EW) also has a balanced rearrangement 46,XX,-16.+der(16) (16;20)(p13.3;q13.3) and normal hematological indices (Hb 11.5 g/dL, mean corpuscular volume [MCV] 87 fL, and mean corpuscular hemoglobin [MCH] 27.9 pg). Because the closest centromeric breakpoint of these chromosomal translocations lies only 1.2 Mb from the α-globin genes, these findings demonstrate that the *cis*-acting sequences required for full α-globin regulation are contained within this region and expression is not perturbed by rearrangements on this scale. In two individuals with unbalanced translocations, and three copies of 16p13.3, the α/β globin chain synthesis ratios were 1.5 and 1.6,[23,24] (and unpublished data) again indicating that the additional, mislocalized copy of the α complex is expressed even though its genomic position has been altered.

Two large duplications of the terminal region have also been described in patients with β thalassemia intermedia (see Chapter 16). Because these patients are simply heterozygotes for the β thalassemia mutations it implies that their relatively severe phenotype results from the production of excess α-globin chains from the α genes in the duplicated regions. In one pedigree, three α clusters (αα:αα:αα) are present on one copy of chromosome 16[25] (and unpublished data). Provisional data suggest that at least two and possibly all three clusters in the duplicated region are fully active. A carrier for this abnormal chromosome (αα:αα:αα/αα), with a total of 8 α genes, has an α/β-globin chain synthesis ratio of 2.7.[25] A recent study has more fully characterized what appears to be a very similar rearrangement in another Italian family with β thalassemia intermedia[26] revealing a duplication of approximately 260 kb (BS in Fig. 13.1). These authors also characterized another duplication of approximately 175 kb of chromosome 16 lying between the end of the α cluster and the telomere (FD in Fig 13.1). Again the phenotype of a compound heterozygote for this rearrangement (αα:αα/αα) and β thalassemia trait suggested that the additional α clusters in the duplicated segment are fully active indicating that all sequences required for fully regulated α globin expression lie in this duplicated segment of chromosome 16.

More recently, these observations, based on "experiments of nature," have been refined by evolutionary studies and experimental observations. Hughes et al[1] cloned and sequenced the α-globin cluster and the surrounding region in 22 vertebrate species spanning 500 million years of evolution. The most informative comparison was with the mouse in which the orthologous α-globin cluster has translocated from its normal telomeric location (seen in most species) to an interstitial position (on mouse chromosome 11). Presumably this translocation, which

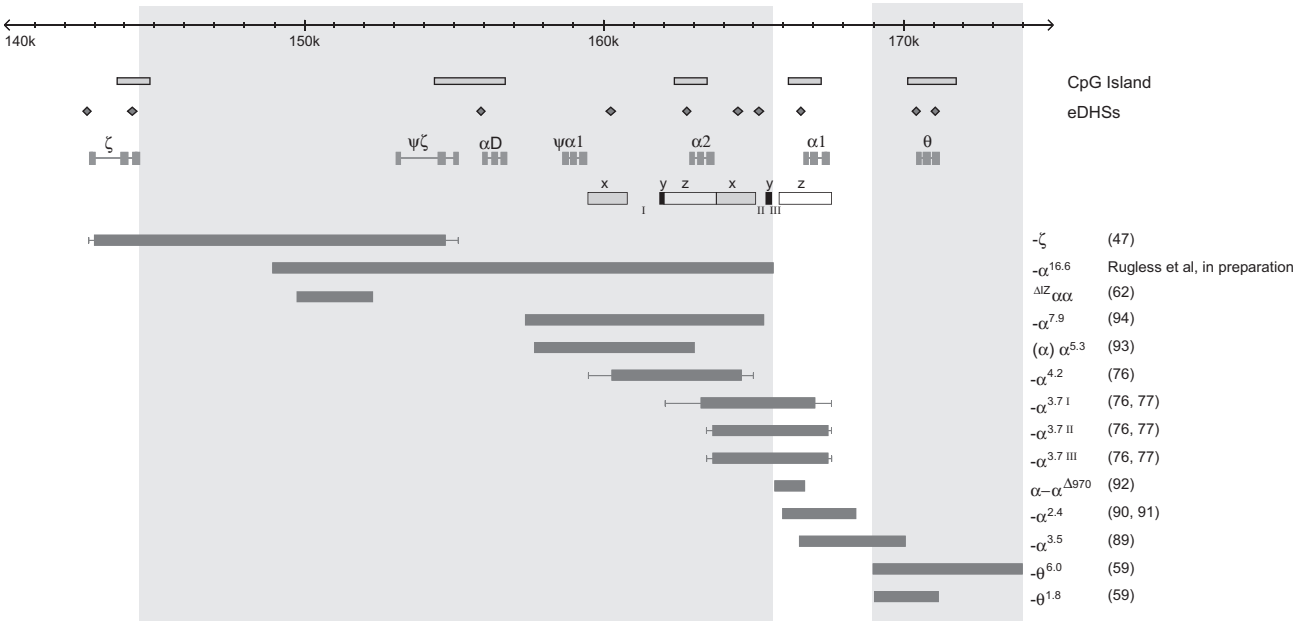

Figure 13.3. Deletions that cause α^+ thalassemia. Above the α-like globin genes, CpG island, and erythroid specific DHS as in Figure 13.1. Below this are shown the duplication units divided into X, Y, and Z boxes with regions of nonhomology (I, II, III). Below the extent of each deletion is represented by a black bar. The thin bars at the end of each thick bar denote the regions of uncertainty for the deletion breakpoints. Primary references for the characterization of these deletions are shown on the right hand side of the diagram. It is interesting to note that based on the observed phenotypes of some of these mutations (discussed in the text), it may be possible to conclude that there are no *cis*-acting sequences critical to the α cluster (other than the α2 gene itself) lying between coordinates approximately 145,000–165,000 (indicated by shaded boxes).

involves approximately 135 kb including the α cluster and its regulatory elements (region of conserved synteny, Fig. 13.1), includes all of the *cis*-acting sequences required to maintain fully regulated tissue- and developmental-stage specific expression of the α globin cluster. To test this, Wallace and colleagues[27] replaced the endogenous mouse α-globin cluster with the syntenic region of the human cluster (humanized mouse in Fig. 13.1) by using homologous recombination and showed that this segment of DNA was sufficient to recapitulate the normal pattern of human α-globin expression in a mouse background. Together these observations have helped to define the region of chromosome 16, which directs fully regulated expression of the human α globin locus.

Variation at the 16p Telomere

The human α globin locus lies very close to the telomere of the short arm of chromosome 16 (Fig. 13.1). There are four alleles in which the α-globin genes lie 170 kb (A), 245 kb (D), 350 kb (B), or 430 kb (C) from the 16p telomeric repeats[28,29] (see Fig. 13.1). Detailed analysis has shown that these polymorphic, subtelomeric alleles are structurally quite different. For example, beyond the region of divergence (*breakpoint in Fig. 13.1), the A and B alleles are more closely related to nonhomologous chromosomes than to each other. The A allele is related to the subtelomeric regions of Xqter and Yqter whereas the B allele is more like Xqter, 10pter and 18pter. Similar long-range polymorphisms have been identified at several other human telomeres.[30] Despite these major structural differences at the 16p telomere, the hematological indices of individuals with A and B alleles are indistinguishable.

Variation in the Number of Globin Genes

As a result of unequal genetic exchange (see later) hematologically normal individuals may have 4, 5 or 6 α genes.[31–35] A recently described individual with 7 α (ααααα/αα) genes had a minor degree of microcytosis.[36] A curiously high frequency of the ααα chromosome (gene frequency ~0.01–0.08) is found in most populations that have been studied although the reasons for this are not yet clear. Although there appears to be an excess of α-mRNA[18,34] and α-globin[34,37–41] produced from the ααα arrangement, homozygotes (ααα/ααα) still appear to be hematologically normal.[31,42] Although it has not been formally analyzed in human, in sheep it has been shown that the efficiency with which multiple α genes are expressed decreases from the 5′ to 3′ position on the chromosome.[43] In this case, as more α genes are added to the cluster (αα to ααα to αααα), any increase in α-globin expression may be less than expected from the addition of fully expressed extra genes.

In addition to these variations in the number of α genes, normal individuals may also have variations (from two to six) in the number of ζ-like genes.[44–47] Chromosomes bearing a single ζ gene (ζ2 rather than the normal ζ2-ψζ1 arrangement see Fig. 13.3) are relatively common

(gene frequency ~0.05) in West Africans[44,47–49] (and unpublished data) and occur sporadically in other populations. There is no discernible phenotype associated with the -ζ/ζζ genotype[44,46,47] and unpublished data) although, to date, only one homozygote (-ζ/-ζ) has been identified who appears hematologically normal.

The triplicated ζ-gene arrangement (ζζζ) has the structure ζ2-ψζ1-ψζ1[10] and was originally identified in Southeast Asia where its frequency is 0.09–0.20;[47,48,50] it is also particularly common throughout Melanesia, Micronesia, and Polynesia where phenotypically normal homozygotes (ζζζ/ζζζ) have been described.[46,48,51] Elsewhere ζζζ is uncommon. Structural analysis of the ζζζ arrangement shows that it has arisen by an unusual interchromosomal recombination event[10,51] between Ia and IId haplotypes (the common α-globin haplotypes are described in Higgs et al.[48] (also see Fig. 13.1, classic haplotype). All of the ζζζ chromosomes studied from Southeast Asia and the Pacific have this unusual structure,[51] suggesting that they have a common, single origin. Some of these chromosomes appear to have been subsequently modified, as indicated by the presence of a Bgl II polymorphism in 8%–15% of cases[51] and the occasional presence of the Hb-CS (Constant Spring). mutation on the linked α2 gene.[47] A single example of a chromosome with four ζ genes (ζζζζ) was described by Titus et al.[45]

Gene Conversion in the Globin Cluster

The DNA strand exchanges involved in misaligned but reciprocal recombination (see later) may resolve with nonreciprocal genetic exchange, known also as gene conversions; reviewed in Strachan and Read.[52] During the process of gene conversion genetic information may be exchanged between allelic (homologous) or nonallelic (paralogous) sequences without any crossovers or chromosomal rearrangements occurring. Gene conversion events between both the α1/α2 pair and the ζ2/ψζ1 pair may occur quite frequently. DNA sequence analysis suggests that gene conversion events have taken place, during evolution, between α1 and α2[53] and ζ2 and ψζ1 genes[10,54] maintaining the sequence identity of the non-allelic duplicated genes (concerted evolution). A likely example of such a conversion event between α2 and α1 has been documented in individuals expressing an unexpectedly high level of Hb-l, an α-variant ($\alpha^{16Lys\rightarrow Glu}$), in which the same mutation is present on both α2 and α1 genes in *cis*[55] (Chapter 24). Further possible examples of nonreciprocal exchange were described by Molchanova et al.[20] who observed identical sequence mutations affecting the α1 and α2 genes on independent chromosomes; one possibility is that these arise by conversion from one gene to another. Additional evidence, consistent with gene conversion, comes from the identification of "patchwork" α genes in which the α2 gene contains sequences characteristic of the α1 gene and vice versa.[33,56] These and other[57] patchwork-like genes have now been found in many, diverse populations suggesting that genetic information is passed between the duplicated regions containing the α genes relatively frequently.

Analysis of the downstream ζ-like gene in several populations has shown that it exists in two distinct forms.[10] In one its structure is clearly that of a pseudogene (ψζ1) and in the other (ζ1) the ψζ1 gene has undergone a gene conversion by the ζ2 gene such that it becomes more similar to the functional ζ gene although it still appears not to be expressed in vivo. The frequency of the ζ2-ζl chromosome varies from one population to another (0.14–0.57), and phenotypically normal individuals homozygous for either ζ2-ψζ1 or ζ2-ζ1 chromosomes have been observed.[10] Conversions of the ζ2 gene by ψζ1 have not yet been described although several candidate chromosomes have been identified.

In addition to these examples of gene conversion it seems likely that, as in other mammalian multigene families[58] short segmental conversions may also be responsible for transferring thalassemic and nonthalassemic variants within and between different chromosomal backgrounds.

Deletions and Insertions Within the α-Complex

Two uncommon deletions involving the θ1 gene remove either 1.8 kb or 6.0 kb from between the intact α1 gene and the α-globin 3′HVR[59] (Fig. 13.3). Neither variant was associated with any phenotypic abnormalities in the neonatal period and an adult, heterozygous for the 1.8 kb deletion also appears normal. The reported individual with the 6.0-kb deletion also had a -ζ chromosome.[59] We have also studied an individual who apparently has the same 6.0-kb deletion and in this case the -ζ arrangement is present in *cis* to the θ1 deletion.[60] Similarly, Ballas et al.[61] found that both of these rearrangements may exist on the same chromosome. Thus these individuals have deletions at both the 5′ (10 kb) and 3′ (6 kb) ends of the cluster with no discernible effect on α-gene expression. In a large survey of newborn babies,[62] a small (2.5-kb) deletion (see Fig. 13.3) between the ζ and ψζ genes was observed in two hematologically normal babies from Sardinia.

Phenotypically silent insertions are also recognized in the α-complex. An insertion of 0.5–0.7 kb between the α2 and α1 genes was identified in the nonthalassemic chromosome of a Chinese individual.[63] This most probably arose from a reciprocal crossover between a normal chromosome (αα) and the common α-thalassemia determinant ($-\alpha^{3.7}$, see later). In addition we have observed an insertion/deletion polymorphism in the 5′ flanking region of the α-complex that appears to involve members of the *Alu* family of repeats[60]

Restriction Site Polymorphisms

It is now known that single nucleotide polymorphisms (SNPs) are found, on average, once every 2 kb[64] in normal individuals and some of these changes were originally identified as restriction fragment length polymorphisms

(RFLPs) within and flanking the α-cluster.[48] SNPs identified in this way were divided into common (the frequency of the rarer allele in most populations being 0.05–0.50) and uncommon (<0.05) variants; the latter were frequently found to be race or population-specific. Analysis of nine common polymorphisms (including the ψζ1/ζ1 polymorphism and the interzeta hypervariable region, IZHVR) showed that linkage disequilibrium exists between these genetic markers and some common α-globin haplotypes (non-random linkage groups) could be derived (classic haplotype[48] [Fig. 13.1]). Although a large number of haplotypes are now recognized, in each population only one or two are common and several others are present at low frequencies. There is, as yet, no evidence that α-globin expression differs between the common α-globin haplotypes.

More recently this type of analysis has been expanded using 80 validated SNPs located in the terminal region of 16p13.3 (coordinates ~20,000–320,000) to study 7 diverse populations and thereby to extend the haplotypes and define regions of linkage disequilibrium (LD) across this segment of the genome (Viprakasit et al. unpublished). From this we have defined two blocks of LD located between the telomere and coordinate approximately 120,000, and approximately 150,000–260,000 (LD blocks 1 and 2 in Fig. 13.1). In theory, the chromatin between these blocks should contain a region of relatively high recombination although, at present, this area does not clearly correlate with any of the other structural or functional features associated with the α globin cluster.

Within block 1, DNA sequence analysis has revealed six minor variants of the HS -40 regulatory element.[65] Again, these polymorphic subhaplotypes are found in normal, nonthalassemic individuals and provide informative examples of in vivo mutagenesis, which allows one to relate the structure of this important regulatory region to its function.

Variable Number of Tandem Repeats

Preliminary Southern blot analysis identified several variable number tandem repeats (VNTRs) in and around the α-globin locus.[66,67] The number of repeats in such arrays may be altered at mitosis or meiosis[68] producing highly polymorphic segments of the cluster. Further DNA sequence analysis of the terminal 300-kb region of 16p[69] identified at least ten VNTRs in this region consistent with the view that such sequences tend to cluster at the ends of human chromosomes.[70] At present we have identified more than 100 tandem repeats but only a few have been tested to establish whether or not they vary in normal human populations. In the α-complex, when analyzed, there appears to be no relationship between the structure of such regions and the associated phenotype. Whatever their function, if any, they are of great value as genetic markers throughout the genome and have been used to produce individual-specific genetic fingerprints.[71,72]

VARIANTS THAT CAUSE THALASSEMIA

As set out previously, analysis of the human α-globin cluster has revealed a remarkable degree of polymorphism due to point mutations, deletions and insertions of DNA. These polymorphisms are found in all populations. Variants that cause α thalassemia are largely limited to tropical and subtropical regions of the world where malaria is, or has been, endemic (see Chapter 26). Some rare and very informative mutations have been found in individuals outside of these regions. In contrast to β thalassemia, in which mutations are frequently due to point mutations in the structural genes (Chapter 16), α thalassemia is most often due to deletions involving one or both of the α genes. Less frequently, deletions removing the α-globin regulatory element (HS-40) are seen. This difference in molecular pathology (deletions rather than point mutations) represents another contrast between the α and β clusters, which may also reflect their different chromosomal environments (see Chapter 3).

α Thalassemia due to Deletions

DNA sequence analysis has shown that the α-globin genes are embedded within two highly homologous, 4-kb duplication units whose sequence identity appears to have been maintained throughout evolution by gene conversion and unequal crossover events.[53,73–75] These regions are divided into homologous subsegments (X, Y, and Z) by nonhomologous elements (I, II, and III, Figs. 13.3 and 13.4). Reciprocal recombination between Z segments (Fig. 13.4), which are 3.7 kb apart, produces chromosomes with only one α-gene ($-\alpha^{3.7}$, rightward deletion, Figs. 13.3 and 13.4)[76] that cause α thalassemia and others with three α-genes ($\alpha\alpha\alpha^{anti3.7}$).[32,34] These events can be further subdivided, depending on exactly where within the Z box the crossover took place into $-\alpha^{3.7I}$, $-\alpha^{3.7II}$ and $-\alpha^{3.7III}$ (Fig. 13.3).[77] These subregions are defined by sequence differences in the Zα2 and Zα1 boxes that can be detected by Southern blot hybridization. Recombination between homologous X boxes, which are 4.2 kb apart, also gives rise to an α thalassemia determinant ($-\alpha^{4.2}$, leftward deletion, Figs. 13.3 and 13.4)[76] and a $\alpha\alpha\alpha^{anti4.2}$ chromosome.[78] Further recombination events between the resulting chromosomes (α, αα, ααα) may give rise to quadruplicated α-genes ($\alpha\alpha\alpha\alpha^{anti3.7}$, $\alpha\alpha\alpha\alpha^{anti4.2}$),[78,79] quintuplicated ($\alpha\alpha\alpha\alpha\alpha^{anti3.7}$),[36] or other unusual patchwork rearrangements[56,57]

The variety of independent recombination events giving rise to -α and ααα and other, related arrangements identified in extant human populations suggests that recombination between the homologous X and Z boxes is relatively frequent and several indirect observations support this notion. Both -α and ααα chromosomes are present in most population groups. Moreover, the -α determinant is associated with many different hemoglobin variants (e.g., see Higgs et al.[60] and Table 17.1) HVR alleles and α-globin

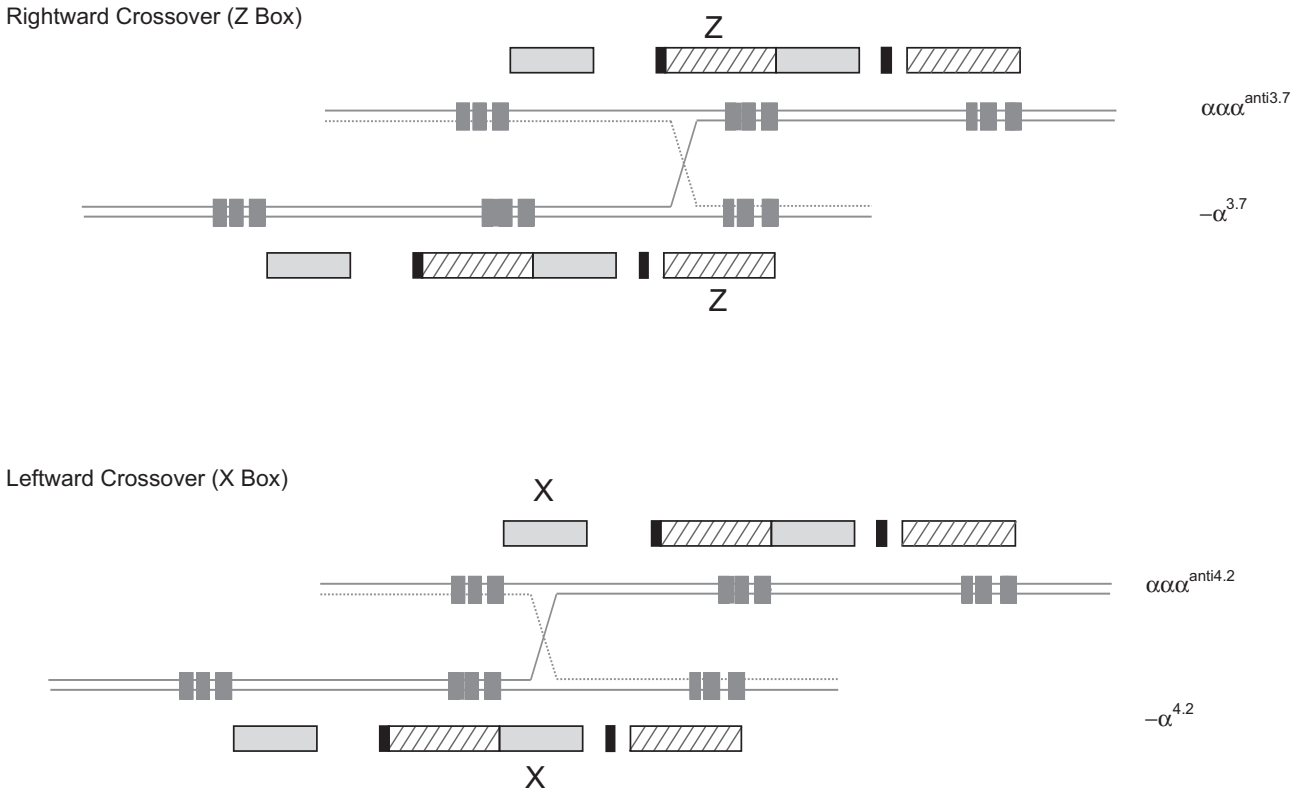

Figure 13.4. The mechanism by which the common deletions underlying α^+ thalassemia occur. Crossovers between misaligned Z boxes give rise to the $-\alpha^{3.7}$ and $\alpha\alpha\alpha^{anti\ 3.7}$ chromosomes. Crossovers between misaligned X boxes give rise to $-\alpha^{4.2}$ and $\alpha\alpha\alpha^{anti\ 4.2}$ chromosomes.

haplotypes.[66,80,81] Furthermore, in population isolates such as Papua New Guinea and Vanuatu the -α determinants are only found on the common α-globin haplotypes for that population suggesting that they have arisen *de novo* in each population group[80] rather than having been "imported" from other populations and selected. Moreover, some α-globin variants (e.g. Hb-G Philadelphia, $\alpha^{68\ Asn\rightarrow Lys}$) are found on both normal (αα) chromosomes and chromosomes bearing an α thalassemia determinant (-α), suggesting a connection between the two through recombination and/or gene conversion. Similar observations have been made for the poly(A) signal mutation found in Saudi Arabia (see later), which is present on both αα and ααα chromosomes.[82]

It is interesting that recombination hotspots in duplicated elements (such as the X and Z boxes) often show patchy gene conversion at the site of crossover,[83–85] emphasizing the connection between these two processes. It has also been noted that the relative frequencies of the various types of α thalassemia observed throughout the world correlate with the length of the homologous segments (X, Y and Z) that serve as target areas for the crossovers involved ($-\alpha^{3.71}$ [1436 bp] > $-\alpha^{4.2}$ [1339 bp] > $-\alpha^{3.7II}$ [171 bp] > $-\alpha^{3.7III}$ [46 bp]). Correlations between frequency of recombination and target size have been noted in other systems;[86] however, because the α-thalassemia determinants are highly selected for in many areas[80] these observations may not truly reflect recombination rates.

Although these long standing observations have pointed to the mechanism by which -α and ααα chromosomes arise it has only recently been shown (using single DNA molecule polyermase chain reaction [PCR]) how they may occur *in vivo*.[87,88] From this work, the overall picture is one of reciprocal recombination (and unequal exchange) occurring in mitosis (premeiotic) in the germ line. The estimated frequencies of -α and ααα arrangements in sperm are in the order of 1–5 × 10^{-5}. Deletions and duplications may also occur in somatic tissues by related mechanisms although deletions detected in blood occur by intrachromosomal rather than interchromosomal recombination.[87] Consistent with the observations in human populations, recombination was found to be associated with patchy gene conversion and the position of crossover was, to some extent, governed by the length of high sequence identity, with the $-\alpha^{3.7}$ chromosome arising more frequently than $-\alpha^{4.2}$.[87] Given the high frequency with which these chromosomes are generated, the authors argue that in populations in which there is no α thalassemia, there must be selection against -α/-α and ααα/ααα homozygotes.[87,88]

In addition to the common -α chromosomes, seven rare deletions that produce α^+ thalassemia have been described (Fig. 13.3). One that removes the entire α1 gene and its

flanking DNA (-$\alpha^{3.5}$) has been observed in two Asian Indian patients.[89] The breakpoints of this deletion have not been examined in detail. Another rare α^+ thalassemia deletion (called -$\alpha^{2.7}$) removing the α1 gene and its flanking DNA was originally described in a Chinese patient with HbH disease.[90] A subsequent report[91] of a Canadian/Chinese patient with HbH disease (in whom the breakpoints were sequenced) identified a deletion, accurately assessed as 2.4 kb (-$\alpha^{2.4}$). It seems likely that these two deletions (-$\alpha^{2.4}$ and -$\alpha^{2.7}$) are the same mutation and hence we have grouped them in Figure 13.3. Recently Poodt et al.[92] described a small deletion (970 bp) removing the entire promoter of the α1 gene and DNA-encoding 26 bp of the 5′ end of the mRNA, which completely inactivates the α1 gene. In all three of these deletions it appears that the remaining α2 gene is fully active.

Three large deletions remove the α2 gene and a variable amount of the α globin cluster lying upstream. The first, referred to as (α)$\alpha^{5.3}$, was observed in a family from Italy.[93] It removes the 5′ end of the α2-globin gene; the 5′ breakpoint lies 822 bp upstream of the mRNA cap site of the ψα1-gene, the 3′ breakpoint is located in IVS1 of the α2 gene. Sequence analysis indicates that this deletion has arisen by an illegitimate recombination event. The second is a deletion of 7.9 kb (-$\alpha^{7.9}$), which was found in two unrelated individuals of Surinam/Indian origins.[94] This deletion removes the ψα1 and α2 genes by non-homologous recombination. The third is a 16.6-kb deletion (-$\alpha^{16.6}$) found in a family of Vietnamese origin (M. Rugless et al., in preparation). The deletion removes the ψζ, α^D, ψα1, and α2 genes by non-homologous recombination and the junction is filled with approximately 360 bp of orphan sequence derived from the intron of the ζ or ψζ gene.

Analyzing the hematological indices, globin synthesis ratios, and genetic interactions involving these three deletions ((α)$\alpha^{5.3}$, -$\alpha^{7.9}$, -$\alpha^{16.6}$) it appears that the remaining α1 gene on each of these chromosomes is expressed at normal or near normal levels. This is of interest when considering regulation of the normal cluster because it implies that, other than the α2 gene itself, no other important, *cis*-regulatory elements are removed by these deletions. When all of the data from the α^+ thalassemias are considered alongside the observations from nonthalassemic variants, it appears that large segments of the α-globin cluster (Fig. 13.3 and legend) are not essential for α-globin expression.

Expression from the α^+ Chromosomes

Although the relative expression of mRNA from the α2 and α1 genes on a normal chromosome is approximately 3:1, there are several lines of evidence indicating that the α-gene in the various -α chromosomes behaves like neither α1 nor α2. For example, homozygotes for the -$\alpha^{4.2}$ determinant who essentially have two α1 genes (-$\alpha^{4.2}$/-$\alpha^{4.2}$) appear to express more α-globin than the predicted 25% of normal[95] and homozygotes for -$\alpha^{3.7III}$, with the equivalent of two α2 genes (-$\alpha^{3.7}$/-$\alpha^{3.7}$), express less than the predicted 75% of normal.[95] Direct measurements of α-mRNA levels in patients with the -$\alpha^{3.7}$ determinant also suggest that the remaining α gene is expressed at a level roughly half way between that of a normal α2 and normal α1 gene.[96] Because the transcriptional units of all the recombined genes (-$\alpha^{3.7I}$, -$\alpha^{3.7II}$, -$\alpha^{3.7III}$, -$\alpha^{4.2}$) are virtually identical to either the native α1 or α2 gene, the alteration in expression most likely results from a change in the rate of transcription of the gene. Assuming that this is a *cis* effect, it could be brought about by the new combinations of flanking sequences, a release of transcriptional interference from the upstream gene,[97] or by the change in chromosome conformation as a result of the deletions.

Another possibility (Fig. 13.2) is that the promoters of the α2 and α1 genes normally compete for interaction with the single α-globin regulatory element (MCS-R2, HS-40) in a similar way to which the γ and β genes are thought to compete for the β-globin LCR (see Chapters 4 and 5). In this case a single promoter in the -α chromosome would have unchallenged access to HS-40 and might consequently be expressed more efficiently than when competing with a second (αα) or third (ααα) promoter. As discussed previously such competition might also help explain the progressively inefficient expression of duplicated genes in the α clusters.

Although there is no a priori reason to anticipate changes in ζ-globin expression in patients with the -α haplotype, it is useful to know that none of the -α mutations is associated with any significant change in ζ-globin expression.[98]

α^0-Thalassemia due to Deletions of the Structural α-Globin Genes

All of the deletions described in this section either completely or partially (e.g., -(α)$^{5.2}$ and -(α)$^{20.5}$) delete both α-globin genes (Figs. 13.5 and 13.6), and therefore no α chain synthesis is directed by these chromosomes in vivo (hence the term α^0 thalassemia). Homozygotes for such chromosomes have the Hb Bart's hydrops fetalis syndrome (see Chapter 14).

Many deletions remove both ζ genes and the α-globin genes (Figs. 13.5 and 13.6). Although heterozygotes for these variants survive and appear to develop normally, homozygotes do not survive even the early stages of gestation because neither embryonic ($\zeta_2\gamma_2$, $\zeta_2\varepsilon_2$, $\alpha_2\varepsilon_2$) nor fetal ($\alpha_2\gamma_2$) hemoglobin (HbF) can be made (see Chapter 7). Some, but not all, heterozygotes for deletions in which the embryonic gene remains intact have continued expression of very small amounts of ζ-globin in both fetal[11] and adult life[99,100] This may be analogous to the persistent γ-globin production documented in patients with similar downstream deletions of the β-complex (see Chapter 16). The amount of ζ-globin present in adults with these types of α thalassemia is considerably less than the level of γ-globin present in individuals with comparable deletions of the

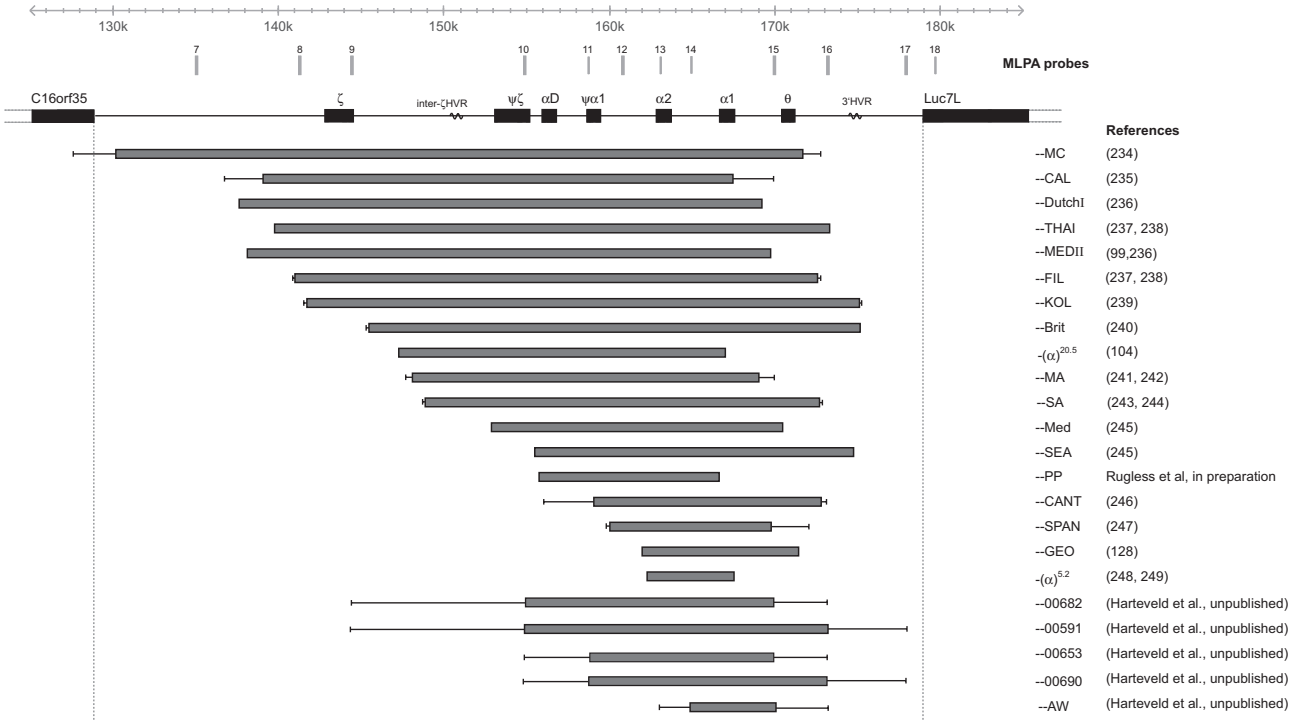

Figure 13.5. Deletions that cause α^0 thalassemia with breakpoints lying within the α-globin cluster. Above, the α-like globin genes are shown (scale in kilobases) and the cluster is delimited by two flanking genes (c16orf35 and Luc7L). The positions of MLPA probes currently used to characterize large deletions from the α-globin cluster[162] are shown. Below, the extent of each deletion is shown by a black bar. Regions of uncertainty for each breakpoint are shown by thin black lines. To the right are the shorthand notations and primary references for the characterization and examples of PCR analysis for each deletion. The $--^{BRIT}$ deletion is probably the same mutation as the rare α^0 thalassemia defect described in a black patient.[164]

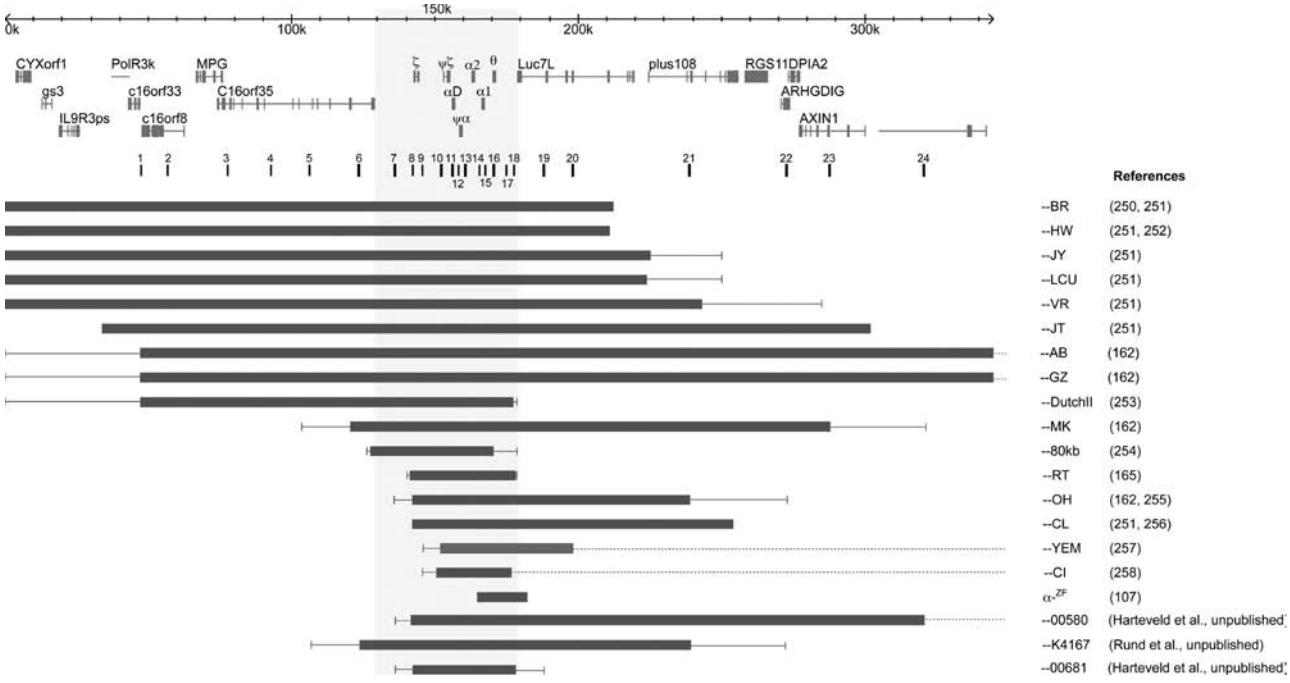

Figure 13.6. Rare, large deletions extending beyond the α cluster that cause α thalassemia but no other associated abnormalities. Above, the terminal 340 kb of chromosome 16p as described in the legend to Figure 13.1 (scale in kilobases). The positions of MLPA probes currently used to characterize large deletions from the α-globin cluster[162] are shown. Below, black bars indicate the extent of each deletion. Regions of uncertainty for the breakpoints are shown by thin black lines. Dashed lines indicate that the 3′ end of two deletions (YEM and CI) has not yet been investigated. To the right, are the shorthand notations and primary references for each deletion.

β-complex. It seems that this increase of embryonic globin expression is not simply due to the increased erythropoiesis because, in one study, no ε- or ζ-globin transcripts were detected in several patients with erythroid hyperplasia.[14]

At the 3′ end of the complex many of these deletions include the θ1-gene whose function is unknown. In individuals, homozygous for --^{SEA}, who have been treated with blood transfusion, both θ1-genes are deleted and yet these children may develop normally despite the complete absence of θ-gene expression (Chapter 14).[101]

With completion of the DNA sequence of 16p13.3[102] and beyond[103] it has been possible to define the full extent of many of the α globin deletions. They can be grouped into those that lie entirely within the α globin cluster (Fig. 13.5) and deletions that extend beyond the α-cluster to include the flanking genes (Fig. 13.6). Although these deletions remove other genes, affected heterozygotes appear phenotypically normal, apart from their α thalassemia; in some patients α thalassemia trait (--/αα) and in others HbH disease (--/-α). In patients with more extensive deletions with monosomy for a large segment of 16p13.3, α thalassemia is associated with developmental abnormalities and mental retardation (see Chapter 15). It is interesting to note that all of the α^0 thalassemia deletions that occur at polymorphic frequencies in human populations are limited to the α-cluster and do not extend into the surrounding genes suggesting that deletion of these genes (even in heterozygotes) may result in a selective disadvantage.

Detailed analysis of several determinants of α^0 thalassemia indicates that they often result from illegitimate or nonhomologous recombination events.[104] Such events may involve short regions of partial sequence homology at the breakpoints of the molecules that are rejoined but they do not involve the extensive sequence matching required for homologous recombination as described in the previous section.

Sequence analysis has shown that members of the dispersed family of Alu repeats are frequently found at or near the breakpoints of these deletions. Alu family repeats occur frequently in the genome (3×10^5 copies) and seem to be particularly common in and around the α-globin cluster where they make up approximately 25% of the entire sequence.[69] These repeats may simply provide partially homologous sequences that promote DNA strand exchanges during replication, or possibly a subset of Alu sequences may be more actively involved in the process. Detailed sequence analysis of the junctions of the α-globin deletions has revealed a number of interesting features including palindromes, direct repeats, regions of weak homology and frequent occurrence of the motif GAGG. Some deletions (e.g., --^{MED}) involve more complex rearrangements that introduce new pieces of DNA bridging the two breakpoints of the deletion. In the --^{MED} deletion this inserted DNA originates from upstream of the α-cluster and appears to have been incorporated into the junction in a manner that suggests that the upstream segment lies close to the breakpoint regions during replication.[104] Orphan sequences from unknown regions of the genome are frequently found bridging the sequence breakpoints of other α^0 thalassemia deletions.

At least two of the deletions (--^{HW} and --^{BR}, Fig. 13.6) result from chromosomal breaks in the 16p telomeric region that have been "healed" by the direct addition of telomeric repeats $(TTAGGG)_n$. This mechanism is described in further detail later.

α^0 THALASSEMIA DUE TO A DELETION OF THE α2-GLOBIN GENE THAT ALSO INACTIVATES THE α1-GLOBIN PROMOTER

We have recently characterized a deletion of approximately 11 kb (called --^{pp}) in a single patient with the phenotype of severe α thalassemia trait (Hb 12.3 g/dL, MCV 71 fL, MCH 21.7 pg and rare HbH inclusions). This deletion (Fig. 13.5) completely removes the α2 gene and the 3′ breakpoint lies within the promoter of the linked α1 gene that is otherwise intact. The phenotype of the patient combined with detailed biochemical analyses (M. Rugless et al., in preparation) has shown that the α1 gene *in cis* is inactivated by this mutation so that there is no α-globin synthesis directed by this chromosome (hence α^0 thalassemia).

α^0 THALASSEMIA DUE TO A DELETION OF THE α1-GLOBIN GENE THAT ALSO INACTIVATES THE α2-GLOBIN GENE

During a study to identify thalassemia in families from the Czech Republic, Indrak et al.[105] reported a novel deletion (>18 kb) involving the α1 and θ gene, α-^{ZF} (Fig. 13.6). Heterozygotes for this deletion have a mild hypochromic microcytic anemia (Hb 12.6 g/dL, MCH 22 pg, MCV 68 fL) with a reduced α/β-globin chain biosynthesis ratio (0.62–0.66) and HbH inclusions. These findings suggested that although the α2 gene appeared to be intact it had been inactivated by the novel deletion.

Barbour et al.[106] and Tufarelli et al.[107] further characterized this mutation and showed that the deletion juxtaposes a downstream gene (Luc7L) next to the structurally normal α2-globin gene. Although this α2 gene retains all of its local (e.g., promoter) and remote (e.g., MCS-R2 or HS-40) *cis*-acting elements, its expression is silenced and its associated CpG island (see Fig. 13.1) becomes completely methylated during early development and the chromatin associated with the promoter remains inactive and inaccessible, even in erythroid cells. From the analysis of experimental models recapitulating this deletion and from further characterization of the affected individual,[107] it was shown that transcription of antisense mRNA from Luc7L, through the α2-globin gene was responsible for methylation of the associated CpG island and silencing of α-globin expression. The mutation is not only important for understanding the molecular basis for this rare form of thalassemia but also

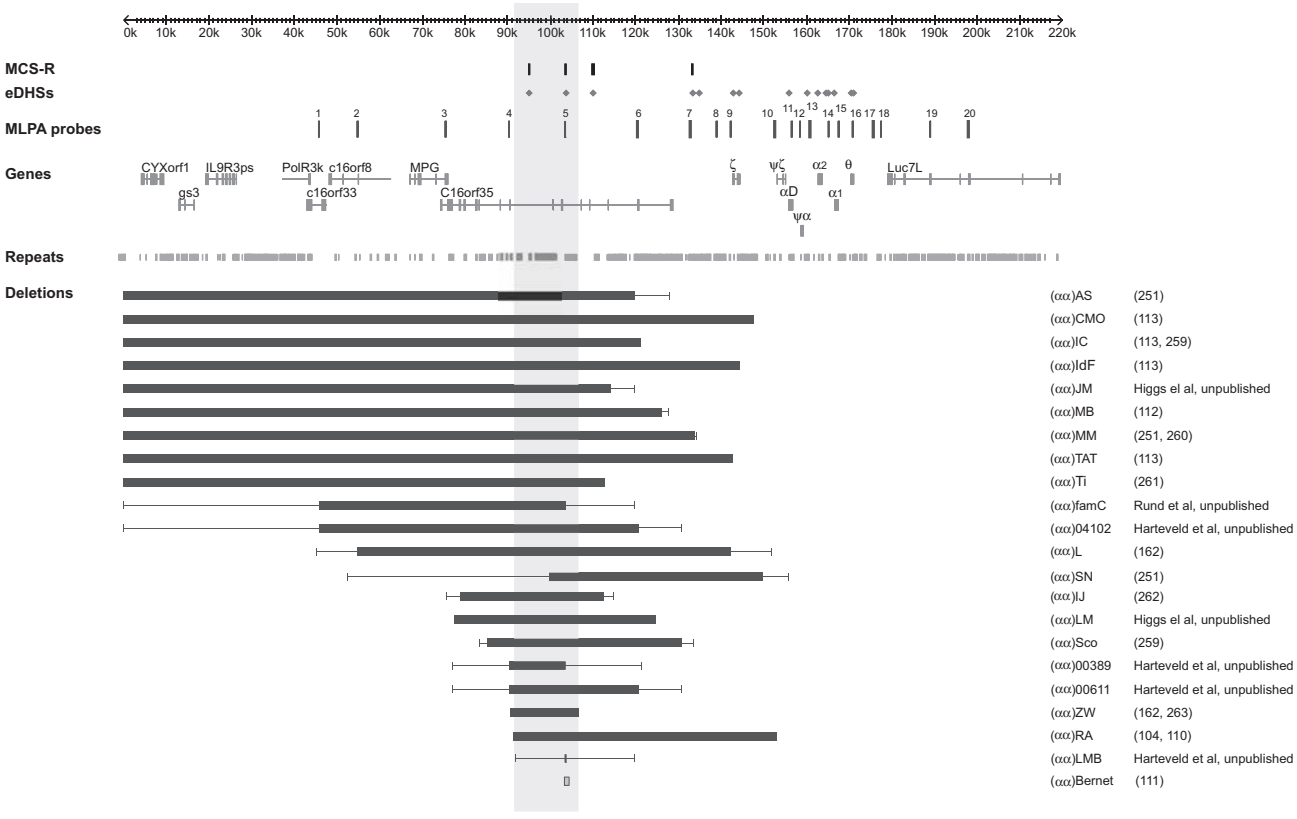

Figure 13.7. Deletions extending upstream of the α-cluster that cause α thalassemia by removing the α-globin regulatory element (HS-40) and a variable amount of flanking DNA. Above, the α-cluster (scale in kilobases) showing the α-like genes, the flanking genes, MLPA probes[162] together with the erythroid-specific DHS and positions of conserved regulatory sequences (MCS-R). The extent of each deletion is indicated by black bars and the uncertainty of breakpoints is shown by thin black lines. The stippled box represents the shortest region of overlap between all deletions, including HS-40 (MCS-R2) and HS-48 (MCS-R1). Primary references and shorthand notations are shown on the right.

illustrated a new mechanism underlying human genetic disease.

α THALASSEMIA DUE TO DELETIONS OF THE α-GLOBIN REGULATORY ELEMENT

As discussed previously, expression of the α genes is critically dependent on a multispecies conserved, noncoding regulatory sequence (MCS-R) that lies 40 kb upstream of the ζ2-globin gene.[2] This region (called MCS-R2[1]) is associated with an erythroid-specific DNase I hypersensitive site, referred to as HS-40. Detailed analysis of MCS-R2 has shown that it contains multiple binding sites for the erythroid-restricted *trans*-acting factors GATA-1 and NF-E2.[1,108,109] The role(s) of other upstream MCS elements (MCS-R1, R3, and R4) are not yet clear (see introduction).

The first indication that remote regulatory sequences might exist came from observations on a patient with α thalassemia.[110] Analysis of the abnormal chromosome $(\alpha\alpha)^{RA}$ from this patient demonstrated a 62-kb deletion from upstream of the α-complex (Fig. 13.7), which includes HS-40. Although both α genes on this chromosome are intact and entirely normal they appear to be nonfunctional. Since this original observation, 20 more patients with α thalassemia due to a deletion of HS-40 and a variable amount of the flanking DNA have been described (see Fig. 13.7). An approximately 15-kb segment of DNA containing both MCS-R1 (HS-48) and MCS-R2 (HS-40) is deleted in all of these chromosomes, and all of these mutations give rise to the phenotype associated with α^0 thalassemia: some patients have the severe form of α thalassemia trait αα/(αα), others have HbH disease -α/(αα).

Interspecific hybrids each containing an abnormal copy of chromosome 16 from such patients have been made by fusing EBV cell lines with mouse erythroleukemia cells (MEL). In contrast to normal copies of chromosome 16, the abnormal chromosomes produce severely reduced (often <1% of normal) levels of human α-globin mRNA, indicating that these deletions severely downregulate expression of the α genes and are responsible for the associated α thalassemia. A specific knockout of MCS-R2 (HS-40) alone[111] from such a chromosome (Fig. 13.7) together with many experiments in transgenic mice[3] strongly suggests that MCS-R2 is the major active element deleted by these arrangements. More recently this observation was further strengthened by showing that removal of just MCS-R2 from

a mouse model which recapitulates human α globin expression (see introduction and humanized mouse in Fig. 13.1) severely reduces α-globin expression.[27]

The mechanisms by which these natural mutations have arisen are quite diverse. In the $(\alpha\alpha)^{RA}$ chromosome the deletion resulted from a recombination event between partially homologous Alu repeats that are normally 62 kb apart.[110] In the $(\alpha\alpha)^{MB}$ chromosome[112] the deletion arose via a subtelomeric rearrangement. The chromosomal breakpoint was found in an Alu element located approximately 105 kb from the 16p subtelomeric region. The broken chromosome was stabilized with a new telomere acquired by recombination between this Alu element and a subtelomeric Alu repeat associated with the newly acquired chromosome end. In at least five cases $(\alpha\alpha)^{CMO}$, $(\alpha\alpha)^{ldF}$, $(\alpha\alpha)^{TAT}$, $(\alpha\alpha)^{IC}$ and $(\alpha\alpha)^{TI}$ the chromosomes appear to have been broken and then stabilized by the direct addition of telomeric repeats to nontelomeric DNA.[113] Sequence analysis suggests that these chromosomes are "healed" via the action of telomerase, an enzyme that is normally involved in maintaining the integrity of telomeres.[113,114]

In the remaining cases the mechanism has not yet been established. It is interesting that some (e.g., $(\alpha\alpha)^{IJ}$, $(\alpha\alpha)^{Sco}$), but not all, of these mutations appear to have arisen *de novo* because neither parent has the abnormal chromosome.

NONDELETION TYPES OF α THALASSEMIA

In all surveys reported so far, α thalassemia is much more frequently due to deletions, as described in previous sections, than single point mutations or oligonucleotide insertions and deletions involving the canonical sequences that control gene expression (so called nondeletion variants, in which the affected gene is denoted α^T). This is in contrast to the situation in β thalassemia in which point mutations affecting almost every stage of gene expression are known (see Chapter 16) and deletions are less frequent.

Nondeletion types of α thalassemia were first described in 1977[115] and shown to result from a variety of mechanisms.[116] At present we know of 69 well-defined causes of nondeletion α thalassemia (Table 13.2). Forty-six of these occur in the α2 gene ($\alpha^T\alpha$), 17 in the α1 gene ($\alpha\alpha^T$) and 5 occur on a -α chromosome ($-\alpha^T$). In 1 case the mutation has not yet been assigned to the α1 or α2 gene.

As a group, the nondeletion α thalassemia determinants ($\alpha^T\alpha$ and $\alpha\alpha^T$) appear to have a more severe effect on α globin expression and hematological phenotype than simple deletions that remove one or other of the α genes (-α) (see Chapter 14). This may be explained by the majority of mutations affecting the α2 gene, whose expression may predominate over the α1 gene (see previous section); this may also lead to a bias in ascertainment. In addition, unlike when one α gene is deleted (see previous section), there appears to be no compensatory increase in expression of the remaining functional α gene when the other is inactivated by a point mutation. Furthermore, some highly unstable variants may have multiple secondary effects on red cell interactions that produce a more severe phenotype than predicted from the anticipated decrease in α gene expression. At present these general assertions are based on a relatively small number of observations and further evaluation of the pathophysiology of each mutation will be needed in the future.

Mutants that Affect RNA Splicing

Eight nondeletion α thalassemia variants affect RNA splicing. With one exception ($\alpha^{Cd22;C\rightarrow T}\alpha$, see below) they all involve either the donor (GT) or acceptor (AG) consensus splice sites of either IVSI or IVSII. Four affect the dominant α2 globin gene and three mutate the α1 gene (Table 17.2). In general, it is now clear that mutations affecting the consensus donor (GT) and acceptor (AG) splice sites severely down regulate expression of the associated gene. The principles are illustrated by one of the first nondeletion determinants described. This splicing mutation ($\alpha^{IVSI;\ del5bp}\alpha$) results from a pentanucleotide deletion at the 5′ donor site of IVS 1 of the α2-globin gene. This affects the invariant GT sequence and eliminates splicing from the normal donor site while activating a cryptic donor consensus that lies in exon l. Aberrantly spliced mRNA was detected in a transient expression system and in bone marrow from an affected patient. By contrast, in peripheral blood very little if any mRNA from the mutated α2 gene was detected, suggesting that the aberrantly spliced RNA is unstable.[19,117] Very often in these types of mutation any aberrantly spliced mRNA transcripts are not only unstable but they also alter the translational frame so that an abnormal truncated protein is produced as seen in the mutation of the acceptor site of IVS1 of the α2 gene ($\alpha^{IIVS1-116A\rightarrow G}\alpha$) described by Harteveld et al.[118]

A different type of splicing defect ($\alpha^{Cd22;C\rightarrow T}\alpha$) was observed in patient of Surinamese–Hindustani origin. Sequence analysis revealed a silent mutation at codon 22 of the α2 globin gene that creates a splice donor consensus. Abnormally spliced mRNA leads to a premature termination between codons 48 and 49 and probably nonsense mediated decay of the abnormal RNA product. The only patient described with this mutation had a moderate hypochromic microcytic anemia.[119]

Of these eight splicing mutations, five affect the dominant α2-globin gene and three mutate the α1 gene. Many but not all of the heterozygotes for these mutations ($\alpha^T\alpha/\alpha\alpha$ and $\alpha\alpha^T/\alpha\alpha$) have readily detectable changes in their red cell indices. Furthermore, where documented, these alleles most frequently interact with α^0 thalassemia to produce HbH disease (e.g. $--/\alpha^T\alpha$ and $--/\alpha\alpha^T$).[120,121]

Mutations Affecting the Poly(A) Addition Signal

The highly conserved sequence motif AATAAA is present 10–30 bp upstream of most poly(A) addition sites and forms

part of the signal for mRNA cleavage and polyadenylation of primary transcripts (see Chapter 3). This sequence is required for transcriptional termination and some evidence suggests that, when mutated, transcription may proceed into neighboring genes and "interfere" with their expression.[122]

At present there are four known mutations of the α2 gene polyadenylation signal (Table 13.2). The first to be identified (AATAAA → AATAAG) was found in the Saudi Arabian population. Heterozygotes have the hematological phenotype of severe carriers of α thalassemia trait but homozygotes have HbH disease.[123] The mechanisms by which this mutation causes such a severe phenotype are not fully understood.

Homozygotes for other nondeletion mutations that inactivate the α2 gene do not always have HbH disease and when present it is often mild with low levels of HbH (see later). By contrast homozygotes for the $\alpha^{PA6:A\rightarrow G}\alpha$ haplotype always have HbH disease with relatively high levels of HbH. It is interesting that in these individuals α2 mRNA is reduced but not absent and therefore, if the α1 gene were fully active, one would expect to see a severe form of α thalassemia trait rather than HbH disease. The implication of these findings is that the poly(A) site mutation down regulates both α2 and α1 genes on the same chromosome. In some rare individuals, the $\alpha^{PA6:A\rightarrow G}$ α mutation is duplicated producing a chromosome with three α genes $\alpha^{PA6:A\rightarrow G}\alpha^{PA6:A\rightarrow G}\alpha$ that still interacts with the $\alpha^{PA6:A\rightarrow G}\alpha$ chromosome to produce HbH disease.[82]

Analysis of the $\alpha^{PA6:A\rightarrow G}$ mutation has shown that it has at least two effects. It reduces the amount of α2 mRNA that accumulates and, in a transient assay, readthrough transcripts extending beyond the mutated poly(A) addition site are detected. Extended transcripts were also detected in reticulocytes of patients with this defect using reverse transcription (RT) –PCR.[124] It seems possible that transcription extending through the normal termination point could run on and interfere with expression of the linked α1 gene. Given the reduction in α chain synthesis associated with the $\alpha^{PA6:A\rightarrow G}\alpha$ haplotype one would predict that compound heterozygotes for this mutation and a common α^0 thalassemia determinant should be severely affected. Although this is not always the case in two families, compound heterozygotes ($--^{MED}/\alpha^{PA6:A\rightarrow G}\alpha$) had severe HbH disease with hydrops fetalis.[125,126]

Since the original description of the $\alpha^{PA6:A\rightarrow G}$ allele, three other poly(A) signal mutations have been described (Table 13.2), including one that results from a 16bp deletion removing sequences from the 3′ untranslated mRNA and the first base of the PolyA site.[127]

At present there are insufficient data to know whether these more recently described mutations down regulate α gene expression in a similar way to the $\alpha^{PA6:A\rightarrow G}\alpha$ allele. Compound heterozygotes for these mutations and α^0 thalassemia have HbH disease as expected[128,129] (unpublished) and homozygotes for the $\alpha^{PA4:A\rightarrow G}\alpha$ or $\alpha^{PA4;del2bp}\alpha$ alleles have HbH disease.[130] Homozygotes for the $\alpha^{PA;del2bp}\alpha$ allele may have severe HbH disease with hydrops fetalis.[131]

Mutations Affecting Initiation of mRNA Translation

Several nondeletion mutations affect mRNA translation and six of them disrupt the initiation consensus sequence CCRCCATG (Table 13.2). Two mutations occur on chromosomes with a single α gene. In one ($-\alpha^{IN;ATG\rightarrow GTG}$) the mutation abolishes translation of mRNA from the gene. It was identified via its interaction with a second α thalassemia chromosome ($-\alpha^{IN;ATG\rightarrow GTG}/-\alpha$); affected patients had the typical hematological features of HbH disease with 2.4 and 7.2% HbH.[132] In another case ($-\alpha^{IN;del2bp}$) a 2-bp deletion from the consensus sequence reduces the level of

mRNA translation by 30%–50%.[133,134] This mutation produces HbH disease in homozygotes ($-\alpha^{IN;del2bp}/-\alpha^{IN;del2bp}$) who have a mild hypochromic microcytic anemia (Hb 9.7–9.9, MCV 63, MCH 18–20) with 4.5%–5.6% HbH.[135]

Two mutations ($\alpha^{IN;ATG\rightarrow ACG}\alpha$ and $\alpha^{IN:\,ATG\rightarrow A\text{-}G}\alpha$) abolish translation of mRNA from the α2 gene. Six of seven homozygotes for the $\alpha^{IN;T\rightarrow C}\alpha$ haplotype have a severe form of α thalassemia trait but one had a mild form of HbH disease with 2.6% HbH[136,137] (unpublished). Compound heterozygotes for this mutation with common α^0 thalassemia defects have HbH disease with substantial amounts of HbH (~8%–24%) in the peripheral blood.

One mutation $\alpha\alpha^{IN;ATG\rightarrow GTG}$ abolishes translation of mRNA from the α1 globin gene.[138] In the single family reported with this mutation compound heterozygotes ($--/\alpha\alpha^{IN;ATG\rightarrow GTG}$) had relatively low levels of HbH (1.5% and 3%) suggesting that mutation of the α1 gene causes a less severe degree of α chain deficit than a similar mutation of the α2 gene. This mutation adds weight to the argument that the α2 gene is expressed at a higher level than the α1 gene.

Finally, Eng et al.[139] reported a single nucleotide deletion from the initiation codon ($\alpha^{IN;\,ATG\rightarrow TG}\alpha$) in a newborn infant who also carried the $--^{SEA}$ mutation. More than 25% Hb Bart's was present at birth, consistent with HbH disease.

Inframe Deletions, Frameshifts, and Nonsense Mutations

Inframe deletions, insertions and nonsense mutations all affect the frame of translation and either cause premature termination of translation (with or without nonsense-mediated decay of the mRNA) or lead to the production of an abnormal protein, which is often unstable.

Four of the mutations described in this section result simply from single base changes in a coding triplet creating a premature stop codon thereby causing premature termination of translation.[140–143] Seven result from single base insertions and deletions that alter the triplet code and give rise to premature termination or the production of an abnormal α-globin.[139,140,144–146] Although some of these may be a relatively frequent cause of α thalassemia in some populations (e.g., $\alpha^{cd19;delG}\alpha$ in Iran), most are rare mutations which either cause α thalassemia trait ($\alpha\alpha^T/\alpha\alpha$ or $\alpha^T\alpha/\alpha\alpha$) or interact with α^0 thalassemia to produce HbH disease ($--/\alpha\alpha^T$ or $--/\alpha^T\alpha$), which in some cases can be clinically severe.

Other mutations are more complex. In 1988 Safaya and Rieder[147] described a Black American with HbH disease and HbG Philadelphia who synthesized only α^G and no α^A chains. The patient was shown to have the genotype $-\alpha/-\alpha^G$ and they therefore concluded that the -α chromosome was inactivated by a further mutation. Sequence analysis showed that this single α gene has a dinucleotide deletion from one or other of the Glu (GAG) or Arg (AGG) codons (30 and 31). The loss of two nucleotides leads to a frameshift and a novel protein sequence in exon II from codons 31–54 followed by a new, in-phase termination codon (TAA) at position 55. Hence the $-\alpha^{cd30/31;del2bp}$ haplotype is an inactive α^0 thalassemia determinant.

A single Spanish family with a frameshift mutation in the α1-globin gene has been described by Ayala et al.[148] Two affected individuals ($\alpha\alpha^{cd51-55;13bpdel}/\alpha\alpha$) have α thalassemia trait. Direct sequence analysis of the α1 gene revealed a 13-bp deletion, between codons 51 and 55. This mutation results in a mRNA reading frameshift that introduces a new stop signal at codon 62.

In another patient a 12-bp deletion of the α2 gene results in the loss of four amino acids (codons 113–116) from the α-chain, which is reduced from its normal length of 141 amino acids to 137. It is thought that this produces an unstable α chain which is rapidly broken down and unable to form a Hb tetramer, like some mutants described later. In a heterozygote this mutation produced the phenotype of α thalassemia trait (Hb Lleida,[149]).

All of these complex rearrangements appear to be relatively uncommon and have been observed sporadically in families with α thalassemia trait and HbH disease.

Chain Termination Mutants

There are potentially nine single nucleotide variants of the natural termination codon (TAA) of the α2-globin gene. Two (TGA and TAG) encode stop (nonsense) mutations; the others encode amino acids.[150] When mutations change the stop codon to one of these amino acids they allow mRNA translation to continue to the next in-phase termination codon (UAA) located within the polyadenylation signal (AAUAAA); in each case extending the α-chain by 31 amino acids from the natural C-terminal arginine (codon 141). Of the six predicted α2 variants, five have been described, each with a unique amino acid at α142. These are Hb Constant Spring (α142 Gin), Hb Icaria (α142 Lys), Hb Koya Dora (α142 Ser), Hb Seal Rock (α142 Glu), and Hb Paksé (α142 Tyr) (Table 17.2). An extended α-globin variant with leucine at position 142 is predicted but has not yet been described.

The mechanism by which chain termination mutants cause α thalassemia has been difficult to elucidate although there are now sufficient observations to provide a plausible explanation. Nevertheless, we still do not fully understand how the unusual hematological phenotype associated with these mutations arises. Heterozygotes clearly have α thalassemia, but the MCV is higher than normally seen (for examples see refs. 150, 151). Homozygotes for the HbCS mutation have an unexpectedly severe form of thalassemia considering that only two of the four α genes are inactive[152,153] and compound heterozygotes for HbCS and an α^0 thalassemia determinant have an unusually severe form of HbH disease (for example see refs. 154, 155 and see Chapter 14).

HbCS is the most extensively studied of this group. Heterozygotes for this mutation $\alpha^{TER;TAA\rightarrow CAA}\alpha/\alpha\alpha$ have

approximately 1% Hb-CS in their red cells rather than the approximately 25% usually found in carriers of α-chain variants.[150] It seems likely that the α2 gene affected by this mutation is transcribed normally, although this has not been formally demonstrated. Substantial amounts of the abnormal α^{CS} mRNA are found in erythroid precursors from the bone marrow but the level decreases during erythroid maturation and is virtually absent from reticulocytes.[18,156] The synthesis of α^{CS}-globin chains follows the same pattern, decreasing from bone marrow to reticulocytes.[150,157] From these findings it was suggested that α^{CS} mRNA is unstable, possibly due to disruption of a sequence(s) in the 3′ noncoding region that is translated inappropriately as a result of the chain termination mutant.[156] Subsequent experimental data support this interpretation. Weiss and Liebhaber[158] showed that translational readthrough disrupts an RNA–protein complex associated with the α2-globin 3′ UTR which is required for mRNA stability in erythroid cells (summarized in introduction and in ref. 17).

Unstable β-Chain Variants Associated with α Thalassemia

It is well established that some globin variants alter the tertiary structure of the hemoglobin molecule making the dimer (αβ) or tetramer ($\alpha_2\beta_2$) unstable. Such molecules may precipitate within the red cell forming insoluble inclusions (Heinz bodies) which damage the red cell membrane. This situation classically causes a chronic hemolytic anemia with equal loss of α- and β-like globin chains from the red cell (see Chapter 24).

Over the past few years it has become apparent that some α globin variants are so unstable that they undergo very rapid, postsynthetic degradation. In this case, because the α chains probably do not form dimers or tetramers, there is no associated loss of normal β chains which remain, in excess, within the red cell: Such patients, by definition, have α thalassemia. Many of these α globin variants are so unstable, that they cannot be detected by conventional protein analysis. Therefore affected patients often present with nondeletional α thalassemia that can only be explained when the mutation is identified by DNA sequence analysis.

The hematological findings in this group of patients are complex because the defects may involve the α1 or α2 gene, may cause different degrees of instability and may be greatly influenced by interacting alleles. For example, some mutants may be fully or temporarily stabilized when incorporated into a dimer or tetramer; the coinheritance of α thalassemia will reduce the normal pool of free α chains and drive abnormal α chains into dimers or tetramers. In this case, subsequent instability may cause loss of both α-like and β-like chains changing the pathophysiology from α thalassemia to a hemolytic anemia. This is discussed further in Chapter 16. The simplest way to look at the effect of these mutations is to consider simple heterozygotes. They usually have the phenotype of α thalassemia trait with low or undetectable amounts of the α-globin variant.

To date, 31 unstable α variants have been shown to produce this phenotype to a greater or lesser extent (Table 17.2). The mutations most frequently affect the heme pocket, internal hydrophobic regions of the molecule that normally maintain its conformation or hydrophobic residues involved in the formation of α1 β1 contacts.

α THALASSEMIA CAUSED BY A MUTATION THAT CREATES A NEW TRANSCRIPTIONAL PROMOTER

α Thalassemia is common throughout Melanesia and is frequently caused by the known $-\alpha^{3.7}$ and $-\alpha^{4.2}$ mutations. It is also documented that in some Melanesian patients (from Papua New Guinea and Vanuatu) with α thalassemia (α thalassemia trait and HbH disease) the α-globin genes are intact,[51] suggesting a nondeletional form of α thalassemia ($\alpha^T\alpha/\alpha\alpha$ or $\alpha^T\alpha/\alpha^T\alpha$). In these patients detailed mapping and DNA sequence analysis of the α genes and all of the upstream MCS elements was normal and yet further studies showed that this form of α thalassemia is linked to the α-globin cluster at 16p13.3.[159] To identify the mutation responsible for this unusual form of α thalassemia, De Gobbi et al.[159] cloned this region from an affected homozygote and resequenced approximately 213 kb of DNA containing and flanking the α-globin cluster, identifying 283 SNPs. The SNP responsible for the mutation was identified when the SNPs were aligned with a tiled microarray analyzed using labeled RNA from the patient's erythroid cells. This revealed a new peak of mRNA expression (located between the ζ and ψζ genes) that coincides with a SNP that creates a GATA-1 binding site. In association studies this SNP is always linked to the phenotype of α thalassemia. Like the MCS elements, this new GATA site binds erythroid transcription factors *in vivo* and becomes activated in erythroid cells. Since the first report of this SNP, we have subsequently identified a second family in which a compound heterozygote for this mutation and the codon 59 mutation described by Chan et al.[160] has HbH disease (Iswari et al., personal communication, 2006).

Why should creating a new promoter-like sequence between the α genes and their regulatory elements cause α thalassemia? Perhaps the most likely explanation is that, because it lies closer to the MCS elements, this new promoter "steals" the activity of the upstream regulatory elements away from the natural α-globin promoters, and down regulates their expression. The details of this mechanism are currently under investigation.

MOLECULAR DIAGNOSIS OF α THALASSEMIA

Patients with well-defined phenotypes of α thalassemia (Chapter 14) have inherited one or more of the determinants described in this chapter. Most common deletional forms of α thalassemia can be diagnosed by analyzing

both α globin–specific *Bam*H1 fragments and ζ globin–specific *Bg*/II fragments using conventional Southern blot analyses.[161] When both the α and ζ globin genes have been deleted (e.g., --^{FIL}, --^{THAI}; Fig. 13.5), breakpoints can only be identified using probes located outside of the α-complex. Over the past few years an increasing number of large deletions extending beyond the α globin cluster have been identified. The use of multiplex ligation-dependent probe amplification (MLPA) analysis[162] has enabled all of the common and rare deletions to be detected and this currently represents the most efficient way to screen for such deletions of the α-globin cluster in an unbiased way.

In addition, many PCR based analyses have been developed to diagnose the common forms of α^+ and α^0 thalassemia in single and multiplex assays (summarized in ref. 163). Now that the entire sequence of the human α globin cluster is available[69,102,103] it is a simple matter to design primers to amplify any of the currently known α globin deletions that have been described. One should bear in mind, however, that although PCR-based assays will identify the deletions for which they are designed they will not identify unexpected mutations that can often be suspected and confirmed by Southern blot and MLPA analysis.

It is more difficult to screen for the nondeletional forms of α thalassemia. Because the α1 and α2 genes can be amplified independently, those that cause a restriction site change can be readily identified. In the remaining cases for which one strongly suspects a nondeletion mutation the simplest procedure is to screen by DNA sequence analysis (Chapter 28).

CONCLUSIONS

This chapter has reviewed all of the natural sequence and structural variants that have been observed in and around the human α-globin gene cluster. These mutations have been of great value in pointing to regions of the chromosome that are important in the regulation of α-globin gene expression. Equally, some have ruled out other segments of the cluster as being important in this respect. From a clinical and hematological point of view it is important to remember that the mutations that cause α thalassemia are among the most frequently encountered human genetic abnormalities and in some areas of the world give rise to severe genetic diseases. The careful definition of these mutants has therefore underpinned the development of logical and comprehensive screening programs (see Chapters 26 and 28) to prevent the most severe forms of α thalassemia.

The Pathophysiology and Clinical Features of α Thalassemia

Douglas R. Higgs

INTRODUCTION

The primary abnormality in patients with α thalassemia is the underproduction of α-globin chains. Important secondary effects occur because of the continued production of excess γ chains in fetal life, which form the γ4 tetramer (Hb Bart's) and excess β-chains in adult life producing a β4 tetramer (HbH). Excess, unmatched non-α-globin chains damage the developing erythroid precursors, giving rise to intramedullary hemolysis or ineffective erythropoiesis. In addition, the presence of Hb Bart's and HbH cause premature destruction of mature red cells, giving rise to the predominant pathophysiology of α thalassemia that involves extravascular hemolysis.[1]

As set out in Chapter 13 and http://globin.bx.psu.edu/hbvar/[2] we currently know of approximately 80 mutations associated with α^+ thalassemia and approximately 40 that cause α^0 thalassemia. There are potentially several hundred different interactions that could take place between the large numbers of determinants described. Phenotypically, these interactions result in one of three broad categories; α thalassemia trait, in which there are mild hematological changes but no major clinical abnormalities, HbH disease, and the Hb Bart's hydrops fetalis syndrome. We shall consider each of these in this chapter.

The information set out in Chapter 13 suggests that the α thalassemia determinants can be arranged in the order of their severity (from αα to --) as shown in Table 14.1. In general the phenotypes resulting from their interactions correlate well with the reduction in α-chain synthesis predicted for each mutation. Although this scheme accurately predicts the outcome of interactions between chromosomes in which α-chain synthesis is abolished (α^0 thalassemia) or reduced (α^+ thalassemia) by a simple deletion, the pathophysiology and consequent hematological effects appear more complex and less predictable when nondeletional defects are involved. One might expect that nondeletional defects affecting the α2 gene would cause a greater reduction in α-globin synthesis than those affecting the α1 gene (see Chapter 13) and in general this appears to be so. Aberrantly processed mRNA or structurally abnormal globin chains may, however, have additional deleterious effects on erythropoiesis and red cell metabolism, producing a more severe effect on phenotype than would be predicted simply from the associated reduction in normal α-globin chain synthesis.

α THALASSEMIA TRAIT

The term α thalassemia trait describes a spectrum of phenotypes spanning the clinical and hematological gap between normal individuals and those with HbH disease (discussed later). Such individuals usually originate from tropical or subtropical regions of the world (see Chapter 26) and have a hypochromic, microcytic blood picture with a normal or slightly reduced level of HbF and HbA_2. The main differential diagnosis is from iron deficiency, the anemia of chronic disorders, the "low HbA_2" types of β thalassemia trait (see Chapter 16) and, rarely, sideroblastic anemia. In addition to the hypochromic microcytic red cell indices,[3] characteristic, diagnostic features of α thalassemia trait include a raised level of Hb Bart's (γ4) at birth,[4,5] the presence of HbH (β4) inclusions in adults (first reported in ref. 6, 7) and the demonstration of a reduced α/β-globin chain synthesis ratio.[8] Unfortunately, these diagnostic parameters fail to identify a significant proportion of carriers for α thalassemia and discriminate poorly between carriers with different molecular defects. Before the application of molecular biology to this problem (around 1980) these 'blunt' diagnostic tools produced a huge amount of confusing literature on the distribution, frequency and genetics of α thalassemia reviewed in Weatherall and Clegg.[9]

The geographical distribution and frequency of α thalassemia are now well documented (Chapter 26) and knowing the ethnic origin of any individual under investigation provides an important initial guide to the potential types of α thalassemia that may be present. We know that α thalassemia trait most frequently results from interactions between a normal haplotype, αα, and one of the α^0 or α^+ thalassemia defects.[10] α Thalassemia trait also occurs in some homozygotes and compound heterozygotes for α^+ thalassemia (e.g., -α/-α, -α/$\alpha^T\alpha$ and some $\alpha^T\alpha/\alpha^T\alpha$).

α/β-Globin mRNA and Globin Synthesis Ratios in α Thalassemia Trait

Experiments using heterologous cell-free assays consistently show that mRNA from the reticulocytes of patients with α thalassemia direct the synthesis of less α- than β-globin.[11–14] Subsequently, it has been shown that this results from under representation of accumulated mRNA in most determinants of α thalassemia.[15–18] Hunt et al.[19] were the first to analyze the α/β-globin mRNA ratios in carriers of α thalassemia and although the precise genotypes of the

Table 14.1. Ineractions producing the phenotype of α thalassemia

			α⁺				α⁰	
		αα	ααᵀ	-α	αᵀα	-αᵀ	(αα)	--
α⁰	--	T	H	H	H,Hy			Hy
	(αα)	T		H				
α⁺	-αᵀ	T		H	T	H		
	αᵀα	T		T	H, Hy			
	-α	T		T				
	ααᵀ	T						
	αα	N						

N = nonthalassemic; T = α thalassemia trait; H = HbH disease; Hy = Bart's hydrops fetalis syndrome.

patients studied were not known, they demonstrated clear differences between normal individuals and obligate carriers of α thalassemia (Fig. 14.1).

Subsequently studies using reverse transcription polymerase chain reaction (PCR)–based quantitation of α- and β-globin mRNA in patients with accurately known genotypes have confirmed these observations.[20,21] Although Hunt et al.[19] showed no overlap in the α/β-globin mRNA ratios of normal individuals and those with α thalassemia trait, other studies demonstrated wider variation.[20,21] Nevertheless, Smetanina et al.[21] confirmed that the α/β-globin mRNA ratios of patients with two functional α genes (-α/-α and --/αα) are quite distinct from those of nonthalassemic individuals (αα/αα).

The α/β-globin chain biosynthesis ratios in patients with well-defined α-globin genotypes, measured by *in vitro* hemoglobin synthesis[8,22–24] broadly reflect the α/β-globin mRNA ratios (Fig. 14.2 and Table 14.2). Again carriers of α thalassemia with two functional α genes (-α/-α and --/αα) can be clearly distinguished from normal individuals (αα/αα).

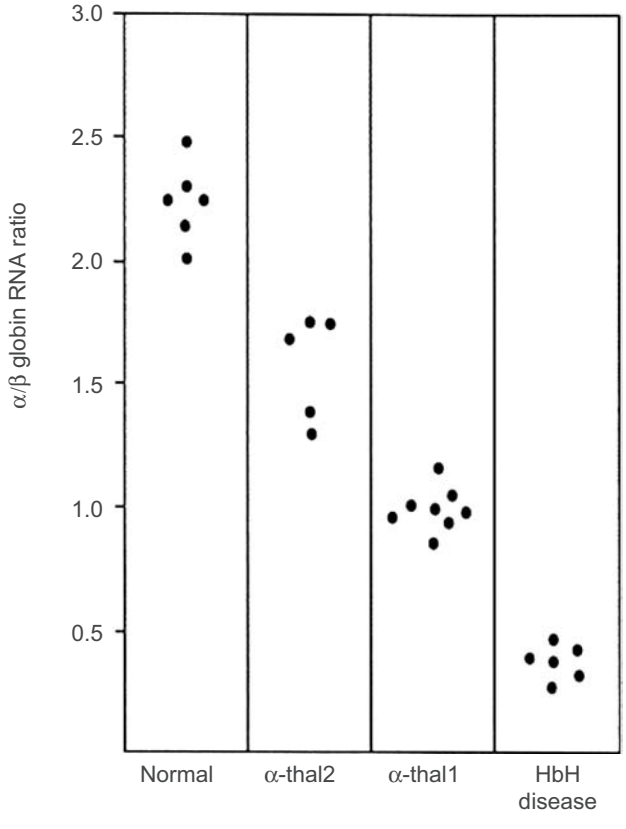

Figure 14.1. α/β-Globin-specific RNA ratios determined by cDNA hybridization with total RNA prepared from the peripheral blood of nonthalassemic individuals or obligate carriers with mild (α^+ thalassemia) or severe (α^0 thalassemia) α thalassemia trait or HbH disease. (The data are redrawn from ref. 19.)

It is interesting that the same trends in α/β-globin mRNA, globin synthesis, and hematological indices (see later) are seen when comparing individuals with four, three, or two functional α genes. In each case individuals with two α genes can be clearly distinguished from those with four genes. The values in those with three genes (-α/αα) overlap the two groups but are more closely related to those with four genes (αα/αα).

At present mRNA and globin synthesis ratios have been evaluated in relatively few patients with nondeletional determinants of α thalassemia. Nevertheless, one would predict that α/β mRNA ratios might be a poor way to evaluate such patients because, in some instances, the red cell precursors will contain nonfunctional mRNA and in many cases structurally abnormal mRNA and globin chains may be metabolized in quite complex ways during erythroid maturation.

All of these observations highlight the absolute necessity for accurate genotype analysis (see Chapter 13) when evaluating and counseling individuals with α thalassemia trait.

Red Cell Indices and Hematological Findings in α Thalassemia Trait

In the following discussion we will first consider the effect of α-globin deletions on red cell indices, comparing normal individuals (αα/αα) and those with α thalassemia trait (-α/αα, -α/-α and -/αα). As discussed in Ganczakowski et al.[25] and Williams et al.[26] we make no distinction between the $-\alpha^{3.7}$ and $-\alpha^{4.2}$ defects. Although the hematological effects of such deletions will be illustrated by reference to specific studies, it is important to remember that these measurements can vary from one normal (αα/αα) population to another,[27] and, in practice, slight variations may also be obtained even in healthy, nonthalassemic individuals.[28]

Unbalanced globin synthesis in α thalassemia leads to a deficiency in the amount of Hb per cell and because Hb accounts for 30%–35% of the red cell content the red cell volume is also reduced producing hypochromic, microcytic cells with an increased surface area to volume ratio (hence target cells). In general, individuals with α thalassemia trait

The number of samples (N), mean (μ), and unbiased estimate of the standard deviation (SD) are shown for the nine possible combinations of the αα, -α, α^T α and -- genotypes (excluding --/--), in increasing order of severity, for the age groups (years) 1–4, 5–9, 10–15, and ≥16 (adult). (The normal data are derived from refs. 240–242; the principal sources for the α thalassemia data are described in the text. In addition to the unpublished datasets acknowledged in ref. 10 further valuable series were contributed by CC Thompson (Hamilton, Ontario) and T Sophocleous (Nicosia).) Because of significant sex differences, the hemoglobin and RBC counts are tabulated separately for adult men and women; although both MCV and MCH tend to be slightly higher in males than females, the relative differences are much smaller (~1 fL and ~0.5 pg, respectively), so these data are pooled, as are the α/β-globin chain synthesis ratios for all ages.

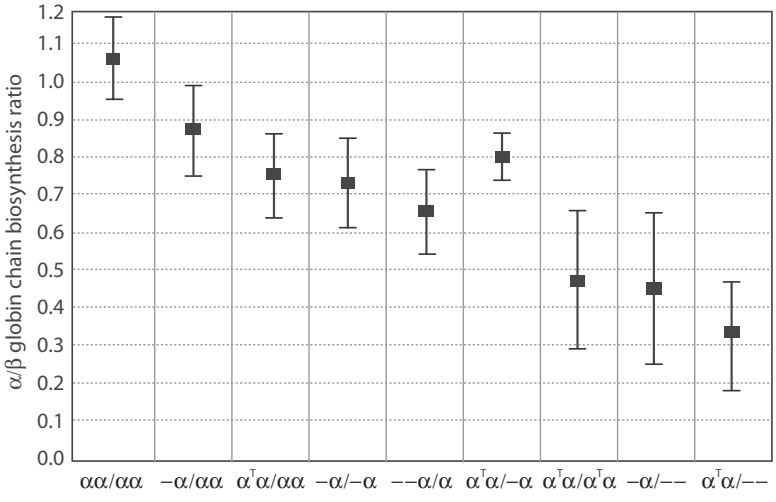

Figure 14.2. The α/β-globin chain biosynthesis ratios in individuals with well-defined α-globin genotypes. (Data derived from the references in the legend to Table 14.2.)

due to simple gene deletions (-α/αα, -α/-α and --/αα) have lower levels of total hemoglobin, mean corpuscular hemoglobin concentration (MCHC), mean corpuscular volume (MCV), and mean corpuscular hemoglobin (MCH) but higher red blood cell (RBC) counts than nonthalassemic (αα/αα) individuals (Table 14.2 and Fig. 14.3).

The degree of abnormality varies from one parameter to another. The greatest differences are seen in MCH (Figs. 14.3 and 14.4); individuals with α thalassemia clearly make less hemoglobin per cell than normal individuals. Despite this, patients with α thalassemia trait maintain adequate hemoglobin levels (within ~1.0–1.5 g/dL of normal) at all stages of development (Figs. 14.3 and 14.4). It appears that the main compensatory mechanism for the underproduction of hemoglobin in each red cell occurs via an increase in the concentration of red cells (RBC count) maintained in the peripheral blood.

Developmental changes in the hematological indices of individuals with α thalassemia trait follow the same patterns as those of normal individuals (αα/αα). Hemoglobin, hematocrit, MCH, and MCV fall rapidly after birth and begin to rise slowly in the second year. The RBC count is relatively low at birth and then rises slowly. Throughout development one can clearly distinguish the hematological indices found in patients with the αα/αα, -α/αα, and -α/-α genotypes. For all parameters there is a greater difference between those with the -α/-α and -α/αα genotypes and those with the -α/αα and αα/αα genotypes. The smaller data set for individuals with the --/αα genotype most closely resembles those with -α/-α genotype. Few differences are seen between males and females prior to puberty after which there are significant sex-dependent differences in both hemoglobin and RBC count in all genotypic groups (Fig. 14.4).

At present there are insufficient developmental data to extend these conclusions to all determinants of α thalassemia. There is now, however, adequate information to compare hematological indices in adults with various interactions that produce α thalassemia trait (Fig. 14.3). Although there is a good correlation between the predicted reduction in α-chain synthesis and hemoglobin, MCV, and MCH, there is considerable overlap. Therefore these indices are of only limited value in distinguishing one genotype from another. It is clear that with the exception of the -α/αα genotype and some carriers of nondeletional mutations[29] most carriers of deletional types of α thalassemia can be distinguished from normal individuals on the basis of their MCH, which is usually less than 26 pg and always below 27 pg (refs. 10, 30, 31 and Table 14.2).

The peripheral blood film in patients with α thalassemia trait is quite variable from one genotype to another but often shows hypochromasia, with occasional poikilocytes and target cells (Fig 14.5). The reticulocyte count is usually raised to 2%–3% in patients with the severe forms of α thalassemia trait. Rees et al.[32] have shown that the levels of soluble serum transferrin receptors (sTfR), which reflect the erythroid cell mass, are raised in individuals with α thalassemia trait (-α/αα and -α/-α). They concluded that even patients with minimal globin chain imbalance have significant ineffective erythropoiesis and/or hemolysis. Red cell survival and erythrokinetic studies have not been performed in many cases of α thalassemia trait. In general, ^{51}Cr-labeled red cells from patients with α thalassemia have a shortened red cell half-life in the circulation,[33] and specifically, red cell ^{51}Cr half-life estimates in two cases of α thalassemia trait reported by Wasi et al.[34] were 25 days and 29.5 days (normal range 25–30 d).

Hemoglobin Analysis in α Thalassemia Trait

The patterns of hemoglobin seen in adult individuals with α thalassemia trait are indistinguishable from those seen in normal individuals, although as a group they may have slightly lower levels of HbA_2. Based on a small survey,[35] there appeared to be no significant differences throughout development in the levels of HbA_2 and HbF between individuals with the αα/αα, -α/αα, and -α/-α genotypes (Fig. 14.6a).

Prior to the application of molecular genetic methods to the diagnosis of α thalassemia there was good evidence that a raised level of Hb Bart's (γ4) in the neonatal period (Fig. 14.7) indicated the presence of α thalassemia;[5] this was reviewed in Wasi et al.[34] It was not clear, however, if normal individuals (αα/αα) produced Hb Bart's at birth or if all individuals with α thalassemia had a raised level of Hb Bart's at birth. Furthermore, the relationship between the amount of Hb Bart's and the underlying molecular defect was not known. These issues have now been evaluated in

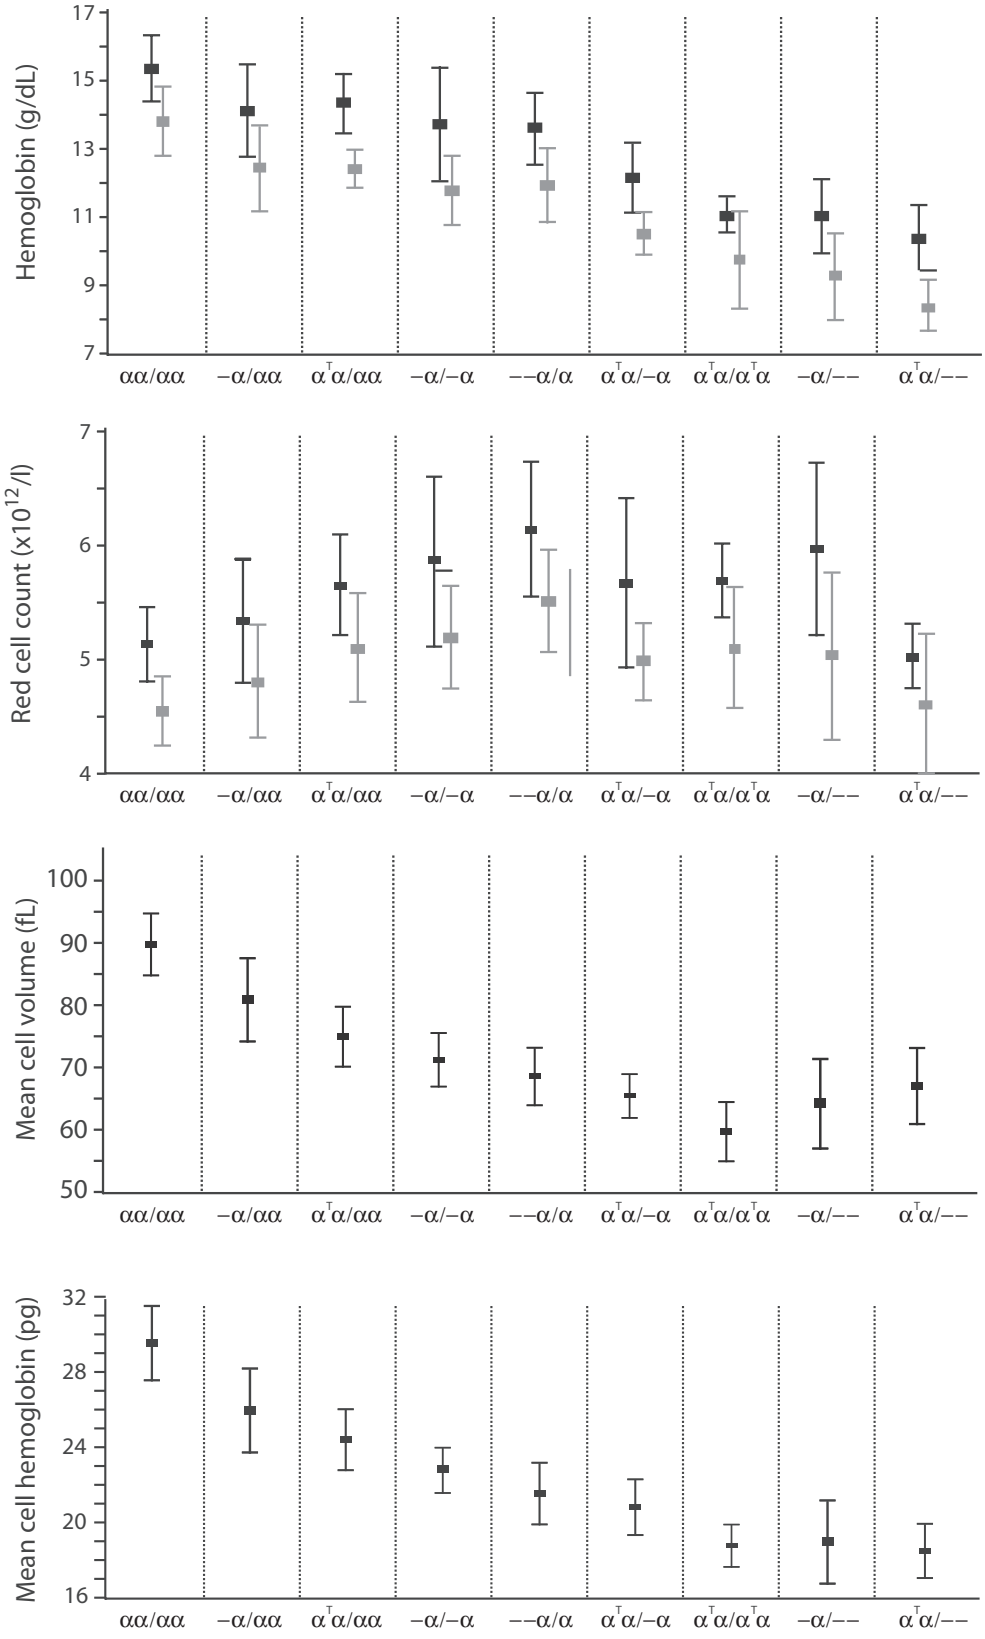

Figure 14.3. The RBC indices in patients with various genotypes associated with α thalassemia. For each set of data the mean and 1 SD is shown. For the level of hemoglobin and estimates of RBC count, differences between males (solid lines) and females (gray lines) are shown. (Data are from ref. 239.)

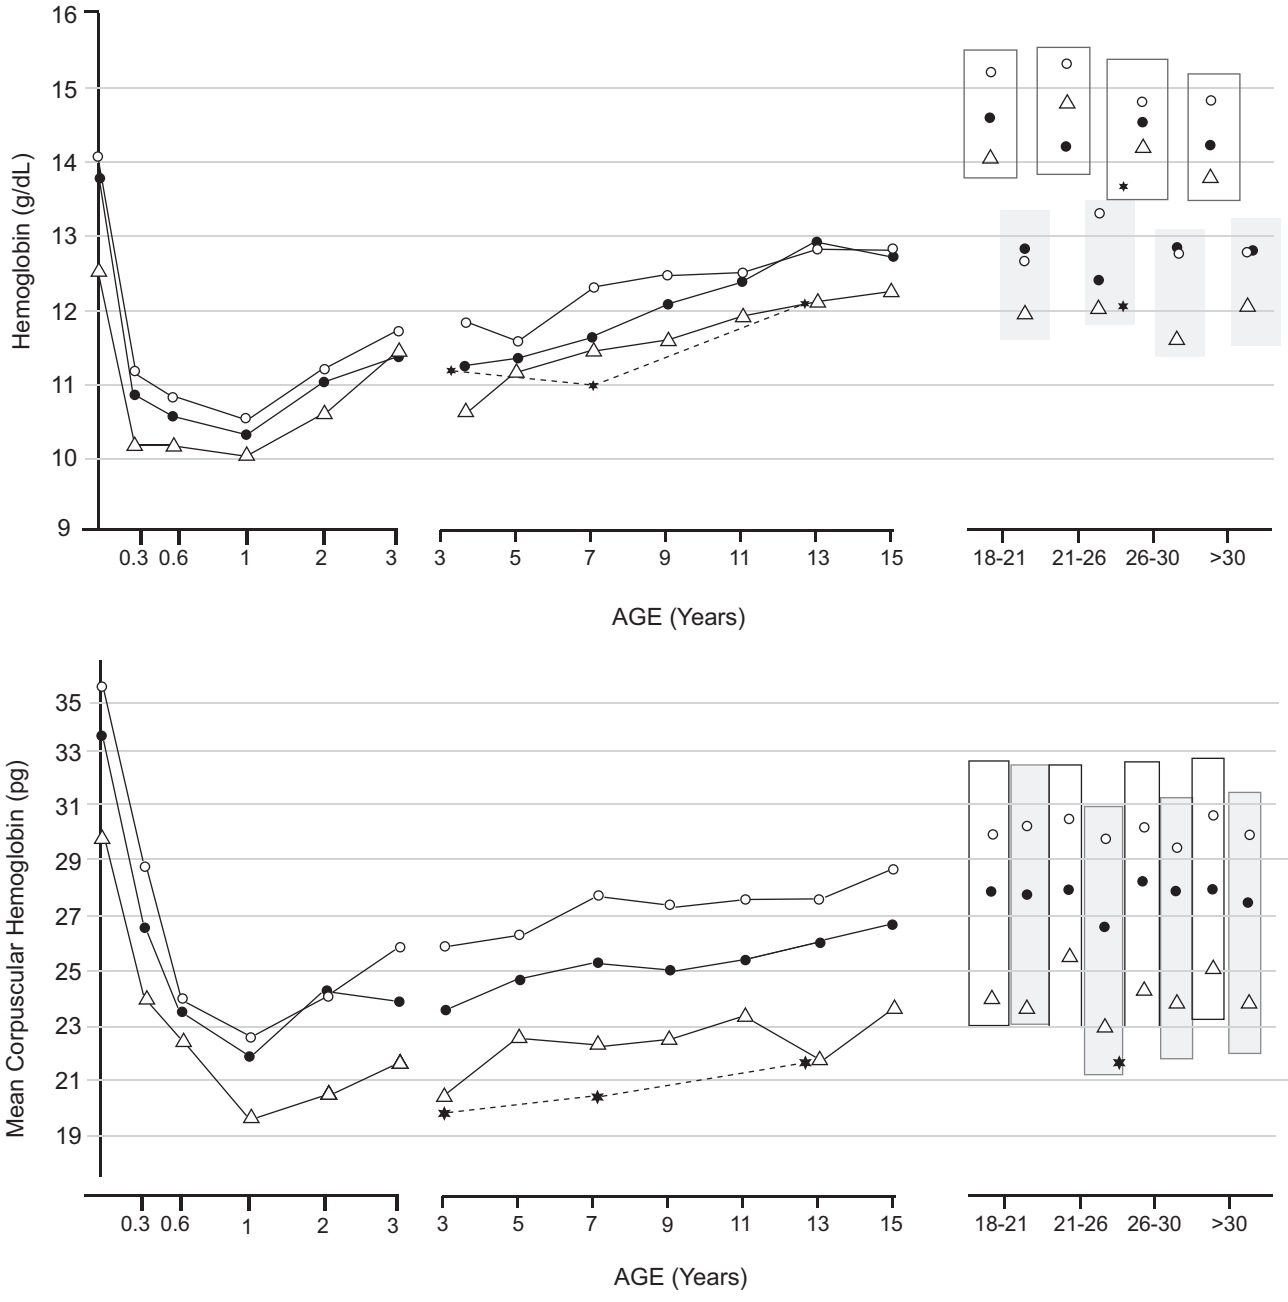

Figure 14.4. Developmental changes in the level of hemoglobin (above) and MCH (below) in individuals with the αα/αα (○), -α/αα (●), -α/-α (△), and –/αα (✱) genotypes. Beyond the age of 15 years results are grouped into males (hatched surround) and females (stippled background).

many surveys correlating the level of Hb Bart's with the α-globin genotype. Most surveys using assays that are sufficiently sensitive to detect a minimum of 0.5%–1% Hb Bart's at birth, detect a large proportion of neonates with α thalassemia but may not detect all cases with the mild -α/αα interaction.[36] Therefore, surveys based solely on the presence of Hb Bart's in the cord blood may underestimate the frequency of α thalassemia. More recent surveys have confirmed that the level of Hb Bart's correlates well with the α globin genotype and that this provides a useful screening tool for α thalassemia.[37,38] Although the levels of Hb Bart's are generally related to the degree of α-chain deficit they do not accurately distinguish the various α genotypes.

During the first 6 months after birth, the level of Hb Bart's in individuals with α thalassemia declines (Fig. 14.6b) and eventually becomes undetectable by conventional assays,[5] although minute amounts may be detected in adults with α thalassemia by using an immunological assay.[39] Similarly small amounts of embryonic ζ-globin chains can be detected (using an enzyme-linked

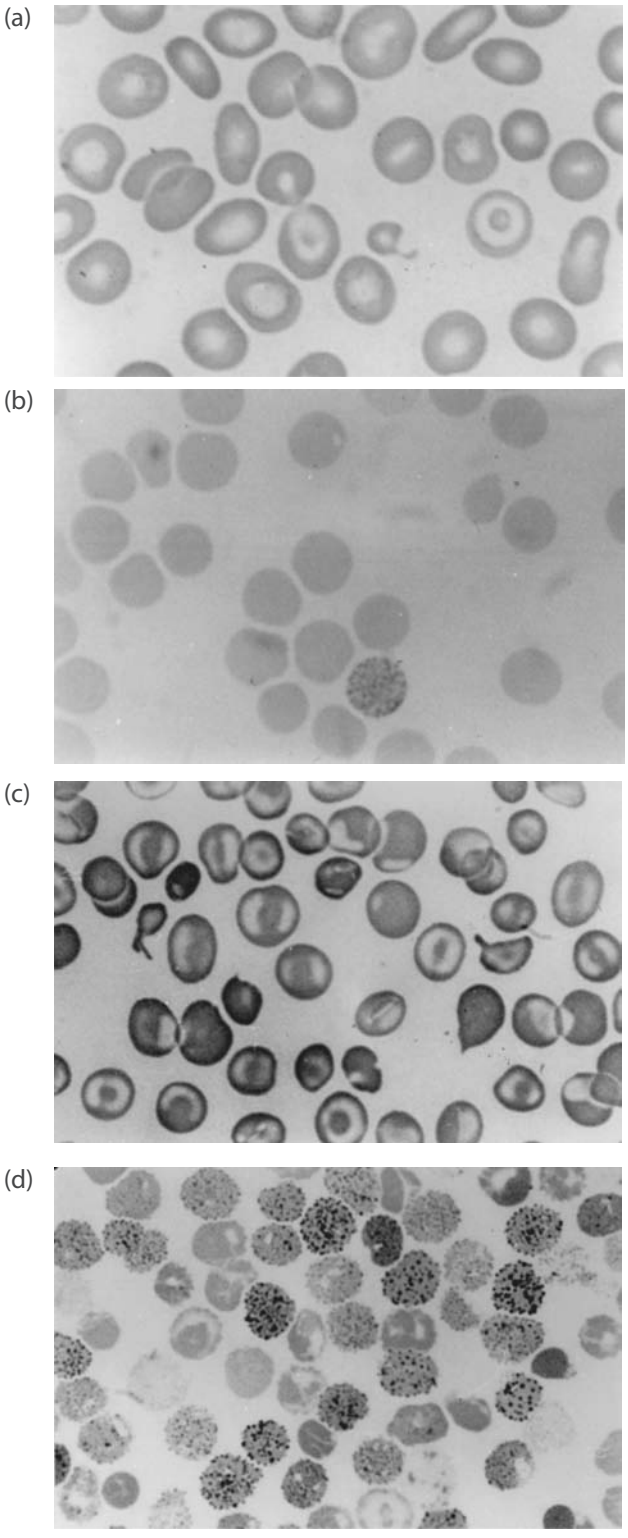

Figure 14.5. Typical hematological findings in patients with α thalassemia trait **(a)** and HbH disease **(c)**. Rare HbH inclusions may be found in patients with α thalassemia trait **(b)**, whereas they are commonly found in patients with HbH disease **(d)**.

immunosorbent assay) in some adults with α thalassemia.[40] It is now clear that this detects a significant proportion of individuals with the $-^{SEA}/\alpha\alpha$ genotype and could be used as a simple way of detecting carriers of this specific mutation (but no others).[41]

Unfortunately, from a diagnostic point of view, Hb Bart's is not replaced by an equivalent amount of HbH in adults; however, occasional cells containing HbH can be detected (Fig. 14.5) in up to 65% of individuals with α thalassemia trait.[42] In our experience using the standard HbH preparations,[43] inclusions are usually found in individuals with α thalassemia trait due to the --/αα, $\alpha^T\alpha/\alpha\alpha$, $-\alpha/\alpha^T\alpha$, $\alpha^T\alpha/\alpha^T\alpha$, and (αα)/αα genotypes but very rarely in those with the -α/αα and -α/-α genotypes (for example see Lafferty et al.[41] and unpublished). Various modifications of the standard HbH preparation may significantly increase the sensitivity of this assay. This is fully discussed in Sabath et al.[44]

α Thalassemia commonly occurs in areas where β-globin variants (e.g., HbS, HbC, and HbE) are also found at a high frequency. The presence of α thalassemia can alter the proportion of variant hemoglobin found in the peripheral blood and therefore, when α thalassemia coexists with β variants the proportion of hemoglobin variant can be a sensitive guide to the presence of α thalassemia (see Chapter 26 and later). In regions where both β thalassemia and α thalassemia are common some individuals with microcytosis and a raised level of HbA_2 may concomitantly harbor α thalassemia.[45] Without correct diagnosis the risk of these individuals producing offspring with HbH disease or Bart's hydrops fetalis (see later) may be overlooked.[30]

Management and Genetic Counseling of α Thalassemia Trait

Individuals with α thalassemia trait are clinically normal and require no specific treatment. Nevertheless, it is important to recognize this condition to avoid unnecessary investigation of the hypochromic microcytic indices and to ensure that the patient does not receive inappropriate treatment with hematinics, which may be harmful.

A diagnosis of α thalassemia trait should be considered in any individual from tropical or subtropical areas of the world (see Chapter 26) who has a reduced MCH but a normal level of HbA_2 (<3.5%) and a normal iron status: Such patients with MCH of 26 pg or less almost always have α thalassemia trait. The geographical and ethnic origin of the patient may provide an important guide to the underlying molecular defect (Chapter 13). In some patients there may be a family history of HbH disease or Hb Bart's hydrops fetalis (see later). In most (at least >70%[41]) patients with α^0 thalassemia and some with α^+ thalassemia, the diagnosis can be confirmed by demonstrating HbH inclusions in the peripheral blood. In most clinical situations there is no need to pursue investigations beyond this stage because a definitive diagnosis can only be made by DNA

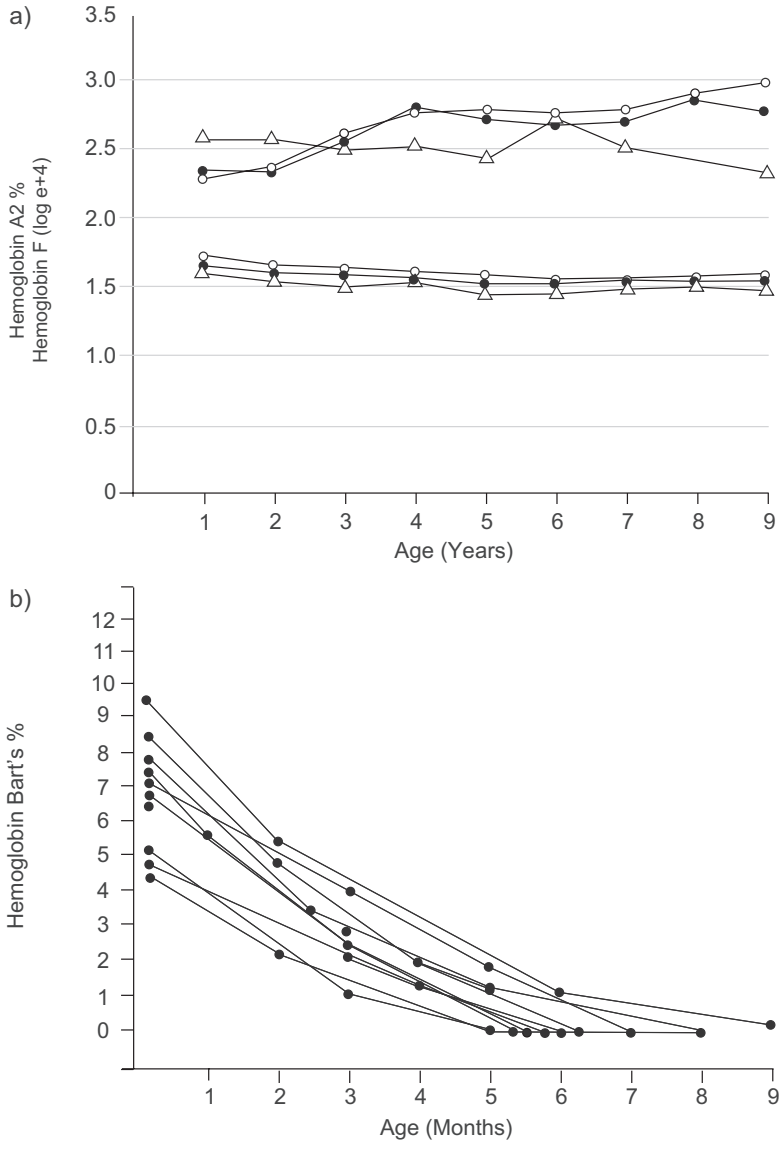

Figure 14.6. Above, developmental changes in the levels of HbA_2 (above in **a**) and HbF (below in **b**) in patients with the αα/αα (○), -α/αα (●), and -α/-α (△) genotypes (data from ref. 35). Below, developmental changes in the level of Hb Bart's in individuals with α thalassemia during the first few months of life. (Redrawn from ref. 5.)

analysis, using one or other of the PCR- and multiplex ligation–dependent probe ammplification–based protocols described in Chapter 13.

The main indication for further investigation occurs when a potential carrier of α thalassemia requires genetic counselling to avoid the Hb Bart's hydrops fetalis syndrome or, rarely, severe transfusion dependent forms of HbH disease (see later). Because resources for genetic screening are limited, efforts should be concentrated on individuals most at risk of producing infants with the Hb Bart's hydrops fetalis syndrome. Ideally, one should identify all southeast Asian women with an MCH of 26 pg or less before or soon after they become pregnant (most carriers of the common α^0 thalassemia defects will have an MCH of between 20 and 26 pg). The partners of such individuals should be screened and if they too have α thalassemia trait, with an MCH of 26 pg or less, the couple should be offered counseling and genotype analysis (see later). If resources are available this approach should be extended to individuals of Mediterranean or mixed ethnic origins who are much less commonly at risk.

α Thalassemia Trait and Pregnancy

The physiological changes of pregnancy result in an increase in plasma volume (~40%–45%) and red cell mass (20%–30%), which by the third trimester results in a variable fall in hemoglobin concentration (10.5–14.5 g/dL) even in normal women.[46] In addition increased maternal and fetal demands for hematinics (iron and folic acid) may lead to a further drop in hemoglobin if there is no supplementation. It is not surprising therefore that pregnant women with HbH disease, and to a lesser extent α thalassemia trait, may become anemic.

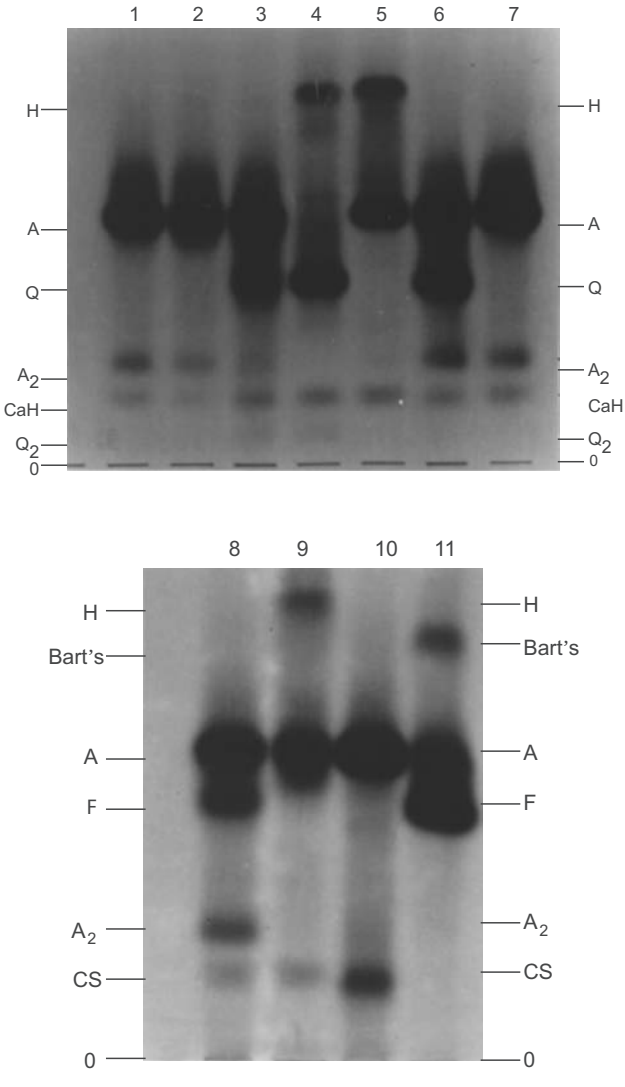

Figure 14.7. Hemoglobin electrophoresis (stained with Coomassie blue) in normal individuals (1, 2, and 7), a heterozygote for hemoglobin Q (3), hemoglobin Q-H disease (4), hemoglobin H disease (5 and 9), a heterozygote for hemoglobin S (6), a homozygote for hemoglobin Constant Spring (CS) (10), and cord blood with an elevated level of hemoglobin Bart's (11). o denotes the origin and CaH indicates the position of carbonic anhydrase.

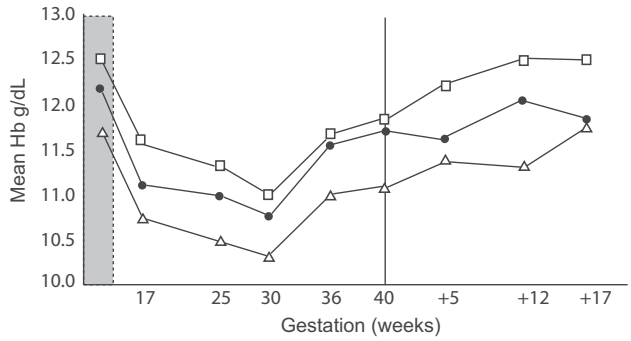

Figure 14.8. Changes in the level of hemoglobin in pregnant women with the αα/αα (□), -α/αα (•), and -α/-α (△) genotypes. Results in shaded area indicate normal values prior to pregnancy. The thick black vertical line denotes the usual time of birth (From M. Ganczakowski and D.K. Bowden, personal communication.)

In a prospective study of 987 pregnancies O'Donnell et al.[47] found that the median Hb concentration (and red cell indices) was significantly lower in women homozygous for α^+ thalassemia than those with a normal α-globin genotype. Similar results have been obtained by others.[48,49] M. Ganczakowski and D.K. Bowden (unpublished) studied 515 pregnant women in Vanuatu with the αα/αα (53%), -α/αα (34%), and -α/-α (13%) genotypes. The changes in hemoglobin (Fig. 14.8) and red cell indices were similar in all three groups: the greatest fall in hemoglobin (~1.4 g/dL) occurring around 30 weeks of pregnancy. Only a small proportion (6%) of women with the -α/-α genotype developed an Hb of less than 9 g/dL, which was not significantly different from those in the αα/αα group, of whom 5% developed an Hb below 9 g/dL. The red cell indices (MCV and MCH) showed a small increase (5%–7% of nonpregnant value) in pregnant women with α thalassemia (-α/αα and -α/-α). In none of these studies were the minor changes in hematological indices and Hb levels associated with any adverse effects on the outcome or course of pregnancy.

α THALASSEMIA CAUSING MILD HEMOLYTIC ANEMIA

As set out previously, carriers for both deletional and nondeletional forms of α thalassemia trait have hypochromic microcytic red cell indices but are asymptomatic. Some homozygotes for nondeletional α^+ thalassemia have more severely affected indices[50] but nevertheless have the phenotype of α thalassemia trait. Homozygotes for other nondeletional mutations (e.g., $\alpha^{T\ Saudi}\alpha/\alpha^{T\ Saudi}\alpha$) may have HbH disease[51] and rarely hydrops fetalis[52,53] (see Table 14.1 and later). Patients homozygous for some nondeletional mutations have a phenotype intermediate between α thalassemia trait and HbH disease with a mild hemolytic anemia; this situation has been particularly well documented in patients homozygous for the Hb Constant Spring mutation ($\alpha^{cs}\alpha/\alpha^{cs}\alpha$).

The homozygous state for Hb Constant Spring was first described by Lie-lnjo et al.[54] Since that time several homozygotes have been described[55,56] with a large survey of 22 patients presented by Pootrakul et al.[57] In this report, all of the patients had mild anemia (hemoglobin 10.3 ± 1.4 g/dL) and the majority of cases had mild jaundice with total serum bilirubin levels elevated in 8 of 14 cases examined. Splenomegaly was detectable in most cases and mild hepatomegaly was present in approximately half.

The hematological indices were very unusual for patients with α thalassemia. The RBC count was low (3.9 ± 0.9 × 10^{12}/L) with a normal mean corpuscular volume (MCV 88 ± 6 fL) and only slightly reduced MCH (26 ± 3 pg). The peripheral blood films showed mild anisocytosis and hypochromia with a few fragmented cells. Approximately 6% of the cells showed basophilic stippling and reticulocyte

counts were consistently raised (6.0% ± 3.3%). Chromium-51 RBC count survival was reduced (17.3 and 20.5 days) in the two patients studied. In 6 of 15 patients studied transferrin iron saturation was greater than 50%. All of these findings suggest that these patients have a mild hemolytic anemia resulting from the attachment of partially oxidized α^{cs} chains on the red cell membrane and its cytoskeleton, which cause increased membrane rigidity and stability. Hemolysis in patients with homozygous Hb Constant Spring may be exacerbated during intercurrent infections or oxidative stress.[58]

Starch gel electrophoresis (for example see Fig. 14.7) provided conclusive evidence that these patients have α thalassemia. One newborn infant had 14.2% Hb Bart's that fell to 4.6% at 8 months.[55] In the study of Pootrakul et al.[57] seven adults had raised levels (1.8%–3.6%) of Hb Bart's and similarly raised levels have been seen in adults in other studies. The levels of Hb Constant Spring varied from 2.6% to 11.6%.

Another surprising aspect of this condition is that prolonged incubation of reticulocytes for *in vitro* globin chain synthesis revealed an α/β-globin synthesis ratio of 1.5 ± 0.16 rather than a reduced ratio as one would expect. This appears to result from the fact that globin synthesis only remains linear in the cells of $\alpha^{cs}\alpha/\alpha^{cs}\alpha$ homozygotes for approximately 30 minutes, an unexpectedly short time for samples with such a high reticulocyte count. This together with the rapid removal of excess β-globin chains accounts for the high α/β ratios observed in 2–3 hour incubations.[59] It remains to be seen if other patients, homozygous for some nondeletional forms of α thalassemia have similar findings to those with Hb Constant Spring.

HEMOGLOBIN H DISEASE

Interactions between the many determinants of α thalassemia (Table 14.1) lead to a spectrum of clinical and hematological phenotypes ranging from normal individuals to infants with the lethal, Hb Bart's hydrops fetalis syndrome. Young children (>6–12 months) and adults with sufficient globin chain imbalance to produce readily detectable levels of HbH (>1%–2%) in the peripheral blood on routine hemoglobin electrophoresis (Fig. 14.7) are said to have HbH disease. HbH inclusions are always detectable in the peripheral blood of such individuals (Fig. 14.5).

Not surprisingly, patients defined in this ad hoc way span a wide range of clinical and hematological phenotypes. The majority are clinically well and in these the epithet HbH "disease" may be inappropriate. Some have thalassemia intermedia. The most severe forms of HbH disease may be lethal late in gestation or in the perinatal period, causing a condition referred to as HbH hydrops fetalis (see later).

Extensive surveys have demonstrated that most cases of HbH disease occur in patients from southeast Asia, the Mediterranean basin, and the middle East (see Chapter 26). This geographical distribution is easily explained now that we understand the molecular basis of this disorder (Table 14.1). HbH disease most commonly results from the interaction of α^0 and α^+ thalassemia. Although α thalassemia is common throughout all tropical and subtropical regions, α^0 determinants (and hence HbH disease) are predominantly found in the Mediterranean and southeast Asia. In southeast Asia the most common genotype associated with HbH disease is $--^{SEA}/-\alpha$ whereas in the Mediterranean $--^{MED}/-\alpha$ and $-(\alpha)^{20.5}/-\alpha$ are the most frequent (reviewed in Chui et al.[1]). Less often HbH disease results from the interaction of α^0 thalassemia with nondeletional forms of α^+ thalassemia (genotype $--/\alpha^T\alpha$) or in homozygotes for some nondeletional forms of α^+ thalassemia (genotype $\alpha^T\alpha/\alpha^T\alpha$).[51,60–67] Again these molecular interactions are most frequently seen in southeast Asia and the Mediterranean but also occur at high frequencies in some areas of the middle East (see Chapter 26).

Despite these useful geographical "rules of thumb," one should be aware that patients with α thalassemia trait and HbH disease have been described in almost every racial group. On detailed examination, patients originating from regions where α thalassemia is otherwise rare are often found to have unusual and biologically interesting molecular defects.

The Pathophysiology of HbH Disease

In HbH disease there is a moderately severe reduction in α globin RNA and α globin chain synthesis (see later). During fetal life excess γ chains form γ_4 tetramers (Hb Bart's). Similarly, in adults (after the γ to β switch, Chapter 5) excess β-globin chains form β4 tetramers (HbH). Both of these homotetramers have high oxygen affinity, lack heme–heme interaction, and do not exhibit any Bohr shift.[68] Therefore, neither of these hemoglobins contributes to oxygen transport and their presence compounds the effects of anemia in patients with HbH disease. The reduced synthesis of HbA together with the production of nonfunctional Hb thus cause anemia and provoke an appropriate response of an increased level of erythropoietin.[62,69]

A second component of the pathophysiology arises from the fact that HbH is unstable and when oxidized forms intracellular precipitates, which cause cell death in a proportion of erythroblasts leading to ineffective erythropoiesis. This is reflected in an increase in the level of serum transferrin receptors (sTfR) reflecting the increased number of erythroid precursors in the bone marrow.[62,69] Thirdly, and most importantly, when HbH precipitates it attaches to the cell membrane in circulating red cells as they age. This in turn causes local oxidative damage and membrane dysfunction. Thus the erythrocytes in HbH disease are rigid and their membrane is more stable than normal.[70,71] Loss of normal membrane phospholipid asymmetry, exposure of phosphatidylserine, and the presence of increased amounts of Immunoglobulin G on the cell surface may

also enhance the engulfment of abnormal, ageing red cells by macrophages. Together these properties are thought to slow the passage of red cells through the microvasculature and promote erythrophagocytosis causing extravascular hemolysis, which is reflected in an increase in the reticulocyte count.[62,69,72,73]

The red cell survival, as judged by ^{51}Cr studies is reduced in patients with HbH disease; reported figures range from 8–17 days.[74–77] External scanning indicates that most of the red cell destruction occurs in the spleen.[76,77] Srichaikul et al.[78] performed full erythrokinetic studies on nine, non-splenectomized patients with HbH disease. They demonstrated a reduced red cell volume, increased plasma volume, and a reduced red cell survival of 6–19.5 days (normal range 25–32 days) with sequestration of ^{51}Cr-labeled red cells in the liver and spleen. In addition they showed that patients with HbH disease have a rapid clearance of ^{59}Fe with relatively good ^{59}Fe incorporation into red cells compared with patients with β thalassemia. They also found that the patient's hematocrit was correlated to the red cell survival. Together these findings suggest that both hemolysis and ineffective erythropoiesis contribute to anemia in HbH disease but most studies have concluded that the predominant mechanism is extravascular hemolysis.

α/β mRNA and Globin Synthesis Ratios in Patients with HbH Disease

As one would expect from the studies of α/β mRNA ratios in carriers of α thalassemia (see previously), the red cell precursors of patients with HbH disease contain approximately one half to one quarter of the amount of α-globin mRNA present in normal red cell precursors[11,16,19,21] as demonstrated in Figure 14.1. Again this is generally reflected in the α/β-globin chain synthesis ratios of patients with the deletional forms of HbH disease (average of 0.44, standard deviation 0.2, see Table 14.2 and Fig. 14.2. Also see Kanavakis et al.[62]). Excess β-globin chains synthesized during erythroid maturation mainly form β4 tetramers but in addition supply a small intracellular pool of β-chains that combine with newly synthesized α chains as they become available. Nevertheless, it is clear that HbH is not present in the peripheral blood in amounts reflecting the rate at which it is synthesized indicating that it must be lost from the red cells while they are in the circulation consistent with the pathophysiology set out previously.

Red Cell Indices and Hematological Findings in HbH Disease

As before, we will first consider the effect of α-globin deletions on red cell indices, comparing individuals with one functional α gene (--/-α) with normal individuals (αα/αα). Those who inherit only a single α gene have lower levels of total hemoglobin, MCH and MCV but higher RBC counts than nonthalassemic (αα/αα) individuals (Table 14.2 and Fig. 14.3). Similar trends have been shown by others.[1,62,73] These differences in hematological indices are seen at all stages of development (see Table 14.2) although at present there are only anecdotal data on infants with HbH disease in the perinatal period or during the early months of life.[73,79] Perhaps the most important hematological finding is that, using data accumulated from a variety of surveys (see Table 14.2) patients with HbH disease are anemic with, on average, approximately 2–g/dL less hemoglobin than age and sex matched normal individuals. It has been noted in some surveys that there may be striking fluctuations in the level of hemoglobin measured sequentially in the same individual over the course of 1–2 years,[34,80] although in our experience, and that of others[73] this is not common.

The peripheral blood film shows hypochromia and polychromasia with variable anisopoikilocytosis and target cells (Fig. 14.5). The reticulocyte count is usually raised to approximately 3%–6%, although higher counts may be observed.[72,73,81] Nucleated red cells and basophilic stippling may be present[34] but in our more limited experience this is quite rare.

Although bone marrow examination is rarely necessary in the investigation of patients with HbH disease, when analyzed it shows erythroid hyperplasia with only slight or absent deposition of hemosiderin.[34] The erythroid hyperplasia is reflected increased levels of sTfR in the peripheral blood.[62,69]

Over the past 10–15 years the precise genotype of many patients with HbH disease has been established. In addition to the common deletional forms (--/-α) discussed previously, HbH disease may also result from interactions involving nondeletional determinants (--/$\alpha^T\alpha$ and $\alpha^T\alpha/\alpha^T\alpha$). Using data from several studies (Table 14.2 and Fig. 14.3), patients with nondeletional HbH disease and the $\alpha^T\alpha/\alpha^T\alpha$ genotype have hematological indices that are similar to those with the deletional type of HbH disease (--/-α), whereas those with the --/$\alpha^T\alpha$ are slightly more anemic with lower RBC counts and higher MCVs (Table 14.2 and refs. 1, 72, 73, 82). Limited data (Table 14.2) indicate that these differences are present throughout development.

Several studies have compared the hematological findings in patients with deletional forms of HbH disease (--/-α) and those with specific nondeletional defects including [--/$\alpha^{cs}\alpha$] (HbH-Constant Spring),[72,79,83] [--/$\alpha^{Nco}\alpha$] and [--/$\alpha^{Hph}\alpha$][61,73,84] and anecdotally many other rarer mutations (reviewed in refs. 1, 73). In all of these nondeletional genotypes one finds lower levels of hemoglobin and RBC counts but higher MCVs than in patients with the pure deletional types of HbH disease.

Hemoglobin Analysis in HbH Disease

Infants who go on to develop HbH disease later in life produce large amounts (19%–27%) of Hb Bart's (γ4) at birth.[34,85,86] During the first few months of development Hb Bart's falls and is replaced by variable amounts of HbH

in adult life. The level of Hb Bart's at birth often exceeds that of HbH in adult life. This is consistent with other observations[87] showing that HbH (β_4) is less stable than Hb Bart's ($\gamma 4$). Adults with HbH disease have 0.8–40% HbH in the peripheral blood. It has been consistently noted that patients with the nondeletional type of HbH disease (--/$\alpha^T\alpha$) produce larger amounts of HbH.[1,61,62,72,73,88,89] Hb Bart's may still be detected in some adults with HbH disease but HbH usually predominates; occasionally the fetal pattern, with an excess of Hb Bart's, persists.[90] The reasons why some patients with HbH disease produce significant amounts of Hb Bart's are not clear. It is possible that some have co-inherited β-globin clusters with point mutations that are associated with increased γ globin synthesis (see ref. 91 and Chapters 5 and 16).

HbH and Hb Bart's are easily detected as fast migrating bands on hemoglobin electrophoresis (Fig. 14.7). In addition HbH can be precipitated from peripheral blood red cells after incubation for 3 hours at room temperature (see ref. 43 for details). These characteristic inclusions are artefacts produced by the redox action of the dye (Fig. 14.5). The proportion of cells containing HbH inclusions is directly related to the level of HbH detected in the peripheral blood. Again patients with nondeletional α thalassemia have a higher proportion of HbH cells than those with the deletional types of HbH disease.[92] Even after prolonged incubation it is unusual to find inclusions in every cell; the reason for this heterogeneity is not clear. Splenectomized patients have large numbers of preformed inclusions in the red cells that can be detected by methyl violet staining.

Other minor changes in the hemoglobin composition found in patients with HbH disease include a tendency to low levels of HbA_2 (1%–2%) probably due to the lower affinity of α-chains for δ- than β-chains; when the supply of α chains is limited less HbA_2 is formed (Chapter 7). In addition, variant chains creating abnormal hemoglobins may be detected in patients with chain termination mutants (for example see ref. 93) and some unstable mutants associated with α thalassemia (e.g., Hb QuongSze and Hb Agrinio, see Chapter 13). Finally some α chain variants, such as Hb J Tongariki and Hb G Philadelphia may be linked *in cis* to α thalassemia variants (see Table 13.2 in Chapter 13).

Clinical Features of HbH Disease

Although HbH disease is quite a common genetic disorder in the Mediterranean, Middle East, and southeast Asia, there have been relatively few systematic studies addressing the natural history of this condition or the relationship between genotype and phenotype. Most physicians caring for such patients agree that there is a remarkably wide clinical spectrum but often comment on the mild nature of this condition. Even from the biased perspective of hospital-based studies, the majority of patients with HbH disease appear to have little disability.[1,9,61,62,72,73,94–97] However, it has emerged over the past 10 years or so that a minority of patients with HbH disease may be severely affected, requiring regular blood transfusion and rare cases may present as hydropic, newborn infants (see later).

The largest clinical experience of HbH disease, including data from 500 adults and 502 children, was summarized over 30 years ago by Wasi et al.[34] More recent studies have reviewed relatively large numbers patients whose molecular defects have been accurately defined,[1,62,72,73,79,82,98] allowing us to make some predictions about the severity of HbH disease based on genotype. The following discussion is largely based on these reviews.

Presentation

At birth, infants destined to develop HbH disease may have near-normal levels of hemoglobin with no hepatosplenomegaly,[34] whereas other newborn infants may already show evidence of hemolytic anemia.[73,79] In many infants, the clinical features of HbH disease (see later) develop in the first year of life. The age at which patients with HbH disease first present varies from birth to older than 70 years and in more than half of the patients the finding of HbH disease is incidental (e.g., associated with health checks or prenatal screening) or found during investigation for an unrelated illness. Some patients may first present at the time of an acute fall in the level of Hb,[62,72] as will be discussed. Anecdotally, survival of patients with HbH disease into adult life appears to be the rule but there are no actuarial data to quantify this assertion.

Episodes of Severe Anemia

The level of Hb in most patients appears to be relatively stable and above approximately 8 g/dL; however, the Hb level may fall (2–3 g/dL) quite dramatically,[34] causing episodes of profound weakness and pallor requiring hospital admission and blood transfusion. The cause of such events is not always understood; they may recur and may vary from one environment to another. They are often thought to arise from increased hemolysis associated with pregnancy intercurrent infection/pyrexia or administration of oxidant drugs such as sulphonamides[76] or transient aplasia due to B19 parvovirus infection.[73] Such events may also occur in patients with hypersplenism.

Blood Transfusion

Blood transfusion is often used in the management of patients who have an acute fall in the level of Hb (see previous discussion). In many studies up to 50% of patients with HbH disease have had a few transfusions during such episodes. In general, those with the lowest steady state levels of Hb (with nondeletional HbH disease) more frequently require such transfusions. It is unusual for patients with HbH disease to require regular blood transfusion and even in cases in which this has been thought necessary, it is not

always clear what criteria have been used to make such a decision. Nevertheless, nearly all such examples occur in patients with nondeletional types of HbH disease.

Hepatosplenomegaly and Jaundice

In addition to pallor and jaundice most patients with HbH disease have enlarged livers and spleens, although clinically significant hepatomegaly is unusual in patients with uncomplicated HbH disease unless they have iron loading. Liver enlargement and spleen enlargement are both more common in patients with nondeletional types of HbH disease. Hypersplenism, which can significantly aggravate the anemia and lead to reduced platelet and white blood cell counts, occurs in approximately 10% of patients;[34] splenectomy may be of benefit to such patients with persistent anemia. Severe liver disease has occasionally been reported in patients with HbH disease but it is not clear that this was directly attributable to thalassemia. Gallstones are quite frequent (up to ~40%) in patients with HbH disease their frequency increasing with age and possibly modified by the co-inheritance of predisposing alleles of the uridine diphosphate glucuronosyl transferase locus.[73,99] Complications of gallstones appear relatively infrequent; for example, in 95 patients followed by Piankijagum et al.[80] for 2 years, there were four episodes of cholecystitis.

Growth and Bone Changes

Approximately one third of patients with HbH disease were said to have bone changes associated with thalassemia.[86] In general these are mild but may affect the facial features. In one study from Thailand 17% of children with deletional HbH disease and almost half of patients with HbH/CS disease had thalassemic facies.[79] In the latter group half of the patients had moderately severe changes with maxillary overgrowth. Approximately 13% of children with HbH disease in Hong Kong and Sardinia had growth rates below the third percentile.[72,73] A study from Thailand found more than half of children with HbH disease had growth impairment.[79] Clinically significant extramedullary hemopoiesis rarely occurs in HbH disease.[9,34,100]

Hemoglobin H Disease and Pregnancy

The normal physiological changes associated with pregnancy are even more challenging in patients with HbH disease than those with α thalassemia trait (see previous discussion). In patients with HbH disease, there is usually an increasing severity of anemia and the level of Hb may fall to approximately 6.0 g/dL[1,73,101] or even less.[34,102] Some patients with the most severe anemias may also be iron deficient.[34] In patients with severe anemia (<6.0 g/dL), blood transfusion may be necessary to maintain the health of the mother and the developing fetus.[34,73,101,103] Even in the absence of specific treatment, the level of the mother's Hb usually returns to 8–10 g/dL a few months after delivery.

Vaeusorn et al.[101] described 34 pregnancies in 29 Thai women. Preeclampsia occurred in 18% of cases, and there were 2 miscarriages and 3 premature births. In a study of 127 pregnancies in Thai women 38 of 111 required caesarean section.[102] In a more recent study Origa et al.[73] described the outcome of 82 pregnancies in 31 Sardinian women with HbH disease. Nine (11%) resulted in miscarriage. Four (5.5%) had preeclampsia. Six children (8.2%) were born prematurely and 22 children were delivered by caesarean section. Therefore, although many women with HbH disease experience no adverse effects during pregnancy, special care is required to ensure that the reduced levels of Hb do not deleteriously affect the mother or developing fetus.

Iron Status in Patients with HbH Disease

The issue of iron overloading, even in normal individuals, is complex and is influenced by genetic background, environment, and diet (Chapter 29). The complexity is even greater in patients with chronic hemolysis and dyserythropoiesis. Ferrokinetic studies have suggested that although iron absorption is increased in HbH disease,[104] iron utilization appears normal, consistent with this being primarily a hemolytic anemia,[78,104] in contrast to β thalassemia, which is predominantly dyserythropoietic. In general, the severe clinical manifestations of iron overload frequently encountered in patients with β thalassemia intermedia and major (Chapter 29) are rarely seen in HbH disease,[9,96,105,106] and Sonakul et al.[107] noticed less tissue hemosiderosis at autopsy in patients with HbH disease than those with homozygous β thalassemia.

Nevertheless, in southeast Asia, some degree of iron overload (as judged by markedly elevated serum ferritin) is present in approximately 70% of adults with HbH,[106,108,109] and the level of ferritin is related to age.[72] In Hong Kong, 51 of 60 patients (85%) evaluated by computed tomography scanning of the liver showed evidence of iron overload.[72,110] In a few patients liver biopsy revealed increased liver iron content and hepatic fibrosis without evidence of hepatitis B or C.[72,111] Rare patients with HbH disease have been reported to have clinically significant cardiac and endocrine complications associated with iron overload.[72,105]

In a large study in Sardinia[73] approximately 20% children, 26% of adult females, and 50% of adult males with HbH disease had serum ferritin levels greater than normal. Again there was a clear age-related correlation and a small number of patients had liver disease, which may or may not have been related simply to iron overload. Clearly the risk of iron overload will be increased in patients with HbH disease who undergo regular transfusion and such patients require appropriate chelation therapy. Whether nontransfused patients with high levels of ferritin will benefit from

chelation is currently being assessed.[112] One should be aware that HbH disease may coexist with the common form of hereditary hemochromatosis,[113] which may account for unexplained, clinically significant iron overload in occasional patients with HbH disease.[61,109]

Rare Complications

Other complications of HbH disease include leg ulcers,[114] which are rare,[34] an increased susceptibility to certain infections,[34,80,115] retinopathy,[116] and risk of thromboembolic disease.[117]

The Relationship Between Genotype and Phenotype in HbH Disease

The numbers of patients studied in detail are too small to draw firm conclusions. Nevertheless, several studies now agree that, in general, patients with nondeletional forms of HbH disease are more anemic and jaundiced with higher levels of HbH than patients with deletional forms of HbH disease. Patients with nondeletion HbH disease also have higher levels of sTfR and serum erythropoietin and greater degrees of hepatosplenomegaly, more severe bone changes, and more episodes of infection than patients with deletional forms of HbH disease. Some studies suggest that patients with nondeletional HbH disease present earlier in life than those with deletional types of HbH disease. These findings are consistent with the more severe hematological phenotype reported in patients with nondeletional HbH disease (as stated previously). They more frequently require blood transfusion and nearly all patients requiring regular blood transfusion have the nondeletional forms of HbH disease (see later). Patients with nondeletional HbH disease most frequently require and benefit from splenectomy.[1,31,61,62,72,73,83,88,89,94,95,118]

Treatment of Patients with HbH Disease

The overwhelming impression is that the majority of patients with HbH disease are clinically well; they are often unaware of their condition and may go on to have families of their own. Therefore, the major point to make about the management of patients with HbH disease is that no specific treatment other than folic acid supplements should be offered unless there are well-defined reasons for doing so.

Oral iron is not required routinely for patients with HbH disease and may be deleterious due to the potential for iron overload (as noted previously). Nevertheless when appropriate, one should suspect and investigate iron, folate, and B12 deficiency in patients with HbH disease and treat just as for nonthalassemic patients. Most clinicians recommend that all patients with chronic hemolytic anemias should be given regular folic acid supplements.[119,120] Women with HbH disease who are not iron overloaded should be given the same supplements in the management of pregnancy as nonthalassemic women according to local obstetrical practices.

Occasional blood transfusions may be required when the level of hemoglobin suddenly dips. Hemolytic episodes occur most commonly in children who should therefore be examined at least every 12 months to determine steady-state levels of hemoglobin (many adult patients are so well that they neglect to come for review). Occasionally both hemolytic and aplastic episodes can result in rapid falls in the hemoglobin level to the point at which transfusion is potentially life saving. Hence education is a very important part of management. Any episodes of profound weakness and pallor should prompt individuals or families to take the patient to the hospital as a matter of urgency. Aplastic episodes usually last only a week or so with rapid recovery, and transfusion is not necessarily required. It is important to exclude the coexistence of glucose-6-phosphate dehydrogenase deficiency in males, which is common in many communities and may cause hemolysis in individuals with HbH disease. Naphthalene, antimalarials, and sulphas are the most common causes of hemolytic episodes in glucose-6-phosphate dehydrogenase–deficient children. In many cases the cause of sudden severe anemia in HbH disease remains unknown. Particular care must be taken to monitor pregnant women with HbH disease who may have especially low levels of hemoglobin. In all of these situations it is reasonable to provide temporary support with blood transfusion.

Chronic blood transfusion should be avoided for all but the most carefully considered cases. Once instituted, the patients will require all the long-term care, including iron chelation, used for patients with homozygous β thalassemia (see Chapter 29). The clearest examples in which this should be considered are 1) patients who are unable to maintain normal cardiovascular function with the given level of hemoglobin; and 2) patients who would otherwise develop the chronic problems associated with erythroid expansion (thalassemic facies, extramedullary tumors, etc.). In most hematologists' experience these criteria rarely apply to patients with HbH disease and when transfusions are required they are usually in patients with nondeletional forms of HbH disease.

Splenomegaly is one of the commonest complications of HbH disease and may be accompanied by hypersplenism. Wasi et al.[86] reported that splenectomy in 50 patients with HbH disease increased the level of hemoglobin by 2–3 g/dL (other reports are reviewed in refs. 118, 121, 122). Although splenectomy may be indicated in some cases to ameliorate the problems associated with splenomegaly or hypersplenism, this should be very carefully balanced against the potential complication of venous thrombosis, which has been reported in some patients with HbH disease following splenectomy.[123–125]

Based on the discussion of iron status, ferritin or iron estimations should be performed at least annually. Iron loading may be caused by regular blood transfusion, inappropriate iron therapy or abnormal absorption: in many patients several mechanisms contribute. Based on preliminary evaluation it may be necessary to assess iron loading by liver biopsy to determine the need for chelation. Alternatively liver iron storage can be evaluated by noninvasive methods such as dual energy computed tomography[72,126] or magnetic resonance imaging,[127] thus avoiding the need for liver biopsy (the detection of iron overloading is discussed further in Chapter 29). At present we do not know whether iron loading in HbH disease can ever be severe enough to cause cirrhosis and liver failure.

Other complications such as leg ulcers have been reported in patients with HbH disease and require the general medical or surgical treatment appropriate for the clinical situation. Gallstones occur commonly and routine ultrasound should be performed at some stage during late teens. When present, gallstones should be managed conservatively; few patients require cholecystectomy.

Genetic Counseling of Patients with HbH Disease

The presence of HbH disease in one or both partners is not known to impair their ability to have children although there are no data to evaluate fertility in such individuals.

Once a diagnosis has been made in any patient of reproductive age it is important to offer them advice about the potential problems of producing children with the Hb Bart's hydrops fetalis syndrome and their partner should be tested to see if they are at risk of producing such a pregnancy. Because there are so many potential interactions (see Table 14.1) it will be necessary to obtain a full genotype analysis from both partners to evaluate the relative risks of all possible outcomes.

In each case the primary aim is to avoid pregnancies leading to Hb Bart's hydrops fetalis or the uncommon, severe forms of HbH hydrops fetalis and transfusion-dependent HbH disease.

HEMOGLOBIN BART'S HYDROPS FETALIS SYNDROME

The combination of generalized edema, ascites, and pleural and pericardial effusions in a developing fetus (hydrops fetalis) may occur in a wide variety of fetal and maternal disorders.[128–132] The predominant causes vary from one population to another. In the West, rhesus immunization used to be the major cause, but with the widespread introduction of immunoprophylaxis and the decline in rhesus isoimmunization[133] "nonimmune" causes (intrauterine infection, chromosomal abnormalities, and congenital cardiac and renal defects) now account for 75% of cases.[131,134] In Southeast Asia, up to 90% of all cases are caused by

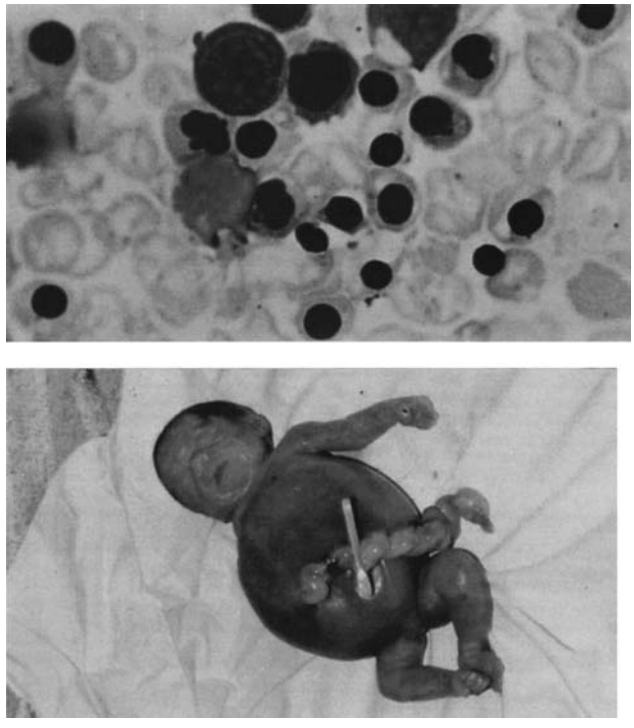

Figure 14.9. Upper the typical peripheral blood films of an infant with the Hb Bart's hydrops fetalis syndrome, showing many immature red cell precursors and hypochromic, microcytic, and anisopoikiolytic red cells. Lower the typical clinical features of a hydropic infant at birth (see text). (See color plate 14.9.)

α thalassemia, giving rise to the Hb Bart's hydrops fetalis syndrome.[132,135–139]

Throughout southeast Asia where the frequency of α^0 thalassemia trait (--/αα) is high (4%–14%, see Chapter 26), up to 1:200 infants may inherit no functional α genes (--/--) from their parents.[140–142] Because α-globin chains are normally produced throughout development, contributing to embryonic ($\alpha_2\varepsilon_2$), fetal ($\alpha_2\gamma_2$) and adult ($\alpha_2\beta_2$) hemoglobins, affected fetuses suffer from severe hypochromic anemia in utero, which causes hypoxia, heart failure and consequently hydrops fetalis (Fig. 14.9). Such infants produce large amounts of nonfunctional Hb Bart's (γ4) and small amounts of functional, embryonic hemoglobin (Hb Portland $\zeta_2\gamma_2$), which allows sufficient tissue oxygenation for them to survive until the third trimester of pregnancy when they are usually born prematurely and die (see later).

The Hb Bart's hydrops fetalis syndrome nearly always results from the coinheritance of two α^0 thalassemia defects (Table 14.1). In southeast Asia, $--^{SEA}/--^{SEA}$ is the most common genotype but in areas where the $--^{FIL\,143}$ and $--^{THAI\,143}$ determinants occur some hydropic babies may be compound heterozygotes ($--^{FIL}/--^{SEA}$ and $--^{THAI}/--^{SEA}$). These two less common defects ($--^{FIL}$ and $--^{THAI}$) remove both fetal/adult (α) and embryonic (ζ) genes. Because homozygotes (e.g. $--^{FIL}/--^{FIL}$) do not produce any normal embryonic hemoglobins (Portland $\zeta_2\gamma_2$, Gower 1 $\zeta_2\varepsilon_2$ and

Gower 2 ($\alpha_2\varepsilon_2$) they die very early in gestation and do not produce the classic hydrops fetalis syndrome.[143] α^0-thalassemia is much less common in other regions of the world. Nevertheless, rare cases of Hb Bart's hydrops fetalis have been reported in individuals of Greek ($--^{MED}/--^{MED}$),[144–147] Cypriot ($--^{MED}/--^{MED}$, $--^{MED}/-(\alpha)^{20.5}$, $-(\alpha)^{20.5}/-(\alpha)^{20.5}$),[148,149] Sardinian ($--^{MED}/--^{MED}$),[150] Turkish ($-(\alpha)^{20.5}/-(\alpha)^{20.5}$),[151] and Asian Indian (J.M. Old, personal communication, 2000) origins. Many of these cases occur in restricted population groups or, in some cases, result from consanguineous marriages. Given the large number of α^0 thalassemia mutations that have been described (Chapter 13) one should be aware of potential, rare interactions in such situations.

Very rarely, severe fetal anemia with or without overt hydrops fetalis may also result from the co-inheritance of α° and nondeletional α^+ thalassemia (Table 14.1), an interaction that normally causes HbH disease (noted previously). There are now several examples of HbH hydrops fetalis and these are described below.

mRNA and Globin Synthesis Studies in Infants with the Hb Bart's Hydrops Fetalis Syndrome

Using complementary cDNA probes Kan et al.[17] were first to demonstrate that there is no detectable α mRNA in patients with the Hb Bart's hydrops fetalis syndrome. This has subsequently been confirmed in several studies (for example see ref. 19). Consequently, no α-globin chain synthesis is detected in the peripheral blood of such infants,[24] although β-globin synthesis appears entirely unaffected, underscoring the fact that there appears to be no regulatory feedback at any level between α- and β-globin chain synthesis.

The Red Cell Indices and Hematological Findings in the Hb Bart's Hydrops Fetalis Syndrome

The peripheral blood of infants with the Hb Bart's hydrops fetalis syndrome contains large, hypochromic red cells and shows considerable anisopoikilocytosis (Fig. 14.9). Some elongated cells are said to have the appearance of "sickle cells".[34] The typical hematological findings in infants with the hydrops fetalis syndrome are summarized in Table 14.3, the most striking abnormality being the severe degree of anemia with a mean hemoglobin of 6.5 g/dL.[152]

The reticulocyte count is high[34] and the blood contains many nucleated red cells (Fig. 14.9). The bone marrow is hyperplastic and there are many sites (liver, spleen, kidney, and adrenals) of extramedullary hemopoiesis, predominantly erythropoietic, with widespread deposition of hemosiderin.

The cause of the anemia is poorly understood and is probably multifactorial, involving underproduction of hemoglobin, hemolysis, and ineffective erythropoiesis. The role of Hb Bart's in the hemolysis and/or ineffective erythropoiesis is not clear; unlike HbH, Hb Bart's is soluble and appears relatively stable. Factors other than anemia (e.g., plasma protein concentration, umbilical blood flow) may contribute to the development of hydrops fetalis.[34,153]

Developmental Changes in Hemoglobin Composition

We now know that the Hb Bart's hydrops fetalis syndrome most commonly results from deletion of all four α genes; α mRNA is undetectable[17] and therefore the primary abnormality is an inability to synthesize the α-globin chains of hemoglobin.

In affected individuals, the embryonic hemoglobins Gower 1 ($\zeta_2\varepsilon_2$) and Portland I ($\zeta_2\gamma_2$) are expressed normally, in the first few weeks of life, although there is no Hb Gower 2 ($\alpha_2\varepsilon_2$). Severe anemia probably develops at approximately 6–7 weeks of gestation when the switch from embryonic (ζ and ε) to fetal (α and γ) gene expression occurs.[154] In the absence of α-chain synthesis no Hb F ($\alpha_2\gamma_2$) can be made and excess γ chains form soluble tetramers (γ_4, Hb Bart's), which makes up to approximately 90% of the total hemoglobin. Toward the end of gestation, as the fetal (γ) to adult (β) switch occurs, small amounts of HbH (β_4) appear

in the fetal blood. Neither Hb Bart's nor HbH display any heme–heme interaction[68,155] or Bohr effect and both bind oxygen very highly, as in the R-state of normal hemoglobin (see Chapter 6). Consequently, oxygen delivery to the fetus is severely impaired throughout most of development and it is remarkable that the fetus survives at all.

It appears that viability depends on the persistent synthesis of embryonic ζ globin chains. In affected individuals Hb Portland I ($\zeta_2\gamma_2$) and to a lesser extent Portland II ($\zeta_2\beta_2$) make up approximately 10%–20% of the fetal blood. Hb Portland displays a normal pattern of oxygen dissociation[156] and can therefore deliver oxygen to the developing fetus.

The molecular and cellular basis for persistent ζ globin expression is not understood. A very small increase in ζ globin chains[40,157–160] is seen in some carriers of deletions that cause α^0 thalassemia and, superficially, this resembles the persistent γ-globin expression that accompanies some deletions that remove the β-globin genes (hereditary persistence of fetal hemoglobin [HPFH], see Chapter 16). The levels of ζ-globin observed in carriers of α^0 thalassemia (<1%) are much lower than levels of γ-globin in HPFH. It seems likely that mechanisms other than increased ζ-globin gene transcription (e.g., cell selection or alterations in ζ-globin mRNA stability) must be operating to allow such high levels of Hb Portland to accumulate. It is interesting, however, that the embryonic Hb Gower 1 ($\zeta_2\varepsilon_2$) does not persist in this condition, suggesting that the effect specifically acts on ζ-globin expression rather than a general effect on embryonic (ζ and ε) globin expression.

Clinical and Autopsy Findings

Following a gestation of approximately 33 weeks (range 23–43) infants with the Hb Bart's hydrops fetalis syndrome usually die in utero, during delivery, or within 1–2 hours of birth.[136,139,152,153,161] Occasionally even without specific treatment, some babies survive for a few days.[161,162] Typically, affected infants are pale, slightly jaundiced, growth retarded, and edematous with a massive, friable placenta (see Fig. 14.9). The skin may be affected by a "blueberry muffin" rash caused by subcutaneous nodules of extramedullary hemopoiesis.[163] In one study the placenta/fetal weight ratio ranged from 0.37 to 1.16 (mean 0.68) compared with the normal ratio of 0.15–0.25.[136] Sometimes the abdomen is distended with ascites but not all cases are grossly hydropic (e.g., ref. 153). Developmental abnormalities have been reported in up to 17% of cases.[136,161,164] These include hydrocephaly,[136] microcephaly,[136] abnormal limb development,[136,165–170] and urogenital abnormalities, including undescended testes, variable degrees of hypospadias, ambiguous genitalia, and even male pseudohermaphroditism (reviewed in refs. 34, 86, 136, 162, 165, 171–173). The cause of these common genital abnormalities associated with Bart's hydrops is unexplained and of interest.

At autopsy ascites is usually pronounced and there are often pleural and pericardial effusions. Organ weights are usually reported with respect to gestational age, body weight, and body length (Fig. 14.10). The combination of edema and disturbed growth in hydropic babies can severely distort these relationships. With this caveat, enlargement of the heart, liver, and to a lesser degree the spleen are usually observed, whereas retarded development of the lung, thymus, adrenals, and kidney are often reported.[34,86,152,161] Of particular interest there is a progressive decrease in brain weight relative to that expected for gestational age from approximately 8 weeks of gestation (Fig. 14.10). Again, many congenital abnormalities have been noted postmortem including cardiac defects,[136,152] pulmonary hypoplasia,[152] and undescended and intraabdominal testes[161] (reviewed in ref. 165).

Histologically, interstitial edema is noted in all tissues. There are multiple sites of extramedullary erythropoiesis. Up to 60%–70% of the liver parenchyma may consist of developing red cells. The placenta is vascular and edematous, containing many nucleated red cells. It has been speculated that hematological changes in this condition may cause occlusion of small blood vessels with subsequent disruption of end organs (e.g., as in abnormal limb development).[166,168]

It is interesting that even though the vast majority of infants with hydrops fetalis have an identical genotype ($--^{SEA}/--^{SEA}$) there is considerable variation in the pace and extent of abnormal development in each fetus.

Maternal Complications

Mothers of infants with this disorder often have a history of stillbirths or neonatal deaths; early miscarriages are probably uncommon. All reports point to an increased incidence of serious maternal complications (see Table 14.4 and refs. 136, 152, 161).

In the antenatal period most problems arise in the third trimester when some mothers note a cessation of fetal movements. Common complications include anemia, preeclampsia (hypertension, fluid retention with or without proteinuria), polyhydramnios (excessive accumulation of amniotic fluid), oligohydramnios (decreased amniotic fluid), antepartum hemorrhage, and the premature onset of labor (Table 14.4). Less common general medical and obstetric complications have also been reported.[136,152,161,164]

Labor and delivery may be particularly difficult and assistance (in the form of embryotomy, breech, forceps, and caesarean section) is required in approximately 50% of cases. Postpartum complications include retained placenta, hemorrhage, eclampsia (fits and coma), sepsis, and anemia.

It has been suggested that, without medical care, up to 50% of women carrying affected fetuses would die as a result of such pregnancies.[152] To date, however, there have

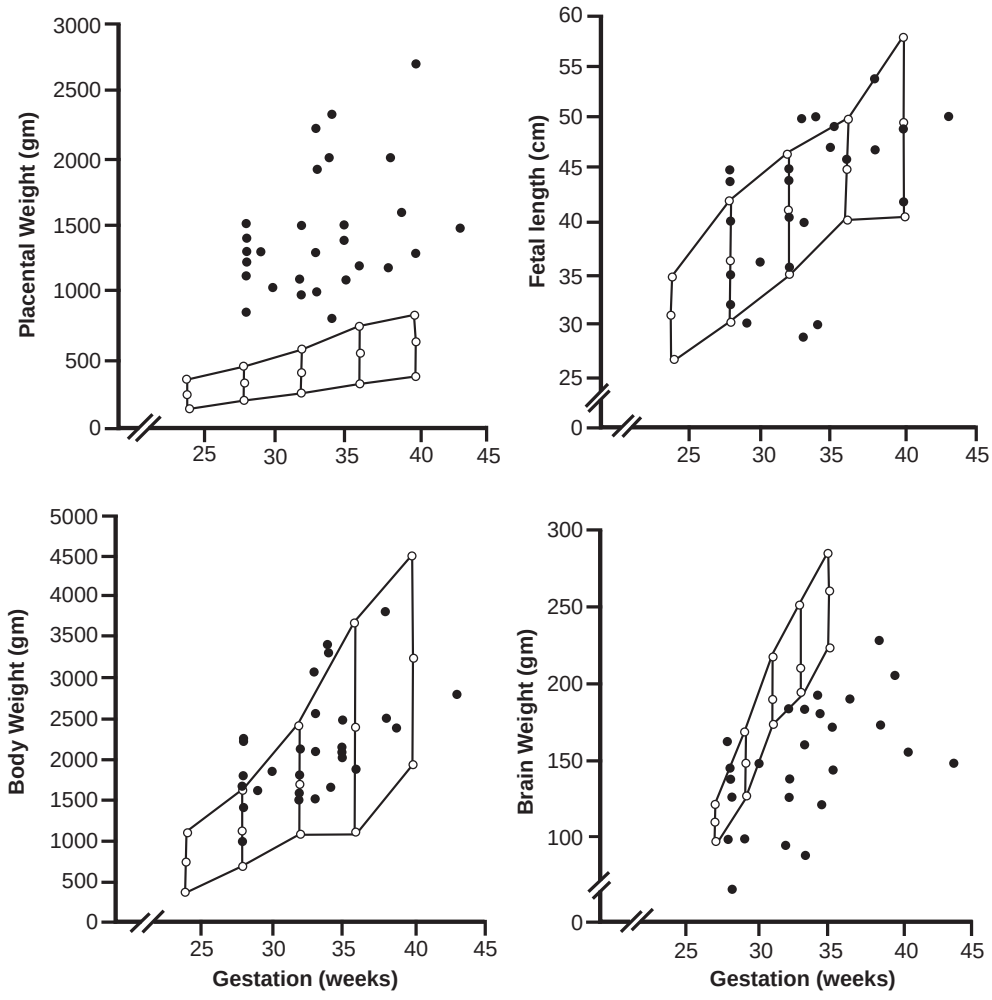

Figure 14.10. The placental weight, body weight, fetal length, and brain weight of a series of infants with the Hb Bart's hydrops fetalis syndrome. The open circles represent the mean normal values and 95% confidence limits. (Redrawn with permission from S. Fucharoen in ref. 152.)

been no retrospective studies of maternal mortality rates in communities where medical assistance is unavailable.

Hemoglobin H Hydrops Fetalis

Nearly all babies with the Hb Bart's hydrops fetalis syndrome inherit no α genes from their parents (genotype --/--). There are, however, several reports describing rare neonates with severe anemia and various changes associated with hydrops fetalis due to the coinheritance of α^0 and α^+ thalassemia. These infants are distinguished from the common forms of Bart's hydrops in that they do make some α-globin chains and they are referred to as having HbH hydrops fetalis. Many of the molecular interactions underlying this condition have been fully characterized.

The first involves the common α° mutations and nondeletional α thalassemia determinants (--/$\alpha^T\alpha$) that result from highly unstable α-globin variants including Hb Adana,[98,174] the $\alpha^{CD30}\alpha$ mutation,[174–176] Hb Dartmouth,[177] Hb Evora,[98] and Hb Quong Sze.[178] HbH hydrops was also seen in a homozygote for Hb Taybe.[52] A second class of interaction involves the chain termination mutant Hb Constant Spring and involves a homozygote ($\alpha^{cs}\alpha/\alpha^{cs}\alpha$,[53]), whereas this interaction normally causes a moderately severe hemolytic anemia. The third type of interaction (--/$\alpha^{PA}\alpha$) occurs between α^0 thalassemia and the polyA addition signal mutations,[179,180] including a homozygote ($\alpha^{PA}\alpha/\alpha^{PA}\alpha$) for the Indian polyA signal mutation.[181] In addition there are several less well characterized examples of HbH hydrops.[135,171,182]

At birth all affected infants were anemic (hemoglobin, 3.4–9.7 g/dL) with large amounts of Hb Bart's (17%–66%). Although approximately 50% of the affected infants died at birth, others survived following intrauterine blood transfusion but have remained transfusion dependent (e.g., ref. 174). Some have developed normally and require no further transfusions after the perinatal period (e.g., refs. 52, 53).

These cases thus represent the transition between severe, transfusion-dependent HbH disease and Hb Bart's hydrops fetalis and some of these patients have been

Table 14.4. Maternal complications in the Hb Bart's hydrops fetalis syndrome

	Hydrops %			Nonhydrops** %

** These figures are only a guide because they will vary greatly depending on the population studied and the level of antenatal care provided.

included as examples of infants surviving with the Hb Bart's hydrops fetalis syndrome (e.g., ref. 173). As accurate molecular diagnosis becomes more common we would expect to identify further similar cases of HbH hydrops fetalis. Mothers of these children often have a history of neonatal deaths due to anemia and in some cases, siblings with the same interactions have severe HbH disease. Nevertheless some siblings with identical interactions have not experienced the same degree of anemia. It is not clear why some patients with $\alpha^{\circ}/\alpha^{+}$ interactions should be so severely affected whereas others with an identical interaction may survive normally.

Long-Term Survival of α^0 Thalassemia Homozygotes

As noted above, there is considerable variability in the clinical course of infants with the Hb Bart's hydrops fetalis syndrome. Although most die *in utero*, during delivery, or within 1 or 2 hours of birth, others may survive for several days:[162,183,184] In some cases the diagnosis may not be immediately obvious in a newborn infant. It is therefore not surprising that during the last 20 years, as neonatal care (e.g., ventilator therapy, and the use of nitric oxide, and surfactant) has continued to improve, several homozygotes for α^0 thalassemia have survived either as a result of treatment prior to confirmation of the diagnosis or as a result of preplanned intervention. This has generated a great deal of interest in how best to counsel and manage parents when the mother carries an affected fetus (reviewed in ref. 185).

In a recent review Lee et al.[186] usefully approached this problem by collating data from live, newborn infants with the Hb Bart's hydrops fetalis syndrome who had received no prior treatment in utero. All of these had naturally survived until delivery and then, some were treated with intensive neonatal care and blood transfusion. One group (11 fetuses) died in the first few hours after delivery[186] or lived for only a few days,[183,184] in keeping with the conventional descriptions of this condition. By contrast, the second group (10 fetuses) have all survived for months or years.[171,186–193] Half of these long-term survivors have abnormal neurodevelopment, variously affecting speech, hearing, and motor function. In addition, these patients have a wide variety of other developmental abnormalities including genital abnormalities and limb deformities. Therefore, despite modern neonatal intensive care, based on these observations, the chance of survival with Bart's hydrops fetalis remains small and at least half of the survivors have abnormal development.

Lee et al.[186] also reviewed the outcome in 16 fetuses that had received early prenatal diagnosis followed by intrauterine therapy, thus correcting the effects of α thalassemia earlier in development.[167,173,185,194–203] Intrauterine therapy included blood transfusion, exchange transfusion, and in two cases[197,203] intrauterine hematopoietic stem cell transplantation. It seems that intrauterine therapy combined with neonatal intensive care results in a relatively low mortality and morbidity. Nevertheless, serious complications and developmental abnormalities still occur in this group (e.g., refs. 194, 195, 200) and even when these are avoided, the affected child and the family may still be committed to lifelong blood transfusion and chelation therapy unless the child undergoes successful transplantation.[173,185]

Prevention and Management

Ideally one should screen and identify couples at risk of conceiving a fetus with the Hb Bart's hydrops fetalis syndrome before or early in pregnancy, as set out in the section on management of patients with α thalassemia trait. The majority of these patients will be of southeast Asian origin but less commonly individuals of Mediterranean or mixed origins may be at risk.[204]

For accurate genetic counselling and prenatal diagnosis, it is essential to determine precisely the parental genotypes by Southern blot or PCR-based strategies (see Chapter 13). If both parents carry one or other of the known α^0 thalassemia defects there will be a one in four chance that they will conceive a fetus with the Hb Bart's hydrops fetalis syndrome. If *both* parents have α^0 thalassemia haplotypes in which both α and ζ genes are deleted (e.g., $--^{FIL}/--^{THAI}$) then they will not produce hydropic infants because homozygotes (e.g., $--^{FIL}/--^{FIL}$) and compound heterozygotes (e.g. $--^{FIL}/--^{THAI}$) for these defects will be lost soon after conception.[143] Compound heterozygotes for the $--^{SEA}/--^{FIL}$ mutations may have the common form of hydrops fetalis.

If at risk couples request prenatal testing, fetal DNA can be obtained from chorionic villi or fetal cells obtained by amniocentesis. DNA and hemoglobin analysis can be performed on blood samples obtained by cordocentesis in the second trimester of pregnancy. These techniques are discussed in Chapter 28.

Ultrasonography can also be useful in the management of at risk pregnancies for the Hb Bart's hydrops fetalis syndrome.[141,164,205–208] In most cases placental thickness is more than two standard deviations above normal[141] after 12 weeks of gestation; by 18 weeks it is abnormal in all cases.[205,209] Similarly, the cardiothoracic ratio is increased (>0.5 between the 12th and 17th week and 0.52 between the 18th and 21st weeks) in most, if not all, affected fetuses by 13–14 weeks gestation.[141,210,211] Other features including subcutaneous edema, hepatomegaly, pleural effusion, pericardial effusion, enlarged umbilical vessels, oligohydramnios, and ascites appear with increasing frequency from approximately 12 weeks onward[210] but are not consistently detected by ultrasonography until 22–28 weeks of gestation.[208]

These findings can be of help in two situations. First they may alert an obstetrician to the diagnosis if this has not been considered earlier in pregnancy. Second, in areas where DNA analysis is currently unavailable, it provides a reasonable way to monitor and select at risk pregnancies for further investigation by hemoglobin electrophoresis of samples obtained by cordocentesis.[210,211] This approach has been used increasingly over the past few years.[212]

At present there is no suitable treatment for the Hb Bart's hydrops fetalis syndrome. Early intervention with intrauterine transfusions (reviewed in ref. 186) are difficult to justify because even when successful the child is committed to lifelong blood transfusion and iron chelation. To address this, there have been three unsuccessful attempts to perform *in utero* hematopoietic stem cell transplantation.[203,213,214] Again survivors of such unsuccessful procedures[203] require life-long transfusion. In addition, we do not yet understand when or why other congenital abnormalities arise in this condition; therefore, current attempts to treat this condition are associated with an unknown risk of rescuing infants with multiple, often severe developmental abnormalities. Until these problems have been adequately addressed and solved (e.g., by using the excellent mouse model developed by Paszty and coworkers,[215,216]) further human experimentation should be avoided. Given the serious obstetrical risk to the mother of an affected fetus it seems most prudent to advise early termination of pregnancy in all cases.

INTERACTIONS BETWEEN α THALASSEMIA AND STRUCTURAL GLOBIN VARIANTS

Historically, interactions between α thalassemia and structural variants of the α- and β-globin chains were of considerable importance in developing our understanding of the genetics of hemoglobin synthesis (Chapter 3). Now that we have a more detailed knowledge, one of the main reasons for considering these interactions is to provide a framework for interpreting the many different patterns they produce on routine hemoglobin electrophoresis. The coinheritance of α thalassemia with some clinically important hemoglobinopathies is discussed in Chapters 16–19.

Interactions Between α Thalassemia and α-Globin Structural Variants

When a patient inherits an entirely normal β-globin genotype (β^A/β^A) and a full complement of α genes with one structural variant ($\alpha\alpha/\alpha^v\alpha$: β^A/β^A or $\alpha\alpha/\alpha\alpha^v$:$\beta^A/\beta^A$) the amount of variant hemoglobin produced will depend on the rate at which it is synthesized, its stability, its affinity for β^A chains (see later) and on whether the mutation affects the α_2 or α_1 gene. As discussed in Chapter 13, although the ratio of α_2/α_1 mRNA is 3:1 there is still some disagreement about the relative contributions of these two genes to hemoglobin synthesis. In addition there is considerable methodological variation in the quantitation of hemoglobin variants. Not surprisingly the reported proportions of α-globin variants range from 0% (e.g., Hb Quong Sze) to approximately 35% (e.g., Hb J Toronto) with an average value of approximately 25% (Chapter 13). Even if one excludes highly unstable α mutants there is still considerable variation, but in general, mutations affecting the α2 gene are present at higher levels than those affecting the α1 gene[217] (data available via http://globin.cse.psu.edu). Hematologically most α-globin variants are quite innocuous, although some give rise to high oxygen affinity (e.g., Hb Luton), congenital cyanosis (e.g., Hb M Boston), or hemolytic anemias (Chapter 25). Some heterozygotes for highly unstable mutants (e.g., Hb Quong Sze) may have the phenotype of α thalassemia trait and these are best considered as determinants of nondeletional α thalassemia (see Chapter 13).

The effect of coinheriting α thalassemia with α-globin variants is to increase the proportion of the variant and to reinforce any associated clinical phenotype (Table 14.5). This principle is best demonstrated by the variant G-Philadelphia (α68(E17)Asn→Lys) (Chapter 13). Individuals with HbG-Philadelphia may have a full complement of four α genes ($\alpha^G\alpha/\alpha\alpha$) and 20%–25% of the variant hemoglobin with no hematological abnormalities.[218,219] In some individuals the HbG-Philadelphia variant is present on an $-\alpha^{3.7}$ haplotype ($-\alpha^G$) giving rise to the $-\alpha^G/\alpha\alpha$, $-\alpha^G/-\alpha$ and $-\alpha^G/-\alpha^G$ genotypes that produce 30%–35%, approximately 45% and 100% G Philadelphia, respectively:[220–222] Such patients have the hematological phenotype of α thalassemia trait. Rarely the $-\alpha^G$ haplotype may interact with α^0 thalassemia to produce HbH disease ($--/-\alpha^G$). Such patients produce only HbH and HbG and have the classic clinical and hematological phenotypes associated with HbH disease. The condition is referred to as HbG-H disease.[222,223] A list of

Table 14.5. Interactions between α-globin variants and α thalassemia

		Predicted + % of variant Hb	Hematological phenotype
αα/α^{v}α	β^{A}/β^{A}	25*–37.5**	normal
αα/αα^{v}	β^{A}/β^{A}	12.5*–25**	normal

+ Assuming that the α^{v} variant is synthesized efficiently, completely stable, and associates with β^{A}-chains with the same kinetics α^{A}-chains.

* Assuming that the relative contribution of α2 and α1 is 1:1.

** Assuming that the contribution of α2 and α1 is 3:1.

As shown in ref. 217, all of these assumptions almost never apply to any known variant and estimated values often differ greatly from these predicted values.

all mutations directly linked to an α thalassemia determinant is given in Table 13.2 in Chapter 13; their interactions with other α-globin haplotypes are very similar to those described for HbG Philadelphia (also see Table 14.5).

The interaction between HbI (α^{16}Lys-Glu) and α thalassemia was initially very puzzling.[224] Most often this variant accounts for 24%–28% of the total hemoglobin.[217] In one family that also had α thalassemia, however, the level was 70%. It is now known that rarely the mutation may occur on both the α2 and α1 genes on the same chromosome, presumably as a result of gene conversion.[225] Thus the patient with the -α/α^{I}α^{I} genotype had approximately 70% Hbl as we would now predict (Table 14.5).

The interactions between α thalassemia and highly unstable α-globin variants have been described previously and in Chapter 13. In general, the -α/α^{v}α and -α/αα^{v} genotypes in these cases give rise to α thalassemia trait and the --/α^{v}α genotype is associated with HbH disease. There is a tendency for such individuals to fall at the severe end of the clinical spectrum of patients with HbH disease, including patients with HbH hydrops.

Interactions Between α Thalassemia and β-Globin Structural Variants

When a patient inherits an entirely normal α-globin genotype (αα/αα) and two β genes, one of which encodes a structural variant (β^{A}/β^{v}), the amount of variant hemoglobin produced will depend on its rate of synthesis, its stability, and the pattern of subunit assembly to form αβ dimers.[226,227] Ideally one would predict that equal amounts of HbA and variant hemoglobin would be present in the red cell, but in reality, as for α-globin mutants, considerable variation is observed.[217] Some β-globin variants (e.g., HbE and Hb Knossos) are synthesized less efficiently than β^{A} and represent less than 50% in heterozygotes. Others (e.g., Hb Köln) are unstable and may represent 30% or less of the hemoglobin. The third factor, differences in the rates of αβ subunit assembly, may influence the accumulated levels of many stable hemoglobin variants.

The formation of αβ dimers is a rate-limiting step in the assembly of hemoglobin. This process is thought to be facilitated by the electrostatic attraction between positively charged α-globin subunits and negatively charged β-globin subunits. Many commonly encountered β-globin variants acquire positive charge (e.g., β^{S} Glu→Val), thereby reducing their ability to compete with β^{A}-chains for hemoglobin assembly. In such cases less variant hemoglobin accumulates than HbA. The opposite is seen with negatively charged β-globin variants (Fig. 14.11). These observations are supported by *in vitro* subunit competition assays using

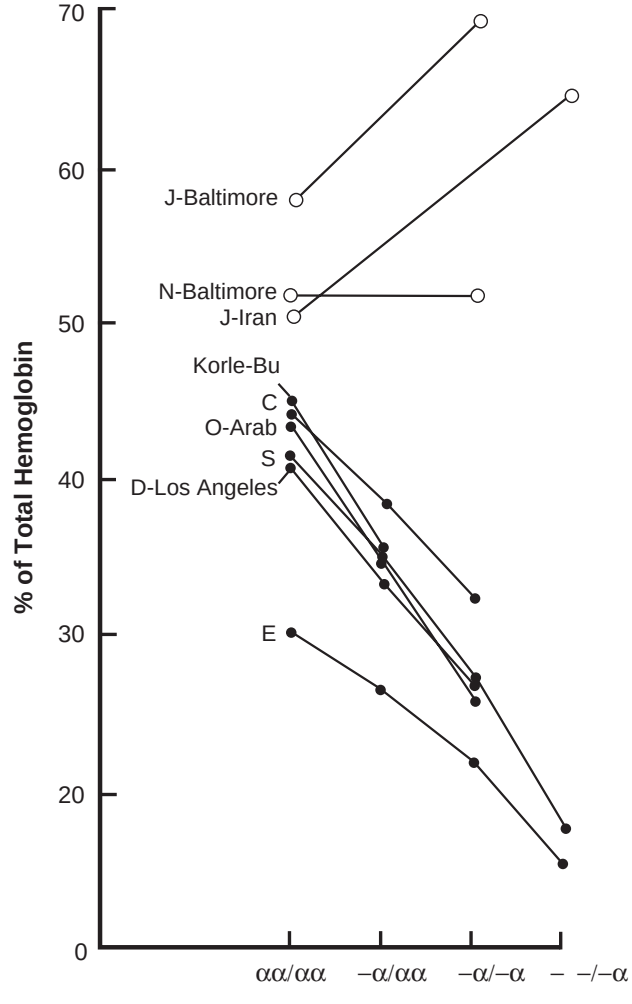

Figure 14.11. Effect of α-thalassemia on the proportion of negatively charged (○) and positively charged (●) β-globin variants in heterozygotes. In all cases HbA constitutes the majority of the remaining Hb. In three-gene deletion α thalassemia (--/-α), a small amount of Hb H (β$_4$) is present. (Redrawn from ref. 227.)

mixtures of normal (β^A) and variant (e.g., β^S and β^C) subunits.[226,227]

In the presence of α thalassemia, in which limiting amounts of α-chains are synthesized in the red cell, these effects are exaggerated. The accumulated levels of positively charged β variants (e.g., β^C, β^O, β^E, β^S) are further decreased in proportion to the deficit in α-globin chains.[226,227] By contrast the levels of negatively charged variants may increase (Fig. 14.11). This is a good rule of thumb although there are exceptions (e.g., HbN-Baltimore) and the situation becomes complex when more than one β variant is involved (e.g., HbS and HbC) or if α-globin variants are also present.

The presence of α thalassemia may influence the levels of HbA_2 in the presence of β-globin variants. The δ-globin subunit is considerably more positively charged than the β-globin subunit. In α thalassemia one would therefore expect the amount of HbA_2 to decrease, and, in general, this is what one sees.[34,86] In the presence of a variant, positively charged β subunit that has less affinity for α subunits, there may be sufficient free α-chains to interact with all δ subunits thereby increasing the level of HbA_2. Such increases have been observed in individuals with sickle cell trait[228] and sickle cell disease.

The presence of α thalassemia may also influence the levels of HbF ($\alpha_2\gamma_2$) and Hb Bart's ($\gamma4$) in some interactions. Several observations suggest that αγ dimers form less readily than αβ dimers. As discussed before there is more Hb Bart's in newborns with α thalassemia than HbH in adults with the same genotype. There is some preliminary evidence that the proportion of HbF in newborns is lower in those with α thalassemia than those with four α genes.[229] Evidence also comes from the study by Chui et al.[91] who described an Italian boy who coinherited HbH disease (--/-α) and the -117 $^A\gamma$ globin HPFH mutation. They found that approximately 90% of the α-chains combined with β-globin chains to form HbA (~78%) and 10% of the α-chains associated with γ to form HbF (9.5%). Although there were sufficient free γ-chains to produce approximately 11% Hb Bart's, there were insufficient free β-chains remaining to detect HbH on electrophoresis, although HbH inclusions were detected. Taken together these findings support the hypothesis that α-globin has a higher affinity for β- than γ-globin. The interpretation of these complex interactions is by no means certain because there are other patients with similar interactions who produce different patterns of hemoglobin expression (e.g. see ref. 230).

Hematological Phenotype of Patients with α Thalassemia and β-Globin Variants

The hematological phenotype of patients with α thalassemia and stable β-globin variants is usually determined by the α-globin status giving rise to α thalassemia trait (-α/αα, -α/-α -/αα) or HbH disease (--/-α) (see Table 14.6). Interactions between nondeletional forms of α thalassemia and β-globin variants follow these same principles.

Table 14.6. Proportion of hemoglobin variant and hematological phenotypes in patients with positively charged β-globin variants

		Predicted level of variant	Hemoglobin hematological phenotype
αα/αα	β^A/β^v	50%*	Normal
-α/αα	β^A/β^v	↓	α thalassemia trait
-α/-α	β^A/β^v	↓↓	α thalassemia trait
--/αα	β^A/β^v	↓↓↓	α thalassemia trait
--/-α	β^A/β^v	↓↓↓↓	HbH disease

* Assuming that the variant is synthesized efficiently, completely stable, and associates with α^A-chains with the same kinetics as β^A-chains.

When a patient inherits only one functional α gene (or its equivalent) and a β-globin variant (β^C, β^S, β^E) they usually have the clinical and hematological phenotype of HbH disease. Splenomegaly is particularly prominent in some patients.[231] Such interactions have been described with HbC,[231] HbE,[232] HbS,[233] and Hb Hope.[234] Hemoglobin analysis usually demonstrates HbA with a very reduced amount (10%–20%) of the variant hemoglobin. The reported levels of HbH are quite variable in this interaction and sometimes undetectable by routine hemoglobin electrophoresis. Nevertheless, HbH inclusions can usually be demonstrated following incubation with brilliant cresyl blue. Hb Bart's may be detectable in some patients and is characteristically present (1%–6%) in carriers for HbE with HbH disease, a condition referred to as AE-Bart's disease (--/-α, β^A/β^E or --/$\alpha^{CS}\alpha$, β^A/β^E)[232,235] (see Chapter 18).

Rare interactions between HbH disease and β-globin variants support the electrostatic model for hemoglobin subunit assembly. Su et al.[236] reported HbH disease in a Chinese patient with the benign β mutant Hb Hamilton, which has the same charge as β^A and it appeared that the level of this mutant was not significantly reduced. Rahbar and Bunn[237] described an Iranian female with HbH disease and HbJ-Iran (β77 His→Asp), a negatively charged subunit. In this case the interaction with α thalassemia produced an increased level (65%) of the variant hemoglobin.

Finally, Chan et al.[238] described a Chinese female with a severe transfusion-dependent hemolytic anemia (hemoglobin 3.4–6.8 g/dL) resulting from the interaction of HbH disease with Hb New York (β113 Val→Glu acid), an unstable negatively charged β-globin variant. In this case the coinheritance of α thalassemia increased the formation of Hb New York and thus exacerbated the hemolytic anemia.

α Thalassemia in Homozygotes and Compound Heterozygotes for β-Chain Abnormalities

α Thalassemia is common wherever β thalassemia occurs. Similarly α thalassemia is found wherever β^E and β^S reach polymorphic frequencies (see Chapter 26). Consequently, there are many potential interactions between the determinants of α thalassemia and these β-chain abnormalities.

In some cases the coinheritance of α thalassemia may significantly alter the phenotype of patients with β-chain hemoglobinopathies. The interactions between α thalassemia and β thalassemia are discussed in Chapters 16 and 17. Interactions between α thalassemia and homozygotes for β^E are set out in Chapter 18 and interactions with homozygotes for β^S in Chapters 19 and 20.

SUMMARY

Given the ever-increasing number of natural mutations affecting the α-globin cluster, the number of potential interactions increases in a corresponding manner and this review provides an update of these interactions. Despite the large number of interactions, there are limited numbers of clinical phenotypes observed in patients with α thalassemia, ranging from the innocuous thalassemia trait, through mild to severe hemolytic anemia in adults and finally to the most severe anemias associated with hydrops fetalis in neonates. The main issues in management are how to counsel and prevent the most severe anemias and how to treat those patients who, despite prenatal counseling and testing, are born and survive with the most severe anemias.

Unusual Types of α Thalassemia

Douglas R. Higgs, Veronica J. Buckle,
Richard Gibbons, and David Steensma

INTRODUCTION

In this chapter we describe three relatively rare, clinically complex syndromes in which the occurrence of α thalassemia provided the clue to understanding the molecular basis of each condition. These conditions exemplify the important interplay between clinical observation and human molecular genetics. Two of these syndromes (ATR-16 [OMIM: 141750] and ATR-X [OMIM: 301040]) in which α thalassemia is associated with multiple developmental abnormalities (including mental retardation, MR) are inherited. The third condition (ATMDS [OMIM: 300448]) is an acquired disorder in which α thalassemia appears for the first time in the context of myelodysplasia.

α THALASSEMIA ASSOCIATED WITH MENTAL RETARDATION AND DEVELOPMENTAL ABNORMALITIES

The rare association of α thalassemia and mental retardation (MR) was recognized more than 25 years ago by Weatherall and colleagues.[1] It was known that α thalassemia arises when there is a defect in the synthesis of the α-globin chains of adult hemoglobin (HbA, $\alpha_2\beta_2$). When these authors encountered three mentally retarded children with α thalassemia and a variety of developmental abnormalities, their interest was stimulated by the unusual nature of the α thalassemia. The children were of northern European origin, where α thalassemia is uncommon, and although one would have expected to find clear signs of this inherited anemia in their parents, it appeared to have arisen de novo in the affected offspring. It was thought that the combination of α thalassemia with MR (ATR), and the associated developmental abnormalities represented a new syndrome and that a common genetic defect might be responsible for the diverse clinical manifestations. What emerged was the identification of two quite distinct syndromes in which α thalassemia is associated with MR.[2,3] In the first condition (ATR-16, OMIM: 141750) there are large (1–2 Mb) chromosomal rearrangements that delete many genes, including the α-globin genes from the tip of the short arm of chromosome 16 and this is an example of a contiguous gene syndrome.[4] In the second syndrome (ATR-X, OMIM 301040), a complex phenotype, including α thalassemia, results from mutations in an X-encoded factor (now called the ATRX protein), which is a putative regulator of gene expression. Mutations in this gene down regulate α globin gene expression and also perturb the expression of other as yet unidentified genes.

THE ATR-16 SYNDROME

To date we know of 40 individuals (from 32 families) who have well-characterized ATR-16 syndrome (Table 15.1a and b). Often one is alerted to this condition by observing the unusual association of α thalassemia and MR in individuals originating from outside of the areas where thalassemia commonly occurs (see Chapters 13 and 14). There are two common patterns of inheritance. In many cases neither parent has α thalassemia ($\alpha\alpha/\alpha\alpha \times \alpha\alpha/\alpha\alpha$) and the affected offspring has the phenotype of severe α thalassemia trait (genotype $--/\alpha\alpha$). Less commonly, one parent has the phenotype of mild α thalassemia trait, the other parent is nonthalassemic ($-\alpha/\alpha\alpha \times \alpha\alpha/\alpha\alpha$) and the child has HbH disease (genotype $--/-\alpha$). In addition to α thalassemia, these patients have variable degrees of facial dysmorphism (Fig. 15.1) and a wide spectrum of associated developmental abnormalities (Table 15.2a and b). In all such cases, initial molecular genetic analyses have shown that affected individuals fail to inherit the entire ζ–α globin cluster from one or other of the parents.

Figure 15.1. The facial appearance of patients with the ATR-16 syndrome. Common features include relative hypertelorism, a small chin and mouth, a "beaked" nose, downslanting palpebral fissures, and crowded teeth.

Defining the Genetic Abnormalities in Patients with ATR-16 Syndrome

In some cases, conventional cytogenetic analysis demonstrated the underlying genetic abnormality. Because the α–globin complex lies very close to the 16p telomere (16p13.3, Fig. 15.2) any chromosomal abnormality affecting this region may give rise to α thalassemia.[2] In some patients with putative ATR-16 syndrome, gross chromosomal abnormalities resulting in deletions,[2] formation of ring chromosomes,[5–7] and translocations[8] have been observed. Although such abnormalities may arise as de novo genetic events, often one parent carries a preexisting balanced translocation, which the child inherits in an unbalanced fashion (Fig. 15.3, summarizing the findings in ref. 9), resulting in monosomy for 16p and loss of the α cluster.

In many cases of ATR-16, initial high-resolution cytogenetic analysis appeared entirely normal. In some of these cases the pattern of inheritance of polymorphisms (such as variable number tandem repeats) within the α-cluster revealed the nature of the underlying molecular defect. In the example given in Fig. 15.3 the parental 16p alleles could be distinguished from each other. The mother in this family was shown to carry a balanced 1:16 translocation, which both of her children inherited in an unbalanced fashion. Her son OD (Tables 15.1 and 15.2) was monosomic for 16p, and therefore was shown to have α thalassemia (in this case HbH disease), whereas her daughter was trisomic for 16p. Both children had MR, dysmorphic facies, and a variety of associated developmental abnormalities.

Fluorescence in situ hybridization (FISH) studies have also been used to analyze ATR-16 families. In this type of study, large segments (~40 kb) of chromosome 16 in cosmid vectors are used as probes to demonstrate the presence or absence of the corresponding sequences in the 16p telomeric region by using fluorescence microscopy.[10] By analyzing the chromosomes of both parents and the affected child it has been possible to define the extent of 16p monosomy and the mechanism by which it has arisen. In the example shown in Figure 15.4, FISH analysis demonstrated that the mother of an affected child with the ATR-16 syndrome carries a balanced 16:20 translocation, which was inherited in an unbalanced fashion (as in Fig. 15.3) by her offspring. Some chromosomal abnormalities can only be detected by FISH or molecular analyses and they are referred to as "cryptic."

Over the past 10 years other methods have also been applied systematically to the characterization of the chromosome abnormalities in these patients. M-TEL FISH[11] involves the hybridization of a panel of subtelomeric probes from each human chromosome to detect both loss of material from and additional material on the short arm

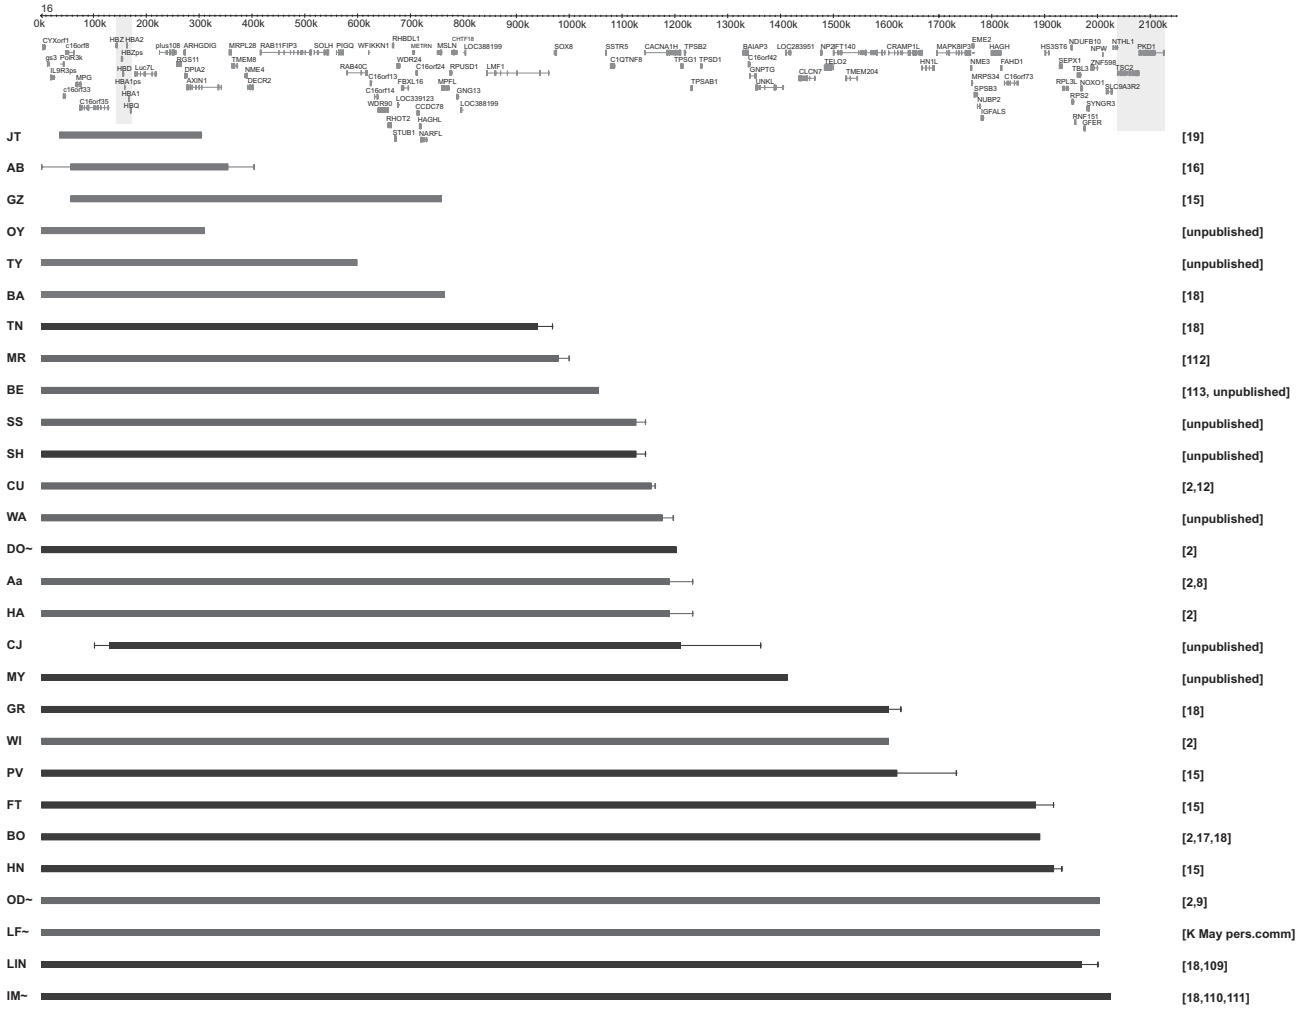

Figure 15.2. Summary of known ATR-16 deletions. The positions of the α-globin cluster and other genes within this region are indicated. Below, the extent of each deletion is shown with the patient code alongside (see Table 15.1). Deletions known to result from pure monosomy for this region are shown in either green (no abnormalities other than thalassemia) or red (ATR-16 phenotype). Chromosomal translocations (all with ATR-16 phenotypes) are shown in blue. Solid bars indicate regions known to be deleted and fine lines indicate the region of uncertainty of the breakpoints. The α genes and the genes that when mutated are associated with tuberous sclerosis and adult polycystic kidney disease are shown (shaded boxes). (See color plate 15.2.)

of chromosome 16. For example, abnormal chromosome 16 in HA (Table 15.1) was shown by this method to be not only monosomic for part of 16p13.3 but also trisomic for part of 16q24 (derived from an inversion/deletion event).

Recently there have been several technical developments that have narrowed the gap between cytogenetics and molecular analyses, enabling high-resolution analysis of the entire human genome. In the first of these types of analyses a large proportion of the genome is interrogated using microarrays consisting of DNA from bacterial artificial chromosomes spanning the genome. Using a competitive genome hybridization (CGH) approach, comparing DNA from one genome with another, it has been possible to detect large regions of monosomy in patients with ATR-16 syndrome.[12] More recently using oligo-based microarrays or bead technologies (originally made to identify single nucleotide polymorphisms) with a modified analysis it has been possible to identify deletions and duplications of greater than approximately 1 kb.[13] The resolution of this type of analysis is continuously improving. One of these approaches (using microbead technology[14]) has recently been applied to previously characterized (and new) cases of ATR-16, nicely demonstrating the large deletions from 16p13.3 and identifying any associated aneuploidy (V. Buckle et al., in preparation). Figure 15.5 shows an example of this type of analysis in a patient (BO, Tables 15.1 and 15.2) with ATR-16 syndrome due to a deletion of 1900 kb from 16p13.3.

In addition to these approaches Harteveld et al.[15] have developed a rapid and simple high-resolution approach to identify and characterize deletions of the terminal 2 Mb of 16p13.3 using the multiplex ligation–dependent probe amplification technique. An established panel of specific, synthetic oligonucleotides can now be used to detect

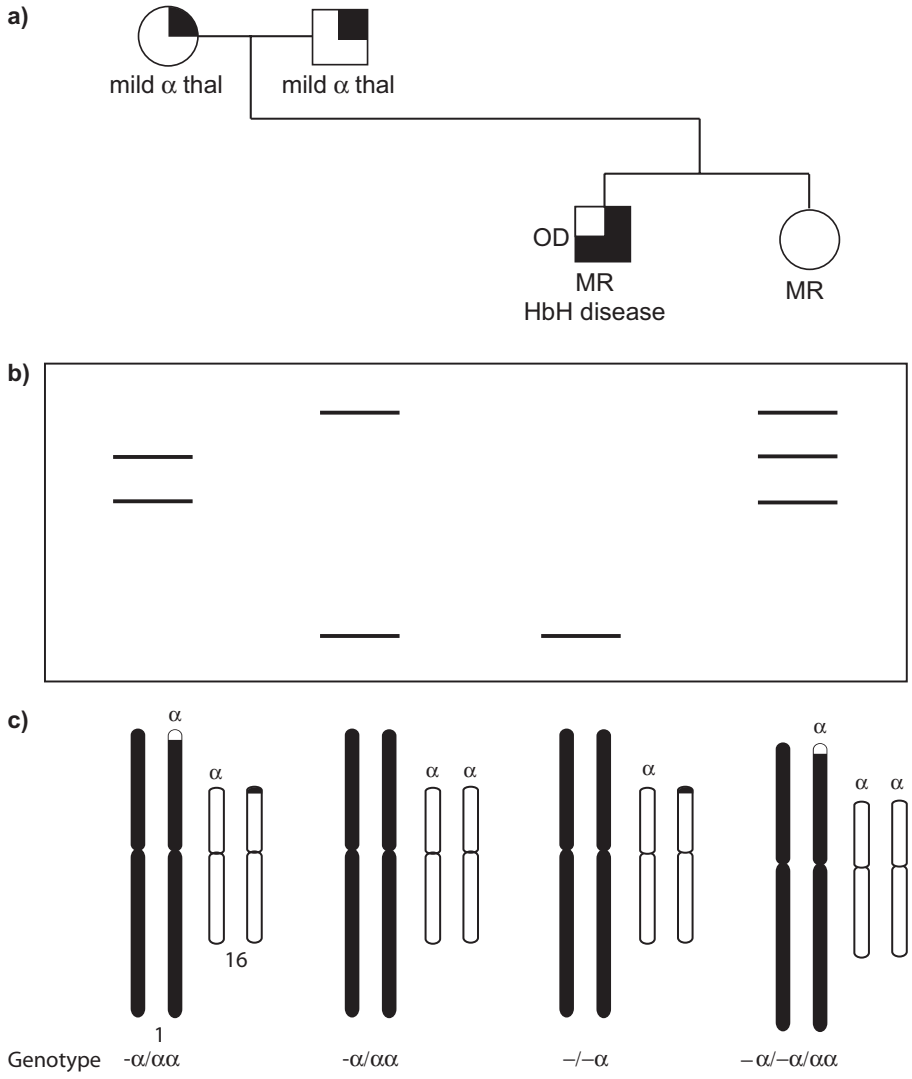

Figure 15.3. Familial subcytogenetic translocation (from ref. 9). **(a)** Pedigree indicating parents with mild α thalassemia only; son (OD) with MR and severe α-thalassemia (HbH disease) and daughter with MR. **(b)** Schematic representation of restriction fragment length polymorphism analysis using a fully informative marker closely linked to the α-globin cluster. Each track corresponds to the individual shown above. **(c)** Segregation of 1:16 translocation and α-globin complex (α) in each family member. The resulting genotype is shown. Note that both children have inherited the paternal chromosome carrying the (-α) allele; it has not been determined whether the mother's normal or translocated chromosome 16 bears her (-α) allele.

deletions in 16p13.3.[15,16] Clearly the resolution of this technique is only limited by the spacing of the appropriate oligonucleotides. An example of this type of analysis applied to a patient with ATR-16 syndrome is shown in Figure 15.5.

Using a combination of conventional cytogenetics, FISH, and molecular analysis at least three types of chromosomal rearrangements (translocation, inversion/deletion, and truncation) have now been found in ATR-16 patients (Fig. 15.2 and Table 15.1). To date, few breakpoints have been fully characterized. The telomeric truncations seen in BO, BA, and MY (Table 15.1 and Fig. 15.2) have been fully analyzed[17] (Green et al., unpublished) and it appears that these chromosomes have been broken, truncated, and "healed" by the direct addition of telomeric repeats $(TTAGGG)_n$ as described for some less extensive 16p deletions in patients with α thalassemia but no MR (e.g., TY in Fig. 13.2 and Chapter 13). In addition, another 11 ATR16 cases, shown to have pure monosomy for 16p13.3 (Fig. 15.2), are likely to fall into this same class.

Although many cases of ATR-16 have doubtless been overlooked, it is nevertheless likely that this syndrome is rare, because each case found to date has been the result of a unique and independent chromosome mutation.

How Do Chromosomal Abnormalities Give Rise to the ATR-16 Syndrome?

Because individuals with ATR-16 syndrome may have quite different degrees of chromosomal imbalance, there is considerable variation in the associated phenotypes

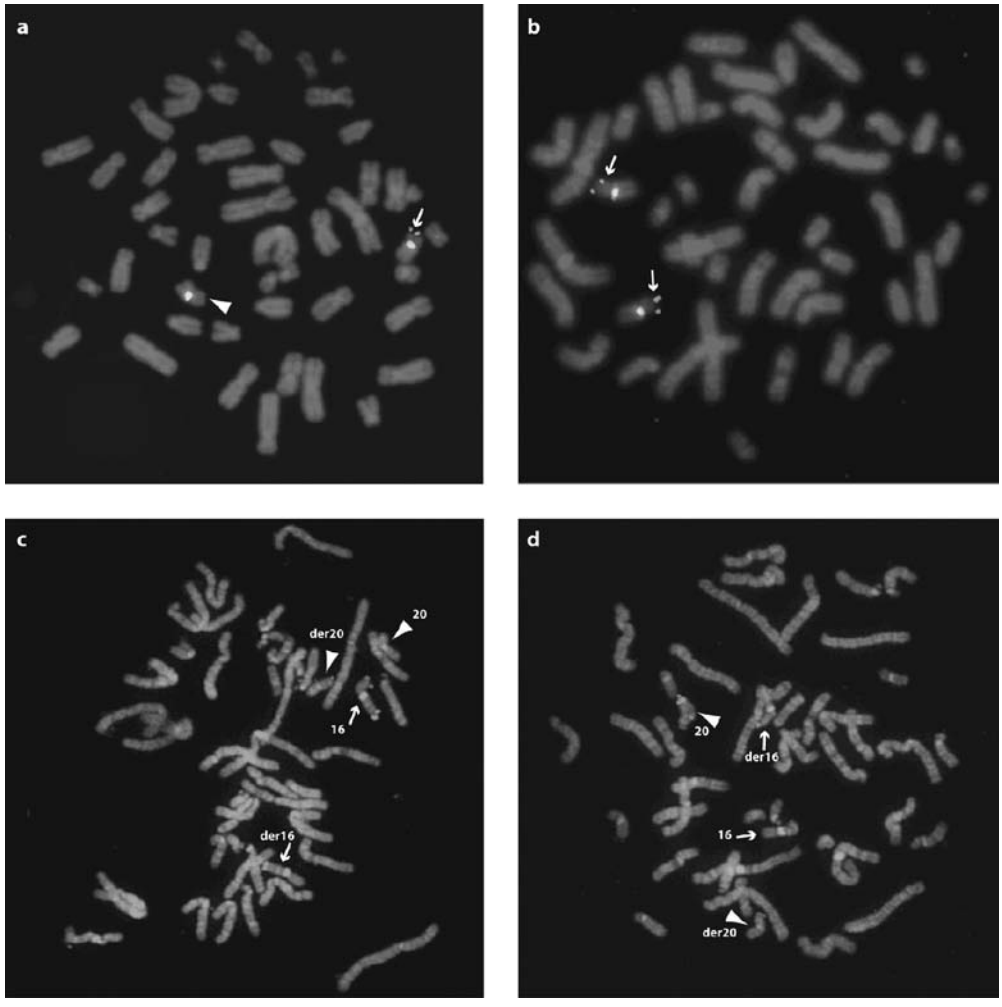

Figure 15.4. High-resolution chromosome analysis using FISH. **(a** and **b)** Examples of FISH on metaphase chromosomes of deletion patient JT. In each case chromosome 16 is identified by a chromosome 16–specific centromere probe. In **(a)** using a cosmid (cGG1) located close to the telomere, fluorescent signal was seen on the normal chromosome (arrow) but not the abnormal copy of chromosome 16 (arrowhead). **(b)** Using a second cosmid located closer to the centromere (not deleted in JT) a signal is seen on both normal and abnormal chromosomes (arrows). **(c** and **d)** FISH on metaphase chromosomes of the mother of WA showing a balanced translocation. In **(c)** and **(d)** both homologs of chromosome 16 are indicated by arrows and chromosome 20 by arrowheads. In **(c)** the subtelomeric probes for 16p and 16q were hybridized to metaphase chromosomes. Green fluorescent signal was seen on the q arm of both homologs of chromosome 16. Red fluorescent signal was seen on the p arm of the normal chromosome 16 and the q arm of the derivative chromosome 20 (der 20) but was absent from the deleted chromosome 16 (der 16). In **(d)** the subtelomeric probe for 20p (red) was seen on both homologs of chromosome 20. Fluorescent signal for 20q (green) was seen on the normal chromosome 20 and the p arm of the derivative 16 (der 16). (See color plate 15.4.)

(Table 15.2). The degree of monosomy in 16p13.3 varies from 0.3 to 2 Mb (Fig. 15.2) but many patients have additional chromosomal aneuploidy and in some cases imbalance of the non-16 material may dominate the clinical picture. For example in DA (Table 15.1) loss of material from chromosome 15 while forming the abnormal derivative t(15:16) chromosome produced the striking phenotype associated with the Prader–Willi syndrome.

Because many patients with ATR-16 have complex genomic rearrangements, to determine the role played by any gene(s), within 16p13.3, in the developmental abnormalities associated with ATR-16 syndrome, future analysis should focus on patients who have pure monosomy for 16p13.3. Clearly, patients with the common forms of α thalassemia have small deletions (~5–40 kb) from the α-globin cluster (Chapter 13) with no abnormalities other than α thalassemia. Nevertheless, rare individuals with much more extensive deletions have been identified. Surprisingly, these studies have shown that patients with deletions of up to 900 kb of 16p13.3 (including 52 genes) have α thalassemia but may be minimally affected[18] (unpublished data) or even normal[2,15–19] (unpublished data). At the other

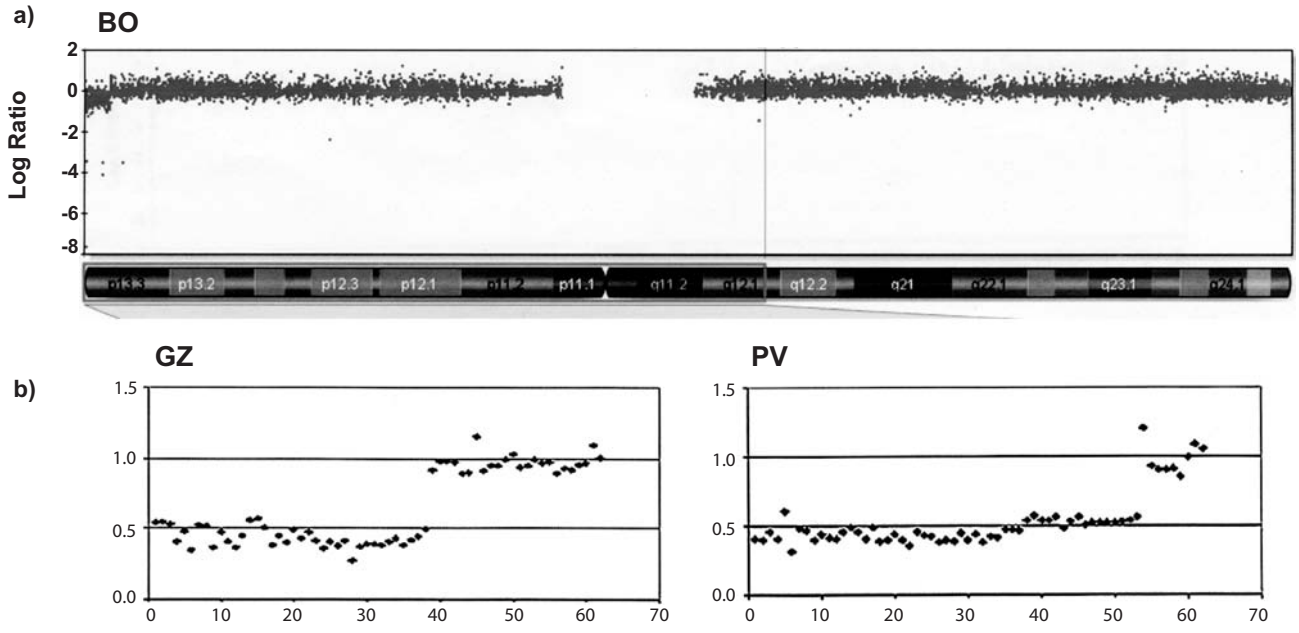

Figure 15.5. Detection of deletions. **(a)** Analysis of chromosome 16 in patient BO[18] with ATR-16 using the QuantiSNP protocol.[14] The Y-axis indicates the log ratio between normal and the test and the X-axis represents the distance along chromosome 16. **(b)** Analysis of two patients (GZ and PV[15] and Fig. 15.2) with large deletions of 16p13.3 using the multiplex ligation–dependent probe amplification protocol[15]). The Y-axis represents the ratio peak height of the test divided by the normal control and the X-axis represents the distance along chromosome 16. (See color plate 15.5.)

extreme, patients with 16p monosomy for the entire terminal region of 16p (e.g., BO, LIN, and IM) have a relatively severe phenotype with α thalassemia, MR, and dysmorphic features and skeletal abnormalities. All patients with deletions from 900 to 1700 kb have some degree of MR and shared but variable dysmorphic features (Table 15.2). In patients whose deletions extend beyond 2000 kb the clinical picture is dominated by more severe MR, tuberous sclerosis, and polycystic kidney disease.[20]

How might monosomy for 16p13.3 cause such developmental abnormalities? One possibility is that deletion of a large number of genes from one copy of chromosome 16 may unmask mutations in its homolog; the more genes that are deleted the greater the probability of this occurring. This is unlikely to be the explanation for most ATR-16 cases because it is estimated that normal individuals only carry a few harmful mutations of this type in the entire genome.[21] A further possibility is that some genes in 16p are imprinted[22] so that deletions could remove the only active copy of the gene. At present there is no evidence for imprinting of the 16p region (reviewed in ref. 23) and in the relatively few ATR-16 cases analyzed there appears to be no major clinical differences between patients with deletions of the maternally or paternally derived chromosomes (Tables 15.1 and 15.2). It therefore seems more likely that there are some genes in the 16p region that encode proteins whose effect is critically determined by the amount produced; so-called dosage-sensitive genes.[24] Examples of such genes include those encoding proteins that form heterodimers, those required at a critical level for a rate-determining step of a regulatory pathway, and tumor suppressor genes (e.g., TSC2). Removal of genes from one copy of 16p13.3 consistently reduces their levels of expression to approximately 50% of normal (Buckle et al., unpublished). If the deletion includes one or more dosage-sensitive genes this could account for the clinical effects seen in ATR-16 patients.

The region lying between 900 and 1700 kb from the 16p telomere, deleted in all patients with the characteristic features of ATR-16 syndrome, contains 16 genes and gene families of known function,[15,18] which have been implicated in a wide range of disorders with few or no features in common with ATR-16. One of these (SOX8) was considered as strong candidate because it is involved in the regulation of embryonic development and is strongly expressed in the brain.[25]A recently described Brazilian patient with a deletion that removes both the α-globin locus and SOX8 was not associated with MR or any dysmorphism however (Harteveld, personal communication, 2007). Clearly, further examples of ATR-16 due to monosomy for 16p13.3 must be characterized to identify the gene(s) responsible for the MR and other developmental abnormalities associated with this condition.

Summary of the ATR-16 Syndrome

The ATR-16 syndrome has served as an important model for improving our general understanding of the molecular basis for MR. It provided the first examples of MR due to

a cryptic chromosomal translocation and truncation. Further work has shown that such telomeric rearrangements may underlie a significant proportion of unexplained MR.[26] The current challenge is to understand in detail the mechanisms by which monosomy causes developmental abnormalities; the ATR-16 syndrome provides an excellent model for addressing this issue.

THE ATR-X SYNDROME

As additional patients with α thalassemia and MR were identified throughout the 1980s, it became clear that a second group of affected individuals existed in whom no structural abnormalities in the α-globin cluster or 16p could be found. In contrast to those with ATR-16 syndrome, this group of patients was all male, presented with a much more uniform phenotype, and had a remarkably similar facial appearance.[3] That this group had a distinct and recognizable dysmorphism was underscored when additional cases were identified on the basis of their facial features alone.[27,28] Ultimately, it was shown that this unusual syndrome of α thalassemia with severe MR results from an X-linked abnormality (see later) and the condition is now referred to as the ATR-X syndrome (OMIM: 301040).

The Clinical Findings of the ATR-X Syndrome

Cases of ATR-X syndrome from over 150 families have now been characterized, and in contrast to ATR-16 a definite phenotype is emerging. The cardinal features of this condition are severe MR and developmental abnormalities associated with a characteristic facial appearance and α thalassemia. The frequency and nature of the most commonly encountered clinical features are summarized in Tables 15.3 and 15.4.

Neonates with ATR-X syndrome usually have marked hypotonia and associated feeding difficulties. Seizures have also been noted in some patients. In early childhood, all milestones are delayed. Many patients do not walk until late in childhood, and some never do so. Most have no speech, although some patients have a handful of words or signs. With some notable exceptions[29–32] most patients with ATR-X syndrome have only situational understanding and are dependent for almost all activities of daily living.

Although head circumference is usually normal at birth, postnatal microcephaly usually develops. As affected individuals age, there is often a tendency toward spasticity and seizures occur in approximately one-third of cases. Vision usually appears normal but sensorineural deafness may occur in some patients. Computed tomography or magnetic resonance brain imaging is generally unremarkable, although mild cerebral atrophy may be seen. In two cases, partial or complete agenesis of the corpus callosum was

Table 15.3. Summary of the major clinical manifestations of the ATR-X syndrome

Clinical feature	Total*	%
Profound MR	160/168	96
Characteristic face	138/147	94
Skeletal abnormalities	128/142	90
HbH inclusions	130/147	88
Neonatal hypotonia	88/105	84
Genital abnormalities	119/150	79
Microcephaly	103/134	77
Gut dysmotility	89/117	76
Short stature	73/112	65
Seizures	53/154	34
Cardiac defects	32/149	21
Renal/urinary abnormalities	23/151	15

* Total represents the number of patients for whom appropriate information is available and includes patients who do not have α-thalassemia but in whom *ATRX* mutations have been identified.

Table 15.4. Clinical manifestations of the ATR-X syndrome

Genital abnormalities	Small/soft testes, cryptorchidism, gonadal dysgenesis, inguinal hernia, micropenis, hypospadias, deficient prepuce, shawl scrotum, hypoplastic scrotum, ambiguous genitalia, female external genitalia (male pseudohermaphroditism)
Skeletal abnormalities	Delayed bone age, tapering fingers, drumstick distal phalanges, brachydactyly, clinodactyly, bifid thumb, fixed flexion deformities of joints, overriding toes, varus or valgus deformities of feet, scoliosis, kyphosis, hemivertebra, spina bifida, coxa valga, chest wall deformity
Renal/urinary abnormalities	Renal agenesis, hydronephrosis, small kidneys, vesicoureteric reflux, pelvoureteric junction obstruction, exstrophy of bladder, urethral diverticulum, urethral stricture
Cardiac defects	Atrial septal defect, ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot, transposition of the great arteries, dextrocardia with situs solitus, aortic stenosis, pulmonary stenosis
Gut dysmotility	Discoordinated swallowing, eructation, gastroesophageal reflux, vomiting, gastric pseudovolvulus, hiatus hernia, hematemesis, recurrent ileus/small bowel obstruction, volvulus, intermittent diarrhea, severe constipation
Miscellaneous	Apneic episodes, cold/blue extremities, blepharitis, conjunctivitis, entropion, cleft palate, pneumonia, umbilical hernia, encephalitis, iris coloboma, optic atrophy, blindness, sensorineural deafness, prolonged periods of screaming/laughing, self injury

Figure 15.6. The facial appearance of patients with ATR-X syndrome as described in the text.

reported.[33] There have been autopsy reports in only three cases. The brain was small in each; in two the morphology was normal, and in one the temporal gyri on the right were indistinct, with hypoplasia of the cerebral white matter.

No systematic study of behavior has been performed in ATR-X syndrome but some recurrent themes are emerging.[34,35] Patients are usually described by their parents as content and of a happy disposition but may exhibit unprovoked emotional outbursts with sustained laughing or crying. Whereas many individuals are affectionate to their caregivers, others exhibit autistic-like behavior. They may be restless, exhibiting choreoathetoid movements and some have repetitive, stereotypic movements (pill-rolling or hand-flapping). Frequently, they put their hands into their mouths and may induce vomiting and sometimes they may engage in self-injurious behavior.

The characteristic facial appearance in ATR-X syndrome is most readily recognized in early childhood (Fig. 15.6). The frontal hair is often upswept and there is telecanthus, epicanthic folds, flat nasal bridge, midface hypoplasia, and a small triangular upturned nose with the alae nasi extending below the columella and septum. The upper lip is tented and the lower lip full and everted, giving the mouth a "carp-like" appearance. The frontal incisors are frequently widely spaced, the tongue protrudes, and there is prodigious dribbling. The ears may be simple, slightly low-set, and posteriorly rotated.

Urogenital abnormalities are seen in 80% of children. These may be very mild, for example, undescended testes or deficient prepuce; the spectrum of abnormality extends through hypospadias to micropenis to ambiguous or external female genitalia. The most severely affected children, who are clinically defined as male pseudohermaphrodites, are usually raised as females. It is of interest that these abnormalities breed true within families.[36] Renal abnormalities (hydronephrosis, renal hypoplasia or agenesis, polycystic kidney, and vesicoureteric reflux) may present with recurrent urinary tract infections.

Various relatively mild skeletal abnormalities have been noted; some of which are probably secondary to hypotonia and immobility.[37] Fixed flexion deformities, and other abnormalities, particularly of the fingers, are common. Short stature is seen in two-thirds of cases.

A wide range of gastrointestinal abnormalities have been reported in patients with this syndrome. Vomiting, regurgitation, and gastroesophageal reflux are particularly common in early childhood. An apparent reluctance to swallow has been reported by several parents and probably reflects the discoordinated swallowing that has been observed radiologically (unpublished). The tendency for aspiration is commonly implicated as a cause of death in early childhood. Excessive drooling is very common, as is frequent eructation. Constipation occurs often, and in some individuals is a major management problem. Martucciello et al.[38] demonstrated ultra-short Hirschsprung disease and colonic hypoganglionosis in two affected children. This may be a consequence of a widespread abnormality in the enteric nervous system leading to abnormal gut motility. Affected individuals may be susceptible to peptic ulceration. Esophagitis, esophageal stricture, and peptic ulcer have been observed endoscopically in single cases.

Finally, a wide range of cardiac abnormalities have also been noted including septal defects (10 cases), patent ductus arteriosus (6 cases), pulmonary stenosis (3 cases), aortic stenosis (2 cases), tetralogy of Fallot (2 cases), and single cases of transposition of the great arteries, dextrocardia with situs solitus, and aortic regurgitation.

Of the 168 patients described to date, there have been 25 deaths. The cause was established in just over half, of which there were 6 cases of pneumonia and four of aspiration of vomitus. Cases appear to be particularly vulnerable in early childhood, with 19 of the deaths occurring before the age of 5 years; this may be associated with the fact that gastroesophageal reflux and vomiting are often more severe in the early years. There are no long-term longitudinal data in this relatively newly described syndrome, but a number of affected individuals are fit and well in their 30s and 40s.

The Hematological Findings of the ATR-X Syndrome

The presence of α-thalassemia (in the form of thalassemia trait or mild HbH disease) with HbH inclusions (see Chapter 14) was one of the original diagnostic criteria for ATR-X syndrome; however, with the identification of further cases, it became clear that the hematological findings (e.g., levels of Hb, mean corpuscular volume [MCV], and mean corpuscular hemoglobin [MCH]) were different from those seen in the common types of α thalassemia. Now

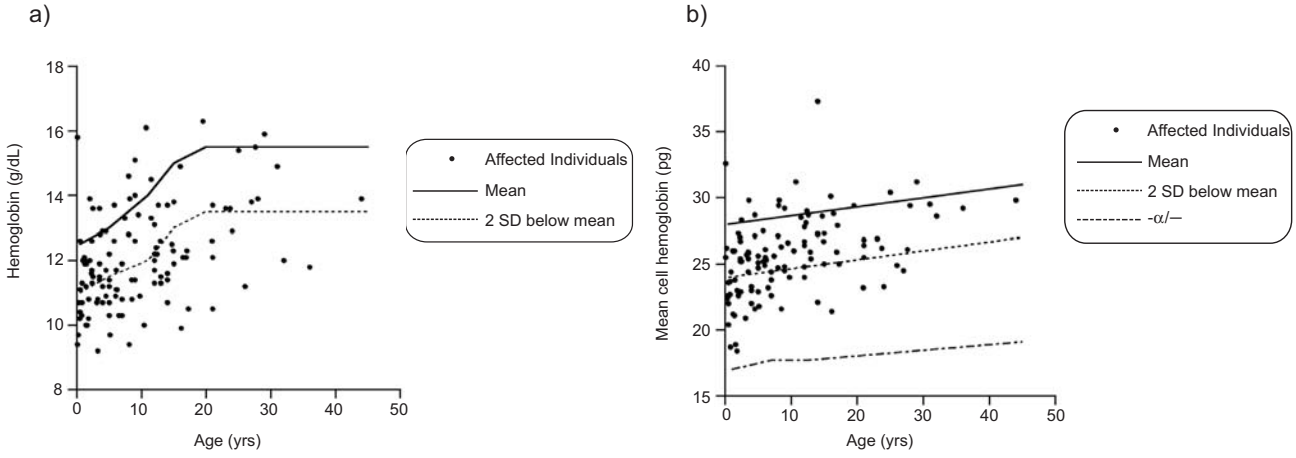

Figure 15.7. (a) Hemoglobin levels in subjects with ATR-X syndrome at various ages. Solid line indicates the mean and dashed line is 2 standard deviations below the mean.[119] For any given subject, only one result within each consecutive 5-year period is given. **(b)** MCH levels in subjects with ATR-X syndrome at various ages. Mean values for individuals with α thalassemia resulting from an -α/-- genotype are shown.

that the disease can be identified via the clinical phenotype or the ATR-X genotype, it is clear that there is considerable variation in the hematological manifestations associated with mutations of the *ATRX* gene. In fact, a number of families have been identified in which some or all of the affected members with mutations of ATRX, and the characteristic phenotype described previously, have no signs of α thalassemia.[39,40] Nevertheless, when the family history and phenotype are strongly suspect, a careful search for HbH inclusions should be made in all affected individuals and repeated if necessary as they may be very infrequent.

The hematology is often surprisingly normal considering the presence of α thalassemia (Fig. 15.7). Neither the level of hemoglobin nor the mean cell hemoglobin is as severely affected as in the classic forms of α thalassemia associated with *cis*-acting mutations in the α-globin complex (see Chapters 13 and 14), and this probably reflects the different pathophysiology of the conditions. In most cases of ATR-X, there is insufficient HbH to be detected by electrophoresis and the number of HbH inclusions is quite variable among different patients, although relatively constant over time in any affected individual.

The ATR-X Syndrome is an X-linked Condition

The five original "nondeletion" cases described by Wilkie et al.[3] were sporadic in nature, and apart from all being male, there were no immediate clues to the genetic etiology. Somatic cell hybrids composed of a mouse erythroleukemia cell line containing chromosome 16 (wherein the α-globin genes lie) derived from an affected boy produced human α-globin in a manner indistinguishable from a similar hybrid containing chromosome 16 from a normal individual. It therefore seemed likely that the defect in globin synthesis lay in *trans* to the globin cluster. This was confirmed in a family with four affected siblings in whom the condition segregated independently of the α-globin cluster.[41]

Because affected individuals were always related via the female line, this suggested that the syndrome mapped to the X chromosome and hence the condition was named the ATR-X syndrome. Subsequently linkage analysis in 16 families mapped the disease interval to Xq13.1-q21.1, confirming that the associated α thalassemia results from a *trans*-acting mutation.[42]

Early genetic studies showed that the ATR-X syndrome behaves as an X-linked recessive disorder; boys are affected almost exclusively. Furthermore, almost all female carriers have a normal appearance and intellect, although approximately one in four carriers has subtle signs of α thalassemia with very rare cells containing HbH inclusions.[42] The majority of carriers have a highly skewed pattern of X inactivation in leukocytes (derived from mesoderm), hair roots (ectoderm), and buccal cells (endoderm). In each case the disease-bearing X chromosome is preferentially inactivated. There is evidence from a recently reported mouse model of ATR-X syndrome[43] that skewed X inactivation results from selection, at key steps during development, against cells that are deficient for ATRX.[44]

Together, these findings showed that ATR-X is an X-linked disease and when the gene is mutated, among many other effects, this leads to downregulation of expression of the α-globin genes on chromosome 16.

Identification of the ATR-X Disease Gene

The isolation of cDNA fragments mapping to Xq13.1-q21.1 provided an opportunity to study candidate genes for ATR-X.[45] A number of these cDNA fragments were hybridized to DNA from a group of affected individuals. An absent

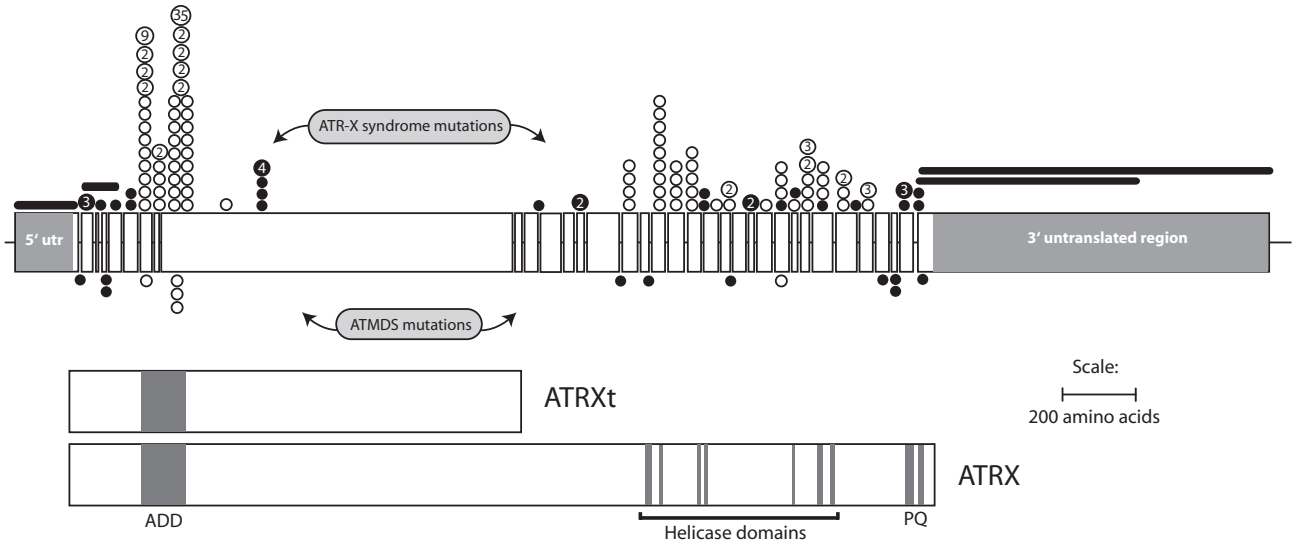

Figure 15.8. Schematic diagram of the *ATRX* gene: boxes represent the 35 exons (excluding the alternatively spliced exon 7); thin horizontal lines represent introns (not to scale). The 3′ and 5′ untranslated regions (utr) are shown flanking the open reading frame. The two protein products ATRX and ATRXt are shown as rectangles. The principal domains, the zinc finger motif (ADD), and the highly conserved helicase motif are indicated, as are the P box (P) and a glutamine-rich region (Q). In the lower part of the figure is a graphic representation of the amino acid similarity between human and mouse ATRX proteins. In the upper part of the figure is illustrated the spectrum of *ATRX* mutations described in boys with ATR-X syndrome (above the gene) and in ATMDS (below the gene). The positions of the mutations are shown by circles: filled circles represent mutations (nonsense or leading to a frameshift) that would cause protein truncation; open circles represent missense mutations and small deletions that maintain the reading frame; deletions are indicated by horizontal lines. Recurrent mutations are illustrated by larger circles, and the number of independent families is indicated.

hybridization signal was noted in one patient when an 84-bp cDNA fragment (E4) was used. E4 was shown to be part of a gene known as XH2/XNP.[46] Subsequently, a 2-kb genomic deletion was demonstrated in this individual with ATR-X syndrome. Subsequently, analysis of a segment of cDNA corresponding to XH2/XNP identified disease-causing mutations in several individuals with the clinical and hematological features of ATR-X syndrome. The X-linked gene was thus renamed as the *ATRX* gene.

Characterization of the *ATRX* Gene and Its Protein Product

We now know that the *ATRX* gene spans approximately 300 kb of genomic DNA and contains 36 exons,[47] although exon 7 may be nonfunctional. It encodes at least two alternatively spliced, 10.5-kb mRNA transcripts that differ at their 5′ ends and are predicted to give rise to slightly different proteins of 265 and 280 kD (Fig. 15.8). A further transcript of approximately 7 kb represents an isoform that retains intron 11 and truncates at this point. This gives rise to a truncated protein isoform (ATRXt) that is conserved between mouse and human.[48]

Within the N-terminal region lies a complex cysteine-rich segment (called the ADD, domain, Fig. 15.8). This comprises a PHD-like zinc finger and an additional C_2C_2 motif just upstream, which is structurally similar to the GATA-1 zinc finger.[49,50] The PHD finger is a zinc-binding domain (Cys_4-His-Cys_3), 50–80 amino acids in length and is a common feature of chromatin-related proteins and thought to mediate protein–protein interactions.[51] The structure of the ADD domain shows that it is highly related to the zinc finger domains of DNA methyltransferases.[50] Several lines of evidence suggest that this domain may bind the N-terminal tail of histone H3 and it is also possible that the upstream GATA-1-like motif in this domain may bind DNA.[52] Both of these issues are under investigation. The functional importance of the ADD segment in *ATRX* is clear. It is highly conserved throughout evolution and it contains over 50% of all mutations found in patients with ATR-X syndrome (Fig. 15.8 and see later).

The central and C-terminal regions of *ATRX* show the greatest conservation between murine and human sequences (94%).[53] The central portion of the molecule contains motifs that identify ATRX as a member of the SNF2 group of proteins. These proteins are characterized by seven highly conserved, colinear helicase motifs. Other members of the SNF2 subfamily are involved in a wide variety of cellular functions, including regulation of transcription (SNF2, MOT1, and brahma), control of the cell cycle (NPS1), DNA repair (RAD16, RAD54, and ERCC6), and mitotic chromosomal segregation (lodestar). An interaction with chromatin has been shown for SNF2 and brahma and this may be a common theme for all members of this group

(reviewed by Carlson and Laurent[54]). The ATRX protein, although showing higher sequence homology to RAD54 than other members of this group, does not obviously fall into a particular functional category by virtue of homology in these flanking segments. RAD54 is a DNA repair enzyme, but there is no clinical evidence of ultraviolet sensitivity or the premature development of malignancy in the ATR-X syndrome, which might point to this being a defect in DNA repair. Furthermore, cytogenetic analysis has not demonstrated any evidence of abnormal chromosome breakage or segregation. Rather, the consistent association of ATR-X with α thalassemia suggests that the protein normally exerts its effect at one or more of the many stages involved in gene expression.

Mutations of the *ATRX* Gene and Their Associated Phenotype

In addition to ATR-X syndrome, mutations in the *ATRX* gene have now been found in many other forms of syndromal X-linked MR (reviewed in ref. 55) and it is also the disease gene associated with the occurrence of α thalassemia in myelodysplasia (discussed later).

To date, 113 different constitutional mutations have been documented in 182 independent families with ATR-X syndrome (reviewed in ref. 55). Missense mutations are clustered in two regions: the ADD domain and the helicase domain. Analysis of the mutations and their resulting phenotypes allows important conclusions to be drawn.

It seems likely that complete absence of ATRX, a true null, would be lethal because in a mouse ATRX knockout (null) model no affected embryos develop beyond approximately 8.5 dpc.[43] Therefore it was surprising to find a number of mutations, predicted to cause protein truncation, scattered throughout the gene in patients with ATR-X syndrome (Fig. 15.8). Such mutations would be expected to result in a major loss of function and yet they are clearly not lethal. In fact, their phenotypes are similar to (and in some cases milder than) those seen with other mutations. For example, one premature stop mutation (R37X) predicted to make a very small, truncated protein produced almost full-length protein.[32,56] This could result from translational initiation at a downstream codon[56] or by skipping the mutation via alternate splicing;[32] whatever the mechanism, this mutation was associated with a remarkably mild phenotype. In fact, similar phenotypic rescue has been seen for all the stop codons upstream of the catalytic domain studied to date.[55]

ATR-X syndrome is frequently caused by missense mutations (Fig. 15.8) and the levels of ATRX protein were shown to be substantially reduced in patients with such mutations involving the ADD domain.[52,57] The structure of the ADD domain casts light on how mutations might affect protein folding and stability.[50] Most mutations affect zinc-binding cysteine residues or residues in the tightly packed hydrophobic core thus reducing its stability. Of greater interest, there is a small cluster of surface mutations (e.g., R246C, G249D) that are associated with higher levels of stable protein. These mutations may interfere with protein function, possibly by disrupting an important protein–protein interaction.

Missense mutations affecting the helicase domain are located adjacent to, rather than within, the seven highly conserved motifs that characterize the SNF2 helicase/adenosine triphosphatase (ATPase) proteins. In other SNF2 proteins, mutations that fall in the motifs completely abolish activity. It is possible that the ATRX mutations alter, rather than abolish, the protein activity. Together, these findings are consistent with a view that mutations seen in patients who survive with ATR-X syndrome decrease rather than abolish ATRX activity.

Is There Any Relationship Between the Types of ATRX Mutation and the Phenotype?

Since the discovery of the *ATRX* gene, most new cases have been defined on the basis of severe MR, with the typical facial appearance associated with a mutation in the *ATRX* gene. This allows a less biased evaluation of the effect of *ATRX* mutations on the commonly associated clinical manifestations. The severity of three aspects of the phenotype (MR, genital abnormality, and α thalassemia) is quantifiable, to some degree.

The greatest variation in intellectual handicap is associated with a truncating mutation (R37X) at the N terminus of the protein.[30] As discussed previously, protein analysis by Western blotting has shown small amounts of full-length protein for each patient affected by this mutation. This may be associated with the use of an alternative, downstream translational initiation codon or alternative splicing. Nevertheless, there is no correlation between the degree of retardation and the amount of full-length protein seen in lymphoblastoid cell lines derived from these patients.

A number of other cases have been described with mild to moderate learning difficulties (reviewed in ref. 55). In a recent small study of 22 patients it was noted that cases with mutations in the ADD domain were less likely to walk than those with mutations affecting the helicase domain.[58] We have now confirmed this finding in a cohort of 83 affected individuals. Whereas 75% of cases with helicase mutations were able to walk only 25% of those with ADD mutations were able to do so (Fig. 15.9).

There are now eight different mutations associated with the most severe urogenital abnormalities.[55] In five, the protein is truncated, resulting in loss of the C-terminal domain, including a conserved element (P in Fig. 15.8) and polyglutamine tract (Q in Fig. 15.8). From the available data, it appears that, in the absence of the C-terminal domain, severe urogenital abnormalities are likely (although not inevitable as one mutation in this region was associated with cryptorchidism), suggesting that this region may play a specific role in urogenital development. Consistent with

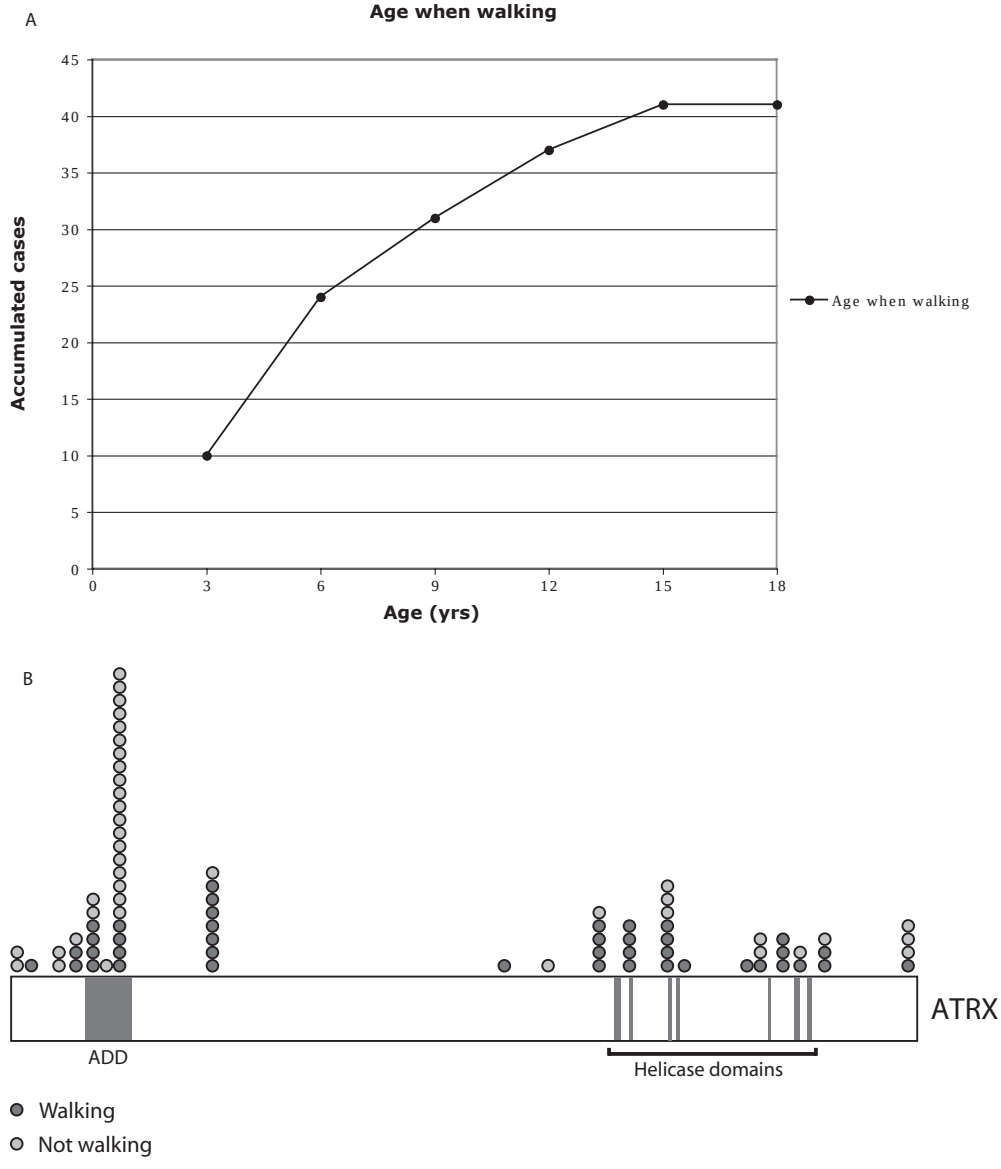

Figure 15.9. A measure of gross motor function is whether the children are able to walk and the age at which this is achieved. Forty-one affected individuals were able to walk. **(A)** Shows the age at which this was achieved. Approximately 75% of these were able to walk by the age of 9 years. None learned to walk after the age of 15 years. **(B)** This figure correlates the ability to walk with the location of the mutation. The 42 individuals who were unable to walk excluded cases who were younger than the age of 9 years at the time of assessment; the range of the ages for this group was 9–30 years. (See color plate 15.9.)

this, in families with such mutations, severe urogenital abnormalities breed true,[36,59] and a nonsense mutation (R2386X) gives rise to a similar phenotype in three unrelated families. In other regions of the protein, however, there is no obvious link between phenotype and genotype, and there is considerable variation in the degree of abnormality seen even in individuals with identical mutations.

The Relationship Between the Types of Mutation in ATRX and Thalassemia

The relationship between *ATRX* mutations and α thalassemia is unclear. Because the presence of excess β chains (HbH inclusions) was originally used to define the ATR-X syndrome, current observations are inevitably biased. Nevertheless, there is considerable variability in the degree to which α-globin synthesis is affected by these mutations, as judged by the frequency of cells with HbH inclusions. Up to 15% of patients do not have HbH inclusions[39,40,60] (Fig. 15.10), although this does not rule out downregulation of α-globin expression because inclusions may not appear until there is 30%–40% reduction in α-chain synthesis (Chapter 14).

It is interesting that patients with identical mutations may have very different, albeit stable, degrees of α thalassemia, suggesting that the effect of the ATRX protein

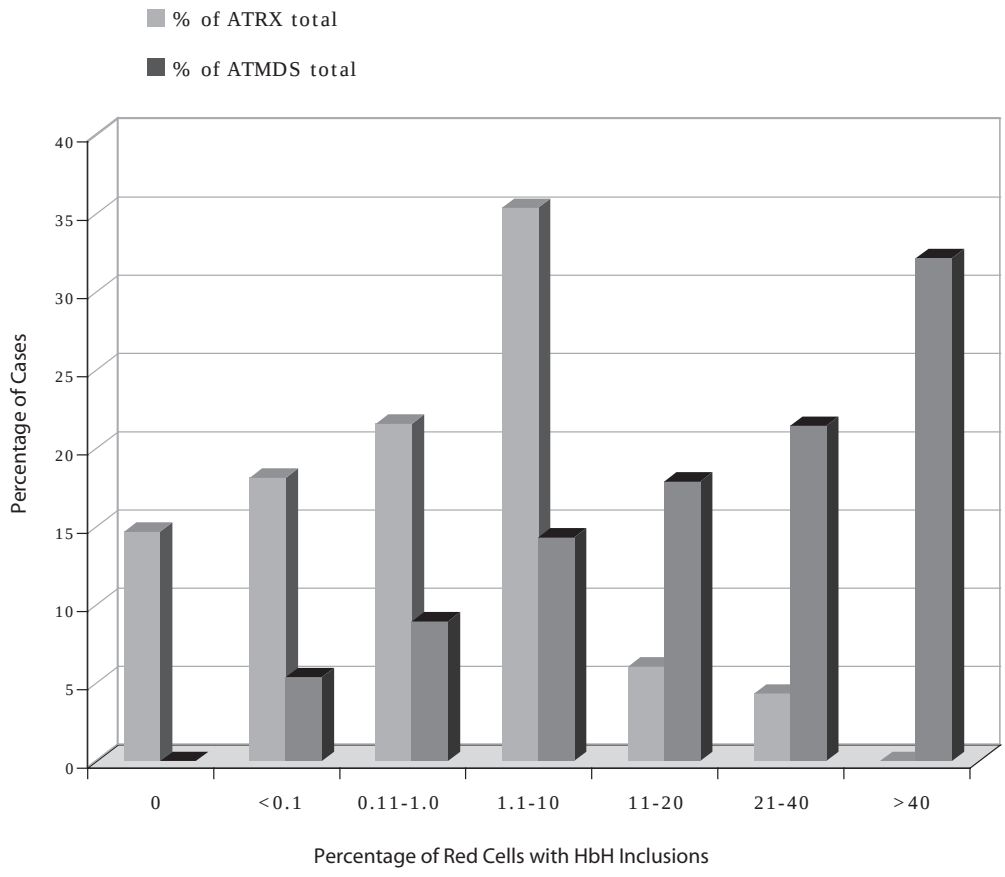

Figure 15.10. Percentage of cells with HbH inclusions in cases of ATR-X syndrome in which the presence of inclusions has been demonstrated and quantified. (See color plate 15.10.)

on α-globin expression may be modified by other genetic factors. This is most clearly illustrated by comparing the hematology of cases with identical mutations. Comparison of the 41 cases from 34 pedigrees with the common 736C>T; R246C mutation shows a wide range in the frequency of cells with HbH inclusions (0%–14%). Preliminary studies indicate that the haplotype of the α-globin locus influences the severity of the thalassemia and presumably there is a feature within this region that is variable and confers different degrees of ATRX dependency (unpublished observation).

What is the Normal Functional Role of ATRX?

In the adult, ATRX mRNA is widely expressed early in development, and continues to be widely expressed throughout development with particularly high expression in the brain, heart, and skeletal muscle.[61] Both isoforms, ATRX (280 kD) and ATRXt (200 kD), are readily detected on Western blots.[48,57] Immunocytochemical analysis and indirect immunolocalization demonstrate that both isoforms are nuclear proteins that predominantly associate with heterochromatin (in interphase and metaphase).[48,57] A significant proportion of ATRX (but not ATRXt) is also found in nuclear speckles (called promyelocytic leukemia bodies) in human cells.[62,63] One additional, striking finding in human metaphase preparations is that ATRX antibodies localize to the short arms of acrocentric chromosomes associated with the rDNA arrays.[64] Undoubtedly, a significant proportion of ATRX can be seen to be associated with heterochromatin and it is possible that the remainder of ATRX, which cannot yet be visualized, may be associated with euchromatic regions of the genome. The next questions are how is ATRX recruited to chromatin and what does it do when it gets there?

Like other members of the SNF2 family, ATRX appears to be part of a multiprotein complex. Preliminary experiments show that ATRX fractionates as a very large complex (approximately 1 Md) by Superose 6 gel filtration. These protein interactions could mediate both recruitment and contribute to ATRX function. One of the proteins with which ATRX has been shown to interact is the heterochromatin protein HP1, a structural adapter, implicated in both gene silencing and supranucleosomal chromatin structure. This interaction has been observed by the yeast two-hybrid experiments,[65] immunoprecipitation,[62]

and indirect immunofluorescence,[57] and the observations are supported by genetic manipulation of the system (SuVar39H1) by which HP1 (and possibly ATRX) is recruited to heterochromatin.[66] ATRX may also be recruited to heterochromatin via other, similar interactions. For example it has been shown that in postmitotic neurons ATRX is recruited to heterochromatin via $MeCP_2$.[67]

The ADD domain of ATRX is another potential site for protein interactions that may recruit ATRX to chromatin. One component of this domain is a PHD zinc finger that, in other proteins, appears to mediate an interaction with chromatin.[51] Recent studies have shown that the PHD finger domains of at least two chromatin-associated proteins (BPTF and ING1) specifically recognize H3 histone tails (H3K4me3).[68,69] In addition, the ADD domain of Dnmt3a binds to the sequence-specific DNA-binding protein RP58.[70] A similar interaction between ATRX and other sequence-specific DNA-binding proteins may be responsible for targeting ATRX to specific loci or alternatively recruiting specific loci to repressive heterochromatin.

What role might ATRX play at chromatin? Like other members of the SNF2 family, both recombinant ATRX[71] and endogenous ATRX (isolated from cells by immunoprecipitation)[63] have been shown to have ATPase activity and weak nucleosome remodeling activity.[63] The ATRX protein (complex) exhibits an impressive ability to move (translocate) along double-stranded DNA[63] (and Mitson et al. in preparation), suggesting that ATRX may be able to move nucleosomes to facilitate access of transcription factors or DNA modifying enzymes, for example. Identifying the preferred substrate that is associated with maximal ATPase activity and the assay best suited to reveal the manner by which ATRX interacts with chromatin requires further work.

Finally a variety of other potential protein interactions with ATRX may be relevant. The strongest candidate is the protein Daxx,[63] which has been implicated in both apoptotic pathways and in the regulation of transcription. It has also been shown that the ADD domain of Dnmt3a interacts with the histone deacetylase HDAC1.[70] Interestingly, the PHD motif of Mi2b also binds HDAC1, and it is possible that this component of the ATRX-associated ADD domain may also bind HDAC. In a directed use of the yeast two-hybrid system, Cardoso et al.[72] investigated the interaction of ATRX with a variety of heterochromatin-associated proteins. An interaction was demonstrated between ATRX (475–734) and the SET domain of polycomb group protein EZH2, an enzyme that modifies chromatin. More work is required to substantiate the importance of these observations in vivo.

Functional Consequences of Mutations

Some clues to the normal role of ATRX may come from observing what happens when the gene is mutated. Perhaps the most striking observation is that mutations in ATRX are associated with changes in gene expression (hence α thalassemia) but the mechanism underlying this is currently unknown.

The effects of ATRX mutations on the chromatin structure of the rDNA arrays located at the tips of acrocentric chromosomes have been studied. Although no gross changes in DNase l, micrococcal nuclease, or endonuclease accessibility were detected, striking differences were noted in the pattern of rDNA methylation between normal controls and patients with ATR-X syndrome.[64] In normal individuals, approximately 20% of the transcribed units were methylated, whereas in ATR-X patients, rDNA genes were substantially unmethylated. The hypomethylated regions in ATR-X individuals localized within the CpG-rich region of the rDNA repeat, which contains the transcribed 28S, 18S, and 5.8S genes and resembles a large CpG island.

Because ATRX is also associated with heterochromatin, which contains a substantial proportion of the highly repetitive DNA in mammalian genomes, these methylation studies were extended to other repetitive sequences containing CpG dinucleotides known to be epigenetically modified by methylation. In this way, two additional sequences were identified that were abnormally methylated in ATR-X patients. Y-specific repeats (DYZ2) were almost all methylated in ATR-X patients, whereas approximately 6% were unmethylated in peripheral blood of normal individuals. Subtle changes in the pattern of methylation were also observed in the TelBam3.4 family of repeats, which are mainly found in the subtelomeric regions.

Perturbations in CpG methylation have been observed with mutations in another mammalian SWI-SNF protein PASG (also known as Lsh and HELLS)[73] and its plant homolog, DDM1.[74] This raises the possibility that ATPase-dependent chromatin-remodeling activities are involved in the establishment or maintenance of DNA methylation and that different SWI/SNF proteins (e.g. ATRX and PASG) may be required for different chromatin environments. To date, no change in the pattern of methylation has been detected in the α-globin gene cluster to explain the presence of α thalassemia.

Summary of the ATR-X Syndrome

Despite considerable progress in defining the phenotype in ATR-X syndrome, describing the properties of the protein and the consequence of mutations, little is known about the function of this protein. In particular, its role in α–globin expression remains elusive. A key puzzle to be solved is how a protein that associates with heterochromatin, and is required for a normal pattern of DNA methylation at repetitive DNA, influences the expression of euchromatic genes. Further progress needs to be made to identify ATRX

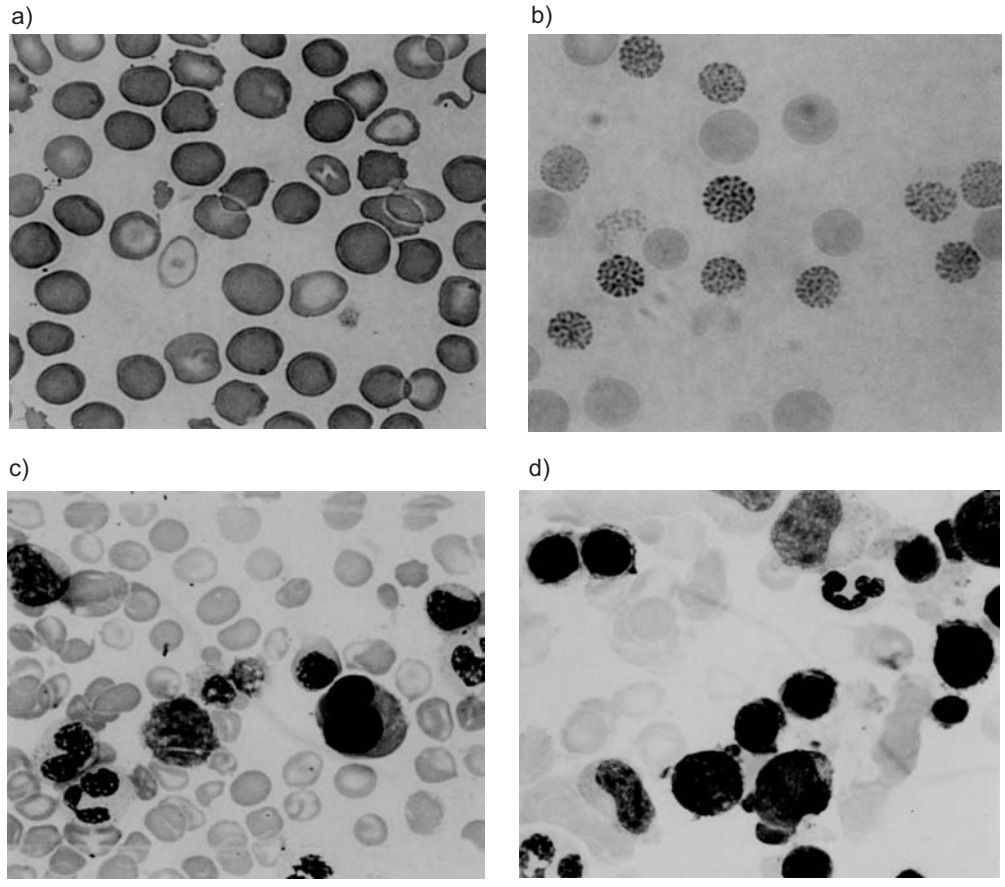

Figure 15.11. (a) May-Grünwald-Giemsa–stained peripheral blood smear from an elderly woman with ATMDS (original magnification, 400X). Many red cells are hypochromic, microcytic, or both, whereas others look relatively normal. As expected, the red blood cell distribution width (RDW) was elevated (19%; normal range, 11%–15%) in this patient. Iron studies were unremarkable. **(b)** Brilliant cresyl blue–stained peripheral blood smear from a 56-year-old man with ATMDS who had characteristic microcytic, hypochromic red cell indices: in this case, an MCH of 19 pg and MCV of 66 fL (original magnification, 600X). Abnormal inclusion-containing "golf ball cells" are easily distinguished from normal reticulocytes and red cells and confirm the presence of HbH (β-globin tetramers.) In this case, supravital staining was performed by incubating fresh blood for 24 hours with 1% brilliant cresyl blue in 0.9% normal saline. **(c)** and **(d)** Bone marrow samples from patients with ATMDS showing dyserythropoietic erythroblasts including binucleate cells. (See color plate 15.11.)

target genes and understand the role it plays at these loci.

AN ACQUIRED FORM OF α THALASSEMIA ASSOCIATED WITH MYELOID MALIGNANCY (ATMDS SYNDROME)

Occasionally, patients who previously exhibited normal erythropoiesis will develop an acquired form of α thalassemia, which most commonly arises within the context of hematological malignancy.[75] The first cases of this "acquired hemoglobin H (HbH) disease" were described in 1960.[76,77] Over the past half century, it has become clear that all cases of acquired α thalassemia arise in the context of an underlying clonal disorder of hematopoiesis, most commonly a form of the myelodysplastic syndromes (MDS) as defined by the latest World Health Organization hematopoietic neoplasia classification scheme.[78] Therefore, this condition is now commonly referred to as α thalassemia–myelodysplastic syndrome (ATMDS; Mendelian Inheritance in Man (OMIM) #300448).[79]]. Although other acquired hemoglobin synthetic defects such as acquired β thalassemia or perturbations in the level of HbF and HbA_2 can complicate MDS or other chronic myeloid disorders, these appear to be less common than α thalassemia, and they have not received a specific syndromic designation.[80–83]

The most dramatic and easily recognized ATMDS phenotype is that of a severe form of HbH disease, characterized by striking hypochromic microcytic anemia, numerous HbH inclusions detectable by supravital staining of peripheral blood (Fig. 15.11), and measurable amounts of HbH in the hemolysate.[84] There are also milder forms of ATMDS, in which rare HbH-containing erythrocytes can be detected on the peripheral smear. In these cases, inclusion-containing cells make up less than 1% of anucleate erythrocytes, and HbH represents such a small fraction

of the total hemoglobin that it is not easily demonstrable by routine chromatographic or gel electrophoretic techniques.[85] Some of these mildly affected patients – along with others with more severe forms of ATMDS who have been recently transfused with red blood cells from healthy donors – exhibit normocytic or even macrocytic red cell indices, and thus may not be recognized by clinicians.

In the past, most mildly affected ATMDS cases were detected incidentally when a supravital stain of the peripheral blood was performed for another reason, usually to evaluate the reticulocyte count. Many clinical hematology laboratories now quantify reticulocytes by dye-based flow cytometric methods rather than by supravital staining, and thus it is likely that many ATMDS cases, especially those cases with small numbers of HbH cells, now go undetected.[86]

General Clinical Features

More than 80 well-documented patients with ATMDS have been described to date; a global ATMDS Case Registry is maintained in Oxford, and can be viewed at: http://www.imm.ox.ac.uk/groups/mrc_molhaem/home_&break;pages/Higgs/ATMDS.xls. Case clustering among clinical groups who have developed an interest in the disorder suggests that the condition is likely to be underreported. Additionally, most described patients with ATMDS have been of European origin (88% of cases in the Registry), yet current understanding of the molecular pathology of the disease (see later) does not offer a reason for such an imbalanced geographical distribution. Instead, the global distribution of reported cases may reflect detection and reporting bias. Patients diagnosed with MDS who have microcytic red cell indices, and who originate from regions of the world where inherited forms of thalassemia are common, might reasonably be assumed to have a previously undetected inherited disorder of hemoglobin synthesis. Regardless, in all ATMDS cases for which archival data are available, there has been no evidence of a preexisting inherited form of α thalassemia.[87]

At present, other than the disease-defining red cell changes, there are no clinical features that clearly distinguish ATMDS from MDS more generally, although there is a greater male predominance than is observed in chronic myeloid disorders overall (85% of ATMDS cases have been men, whereas the male/female ratio in MDS in general is ~1.5:1).[75] The reason for this dramatic sex imbalance in ATMDS is unclear. Patients with ATMDS are diagnosed at similar ages to patients with chronic myeloid disorders who lack thalassemia (median age, 68 years), have similar marrow findings and karyotypic results, have a median survival typical for MDS overall (2–3 years), and die of the same complications – primarily death from infection and, in approximately 25% of cases, of complications of progression to acute myeloid leukemia.[75] When ATMDS progresses to acute myeloid leukemia, and the ability of hematopoietic cells to differentiate is further impaired, some patients still continue to have detectable HbH, whereas in other cases the HbH inclusions disappear entirely.

Most patients with acquired α thalassemia have MDS (>80%), but a few have chronic idiopathic myelofibrosis or another form of myeloproliferative disease, and rarely patients with acquired HbH disease present with acute myeloid leukemia without an apparent antecedent chronic myeloid disorder.[75] There was also a single case report of acquired α thalassemia in association with TdT-positive acute lymphoblastic leukemia; this case predated the modern era of molecular diagnostics and leukemia immunophenotyping.[88] No other cases of acquired thalassemia have been described in association with a lymphoproliferative disorder or plasma cell dyscrasia.

α/β Globin mRNA and Globin Chain Synthesis Ratios in Patients with ATMDS

The α- to β-globin mRNA ratio has only been studied in a few patients with ATMDS, but it was severely reduced in all these cases (range, 0.06–0.50).[89] Likewise, the reticulocyte α/β-globin chain synthesis ratio was similarly reduced in all 25 patients in whom this ratio has been analyzed (mean 0.28, range 0.05–0.67; normal 0.9–1.2). In the most severely affected individuals, α-chain synthesis is almost completely abolished (Fig. 15.12). The α/β-chain synthesis ratio may vary quite considerably during the course of the disease, and this is reflected in varying proportions of HbH-containing cells on serial supravital staining.[89] In contrast to the typical findings in ATMDS, the α/β-chain synthesis ratio was reported as elevated in a small series of MDS patients without thalassemic red cell indices.[90]

Red Cell Indices and Hematological Findings in ATMDS

Patients with ATMDS are always anemic at presentation (mean hemoglobin 8.5 g/dL), with a reduced red blood cell count (mean 4.3×10^{12}/L) and markedly hypochromic and microcytic red cell indices (average MCH 22 pg and MCV 75 fL).[75] These abnormalities are even more striking when compared with a control population of patients with MDS without thalassemia, who at presentation tend to have slightly higher than normal MCH and MCV values (average MCH 31 pg and MCV 97 fL) (Fig. 15.13). The red cell distribution width has been increased in all ATMDS patients studied.

These hematological findings are reflected in the typical peripheral blood red cell morphology (Fig. 15.11). All patients examined have had at least some hypochromic microcytic red cells, and in many cases there is marked anisopoikilocytosis. In some cases, it appears that there are at least two populations of red cells: some are quite well hemoglobinized and of relatively normal appearance, whereas others contain scant hemoglobin and are often

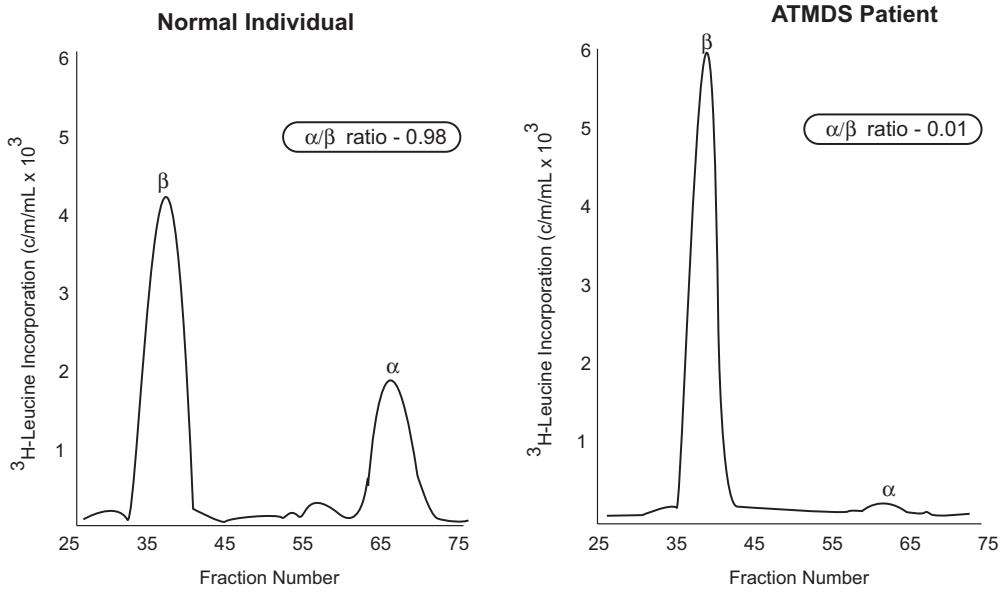

Figure 15.12. Measurement of reticulocyte α/β-globin chain synthesis ratio by radioisotope labeling and CM cellulose chromatography in a patient with ATMDS. In this case, α-globin production was markedly downregulated, and the α/β-chain synthesis ratio estimated by an area-under-the-curve method was only 0.01 (normal, 0.9–1.2). A normal chromatogram is depicted at left, for comparison. (See color plate 15.12.)

little more than "ghost cells." This picture is likely to be a consequence of mixed clonality of the bone marrow in MDS and ATMDS, with residual normal hematopoietic cells coexisting with dysplastic clones, including (in ATMDS) progenitor cells with thalassemic erythrocyte progeny that have HbH inclusions and synthesize little or no normal hemoglobin.

Hemoglobin Analysis in ATMDS

All patients with ATMDS by definition have detectable amounts of HbH in their peripheral red blood cells at some stage of the disease. In general, levels of HbH measured by column chromatography or agarose gel electrophoresis are lower than the proportion of anucleate erythrocytes that contain HbH inclusions on a supravital stained-peripheral blood smear. At the time of first detection of ATMDS, the proportion of red cells containing HbH inclusions after incubation with brilliant cresyl blue varies between less than 0.1% and 95% (median, 30%). HbH as a proportion of total hemoglobin ranges between 1% and 57% (median, 15%). Often it is not possible to obtain accurate estimations of HbH in a given ATMDS case because of prior blood transfusions. In some patients, trace amounts of Hb Bart's

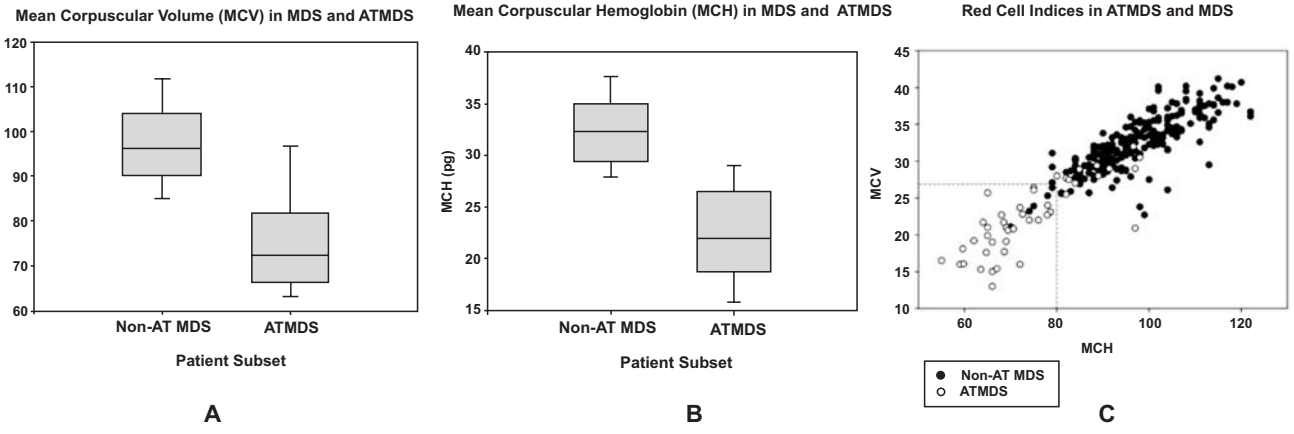

Figure 15.13. Distribution of red cell indices in patients with ATMDS compared with a more general population of patients with MDS. **(A)** MCV at the time of initial presentation in ATMDS (n = 55) vs. MDS (n = 282). Boxes enclosed 25th through 75th percentiles; middle bar denotes the median; whiskers outline the 10th through 90th percentiles. **(B)** MCH in ATMDS vs. MDS. **(C)** Scattergram of MCH vs. MCV distribution in patients with ATMDS (open circles) vs. MDS (closed circles). (γ globin tetramers) can be found. In the presence of these high oxygen affinity hemoglobins, the whole blood oxygen dissociation curve is shifted to the left, exacerbating the physiological consequences of anemia.[1] Levels of HbA_2 and HbF in ATMDS are variable and inconsistently abnormal.

The Molecular and Cellular Basis for ATMDS

For many years, the molecular etiology of ATMDS was mysterious, but recently, considerable progress toward a mechanistic explanation has been made.[91] It is now clear that most patients with ATMDS have an acquired, somatic point mutation or an mRNA intron–exon splicing abnormality involving *ATRX*, the X-linked gene that encodes the chromatin remodeling factor ATRX (Fig. 15.8).[92,93] This exciting finding provides a partial explanation for the ATMDS phenotype.

Although almost all of the common inherited forms of α thalassemia worldwide are due to deletions or, less commonly, point mutations involving the α-globin gene cluster and its major upstream regulatory element (HS-40), this class of mutation is not typically found in ATMDS.[94] ATMDS cases selected for initial molecular evaluation were those with less than 10% of the normal levels of α-globin mRNA and α-globin synthesis. This extreme degree of impairment of α-globin synthesis is even greater than one typically sees in patients with only a single functional α-globin gene, suggesting that all four α genes are downregulated in ATMDS. Detailed structural analysis of the α-globin genes and approximately 130 kb of their flanking regions on chromosome 16p in these cases consistently revealed no abnormalities, even in the most severely affected patients.[79] In addition, direct sequencing of the globin genes was unremarkable.

In a single reported ATMDS case, the telomeric end of chromosome 16p, including the α-globin cluster, was deleted in a clonally restricted fashion as part of a complex MDS-associated karyotype with numerous large chromosomal rearrangements.[95] This case – in which the extent of the deletion was mapped by FISH – proved exceptional, and no other ATMDS cases have been found to harbor rearrangements of chromosome 16p. Because the presence of multiple cryptic *cis*-acting mutations seemed an unlikely basis for ATMDS, investigators' attention focused next on the possibility of a *trans*-acting mutation, either involving a factor that normally controls α-globin gene expression or a novel gene that exerts a dominant negative effect.

Further support for the possibility of a *trans*-acting defect came from the generation of an interspecific hybrid between bone marrow from an ATMDS patient and adenine phosphoribosyl transferase (APRT)–deficient mouse erythroleukemia (MEL) cells.[96] (APRT is encoded on chromosome 16q24 in humans.) After selection for restored APRT activity, such hybrids retained human chromosome 16 derived from the ATMDS patient in a murine erythroid background, and the human chromosome directed normal levels of human α-globin synthesis. Although these findings would appear to exonerate chromosome 16p in ATMDS, it is also possible that the human cell that originally fused with the MEL cell could have been from an unaffected hematopoietic clone in view of the mixed clonality of MDS. Thus, even this result was not considered definitive evidence of a *trans*-acting defect.

The major clue that led directly to identification ATRX mutations as the specific *trans*-acting molecular defect underlying most ATMDS cases came from a cDNA microarray experiment, in which granulocyte RNA from a patient with severe, newly diagnosed ATMDS was compared with pooled granulocyte RNA from seven healthy donors.[92] Granulocyte RNA was chosen because it is likely to be enriched for mutant clones in chronic myeloid neoplasia, compared with other easily isolated blood cell populations that might also have been suitable for genetic analysis. Strikingly, in this pilot cDNA microarray study, *ATRX* was one of the genes with the very lowest expression in the patient with ATMDS compared with the healthy controls. Sequencing of granulocyte-derived genomic DNA from the ATMDS patient demonstrated a G>A point mutation in the canonical splice donor motif of *ATRX* intron 1, probably resulting in nonsense-mediated decay of the ATRX transcript.[92] In contrast to granulocytes, the patient's buccal cells were ATRX wild type, supporting the clonally restricted nature of the mutation. In view of the important role that ATRX mutations play in congenital ATR-X syndrome (including an association with variable degrees of α thalassemia), ATRX mutations seemed biologically plausible as the cause of α-globin downregulation in ATMDS.[97] Precisely how mutations in ATRX result in down-regulation of α-globin expression is the subject of active investigation, and our current understanding is discussed in detail elsewhere in this text.

Subsequent molecular analysis of archival material from 18 other ATMDS patients revealed ATRX mutations or pre-mRNA splicing abnormalities in almost all cases (14 of 19 total).[93] There is considerable allelic heterogeneity (Fig. 15.8). Reassuringly, when new ATMDS cases with substantial amounts of HbH have come to light, they have also consistently had point mutations involving evolutionarily conserved regions of ATRX.[98–100] This is true not only for men, who have hemizygous ATRX mutations, but also for the rare women with ATMDS, who can be demonstrated to have heterozygous mutations in ATRX.[100] Presumably, the retained wild-type ATRX allele in these women is located on the copy of the X chromosome that was inactivated during embryogenesis, and it is not expressed at a high enough level to "rescue" α-globin expression in the progeny of the ATRX-mutant clone.

Implications of ATRX Mutations in ATMDS

In general, patients with ATMDS have a more severe form of α thalassemia than boys with inherited ATR-X syndrome.

More than 30% of described ATMDS patients have had more than 50% of circulating erythrocytes containing HbH inclusions, whereas 90% of boys with ATR-X syndrome have less than 10% HbH-containing cells.[93,101] Even when an identical or similar ATRX mutation is detected in the germline in ATR-X syndrome and as a somatic change in the hematopoietic cells in ATMDS, the thalassemic phenotype is consistently more severe in ATMDS than in ATR-X. For instance, a boy with germline c.576G>S, p.L192F ATRX mutation had 0.1% HbH, whereas a man with ATMDS who had the identical mutation as an acquired phenomenon had 50% HbH. The reason for this striking difference is unclear and is suspected to be dependent on the cellular context, perhaps pointing to an interaction between ATRX mutations and a disturbed genetic or epigenetic background in MDS cells that is due to other mutations not present in boys with inherited ATR-X syndrome.

In a few patients with ATMDS, an ATRX point mutation has not been detected, despite careful investigation. Most of these patients have had less than 10% HbH, and issues related to sensitivity of the tools used for mutation detection may account for the negative results, although it remains possible that mutations in another as yet undefined *trans*-acting factor can cause an ATMDS phenocopy. Direct fluorescent dye chemistry-based DNA sequencing can only detect mutations at a level of approximately 20%–30% mutant DNA in a wild-type background, and may miss acquired mutations that are present at lower levels of clonality.[93] Other mutation screening techniques, such as denaturing high-performance liquid chromatography and denaturing-gradient gel electrophoresis, offer higher analytical sensitivity (down to ~1% mutant DNA), but these techniques also do not detect ATRX mutations in all ATMDS cases. In some ATMDS cases, only genomic DNA has been available for screening, and it is possible that some of these cases actually have an alteration in ATRX pre-mRNA splicing, as has been described in several ATMDS cases in which both DNA and RNA were accessible for analysis.[92,93,98,102]

Supravital staining of unselected MDS cases (i.e., without regard for red cell indices) demonstrates small numbers of HbH inclusion-containing cells in 8% of cases; these cells are not present in other forms of anemia not associated with a clonal myeloid disorder, and therefore are not simply a byproduct of disordered erythropoiesis.[85] It seems likely that α thalassemic clones arise fairly commonly in the marrow milieu of MDS, for unclear reasons, and that these changes alone do not give the cells that bear them any sort of competitive advantage. Additional mutations are probably required to provide a clone that happens to be thalassemic with a survival or proliferative advantage, leading ultimately to clonal dominance, and these secondary changes may account for the more dramatic ATMDS phenotypes.

Remaining Questions About ATMDS

One of the most exciting prospects for the discovery of ATRX mutations in ATMDS is that this finding may yield some new general insights into the pathobiology of MDS. Such advances would be welcome, as MDS has proven to be a rather intractable disorder, both from the standpoint of analysis of disease mechanism and from a therapeutic perspective.[103] Since the discovery of ATRX mutations in ATMDS, candidate gene analysis in MDS has focused on genes encoding known or suspected ATRX binding partners (HP1, DAXX, EZH2) or homologous SWI/SNF2 family members implicated in leukemogenesis (HELLS/LSH/SMARCA6), but these studies have thus far been unrevealing.

The reason for the sex imbalance in ATMDS remains unclear. The fact that ATRX is an X-linked factor can provide only a partial answer, as other conditions that are caused by acquired mutations in genes on the X chromosome (e.g., paroxysmal nocturnal hemoglobinuria) do not display such a striking sex distinction.

The fact that germline ATRX mutations are known to be associated with diverse alterations in DNA methylation across the genome has particular relevance in MDS, in which methylation changes are common and which some investigators have labeled an "epigenetic disease."[64,104,105] Two of the first three drug therapies approved by the United States Food and Drug Administration for the treatment of MDS – azacitidine (approved in 2004) and decitabine (approved in May 2006) – are aza-substituted cytosine nucleoside analogs that irreversibly bind to DNA methyltransferase 1 (DNMT1) and inhibit its enzymatic activity.[106–108] DNMT1 inhibition that persists through the cell cycle results in alteration in the 5′ methylation status of cytosine in CpG dinucleotides in gene promoters, with subsequent changes in gene expression. Anecdotally, one ATMDS patient treated with hypomethylating therapy experienced unusually profound and prolonged marrow aplasia, but it is uncertain whether this is merely a coincidence or is mechanistically related.[99]

Summary of ATMDS Syndrome

Over the past few years, considerable progress has been made in understanding the molecular basis for the rare syndrome of ATMDS, when α thalassemia is acquired as a "passenger" mutation (rather than a causative mutation) in MDS. We now know that the associated α thalassemia results from mutation in the X-encoded *ATRX* gene, which is also the disease gene in the inherited condition ATR-X syndrome. A remaining puzzle is why the same mutation in ATRX causes a mild form of thalassemia, whereas in ATMDS it causes severe HbH disease. It seems likely that the ATRX mutation is somehow made more severe when it interacts with one or more of the common genetic or

epigenetic mutations in MDS. Understanding the mechanism underlying the severe α thalassemia in this fascinating syndrome may shed some light on the molecular basis of the common forms of MDS.

SECTION FOUR

THE β THALASSEMIAS

Bernard G. Forget

Over the years, study of the thalassemia syndromes has served as a paradigm for gaining insights into the factors that can regulate or disrupt normal gene expression. The thalassemias constitute a heterogeneous group of naturally occurring, inherited mutations characterized by abnormal globin gene expression resulting in total absence or quantitative reduction of α- or β-globin chain synthesis in human erythroid cells. α Thalassemia is associated with absent or decreased production of α-chains, whereas in the β thalassemias, there is absent or decreased production of β-chains. In those cases in which some of the affected globin chain is synthesized, early studies demonstrated no evidence of an amino acid substitution. In all cases in which genetic evidence was available, the thalassemia gene appeared to be allelic with the structural gene encoding α- or β-globin. The elucidation of the nature of the various molecular lesions in thalassemia has been a fascinating process, and full of surprises. Increase in our knowledge of the molecular basis of β thalassemia has closely followed and depended on progress and technical breakthroughs in the fields of biochemistry and molecular biology. In particular, recombinant DNA and polymerase chain reaction–based technologies have contributed to a virtual explosion of new information on the precise molecular basis of most forms of thalassemia. The accrual of this knowledge has, to a great degree, paralleled the acquisition of new, detailed information on the structure, organization, and function of the normal human globin genes, as described in the preceding chapters. Historically, as new techniques have been developed for the study of protein synthesis and gene expression, they have been rapidly applied to the study of normal human hemoglobin synthesis and the abnormalities associated with abnormal globin gene expression in thalassemia. As a result, there has gradually emerged a progressively clearer and increasingly complex picture of the molecular pathology of this group of genetic disorders. One major conclusion that was drawn as this mystery unfolded was that a relatively limited number of phenotypes can result from a surprisingly large number of varied genotypes.

The chapters that follow will describe in detail the knowledge and progress that have accrued over the last 3–4 decades on the understanding of the pathophysiology, the molecular genetics, and the clinical manifestations and management of the various β thalassemia syndromes and related disorders.

There are many primary and secondary causes for the anemia observed in β thalassemia. It is easy to understand how reduced synthesis of β-globin chains of Hb A ($\alpha_2\beta_2$) will result in an overall deficit of hemoglobin accumulation in red cells and cause a hypochromic, microcytic anemia with a low mean corpuscular hemoglobin concentration in affected erythrocytes. This is true in both the heterozygous and homozygous states. In the homozygous state, however, another pathophysiological process worsens the anemia and is responsible for the major clinical manifestations in the syndrome referred to as β thalassemia major or Cooley's anemia. The continued synthesis in normal amounts of normal α-globin chains results in the accumulation, within the erythroid cells, of excessive amounts of these chains. Not finding complementary globin chains with which to bind, these chains form insoluble aggregates and precipitate within the cell, causing membrane damage and premature destruction of the red cells. The α-chain aggregates are called inclusion bodies or, perhaps improperly, Heinz bodies. In contrast to true Heinz bodies, which are made up of total precipitated hemoglobin tetramers, these inclusion bodies have been shown to consist only of α-globin chains, which do have some attached heme in the form of hemichromes. The process of inclusion body formation occurs not only in mature erythrocytes, but in particular in the erythroid precursor cells of the bone marrow. As a result, there is extensive intramedullary destruction of erythroid precursor cells, a process that is called ineffective erythropoiesis.

The severity of the clinical manifestations in β thalassemia generally correlates well with the size of the free α-chain pool and the degree of α- to non-α-globin chain imbalance. Therefore, the fortuitous coinheritance of α thalassemia together with homozygous β thalassemia reduces the degree of α- to non-α-globin chain imbalance and leads to a milder clinical course. Similarly, coinheritance of β thalassemia with conditions that are associated with increased levels of synthesis of γ-chains of HbF ($\alpha_2\gamma_2$) leads to less imbalance between α- and non-α-globin chain synthesis, resulting in decreased formation of α-chain inclusion bodies, increased effective production of red cells, and their prolonged survival in the circulation.

The clinical course in most cases of homozygous β thalassemia is severe. Although anemia is not evident at birth, severe hypochromic, microcytic, hemolytic anemia develops during the first year of life and a regular transfusion program must be undertaken to maintain an adequate circulating hemoglobin level. The clinical manifestations

of homozygous β thalassemia in childhood have changed considerably over the last 3–4 decades, owing to changes in the philosophy and practice of transfusion therapy. With modern transfusion therapy, most children will develop normally, with few or no skeletal abnormalities, and will have a reasonably good quality of life. To avoid iron overload from transfusional hemosiderosis, transfusion therapy is usually coupled with a vigorous program of iron chelation, typically using parenterally administered desferrioxamine and more recently, orally effective iron-chelating agents. Although it is possible to maintain iron balance with such a management program, compliance is often difficult to achieve. Iron overload eventually develops in most patients and is the major cause of morbidity and mortality in young adults. The one therapy that is curative is bone marrow or stem cell transplantation, which is being increasingly practiced when feasible. The hope for the future is the development of even more effective oral iron-chelating agents and improved approaches to gene therapy.

Studies of the molecular basis of β thalassemia have demonstrated that the gene defects responsible for the disorder are quite heterogeneous. In contrast to α thalassemia, in which deletions in the α-globin gene cluster account for most of the mutations, the molecular defects associated with β thalassemia are usually point mutations involving only one (or a limited number of) nucleotide(s), but resulting in a major defect of β-globin gene expression either at the transcriptional or posttranscriptional level, including translation. Practically every conceivable type of defect in gene expression has been identified in one form or another of β thalassemia. Over 175 point mutations have been identified. Some deletion types of β thalassemia have also been described. In cases of β thalassemia in which β-globin gene expression is not totally absent (so-called β^+ thalassemia), the β-chain that is synthesized is usually structurally normal. There is a syndrome called dominant β thalassemia in which a highly unstable, structurally abnormal β-globin chain is synthesized, resulting in inclusion body formation in the heterozygous state. The coinheritance of HbE ($\alpha_2\beta_2$ glu26lys) with β thalassemia is very prevalent in southeast Asia and results in markedly variable and heterogeneous clinical manifestations, the basis for which is poorly understood. Finally, there are a number of β thalassemia-like disorders, called δβ thalassemia and hereditary persistence of fetal hemoglobin, that are distinguished from the more typical forms of β thalassemia by the presence of a substantial elevation of HbF in heterozygotes, as well as in homozygotes and compound heterozygotes. These disorders are usually due to deletions of different sizes involving the β-globin gene cluster, although nondeletion types of these disorders have also been identified.

The great heterogeneity of molecular lesions causing β thalassemia may appear at first glance to create insurmountable problems in putting this knowledge to practical use in the form of prenatal diagnosis and genetic counseling. The availability of rapid and accurate polymerase chain reaction–based assays for the detection of specific mutations in small samples of DNA has resulted in a number of surveys for the detection of the prevalence of different β thalassemic mutations in various population groups. The results of these surveys indicate that a given mutation is usually found only within one racial group and not another. Furthermore, a small number of different mutations, usually five or six, frequently accounts for 90% or more of the cases of β thalassemia in a given population group. Thus, it is possible to devise efficient and precise prenatal diagnosis programs using DNA-based approaches. Such programs have led to a striking decrease in the number of births of infants with homozygous β thalassemia in many countries where the disease is prevalent.

The Molecular Basis of β Thalassemia, δβ Thalassemia, and Hereditary Persistence of Fetal Hemoglobin

Swee Lay Thein and William G. Wood

INTRODUCTION

The β thalassemias and related disorders are characterized by a quantitative reduction in the production of β-globin chains of HbA. More than 200 β thalassemia alleles have now been characterized (http://globin.cse.psu.edu) involving mutations affecting any of the steps in the transcription of the β-globin gene, posttranscriptional processing of its pre-mRNA, or the translation of its mRNA into protein. The vast majority of simple β thalassemias are caused by point mutations within the gene or its immediate flanking sequences, although small deletions involving the β gene may also occur. If β-chain production is totally abolished by the mutation it is referred to as β^0 thalassemia, whereas reduced output of β-chains (of normal structure) produces β^+ thalassemia, with the mildest forms sometimes referred to as β^{++} or "silent" β thalassemia. These common forms of β thalassemias are inherited as haploinsufficient mendelian recessives.

Some structurally abnormal β-chain variants are also associated with quantitative deficiencies of β-globin chain production and have a phenotype of β thalassemia, in which case they are referred to as "thalassemic hemoglobinopathies," for example, HbE (β26 Glu→Lys). In others, the β-globin variants are so unstable that they undergo very rapid postsynthetic degradation giving rise to a functional deficiency. These hyperunstable β-chain variants act in a dominant negative fashion, causing a disease phenotype even when present in the heterozygous state, and hence have been referred to as "dominantly inherited β thalassemia."[1] β Thalassemia mutations that segregate independently of the β-globin cluster have been described in occasional families. In such cases, *trans*-acting regulatory factors are implicated.[2–4]

The δβ thalassemias and hereditary persistence of fetal hemoglobin (HPFH) are disorders related to the β thalassemias that also involve down-regulation of β-globin gene expression. In δβ thalassemia the δ gene is also affected and there is variable compensation from increased HbF production. These disorders result from more extensive deletions within the β-globin gene cluster, as do the deletion forms of HPFH in which HbF compensation is sufficient to minimize hematological abnormalities. Other forms of HPFH result from mutations in the promoters of the γ-globin genes that not only increase HbF production in adult life but are accompanied by reduced β-chain production.

This chapter outlines the molecular mechanisms underlying the different types of β thalassemia. The common denominator is absent or decreased synthesis of β-globin chains, resulting in the accumulation of excess α-globin chains that are responsible for the pathophysiology of the disorder. The severity of the phenotype is usually related to the degree of imbalance between α- and non-α-globin chain synthesis, and the size of the free α-chain pool. Hence severity is related to the type of β allele (β^0, β^+, β^{++}), ameliorated by an interacting α thalassemia (by reducing the α-chain excess) and any increased production of γ-chains (that decrease the excess of free a α-chains by binding to them to form HbF).

The molecular bases of β thalassemia and related conditions have provided a paradigm for our understanding of much of human genetics. Detailed references to earlier work are not provided here but readers are referred to the chapters by Forget,[2,5] Thein,[6] and Wood[7] in the first edition of this book, as well as to the comprehensive monograph by Weatherall and Clegg.[4]

The β THALASSEMIAS

Nondeletion Forms of β Thalassemia

These defects account for the majority of the β thalassemia alleles. They involve single base substitutions, small insertions or deletions within the gene or its immediate flanking sequences, and affect almost every known stage of gene expression. Allele frequency varies widely from one population to another but within any population there are usually a small number of common alleles together with many alleles that are rare for that population (see Chapter 15). They are listed in Table 16.1 according to the mechanism by which they affect gene function: transcription, RNA processing, or RNA translation. The mutations have been cataloged by Huisman et al.[8] and the updated listing is accessible electronically through the Globin Gene Server Website:[9] http://globin.cse.psu.edu. Heterozygotes have minimal anemia but hypochromic (mean corpuscular hemoglobin [MCH] 18–24 pg), microcytic (mean corpuscular volume [MCV] 65–80 fL) red blood cells. They are characterized by an increased proportion of HbA_2 (normal <3.2%, β thalassemia trait 3.5%–6.0%), and HbF levels that vary from normal (<1.0%) to slightly raised (1.0%–3.0%).

* Unlike the majority, some heterozygotes for the CD121 G→T mutation do not have an unusually severe phenotype.

** This frameshift leads to predicted truncated β variant of 138aa with an abnormal carboxy terminal. Heterozygotes do not appear to have an unusually severe phenotype.

*** Occurs *in-cis* to the IVS2-745 C→G mutation.

$^{+}$ Also occurs *in-cis* to 7201-bp deletion involving δ gene.

$^{++}$ Occurs *in-cis* to δ59-A.

$^{+++}$ Probably de novo.

TRANSCRIPTIONAL MUTANTS

Mutations affecting transcription involve the conserved DNA sequences that form the β-globin promoter (from 100 bp upstream to the site of the initiation of transcription, including the functionally important CACCC, CCAAT, and ATAA boxes) and the stretch of 50 nucleotides in the 5′ untranslated region (UTR).

Mutations in all of the three conserved sequence motifs in the β promoter, the two CACCC, CCAAT,[10] and ATAA boxes, have been identified in different patients with β thalassemia. In general, the degree of diminished β-globin synthesis associated with mutations of the β-globin gene promoter including the latest mutation (−73 A–T) within the CCAAT box[10] is relatively minor. This finding is consistent with transcription studies of the mutant genes in tissue culture cells, which reveal only a mild-to-moderate decrease in transcriptional activity of these genes.[2]

Although these defects have been described in diverse ethnic groups, ethnic variation in phenotype has been observed. Black individuals homozygous for the −29 A→G mutation have an extremely mild disease,[11] whereas a Chinese individual homozygous for the same mutation had thalassemia major.[12] The cause of this striking difference in phenotype is not known but may be related to the different chromosomal backgrounds on which the apparently identical mutations have arisen or to the C-T polymorphism at position −158 upstream of the $^{G}\gamma$ globin gene (*Xmn*1-$^{G}\gamma$ site), which is associated with increased HbF production under conditions of erythropoietic stress. The *Xmn*1-$^{G}\gamma$ site is present in the β chromosome carrying the −29 A→G mutation in Blacks but absent in that of the Chinese.[13]

Of the mutations in this category, the C-T mutation at position −101 to the β-globin gene appears to cause an extremely mild deficit of β-globin. The allele is so mild that heterozygotes are "silent" with borderline reduced/normal red cell indices.[14,15]

An increasing number of mutations in the 5′ UTR have been characterized since the original CAP +1 A-C allele.[16] The defects include single base substitutions and minor deletions distributed along the stretch of 50 nucleotides. As in the −101 C-T mutation, heterozygotes for this class of mutations are silent; the extremely mild phenotype is exemplified in a homozygote for the +1 A-C mutation who has the hematological values of a thalassemia carrier.[16] It is not known whether the CAP mutation causes β thalassemia by decreasing β-globin gene transcription or by decreasing the efficiency of capping (posttranscriptional addition of m^7G) and mRNA translation. In vivo and in vitro studies show that the +33 C→G mutation leads to a reduction of β mRNA that is 33% of the output from a normal β gene, milder than the mutations involving the promoter elements.[17] Compound heterozygotes for these transcriptional mutations and the more severe β thalassemia alleles tend to have a milder disease.

MUTANTS AFFECTING RNA PROCESSING

Mutations of the Splice Site Junction

Intervening sequences must be precisely removed from the precursor mRNA and the coding regions spliced to produce functional mRNA. Sequences critical in the splicing process include the invariant dinucleotides GT at the 5′ (Donor) and AG at the 3′ (Acceptor) splice junctions in the introns.[5] Mutations that affect either of the invariant dinucleotides in the splice junction completely abolish normal splicing and produce the phenotype of β^0 thalassemia. These mutations can be base substitutions that change one or the other of invariant dinucleotides or short deletions that remove them. Genes bearing these mutations appear to transcribe normally and, although some alternative splicing occurs using "cryptic" donor or acceptor sites, the misspliced mRNA do not translate into functional β-globin. The misspliced mRNA species can sometimes be detected in small amounts in affected erythroid cells. They are nonfunctional because translation of the abnormally spliced or frameshifted mRNAs would usually stop prematurely due to the introduction of chain termination (nonsense) codons.[18]

Mutations of Splice Site Consensus Sequence

Flanking these invariant dinucleotides are sequences that are fairly well conserved and a consensus sequence can be recognized at the exon–intron boundaries. They encompass the last three nucleotides of the exon and the first six nucleotides of the intron for the 5′ donor site; and the last 10 nucleotides of the intron and the first nucleotide of the exon for the 3′ acceptor site. Mutations within the consensus sequences at the splice junctions reduce the efficiency of normal splicing to varying degrees and produce a β thalassemia phenotype that ranges from mild to severe. For example, mutations at IVS1 position 5, G→C, T, or A considerably reduce splicing at the mutated donor site compared with normal. The mutations appear to activate the use of three "cryptic" donor sites (sequences that mimic the consensus sequence for a splice site but are not normally used), two in exon 1 and one in IVS1, which are utilized in preference to the mutated donor site.[19] On the other hand, the substitution of C for T in the adjacent nucleotide, IVS1 position 6, only mildly affects normal RNA splicing even though it activates the same three cryptic donor sites as seen in the IVS1–5 mutants.[19] Although the IVS1–6 T-C mutation is generally associated with milder β thalassemia, studies have shown that in some cases apparently identical mutations can be severe;[20–22] and again this is presumably related to the chromosomal background on which the mutations have arisen.

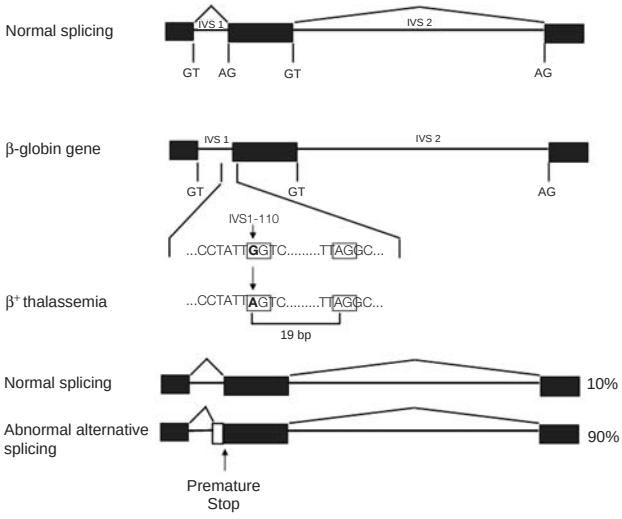

Figure 16.1. Alternative splicing of precursor β-globin mRNA resulting in β^+ thalassemia associated with the IVS1–110 G→A mutation. The G to A substitution at position 110 creates an AG dinucleotide within a potential 3′ acceptor splice site resulting in approximately 90% mRNA aberrantly spliced and 10% normally spliced.

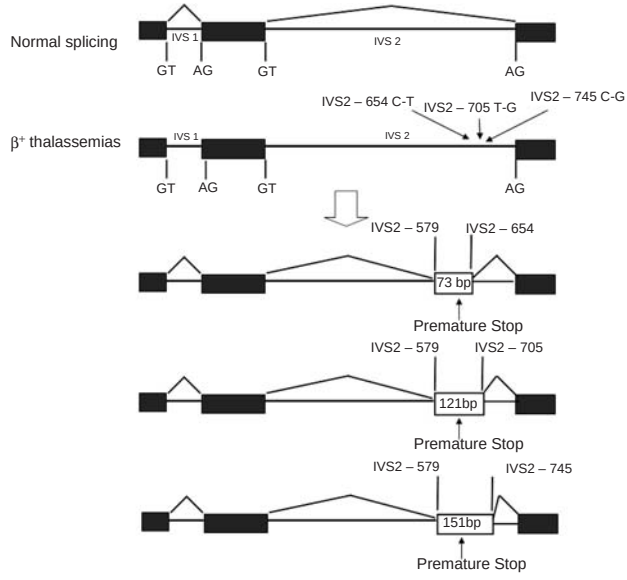

Figure 16.2. Alternative splicing of precursor β-globin mRNA due to three base substitutions; C→T at position 654, T→G at position 705, and C→G at position 745 in intron 2 of the β-globin gene. Each of these mutations creates a 5′ donor site that is preferentially spliced to the normal 3′ acceptor site, whereas the same acceptor site is activated upstream at position 579 in intron 2 and spliced to the normal donor site at the exon 2–intron 2 junction. This results in the incorporation of 73, 121, and 151 nucleotides of intron 2 into the aberrantly spliced mRNA associated with each of the different intron 2 mutations, respectively.

Mutations that Create New Alternative Splice Sites in Introns

A third category of splicing mutation is due to base substitutions in introns that generate new splicing signals, which are preferentially used instead of the normal splice sites. Five such mutations have been identified in the β-globin gene: two in IVS1 and three in IVS2 (Table 16.1).[2,13] The associated phenotype may be either β^+ or β^0 thalassemia, depending on the site and nature of the mutation.

The splicing mutation at position 110 of IVS1 was the first base substitution identified in a β thalassemia gene.[2,23,24] This mutation has subsequently been shown to be one of the most common form of β thalassemia in the Mediterranean population. The mutation is a substitution of G to A that creates an acceptor AG in a favorable consensus sequence environment, 19 bp 5′ to the normal acceptor AG of IVS1 (Fig. 16.1). In vitro expression studies have shown that this newly created alternative splice site is preferentially used in 80%–90% of the transcripts, whereas the normal splice site is used in only 10%–20% of the transcripts,[25,26] thus giving the phenotype of β^+ thalassemia (Fig. 16.1). The mutant mRNA is hardly detected in affected erythroid cells presumably because the 19-bp segment of retained intronic sequence contains an in-phase premature termination codon and thus subjected to the nonsense mediated decay surveillance mechanism (see section on dominantly inherited β thalassemia and Huang and Benz 2001[18]).

Another β thalassemia gene with a T→G substitution in position 116 of IVS1, leads to a newly created 3′ acceptor site. In this case, the normal acceptor sequence, although intact, is not used, and little or no normal β mRNA is produced resulting in a β^0 thalassemia phenotype.[27]

Three other β thalassemia genes have substitutions within IVS2 that generate new donor sites[2–4] (Fig. 16.2). They include the IVS2 position 654 C→T, 705 T→G, and 745 C→G. In each case, an upstream acceptor site at position 579 is activated such that the normal 5′ donor site at exon 2/IVS2 is spliced to the activated site at position 579 and the newly created donor site is spliced to the normal 3′ acceptor site at IVS1/exon 3. This two-stage splicing results in the retention of 73 bp of IVS2 in the misspliced β mRNA for the IVS2 654 mutation. Variable amounts of splicing from the normal donor to the normal acceptor also occurs, resulting in phenotypes that range from β^+ to β^0 thalassemia. Several individuals heterozygous for the IVS2 654 C-T mutation with an unusually severe phenotype have been described.[13] In a father and son, the ratio of aberrant β mRNA to normal β mRNA was 10-fold that in asymptomatic heterozygotes for the same mutation.[28] The unusually severe disease in these individuals is thought to result from the accumulation of the misspliced mRNA, which was predicted to translate into a highly unstable β chain variant with a dominant negative effect.

The mutation at position 745 also creates a new alternative donor splice site and is associated with a similar two-step excision of IVS2 with utilization of the newly created acceptor at position 579.[19] Some normal splicing of IVS2

occurs; therefore, this mutation results in β^+ rather than β^0 thalassemia. The β^0 versus β^+ phenotype associated with these different mutations must be related to different affinities of the enzymatic splicing complex for a given mutant splice site versus the normal splice sites.[5]

Mutations that Create Alternative Splice Sites in Exons

Four mutations have been identified in exon 1 that are associated with activation of cryptic or alternative splice sites.[2,4,13] Three of these mutations modify the cryptic splice site spanning codons 24–27 in exon 1 so that it more closely resembles the consensus splice sequence AAGGTGAGT and activates it. The reduction in normal splicing is the molecular basis for the mild β^+ thalassemic phenotype of these variants, including the β^E allele. The β^E allele is particularly prevalent in southeast Asia where it can reach up to a frequency of 75% in northeast Thailand. Its interaction with β thalassemia accounts for a large proportion of the thalassemia major in southeast Asia.[4]

Similarly, the A→G mutation in codon 19 activates another cryptic donor site spanning codons 17–19 in exon 1 resulting in a reduced level of normally spliced β mRNA that contains the codon 19 mutation encoding Hb Malay.[29]

MUTATIONS CAUSING ABNORMAL POSTTRANSCRIPTIONAL MODIFICATION

The nascent precursor globin mRNA molecule is modified at both of its ends; a methylated (m^7G) cap structure is added at the 5′ end, and a poly(A) tail is added at the 3′ end of the mRNA. One mutation of the cap site has been described,[16] although it is not known whether the principal effect of the mutation is on transcription or on the capping modification. On the other hand, a number of different β thalassemias have been associated with defective polyadenylation owing to mutations involving the consensus sequence AATAAA required for the cleavage–polyadenylation reaction. Mutations involving the polyadenylation signal include seven base substitutions at different positions of the consensus sequence, two short deletions of 2 and 5 bp each, and one deletion of the total AATAAA sequence (Table 16.1). These mutations markedly decrease the efficiency of the cleavage–polyadenylation process but do not abolish it completely. Therefore, the associated phenotype is that of β^+ thalassemia of moderate severity because approximately 10% of the mRNA is properly modified. The remainder of the transcripts extend far beyond the normal polyadenylation site and are probably cleaved and polyadenylated after the next AATAAA consensus sequences, which occur approximately 0.9–3 kb downstream.[30] Mutations affecting other sites in the 3′ UTR, a C→G substitution at nucleotide 6, and a 13-bp deletion at nucleotides 90 downstream of the termination codon, also result in β^+ thalassemia.[2,13]

MUTANTS RESULTING IN PREMATURE TERMINATION OF TRANSLATION

Approximately half the β thalassemia alleles result from the introduction of premature termination codons, either due to direct mutations creating a stop codon or to a change in the reading frame by insertion or deletion of a single to a few nucleotides. These frameshift defects cause premature termination further downstream when the next nonsense codon is reached.[5]

One of the first nonsense mutations to be characterized and extensively studied was the mutation at codon 39 (CAG–TAG). This mutation is the second most common cause of β thalassemia in the Mediterranean population and accounts for most of the cases of β thalassemia in Sardinia. An interesting feature of this and other nonsense mutations is the finding of very low levels of the mutant β-globin mRNA in affected erythroid cells. Initial studies of this phenomenon revealed that the gene was transcribed normally, but there appeared to be defective β mRNA stability in the nucleus or defective processing and/or transport of the mRNA from nucleus to cytoplasm; mRNA stability in the cytoplasm appeared to be normal.[18] It is now clear that reduced levels of the mutant β mRNA is a result of the nonsense mediated decay quality control mechanism.[31]

The frameshift and nonsense mutations that result in typical recessively inherited β^0 thalassemia all result in premature termination within exon 1 and 2 with a couple of exceptions terminating prematurely in exon 3.[13] In recent years it has become clear that the concentration of the different in-phase termination mutants in exon 1 and 2 is related to the "positional" effect on nonsense mediated decay of the mutant β mRNA (for reviews see[31–33]) that are associated with minimal steady-state levels of abnormal β mRNA.[18] In heterozygotes for such cases, no β chain is produced from the mutant allele, resulting in a typical asymptomatic phenotype. In contrast, in mutations that produce in-phase termination later in the β sequence, in exon 3, the mRNA does not undergo nonsense-mediated decay and produce normal amounts of mutant β mRNA, which presumably gets translated into variant β-chains.[34] As these cells have to deal with the excess α-chains as well as the abnormal β-chains, the proteolytic machinery is overcome and a severe phenotype results. These mutants are usually dominantly inherited, therefore, in contrast to the typical recessive inheritance of β thalassemia (see later). It is not clear how nonsense-mediated decay takes place but the mechanism could be related to coupling between transcription and translation and exerted at the nuclear membrane.[32]

MUTATIONS AFFECTING THE INITIATION CODON

Nine mutations affecting the initiation codon (ATG) have been described and all produce β^0 thalassemia (Table 16.1).

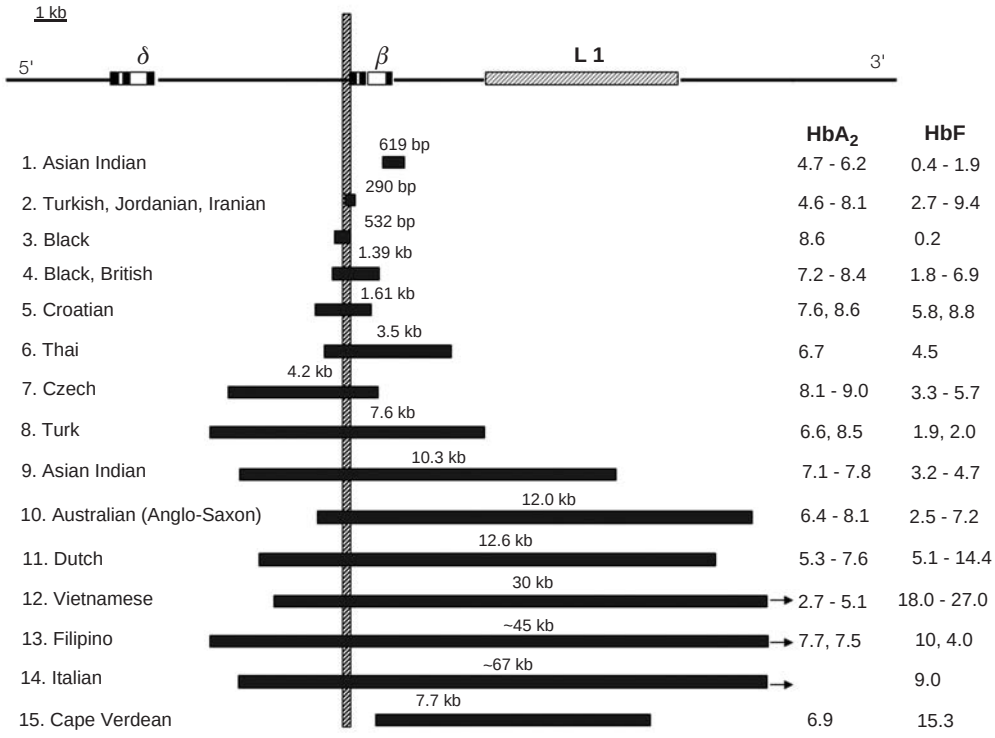

Figure 16.3. Deletions restricted to the β-globin gene. The hatched box represents the 6.4 *Kpn* repeat 3′ of the β-globin gene. Deletions are represented by the horizontal black boxes below. The 3′ ends of three deletions (Vietnamese, Filipino, and Italian) have not been characterized as indicated by an arrow. The vertical shaded box represents the common region (from positions −175 to +128 relative to the β mRNA CAP sites) lost in all the deletions except for the 619 bp (Asian Indian) and the 7.7 kb (Cape Verdean). The corresponding levels of HbA_2 (%) and HbF (%) observed in heterozygotes for the different deletions are shown on the right.

One mutation involves an insertion of 45 bp between positions –22 and +23, thus affecting the initiation codon.[35] The rest are single base substitutions, two affecting the first (A), three the second (T), and three the third (G) nucleotide of ATG.[2,4,13] It is theoretically possible for mutant β mRNAs to be initiated at the next downstream initiation codons, which are located at codons 21 and 22 or codon 55. It is predicted, however, that these alternative initiation codons would result in premature termination and that mutant mRNAs would be nonfunctional and subjected to nonsense-mediated decay surveillance.[5]

DELETIONS RESTRICTED TO THE β-GLOBIN GENE

These deletions involve only the β-globin gene and its flanking DNA without affecting any of the other neighboring β-like globin genes and range from 105 bp to approximately 67 kb in size (Fig. 16.3). The phenotype associated with these deletions is that of β^0 thalassemia.

Two deletions remove the 3′ end but preserve the integrity of the 5′ end of the β-globin gene. The 0.6-kb deletion involving the 3′ end of the β-globin gene is a relatively common cause of β^0 thalassemia in Asian Indians and accounts for approximately one third of the cases of β thalassemia in this population.[2,4,13] The second deletion was recently described in compound heterozygosity with HbS in a woman from Cape Verde Islands who presented with mild sickle cell disease.[36] She had a rare deletion that removes 7.7 kb, starting in IVS2 of the β-globin gene and extending 7.1 kb downstream, in the midst of the *Kpn I* family of L1 receptor elements.

The other deletions, although extremely rare, are of particular functional and phenotypic interest. These deletions differ widely in size, but remove in common a region (from positions −125 to +78 relative to the mRNA cap site) in the β promoter, which includes the CACCC, CCAAT, and TATA elements. They are associated with unusually high levels of HbA_2 and variable increases of HbF in heterozygotes. It has been proposed that deletion of the β promoter removes competition for the upstream β locus control region (LCR) and limiting transcription factors, thus allowing enhanced expression of the *cis* δ and γ genes. Indeed, studies of an individual heterozygous for the 1.39-kb β thalassemia deletion and a δ-chain variant showed that there is a disproportionate increase of HbA_2 derived from the δ gene in *cis* to the β gene deletion.[37] Although the increases in HbF are variable and slight in heterozygotes, they can be sufficiently increased to partially compensate for the complete absence of β-globin in homozygotes; two individuals homozygous for different deletions in this group are not transfusion dependent with a mild disease.[13]

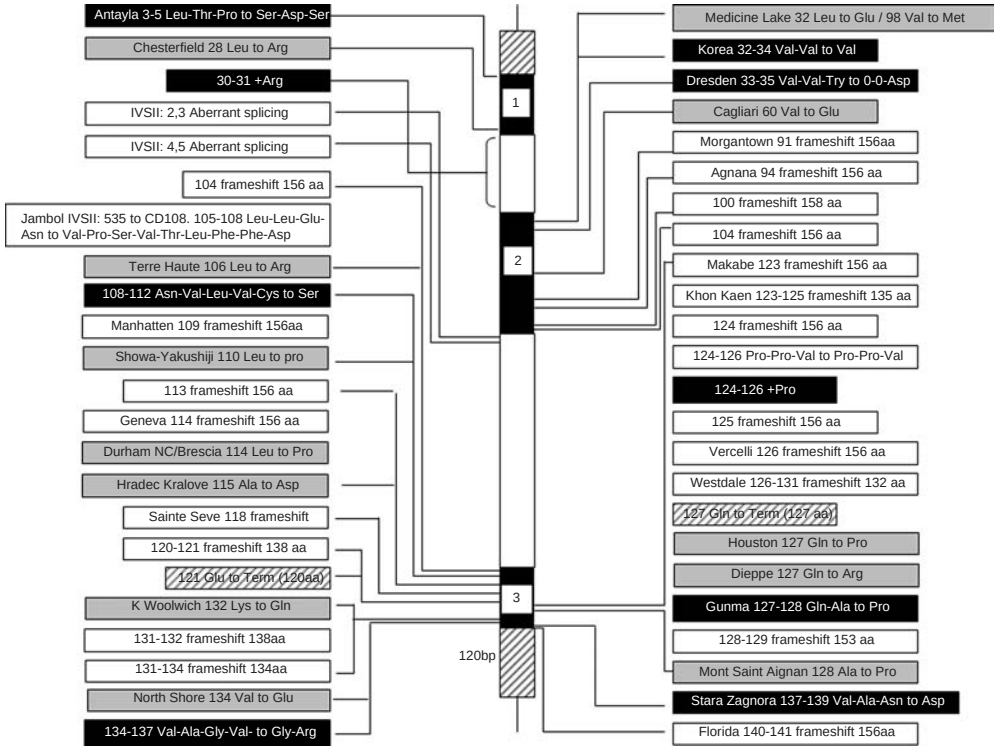

Figure 16.4. Structural variants associated with a β thalassemia phenotype. The β-globin gene with the location of the various mutations leading to the production of variants associated with a β thalassemia phenotype. Missense mutations are represented by gray boxes, deletions or insertions of intact codons that lead to destabilization are represented by black boxes; premature terminations by shaded boxes, and frameshift mutations by plain boxes. Note the concentration of mutations in exon 3.

DOMINANTLY INHERITED β THALASSEMIA

Among the thalassemic hemoglobinopathies are the group of hyperunstable β-globin chain structural variants that are assumed to be synthesized at a normal rate but are so unstable that they are not able to form tetramers, resulting in a quantitative deficiency of β-globin chains.[1] Unlike the typical β thalassemias, the hyperunstable β-globin chain variants cause a disease phenotype even in heterozygotes, thus the alternative term, "dominantly inherited β thalassemia."

This unusual form of β thalassemia was first described in an Irish family in 1973; moderately severe anemia, jaundice and splenomegaly was transmitted through three generations as a single allele in a dominant fashion.[38] Apart from the usual features of heterozygous β thalassemia such as increased levels of HbA_2 and increased α/β-globin chain biosynthesis ratios, this group of β thalassemias was characterized by severe dyserythropoiesis associated with intraerythroblastic inclusion bodies. Similar clinical features associated with inclusions in erythroblasts were observed in a Swiss-French family[39] prompting the term "inclusion body β thalassemia." Because similar intraerythroblastic inclusions are found in all severe forms of β thalassemia, this term was deemed inappropriate and the designation "dominantly inherited β thalassemia" preferred, as this nomenclature also differentiates these disorders from the typical recessive forms of β thalassemia prevalent in the tropical and subtropical regions.

The molecular lesion in the Irish family was a complex rearrangement in exon 3 of the β-globin gene involving two deletions of 4 and 11 bp interrupted by an insertion of 5 bp giving rise to a frameshift and the predicted synthesis of an elongated β-globin chain variant with an abnormal carboxy terminal.[40]

Numerous dominantly inherited β thalassemia alleles associated with similar clinical features have now been identified in families of disparate ethnic origins.[1,6] Some are due to missense mutations in which the amino acid substitution is directly responsible for an unstable globin chain or mutants in which deletion or insertion of intact codons disrupts the structure. Others are caused by premature termination codons (nonsense mutations) in exon 3, which fail to undergo nonsense-mediated decay of the RNA. Frameshifts may also result in aberrant splicing producing elongated or truncated β-globin chain variants with abnormal carboxy terminal ends (Table 16.2; Fig. 16.4).

Missense Mutations

An example of a missense mutation causing β thalassemia intermedia is Hb Terre Haute (β106 Leu→Arg).[41] This mutant was initially described as Hb Indianapolis

Table 16.2. Structural variants associated with a β thalassemia phenotype

Mutations	Exon	Hb variant	Phenotype	Ethnic group	Refs
I. Missense mutations					
1) CD 28 (C**T**G→C**G**G) Leu to Arg	1	Hb Chesterfield*	Thalassemia intermedia, inclusion bodies	English	6
2) CD 32 (C**T**G→C**A**G) Leu to Glu in cis with CD 98 (**G**TG→**A**TG) Val to Met, Hb Köln	2	Hb Medicine Lake*	Severe thalassemia	US Caucasian	6
3) CD 60 (G**T**G→G**A**G) Val to Glu	2	Hb Cagliari*	Thalassemia intermedia, inclusion bodies	Italian	6
4) CD 106 (C**T**G→C**G**G) Leu to Arg	3	Hb Terre Haute	Thalassemia intermedia	N European, French	6
5) CD 110 (C**T**G→C**C**G) Leu to Pro	3	Hb Showa-Yakushiji	Thalassemia intermedia	Japanese	6, 223
6) CD 114 (C**T**G→C**C**G) Leu to Pro	3	Hb Durham NC/Hb Brescia*	Thalassemia trait/Thalassemia intermedia	US Irish, Italian	6
7) CD 115 (G**C**C→G**A**C) Ala to Asp	3	Hb Hradec Kralove	Thalassemia intermedia, inclusion bodies	Czech	6
8) CD 127 (C**A**G→C**C**G) Gln to Pro	3	Hb Houston	Thalassemia intermedia, inclusion bodies	US English	6
9) CD 127 (C**A**G→C**G**G) Gln to Arg	3	Hb Dieppe	Thalassemia intermedia	French	6
10) CD 128 Ala to Pro	3	Hb Mont Saint Aignan	Thalassemia trait, hemolytic anemia	French Caucasian	45
11) CD 132 Lys to Gln	3	Hb K Woolwich	Thalassemia trait	West Indian	6
12) CD 134 Val to Glu	3	Hb North Shore	Thalassemia trait	Finnish	6
II. Deletion or insertion of intact codons → destabilization					
1) CD 3 (+T), CD5 (−C) Leu-Thr-Pro to Ser-Asp-Ser	1	Hb Antalya	Thalassemia trait/ thalassemia intermedia	Turkish	224
2) CD 30–31 (+CGG) +Arg	1/2		Thalassemia intermedia, inclusion bodies	Spanish	6
3) CD 32–34 (−GGT) Val-Val to Val	2	Hb Korea*	Thalassemia intermedia	Korean	6
4) CD 33–35 (−TGGTCT) Val-Val-Tyr to 0–0-Asp	2	Hb Dresden	Thalassemia intermedia, hemolysis	German	6
5) CD 108–112 (−12bp) Asn-Val-Leu-Val-Cys to Ser	3		Thalassemia trait	Swedish	6
6) CD 124–126 (+CCA) +Pro	3		Thalassemia intermedia	Armenian	6
7) CD 127–128 (−AGG) Gln-Ala to Pro	3	Hb Gunma	Thalassemia trait/ thalassemia intermedia	Japanese	6
8) CD 134–137 (−12, +6) Val-Ala-Gly-Val to Gly-Arg	3		Thalassemia intermedia	Portuguese	6
9) CD 137–139 (−TGGCTA) Val-Ala-Asn to Asp	3	Hb Stara Zagnora*	Thalassemia intermedia, hemolysis	Bulgarian	54

Note: Some of these variants are not associated with elevated A_2 in heterozygous state, for example, Hb Dresden, Hb Jambol, Hb Morgantown, Hb Stara Zagnora.

* Spontaneous mutations.

** Several families reported including one spontaneous mutation.

*** Coinheritance of extra α-globin gene (genotype $\alpha\alpha\alpha/\alpha\alpha$) contributed to unusually severe thal intermedia in proband.

\+ Difficult to evaluate phenotypes of heterozygotes as only homozygote and compound heterozygotes reported.

(β112 Cys→Arg,[42] which was subsequently reported in two families [Spanish and Italian] in whom affected members had evidence of mild hemolytic anemia with 2%–4% reticulocytosis[43,44]). In two patients heterozygous for Hb Terre Haute, globin-chain biosynthesis studies showed an α/non-α ratio of approximately 1.0 in bone marrow erythroblasts compared with a ratio of approximately 2.0 in peripheral blood reticulocytes. Although the variant β-globin chain was synthesized at a level almost equal to that of the normal β-globin chain, most of it was rapidly precipitated on the red cell membrane. The half-life of this globin variant was less than 10 minutes, and the abnormal hemoglobin was not detectable by standard techniques. Other examples of missense variants include Hb Chesterfield, Hb Cagliari, Hb Showa-Yakushiji, Hb Durham NC/Brescia, Hb Houston, and more recently, Hb Mont Saint Aignan.[1,6,45] In the example of Hb Chesterfield, an abnormal peak in the position expected for the β-globin chain variant but without detectable corresponding protein was demonstrated by globin-chain biosynthesis studies.[46] Hb Mont Saint Aignan [β128 (Hb) Ala→Pro], in comparison, appeared mildly unstable;[45] the abnormal β-chain could be isolated by selective isopropanol precipitation and the structure determined by protein chemistry methods.

Most of the other abnormal hemoglobins were not detected by routine hemoglobin electrophoresis. Hb Cagliari was identified postsplenectomy on isoelectrical focusing (IEF) and formed 9% of the total hemoglobin.[47] Mass spectrometry electrospray analysis estimated Hb Mont Saint Aignan to be approximately 20% of total hemoglobin.[45] Hb Indianapolis was mildly unstable; on IEF, the variant β-globin chain formed 38%–45% of the total β-globin chains.

Deletion or Insertion of Intact Codons

Deletions or insertions of entire codons allow the reading frame to remain in phase, and the remaining amino acids are normal. Both Hb Korea and Hb Gunma have 145–amino acid residues each; in Hb Gunma, the β127–128 Gln-Ala dipeptide is replaced by a proline residue due to the deletion of three bases (AGG),[48] whereas in Hb Korea, the deletion of three bases (GGT) removes one of the Val residues from codons 32–34.[49] Other β-globin chain variants have extra residues and include the insertion of Arg in codons 30–31 in a Spanish family[50] and insertion of a single proline in codons 124–126 in an Armenian patient.[51]

In all cases, no trace of abnormal hemoglobin could be detected by the standard techniques of IEF, high-performance liquid chromatography, or heat stability tests. One mechanism that could explain the lack of detection of these structural β-globin chain variants is that the affected amino acids are involved in α1β1 contacts. In the normal β-globin chain, β30 Arg (β 12), β33 Val (β 15), β34 Val (β 16), β108 Asn (γ 10), β112 Cys (γ 14), β124 Pro (H2), β125 Pro (H3), β127 Gln (H5), and β128 Ala (H6) are essential for α1β1 dimer formation.[52] Deletion or substitution of these critical amino acids would be likely to prevent the formation of αβ subunits and, effectively, lead to a functional loss of half of the β-globin chains.

The third example in this category involved a deletion of 12 nucleotides and an insertion of 6 nucleotides, leading to the substitution of the normal Val-Ala-Gly-Val by Gly-Arg in codons 134–137 and a β-globin subunit that was two amino acids shorter than normal. Affected individuals of this Portuguese family had moderately severe anemia, splenomegaly, and leg ulcers.[53]

A recent example of a hyperunstable β chain variant in this category is Hb Stara Zagnora (codons 137–139 [−6 bp]) found in a 2-year-old Bulgarian boy. Deletions of 6 bp spanning β codons 137–139 replaces Val-Ala-Asn with Asp and results in a hyperunstable variant associated with hemolysis and dyserythropoietic anemia with mild globin chain imbalance (α/β synthesis ratio 1.40), although HbA_2 levels were within normal limits.[54]

Premature Termination (Nonsense Mutation)

Probably the most common of the dominantly inherited β thalassemia alleles is a GAA→TAA termination codon at codon 121, which leads to the synthesis of a truncated β-globin chain. Although substantial amounts of mutant β-globin mRNA could be demonstrated in individuals with such mutations, showing the presence of the truncated β-globin variant has been difficult.[34] Presence of the predicted truncated variant was implicated from a large difference between the total radioactivity incorporated into newly synthesized chains and the total amount of protein in globin biosynthesis studies.[55] In another study, the truncated β-globin chain was estimated to comprise only 0.05% −0.1% of the total non-α-globin.[56] Another case of thalassemia intermedia caused by heterozygosity for the premature stop codon in β127 was recently reported in a 29-year-old French Caucasian woman.[57]

Elongated or Truncated Variants with Abnormal Carboxy Terminal Ends

In general, the elongated or truncated β-globin gene variants in this group have arisen from frameshift mutations that generated distal premature termination codons. Despite the altered charge created by the abnormal carboxy terminal end, the abnormal β-globin variants were not detected in any of the cases by hemoglobin electrophoresis or globin biosynthesis studies; however, in all cases an imbalanced synthesis of α- and β-globin chains was present.

Elongated β-globin subunits could also arise from aberrant splicing of precursor mRNA, as described in a deletion of two nucleotides affecting the IVS2 consensus donor splice site.[58] Unusually severe anemia associated with intraerythroblastic inclusions was transmitted as a single

allele in five generations of this Portuguese family and the disorder was transmitted in a dominant fashion.

Since the last edition, eight additional hyperunstable β variants belonging to this category have been described (Table 16.2). Hb Jambol[54] has an unusual molecular defect caused by a complex rearrangement involving an insertion of 23 nucleotides after position 535 of βIVS2 and deletion of 310 nucleotides from position 550 of βIVS2 to the first nucleotide of β codon 108 interrupted by an insertion of 28 nucleotides at the deletion junctions. The mutation results in the replacement of Leu-Leu-Glu-Asn at codon 105–108 with nine residues (Table 16.2) and was associated with severe hemolytic anemia and mildly imbalanced globin synthesis ratio.

Pathophysiology of Dominant β Thalassemia

The common denominator of these mutations is the synthesis of the highly unstable β-chain variants. In many cases, the variants are so unstable that they can be detected only when newly synthesized, whereas in others, they are not detectable but predicted from the DNA sequence. The predicted synthesis is supported by the presence of substantial amounts of mutant β-globin gene mRNA in the peripheral blood reticulocytes, comparable in amounts to that of the other normal β-globin allele.[34,55] Indeed, the large intraerythroblastic inclusions, which are so characteristic of this form of β thalassemia, have subsequently been shown to be composed of both α- and β-globin chains.[55] In contrast, the inclusion bodies in homozygous β thalassemia consisted only of precipitated α globin.[55]

The molecular mechanisms underlying the instability include: substitution of the critical amino acids in the hydrophobic heme pocket displacing heme, leading to aggregation of the globin variant; disruption of secondary structure due to replacement of critical amino acids; substitution or deletion of amino acids involved in αβ dimer formation; and elongation of subunits by a hydrophobic tail.

Nonsense-mediated Decay

How is it that some premature termination mutations cause thalassemia intermedia whereas the majority are clinically asymptomatic in the heterozygous state? The answer appears to lie in the differential effects of these in-phase termination mutants on the accumulation of mutant mRNA.

Nonsense-mediated decay is an mRNA quality-control mechanism that degrades abnormal mRNAs that arise from mistakes in gene expression such as those caused by premature termination codons. In mammalian cells, a termination codon is recognized as premature if it is located upstream of a boundary of 50–55 nucleotides 5′ to the final exon–exon junction.[59] In the β-globin gene, this corresponds to exon 1 and the 5′ region of exon 2. Hence, in the β-globin gene, premature termination condons that terminate in exon 1 or 2 are recessively inherited, whereas those that are dominantly inherited terminate much later in the sequence of the β-globin gene, in the 3′ part of exon 2 and exon 3. Premature stop codons near the 3′ end of the gene, in exon 3 of β gene, are less likely to trigger the surveillance mechanism of nonsense-mediated decay, leading to an accumulation of the mutant β mRNA and to the synthesis of unstable β-chain variants. These in-phase termination mutations exemplify how shifting the position of a nonsense codon can alter the phenotype of recessive inheritance caused by haploinsufficiency to a dominant negative effect due to the synthesis of an abnormal and deleterious protein. Exceptions to the 50–55 nucleotide boundary rule have been reported.[60] β mRNA with nonsense mutations in codons 5, 15, and 17 within exon 1 were detected at high levels, similar to those of wild-type β-globin mRNA. It is possible that early premature termination condons within β-globin mRNA and proximity to the translation initiation codon (ATG) can override the 50–55 nucleotide boundary rule.[31]

Similarly, frameshift mutations that occur later in the sequences terminate later and tend to lead to accumulation of the mutant message and the synthesis of elongated β-globin variants. These elongated variants have abnormal carboxy-terminal ends made up of hydrophobic sequences, which cause their instability. Furthermore, these β-globin variants would not be able to form αβ dimers as most of the α1β1 contact residues would have been removed.[52] Because the heme contact site codons – mostly located in exon 2 – are retained, these elongated variants should have some tertiary structure, be less susceptible to proteolytic degradation, and presumably, form the characteristic inclusion bodies. Prominent inclusions were noted in individuals heterozygous for Hb Geneva, Hb Makabe, Hb Agnana, Hb Vercelli, and the frameshift mutation at codon 128 – the original Irish family reported by Weatherall et al. 1973.[38]

VARIANTS OF β THALASSEMIA

Normal HbA_2 β Thalassemias

The diagnostic feature of β thalassemia is the hypochromic microcytic red cells and an elevated level of HbA_2 in heterozygotes, whether β^+ or β^0. Normal HbA_2 β thalassemias (previously referred to as type 2) refers to the form in which the blood picture is typical of heterozygous β thalassemia except for the normal levels of Hb A_2,the red cell phenotype being similar to that in carriers for β thalassemia. Most cases of normal HbA_2 β thalassemia result from coinheritance of δ thalassemia (δ^0 or δ^+) in *cis* or *trans* to a β^0 or β^+ thalassemia gene.

One relatively common form of normal HbA_2 thalassemia in the Middle East and Mediterranean is that associated with Hb Knossos (β27 Ala→Ser). Like HbE, the mutation β27(GCC→TCC) activates an alternative splice site, reducing the amount of normal transcript that contains the variant. Unlike HbE, the HbA_2 level is not elevated in

heterozygotes as there is a δ^0 thalassemia (Cd59-A) mutation in *cis* to the β27 Ala→Ser mutation.[61]

Another relatively common cause of normal HbA_2 β thalassemia phenotype in the Greek population is the Corfu form of δβ thalassemia, a 7.2-kb deletion that includes the 5′ part of the δ gene.[62,63] Commonly the β-globin gene in *cis* is down regulated by a G→A mutation in position 5 of the IVS1. Heterozygotes have a slight increase in HbF (1.1%–2.8%) and low to normal HbA_2 levels but homozygotes have a milder than expected phenotype of thalassemia intermedia. They have almost 100% HbF with no HbA_2 and trace levels of HbA, suggesting that the effect of the deletion is to allow increased γ chain production under the stress of anemia. Studies in primary erythroid cell cultures from heterozygotes, homozygotes and compound heterozygotes for the Corfu deletion suggest that γ mRNA accumulation and HbF expression is indirectly dependent on the total amount of viable β mRNA.[64] Reduction of β mRNA below a critical threshold, as in compound heterozygotes and homozygotes, allows full expression of HbF, and hence the unusually high HbF in such individuals. The Corfu mutation has been described as separate lesions in two different populations. The normal β gene in *cis* to the 7.2-kb deletion in an Italian individual is expressed at normal levels,[65] whereas Algerian homozygotes for the βIVS1–5 G→A mutation have a severe transfusion-dependent anemia.[66]

The phenotype of normal HbA_2 β thalassemia is also seen in heterozygotes for εγδβ thalassemia (see later).

"Silent" β Thalassemia

Heterozygotes for 'silent' β thalassemias do not have any evident hematological phenotype; the only abnormality being a mild imbalance of globin chain synthesis. These mutations have been identified in homozygotes who have a typical β thalassemia trait phenotype[16] or in the compound heterozygous state with a severe β thalassemia allele where they cause thalassemia intermedia.[14] Silent β thalassemia alleles are not common except for the C→T mutation at position −101 of the β-globin gene, which accounts for most of the milder forms of β thalassemia in the Mediterranean.[15] It has been noted that carriers for this mutation have highly variable HbA_2 levels despite similar hematological parameters and globin chain synthesis ratios.[15] Coinheritance of δ thalassemia mutations were implicated but sequence analysis of the δ globin genes in one family excluded this possibility.[67] Recently, a C→G transversion has also been reported in the same −101 position and heterozygotes have a silent phenotype.[68] Several other mutations in the 5′ and 3′ UTRs are also silent.[4]

It has been suggested that the $[TA]_x[T]_y$ sequence variation at position −530 of the β-globin gene may be responsible for some silent β thalassemia carriers and that the reduced β-globin expression may be related to increased binding of the BP1 repressor protein.[69] Population surveys and clinical studies do not show a consistent correlation between the $[TA]_x[T]_y$ variants and a β thalassemia phenotype, suggesting that it is a neutral polymorphism.[70]

β Thalassemia Trait with Unusually High HbA_2

Despite the vast heterogeneity of mutations, the increased levels of HbA_2 observed in heterozygotes for the different β thalassemia alleles in different ethnic groups are remarkably uniform, usually 3.5%–5.5% and rarely exceeding 6%.[71] Unusually high levels of HbA_2 over 6.5% seem to characterize the subgroup of β thalassemias caused by lesions that affect the regulatory elements in the β promoter. As discussed earlier, the unusually high HbA_2, often accompanied by modest increases in HbF, may be related to the removal of competition for the upstream LCR and transcription factors, allowing an increased interaction with the *cis* δ and γ genes.[72]

UNUSUAL CAUSES OF β THALASSEMIA

Insertion of a Transposable Element Causing β Thalassemia

Transposable elements may occasionally disrupt human genes and result in their inactivation. The insertion of such an element, a retrotransposon of the L1 family has been reported with the phenotype of β^+ thalassemia.[73] Despite the insertion of 6–7 kb DNA into its IVS2, the affected gene expresses full-length β-globin transcripts at a level corresponding to approximately 15% of normal β-globin mRNA.[73]

Trans-acting Mutations

Population studies have shown that approximately 1% of β thalassemias remain uncharacterized despite extensive sequence analysis, including the flanking regions of the β-globin genes.[13] Recently, it has been found that mutations in *XPD* that cause trichothiodystrophy are frequently associated with a phenotype of β thalassemia trait,[74] supported by reduced levels of β-globin synthesis and reduced β-globin mRNA. The *XPD* protein is a subunit of the general transcription factor TF11H that is involved in basal transcription and DNA repair. Some mutations in the transcription factor *GATA-1* on the X-chromosome have also been reported to cause β thalassemia in association with thrombocytopenia.[75,76] This was the first example of β thalassemia in humans caused by a mutation in the erythroid-specific transcription factor. There are several other families with β thalassemia in which no mutations have been detected and *trans*-acting regulatory factors have been implicated.[77–79]

Somatic Deletion of β-Globin Gene

This novel mechanism was recently described in three unrelated families of French[80] and Italian origins.[81] Affected

individuals had moderately severe anemia with hepatosplenomegaly despite being constitutionally heterozygous for a typical β thalassemia mutation (β^0 39 C→T) with a normal α genotype. Subsequent investigations revealed a somatic deletion of chromosome 11p15, including the β-globin complex, in *trans* to the mutation in a subpopulation of erythroid cells. This results in a somatic mosaic: 10%–20% of erythroid cells were heterozygous with one normal copy of β-globin gene and the rest hemizygous, that is, without any normal β-globin gene. These unusual cases once again illustrate that the severity of anemia of β thalassemia reflects the quantitative deficiency of β-globin production. The implication for gene therapy is that expression in approximately 20% of erythroid cells may be sufficient to convert a transfusion-dependent state to transfusion independence.[3,82]

εγδβ THALASSEMIA

Clinically, the εγδβ thalassemias are characterized in newborns by anemia and hemolysis, which is self-limited, and in adults by the hematological phenotype of β thalassemia trait with normal levels of HbA_2 and HbF.[4] The severity of anemia and hemolysis may be variable (even within a family) and in some cases, blood transfusions are necessary during the neonatal period.[83,84] Only heterozygotes have been identified; homozygotes, presumably, would not survive early gestation. At the molecular level, the deletions fall into two categories: group I removes all or a greater part of the β-globin complex, including the β-globin gene; group II removes extensive upstream regions leaving the β-globin gene itself intact, despite which, its expression is silenced because of absence of the upstream β LCR. To date, a total of 18 deletions causing εγδβ thalassemia have been described – eight group II upstream deletions[13,84–86] and 10 in group I[13,83,84] that includes the β-globin gene (see Fig. 16.5). All these deletions are extremely rare and unique to the families in which they have been described. The associated phenotypes of the two groups are similar.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN AND δβ THALASSEMIA

HPFH[87] and δβ thalassemia are descriptive terms used for a range of disorders that are characterized by decreased or absent β-globin production and a variable compensatory increase in γ-chain synthesis. HPFH was first observed in two healthy West African individuals with only Hbs S and F[88] who produced children with HbA and with a high level of HbF. Further cases were discovered in the West Indies and the United States, and the first homozygote was found.[89] He was clinically normal and had 100% HbF, indicating a complete absence of δ and β chain production.

The first type of δβ thalassemia to be described was Hb Lepore[90] containing a fusion δβ-globin chain produced by a misaligned crossover between the δ and β genes.[91] Soon afterward a form of thalassemia with normal HbA_2 and unusually high levels of HbF was described in several different racial groups.[92,93] When the first homozygote for this condition was observed[94] with a thalassemic disorder and 100% HbF, it was clear that no δ- or β-chains were produced in this condition and hence it became known as δβ thalassemia.

Further heterogeneity in these conditions was demonstrated after it was discovered that there are two types of γ chain.[95] Although the HbF in many HPFHs and δβ thalassemias contained both $^{G}\gamma$ and $^{A}\gamma$ chains, other cases had one or the other.

Once the β-like globin genes had been cloned, these conditions were analyzed at the molecular level and it became clear that different deletions within the β-globin gene cluster underlay most cases of δβ thalassemia and many cases of HPFH. The size and positions of the deletions bore no obvious relationship to the underlying phenotypes, but these studies demonstrated that HPFH and δβ thalassemia were closely related conditions. The discovery that some HPFH conditions were not due to deletions demonstrated that there was even further heterogeneity within these disorders.

Classification

HPFH and δβ thalassemia were originally distinguished on what appeared to be clear-cut hematological and clinical grounds. Heterozygous δβ thalassemia had a similar red cell picture to β thalassemia, with hypochromic and microcytic erythrocytes, but a normal level of HbA_2 (<3.0%). In addition, there was a raised level of HbF (5%–15%) that had a heterogeneous intercellular distribution. Homozygotes or compound heterozygotes with β thalassemia had a clinical picture of thalassemia intermedia or major. In contrast, HPFH heterozygotes had essentially normal red cell indices, a normal level of HbA_2 and even higher levels of HbF (15%–30%) with a more homogeneous, pancellular distribution. HPFH homozygotes were clinically normal, albeit with reduced MCV and MCH, whereas compound heterozygotes with β thalassemia were clinically very mild. As more and more cases and different molecular types of the two conditions were described, these differences became blurred and it is now clear that there is considerable overlap in many of the parameters that were initially used to differentiate them (see later).

Many forms of HPFH and most types of δβ thalassemia are due to gene deletions and are classified as either HPFH or δβ thalassemia largely on the basis of the level of HbF in the heterozygotes and the clinical severity in homozygotes or compound heterozygotes with β thalassemia, when known. Included within the HPFH conditions is Hb Kenya, in which production of a hybrid $^{A}\gamma\beta$-chain is accompanied by increased $^{G}\gamma$-chain synthesis.

The δβ thalassemias are subdivided into those that produce both $^{G}\gamma$- and $^{A}\gamma$-chains, $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemia

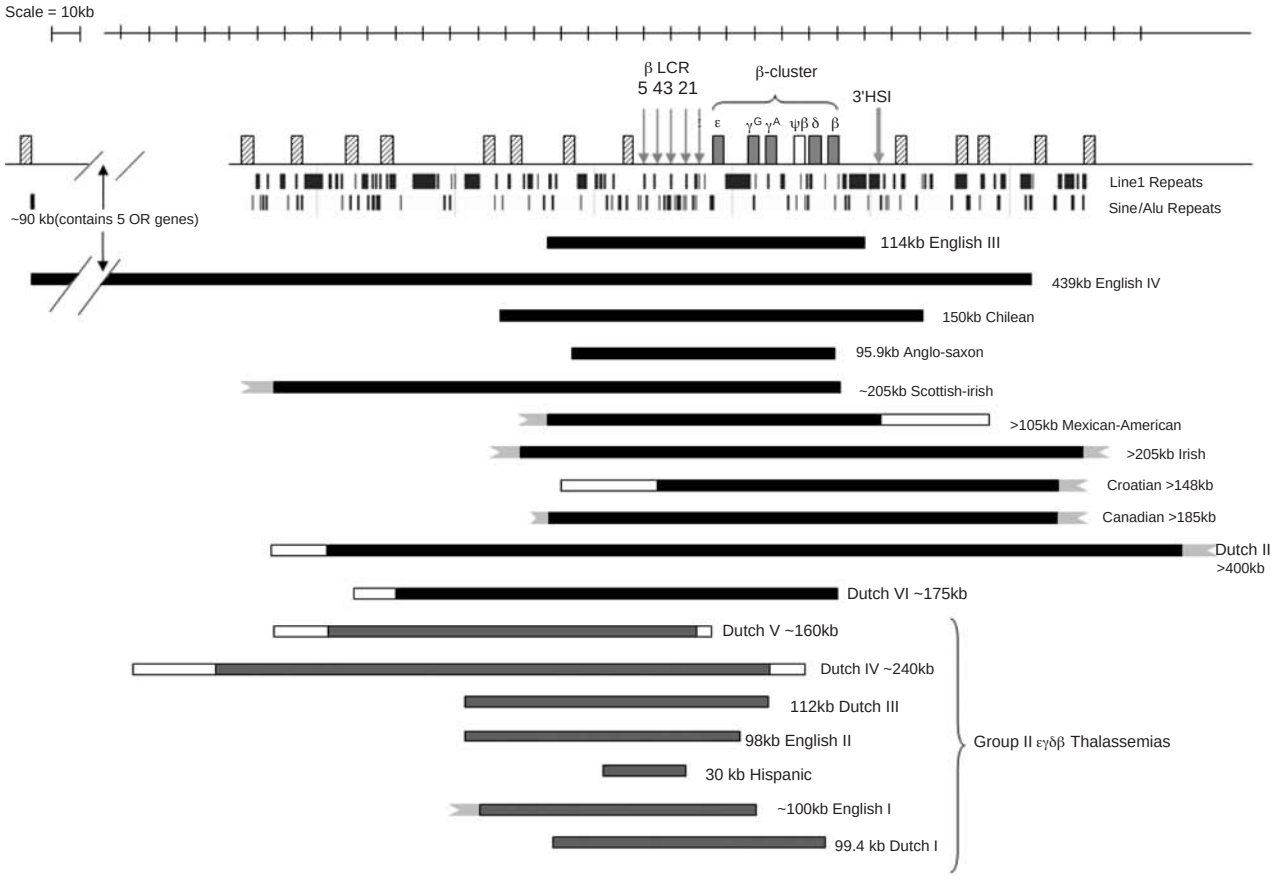

Figure 16.5. Deletions of the β-globin gene cluster causing $(\varepsilon\gamma\delta\beta)^0$ thalassemia. Top part of the figure shows the β-globin cluster and its flanking regions on chromosome 11p. The ε, $^{G}\gamma$, $^{A}\gamma$, δ, and β-globin genes are shown as gray boxes, whereas the hatched boxes represent the human olfactory receptor genes (HOR) named according to ensemble database (Ch 11:5110000–5600000). The 5′ hypersensitive sites that comprise the β LCR and the 3′ hypersensitive site (3′HS1) are shown as vertical arrows. The Line 1 and Sine/Alu repeat sequences are shown below the β-globin gene cluster as short vertical lines and boxes. The 18 deletions causing εγδβ thalassemia are shown below; the extents of the deletions are marked as complete boxes if endpoints have been determined precisely, jagged ends if undetermined, and white boxes as endpoint regions. Boxes in black are the deletions that include the β-globin gene (group I) and gray boxes represent the group II upstream deletions that leave the β-globin intact. (See color plate 16.5.)

(including Hb Lepore with a hybrid δβ-chain) and those that only contain $^{G}\gamma$-chains, $^{G}\gamma(^{A}\gamma\delta\beta)^0$ thalassemia. Within each of these three groups, there are several different deletions that share a similar clinical and hematological phenotype; they are usually named after the region in which they were first described.

Conditions associated with increased HbF in adult life that are not due to deletions of the β-globin cluster can also be subclassified. Those in which there is an increase of only the $^{G}\gamma$- or $^{A}\gamma$-chains are usually due to mutations in the promoters of the respective genes, resulting in a variable level of persistent HbF. Several other inherited conditions have been characterized and shown to be due to genes that increase γ gene expression but that are not linked to the β-globin complex. These include ones localized to chromosomes 2, 6, and 8 and another that appears to be X-linked. Additional genes are known to occur but have yet to be localized.

The broad classification of the deletion conditions into three groups, although useful, is rather arbitrary. When the mean levels of HbF and red cell indices are plotted out for each individual deletion it becomes apparent that there is a continuum between δβ thalassemia and the HPFHs and that not all conditions fit neatly into one of these groups.[7] For instance, the condition referred to as Indian HPFH or HPFH 3 has 20%–25% HbF in heterozygotes, consistent with an HPFH condition but it produces a relatively severe disease when inherited together with β thalassemia, a feature usually associated with δβ thalassemia. The two common types of HPFH of African origin are asymptomatic as homozygotes and appear to be mild in combination with β thalassemia. The most common Black β thalassemia alleles are themselves mild, and it is possible that if these HPFHs were coupled with a severe β thalassemia allele, a more severe clinical picture might emerge.[96] Among the $^{G}\gamma(^{A}\gamma\delta\beta)^0$ thalassemias, the Thai type has unusually high

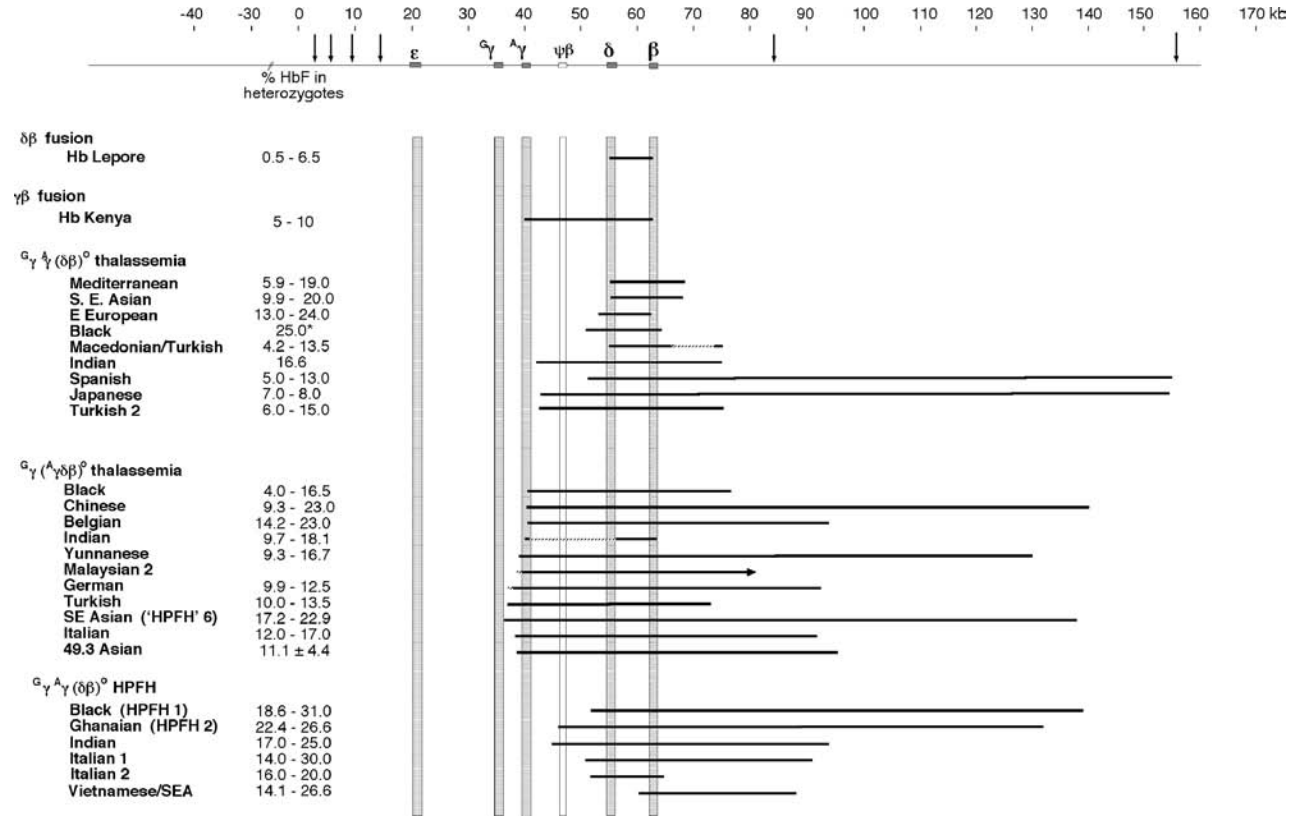

Figure 16.6. Deletions of the β-globin cluster causing HPFH, $^{G}\gamma(^{A}\gamma\delta\beta)^{0}$ thalassemia, and $^{G}\gamma^{A}(\gamma\delta\beta)^{0}$ thalassemia. Arrows in the cluster at the top of the diagram indicate DNase1 hypersensitive sites; those to the left of the ε gene define the LCR. The inverted region in the two double-deletion/inversion cases are shown as a dashed line. * This deletion has only been found in *trans* to HbS.

levels of HbF and it has been referred to as HPFH 6,[97] but from a structural point of view it clearly belongs to the $^{G}\gamma(^{A}\gamma\delta\beta)^{0}$ thalassemias.

Deletions that remove only the β-globin gene and hence produce a β thalassemia phenotype with a raised HbA_2 also tend to have increased HbF levels compared with nondeletion β thalassemias. The levels in some of these individuals overlap with those seen in δβ thalassemia. There are grounds, therefore, for abandoning this classification and combining all the deletion conditions into one group. Because we do not fully understand the mechanisms responsible for the increased HbF in these conditions, this might be premature and a different classification might naturally emerge with increased knowledge. In the meantime, therefore, we have retained the scheme with which most people are conversant.

DELETIONS RESULTING IN HPFH OR δβ THALASSEMIA

The structure of the β-globin gene cluster and the surrounding area is illustrated in Figures 16.5 and 16.6. The β LCR, the major regulatory region marked by erythroid-specific DNase1 hypersensitive sites, lies 5′ to the ε gene. Loss of the β LCR, which occurs in the $(\varepsilon^{G}\gamma^{A}\gamma\delta\beta)^{0}$ thalassemia, results in inactivation of any remaining β-globin genes. The erythroid-specific DNase1 hypersensitive sites that have been mapped around the cluster are shown by arrows on the map. Additional regulatory regions include sequences that have enhancer-like activity in transient transfection assays. These have been identified 3′ to the $^{A}\gamma$ gene, within IVS2 of the β gene, 3′ to the β gene and at three sites in the downstream region, immediately beyond the breakpoints of HPFH-1, HPFH-5, and the SE Asian $^{G}\gamma(^{A}\gamma\delta\beta)^{0}$ thalassemia. These are illustrated on the map with filled circles. Olfactory receptor genes have been localized in the vicinity of the cluster and the area is rich in repetitive sequences, particularly Alu and L1 repeats.

The deletions resulting in HPFH or δβ thalassemia that have been characterized to date are illustrated in Fig. 16.6 and details of characterized breakpoints are given in Table 16.3. The hematological and clinical aspects of these conditions will be dealt with in a later section. In both the $^{G}\gamma^{A}\gamma(\delta\beta)^{0}$ HPFHs and the $^{G}\gamma^{A}\gamma(\delta\beta)^{0}$ thalassemias the deletions remove both the δ and β genes and extend a variable degree 3′ to the cluster, in some cases for up to 100 kb. The $^{G}\gamma(^{A}\gamma\delta\beta)^{0}$ thalassemias differ in that the 5′ end of the deletion partially or totally removes the $^{A}\gamma$ gene in addition to the δ and β genes.

Table 16.3. Deletion breakpoints in δβ thalassemia and HPFH

Condition	Type	5′ Break-point	3′ Break-point	Deletion size (kb)

Breakpoints are given according to the reference sequence entry in GenBank U01317 for the β-like globin genes.

DELETION HPFHs

Six deletion forms of HPFH have been described in Africans, Mediterraneans, Indians and southeast Asians. Their size ranges from 13 to 85 kb resulting in HbF levels in heterozygotes that overlap within the range of 14%–31% (Fig. 16.6). Both δ and β genes are deleted in five cases but the δ gene remains intact in the southeast Asian form. The most common forms are the Black HPFH-1 and -2, which have large (>80 kb) deletions staggered by approximately 5 kb at the 5′ and 3′ ends. Details of the individual types and their breakpoints and original references are given in Wood.[7]

Hb Kenya. Structural analysis of the abnormal β chain in Hb Kenya showed it to be a hybrid chain in which the 5′ end was derived from γ and the 3′ end from β.[98,99] The interpretation that this resulted from crossover between the $^{A}\gamma$ gene and the β gene, with deletion of the sequences that lie between them was confirmed by molecular analysis.[100] The frequency of Hb Kenya is unknown but is clearly relatively rare and most cases appear to originate from East Africa.

$^{G}\gamma^{A}\gamma(\delta\beta)^{0}$ THALASSEMIAS

$^{G}\gamma^{A}\gamma(\delta\beta)^{0}$ thalassemias have a broad worldwide distribution although many of the nine characterized deletions are restricted to one or a few families. The exception to this is the Mediterranean type, which is relatively common and may comprise up to 5% of all β thalassemias in some regions. The deletions all encompass parts or all of the δ and β genes and most are of a restricted size of 10–30 kb. A Macedonian/Turkish form consists of two deletions separated by an inverted sequence, whereas a Japanese and a Turkish case are greater than 100 kb and extend beyond 3′ ends of the large HPFH 1 and 2 deletions. The HbF levels range mostly between 5% and 20% and do not distinguish the various molecular types.

Table 16.4. Hematological data (mean ± SD) on δβ thalassemia and deletion HPFH heterozygotes and homozygotes (defined by molecular analysis)

Condition	Hb g/dL	MCV fL	MCH pg	HbA_2%	HbF	$^{G}\gamma$	α/non-α synthesis	Distribution
Heterozygotes								
$^{G}\gamma^{A}\gamma$ $(\delta\beta)^0$ thalassemia	12.3 ± 0.9	68.3 ± 4.7	23.6 ± 1.8	2.6 ± 0.3	10.5 ± 3.7	35–72	1.4–1.5	Heterocellular
$^{G}\gamma$ $(^{A}\gamma\delta\beta)^0$ thalassemia	13.1 ± 0.6	75.1 ± 3.6	24.4 ± 1.5	2.3 ± 0.3	12.2 ± 1.5^{+}	83–100	1.4–2.0	Heterocellular
HPFH	13.2 ± 0.6	82.6 ± 4.1	26.3 ± 1.4	2.2 ± 0.4	24.1 ± 2.7	16–71	1.1–1.5	Pancellular
Homozygotes								
$^{G}\gamma^{A}\gamma$ $(\delta\beta)^0$ thalassemia	10.9 ± 0.9	78.4 ± 2.7	24.2 ± 2.4	0	100	50–61	2.3–5.2	Pancellular
$^{G}\gamma$ $(^{A}\gamma\delta\beta)^0$ thalassemia	10.5 ± 1.2	71.2 ± 5.8	21.6 ± 1.6	0	100	100	3.8–4.9	Pancellular
HPFH	16.6 ± 1.1	71.9 ± 3.4	24.5 ± 1.3	0	100	54–65	1.7–2.5	Pancellular

$^{\alpha}$ Thalassemia not excluded in all cases; extreme outliers omitted. + not including southeast Asian form with a HbF level of 18.8 ± 2.3%.

Hb Lepore. The Lepore globin chain is a hybrid δβ-chain produced by misaligned crossing over between the δ- and β-globin genes. Three different types have been distinguished depending on the position of the crossover: Lepore Washington/Boston, δ87-β116, Lepore Baltimore, δ50-β86, and Lepore Hollandia, δ22-β50. Lepore Washington/Boston is the most common but both it and Lepore Baltimore have been found in Mediterraneans and those of African origin. Lepore Hollandia has been found in individuals from Papua New Guinea and Bangladesh.

$^{G}\gamma(^{A}\gamma\delta\beta)^0$ THALASSEMIA

$^{G}\gamma(^{A}\gamma\delta\beta)^0$ thalassemias are due to deletions that include part or all of the $^{A}\gamma$ gene and produce HbF containing only $^{G}\gamma$ chains. They are also geographically widespread and mostly restricted to a few families. In size, they are more extensive than most $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemias (Fig. 14.6) and the Indian type has two deletions separated by an inverted region similar to the Macedonian/Turkish form of $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemia. The HbF levels generally are between 10% and 20% but in southeast Asian type these tend to be higher and this condition has been referred to as HPFH 6.[97,101]

Nondeletion δβ Thalassemia

Two Chinese families have been described with the phenotype of δβ thalassemia (hypochromia, microcytosis, normal HbA_2, and a raised HbF of ~22%) but with no detectable deletion.[102,103]

HEMATOLOGY RESULTS AND HEMOGLOBIN ANALYSIS

The hematology results and hemoglobin analyses on the deletion conditions are listed in Table 16.4. In these analyses, only cases for which the molecular basis has been determined have been included.

Hb Kenya. Hb Kenya carriers have near-normal hematological findings. Hemoglobin analysis reveals low-normal levels of HbA_2 (1.4%–1.8%), raised HbF levels (7%–12%), Hb Kenya, and HbA. The proportion of Hb Kenya is more variable, with levels ranging from 5% to 23% and some suggestion of bimodality, with peaks at approximately 10% and 20%. The HbF contains only $^{G}\gamma$-chains. On interaction with HbS, higher levels of Hb Kenya (17%–19%) are observed than in HbA/Kenya cases, whereas the HbF level (6.6%–11%) remains unchanged.[99]

$^{G}\gamma^{A}\gamma(\delta\beta)^0$ HPFH. Heterozygotes for $^{G}\gamma^{A}\gamma(\delta\beta)^0$ HPFH are characterized by normal HbA_2 levels and HbF levels of 15%–30%. There are only minor reductions in the red cell indices, which are frequently within the normal range (Table 16.4). In many of the reported cases, the presence of α thalassemia was not excluded and may explain some cases with reduced MCV and MCH.

Homozygotes have been described for both HPFH-1[89,104–106] and HPFH-2[107–111] and they are indistinguishable; their hemoglobin consists entirely of HbF (Table 16.4). They are clinically unaffected and have normal or high Hb levels (15 g/dL–18 g/dL), presumably as a result of the higher oxygen affinity of HbF. They have microcytic, hypochromic red cells, and globin chain imbalance can be demonstrated, with α/γ ratios of approximately 2.0. This shows that the output of γ chains is not sufficient to compensate fully for the lack of β-chains.

Compound heterozygotes with β thalassemia are usually clinically silent and have similar hematological indices to β thalassemia heterozygotes. Most cases were reported before characterization of the β thalassemia alleles was feasible and presumably involved mild β thalassemia mutations, as they are the most common in this racial group. HbA_2 levels are normal or slightly raised and HbF levels usually fall within the range of 60%–75%. Compound heterozygotes with the Indian type of HPFH with β thalassemia, observed in four families, were all anemic with Hb levels of 5.5 g/dL–9.0 g/dL and were classified clinically as thalassemia intermedia.

Compound heterozygotes for HPFH and HbS are generally healthy and have a mild sickling disorder. They are not usually anemic and there is little evidence of hemolysis. This is ascribed to the high level of HbF contributed by

the HPFH condition (~30% HbF), significantly higher than HbA/HPFH heterozygotes and sufficient to interfere with the polymerization of the HbS molecules.

There are significant differences in the $^{G}\gamma/^{A}\gamma$ ratios of the HbF produced in the various deletions that result in HPFH. Heterozygotes for the Black HPFH-1 deletion have equal amounts of both chains ($^{G}\gamma = 50.7\% \pm 4.3\%$), significantly higher than in the Ghanaian HPFH (32.3% ± 4.8%) and significantly lower than in the Indian type (70.9% ± 2.9%); the narrow distributions among these ranges means that there is little or no overlap between these groups.[7] The Italian type ($^{G}\gamma = 35.0\% \pm 3.2\%$) overlaps with the Ghanaian, whereas the Sicilian (with only two cases) has the lowest $^{G}\gamma$ level (15% and 17%) and the southeast Asian values (61.6% ± 1.7%) lie between the Black and Indian types. There appears to be no correlation between the percentage of HbF and the percentage of $^{G}\gamma$ either within or between the various types of HPFH. Furthermore, the differences in the $^{G}\gamma/^{A}\gamma$ ratios between heterozygotes for HPFH-1 and -2 are not maintained in the homozygotes (both ~60% $^{G}\gamma$) and the proportion of $^{G}\gamma$ is also increased in HPFH/HbS and HPFH/β thalassemia cases.

The significance of these observations is not clear at present. The differences in ratios between the different types could reflect a direct effect on γ gene expression of the individual deletions; alternatively they may result from differences in polymorphic sequences in and around the γ genes (e.g., −158 C or T) that differ on the chromosomes where the deletions arose.

Hb Lepore. The hematological picture in heterozygous Hb Lepore is almost identical to that of β thalassemia trait. Hemoglobin analysis shows normal levels of HbA_2 together with 5%–15% Hb Lepore; the Lepore levels do not vary between the different types. HbF levels are usually raised but in most cases do not exceed 5%. Direct comparisons between Hb Lepore and β thalassemia heterozygotes within the same laboratory demonstrate a small but significantly higher HbF level in the Lepore cases[112] (β thalassemia HbF = 1.39% ± 1.12%, Lepore W/B HbF = 3.19% ± 1.48%). HbF levels are higher in the Baltimore type (mean of 11 cases 4.9%, range 2.7%–11%) than in the Washington/Boston cases (mean of 12 cases 2.75%, range 0.8%–5.4%).[113] This difference is probably due to the C to T difference at position −158 in the $^{G}\gamma$ gene as shown by the higher proportion of $^{G}\gamma$-chains in the Baltimore type (65.9% versus 34.8%).

Homozygotes for Hb Lepore contain HbF together with 10%–30% Hb Lepore. Their clinical manifestations are rather variable, ranging from a picture of transfusion-dependent thalassemia major to a much milder thalassemia intermedia course. A variable clinical picture is also observed in compound heterozygotes with β thalassemia, the severity being at least in part dependent on the severity of the β thalassemia allele.

$^{G}\gamma^{A}\gamma(\delta\beta)^0$ Thalassemias. The hematological findings in the various types of $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemias are all very similar, with red cell morphology and indices in heterozygotes somewhat milder than those seen in β thalassemia trait (Table 16.4). Hemoglobin analysis shows normal levels of HbA_2 and HbF levels mostly in the range of 5%–15%. The intercellular distribution of HbF in these conditions is heterocellular by the acid elution technique and usually by immunofluorescence, with no clear-cut differences in the $^{G}\gamma/^{A}\gamma$ ratios between the different types.

Homozygotes for the Mediterranean, Spanish, Macedonian, and Japanese types have been described (Table 16.4). They all have a similar clinical picture of a mild form of thalassemia intermedia, with Hb levels of 10 g/dL–13 g/dL and only mild hepatosplenomegaly. They can develop more severe anemia during intercurrent infections. The red cell morphology is more severely abnormal than in β thalassemia trait and the hemoglobin consists of 100% HbF, containing both $^{G}\gamma$- and $^{A}\gamma$-chains. Compound heterozygotes with β thalassemia show a more variable clinical course, ranging from mild to severe thalassemia intermedia and presumably dependent on the severity of the β thalassemia allele. Insufficient numbers of cases have been reported in which both the δβ and β thalassemia types have been characterized to determine the precise genotype–phenotype relationship.

$^{G}\gamma(^{A}\gamma\delta\beta)^0$ Thalassemias

Hematological analyses of heterozygotes show similar microcytosis and hypochromia to the other δβ thalassemia traits (Table 16.4). Hemoglobin analysis shows the same pattern of normal HbA_2 levels and increased HbF with a heterocellular distribution as the $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemias. The two conditions are distinguished by the γ-chain composition of the HbF, which contains nearly all $^{G}\gamma$ in $^{G}\gamma(^{A}\gamma\delta\beta)^0$ thalassemia; the small amounts of $^{A}\gamma$ present are derived from the normal chromosome in *trans*. The level of HbF is very similar in all the different forms (mean values all lie between 11.1% and 14.5%) except the southeast Asian type in which they are higher (~19%).

Homozygotes have been described for the Indian, Yunnanese, Turkish, Malay 2, and 49.3-kb Asian[114] types of $^{G}\gamma(^{A}\gamma\delta\beta)^0$ thalassemia. Homozygotes appear to be slightly more severely affected than $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemia homozygotes, with Hb levels of 7 g/dL–11 g/dL and greater hepatosplenomegaly (Table 16.4). The hemoglobin consists of 100% HbF containing all $^{G}\gamma$-chains. Compound heterozygotes with β thalassemia show a similarly variable clinical course to those with $^{G}\gamma^{A}\gamma(\delta\beta)^0$ thalassemia.

Intercellular Distribution of HbF in HPFH and δβ Thalassemia

The major feature of the δβ thalassemia and HPFH conditions that is not well understood is the intercellular distribution. In δβ thalassemia cases in which the HbF level is below 10%, the distribution is clearly heterocellular and

even using a sensitive immunofluorescence technique, a proportion of cells are devoid of HbF. In deletion HPFH cases, in which the HbF levels is approximately 20%, all of the cells contain detectable HbF, that is, a pancellular distribution, but there still appears to be heterogeneity in the amount from cell to cell. Centrifugation of cells from δβ thalassemia heterozygotes shows increasing amounts of HbF in the older cells,[115] whereas there is no such trend in HPFH heterozygotes.[116] This suggests that there is selective cell survival in δβ thalassemia, with those cells with most γ-chain production having least chain imbalance.

As the same molecular defect is present in all the cells in an individual, why should there be this cellular heterogeneity in γ-chain production? One explanation is that this is an example of position effect variegation brought about by the altered chromosomal environment that surrounds the globin genes as a result of the deletion. This could alter the probability and/or stability of interactions between the γ gene promoters and their enhancers. If γ gene expression varies stochastically in these conditions, when overall expression is low as in δβ thalassemia, intercellular variability could vary from undetectable to several picograms, that is, a heterocellular pattern. With the higher overall levels seen in HPFH, the spectrum of HbF/cell would be shifted upward such that all cells would contain detectable but still variable levels, giving the pancellular but heterogeneous HbF distribution observed.

Mechanisms Producing Deletions that Result in δβ Thalassemia and HPFH

Most deletions are due to illegitimate recombination and there is only minimal homology of a few nucleotides at the breakpoints. Most show clean breakage and reunion, although in some cases a few "orphan" nucleotides of unknown origin have been inserted. Several of the deletions start or end within repetitive sequence elements (Alu or LINES) and although breakpoints with the globin genes themselves seem to occur more often than would be expected, this is possibly due to ascertainment bias.[117]

HOW DO DELETIONS CAUSE RAISED HbF IN ADULTS?

A perusal of the extent of the different δβ thalassemia and HPFH deletions that have been characterized at the molecular level (Fig. 14.6) shows that neither the size nor the position of the deletions distinguishes the δβ thalassemias from the HPFHs and as more deletions have been characterized it has become increasingly difficult to provide a simple, unifying explanation. Several hypotheses have been proposed, which will be considered in turn.

Loss of Regulatory Regions

Huisman et al.[118] first suggested that a regulatory region responsible for repressing γ gene expression in adult life might lie between the $^{A}\gamma$- and δ-globin, an idea that was extended to suggest that there were two mutually exclusive domains within the cluster, one fetal and one adult, marked by boundaries.[119] Although other evidence in favor of fetal and adult domains defined by one or more elements lying between the $^{A}\gamma$ and δ genes has been adduced,[64,120,121] no increase in γ gene expression was observed in mice containing a human β-globin YAC from which the $^{A}\gamma$-δ region was deleted.[122]

Competition between $^{G}\gamma^{A}\gamma$ and δβ

It has been suggested that because globin gene expression appears to involve interaction of the LCR with gene promoters, the γ genes may be in competition with the δ and β genes for expression during adult life. In normal circumstances, this competition would favor the δ and β genes as a result of the chromatin conformation or stage-specific *trans*-acting factors or both. When both the δ and β gene promoters are deleted, the γ promoters may be free to interact with the LCR, albeit at submaximal levels, resulting in the persistent HbF.[123,124] This suggestion was strengthened by analyses of nondeletion HPFH (see later) in which there does seem to be clear evidence of competition in *cis* between the β and γ genes.

Evidence for promoter competition within the β-globin cluster is provided by the extremely high levels of HbA_2 in heterozygotes for β thalassemia alleles involving a deletion of the β gene promoter. The increased output of the δ gene occurs in *cis* and appears to be the result of increased transcription of the δ gene. It also appears that such patients have slightly higher levels of HbF compared with those with alleles that leave the β promoter intact. In most of the HPFH and δβ thalassemia deletions both δ and β gene promoters are missing; however, the southeast Asian HPFH is a clear exception because the δ gene remains entirely intact in this case and yet HbF levels of more than 20% are found in heterozygotes. Furthermore, in three of the $^{G}\gamma^{A}\gamma(\delta\beta)^{0}$ thalassemia disorders (Mediterranean, southeast Asian, and Macedonian/Turkish), the 5′ end of the deletion lies within the body of the δ gene, leaving the promoter intact.

Competition between β and γ could not, on its own, explain the phenotypic differences between the $^{G}\gamma^{A}\gamma(\delta\beta)^{0}$ thalassemias and the HPFH conditions. Furthermore, it does not fit with the data in transgenic mice that show autonomous regulation and switching off of γ gene expression during development in constructs that lack of the β-globin gene.[125–127] Given that the mouse does not have a fetal hemoglobin and the human γ gene is expressed largely in embryos in mice, it is not clear whether this model system faithfully reflects all aspects of human globin gene regulation.

Newly Apposed Enhancer Sequences

An alternative explanation for the persistent γ gene expression is that there is a positive influence of the newly apposed sequences translocated to the 3′ end of the complex.[128,129] It was proposed, for instance, that in the Hb Kenya deletion, fusion of the $^{A}\gamma$ and β genes allows the

β IVS2 and 3′ enhancers to activate the promoter of the $^{A}\gamma\beta$ gene and also activate the $^{G}\gamma$ gene.

Analysis of the sequences immediately 3′ to the large HPFH-1 deletion showed that this sequence has enhancer activity in a classic transient transcription assay.[128,129] The region is marked by an erythroid-specific DNase I hypersensitive site extending from 1.1 to 1.4 kb 3′ to the HPFH-1 breakpoint.[130] Furthermore, this site is no longer hypersensitive on a chromosome from which the LCR has been deleted, suggesting that it is influenced by LCR activity even though it lies more than 150 kb away.[131] As a result of the HPFH-1 and -2 deletions, this sequence is brought to within 10–15 kb of the γ genes.

Because enhancers detected in transient transfection assays do not always show the same activity when they are incorporated into a chromosome, particularly if they come under the influence of strong regulatory elements such as the LCR, it was important to test this element in vivo. Arcasoy et al.[125] produced transgenic mice involving various constructs containing the β LCR core elements, the two γ genes and the enhancer from 3′ to the HPFH-2 deletions. Only mice containing the construct with all three elements produced significant amounts of γ gene expression in adult life. This demonstrated the enhancer activity of this element in this experimental model and suggested that it was likely to function in the same way in the HPFH patients. When the HPFH-2 deletion was reconstructed in the context of a 213-kb β YAC, however, no γ gene transcription was found in adult transgenic mice.[132]

Two other regions with enhancer activity in transiently transfected erythroid cells have been identified, one immediately 3′ to the HPFH-3 3′ breakpoint[133] and one in the region between the breakpoints of the Thai (HbF 13%) and Chinese (HbF 20%) $^{G}\gamma(^{A}\gamma\delta\beta)^{0}$ thalassemia deletions.[97,101] These elements, in cosmid constructs showed little or no increased γ gene expression in transgenic mice.[134]

It may be that there is no simple explanation for persistent γ gene expression in the deletion HPFH conditions. Although there may be a unifying mechanism linking them all, it seems equally likely that all of the aforementioned mechanisms may play a role in this process, with the relative importance of each varying from deletion to deletion. Given the large number of elements around the β-globin cluster that affect the regulation of the genes (both positively and negatively) it may not be surprising that other elements capable of these functions reside outside of the gene cluster. The precise balance between regulatory sequences that tend to increase the interaction of the LCR with the γ gene promoters over those that might disrupt this function may ultimately determine the amount of HbF in the red cells and hence the degree of compensation for the lack of β-globin production.

NONDELETION HPFH

There are a number of conditions associated with persistent HbF production that do not result from gene deletions within the β-globin cluster. Many are due to mutations within the promoters of either of the γ genes, leading to variably increased HbF containing preponderantly only one of the γ-chains. In addition, other sequence changes within the cluster may be associated with the potential for increased HbF, although there are clearly genes not linked to the cluster that also influence HbF levels.

Mutations of the γ Gene Promoters

Forms of HPFH that differed by lower HbF levels from those previously reported in Blacks were recognized as relatively common in Greece[135,136] and the HbF contained only $^{A}\gamma$-chains.[137] Because several compound heterozygotes with β thalassemia all had more than 50% HbA, it was suggested that there may be β-chain production in *cis* to the HPFH determinant.

Huisman et al.[138] described a family in whom the propositus had a hemoglobin pattern of approximately 50% HbS, 25% HbA, a low level of HbA_2, and 25% HbF, containing almost entirely $^{G}\gamma$ chains. A British HPFH family with heterozygous HbF levels of approximately 8% and containing only $^{A}\gamma$ chains included three homozygotes with approximately 20% HbF normal levels HbA_2 and the remainder HbA. This is clearly demonstrated that the γ, δ, and β genes must be active on the same chromosome.[139]

Reports on a number of other conditions in which the HbF contained only $^{G}\gamma$- or $^{A}\gamma$-chains followed and these conditions were shown not to be due to gene deletions.[111,119,140] Collins et al.[141] first showed that the $^{G}\gamma$ gene from a $^{G}\gamma\beta+$ HPFH chromosome carried a mutation of C→G at position −202 of the $^{G}\gamma$ gene and similar reports of mutations in the promoter of either the $^{G}\gamma$ or $^{A}\gamma$ genes rapidly followed.[142–147] Finally, direct evidence that the point substitutions were responsible for persistent γ gene expression was provided in transgenic mice.[127,148,149]

The mutations in the $^{G}\gamma$ or $^{A}\gamma$ gene promoters that have been described to date are listed in Table 16.5 and shown in Fig. 16.7. In addition to the British HPFH, homozygotes have also been described in the Greek and Tunisian nondeletion types of HPFH.

HbF levels in these conditions vary from 3% to 35% with a preponderance of either $^{G}\gamma$- or $^{A}\gamma$-chains according to the gene promoter containing the mutation.

Analyses of the proteins that bind to the promoters have demonstrated the complexity of the region, in which binding sites for different proteins frequently overlap (Fig. 16.7). Altered binding of GATA-1, Oct 1, CP1, CDP1, NF-E3, and the stage selector protein have been reported[150–162] and several mutants have also been studied in transient transfection assays or in vitro transcription assays. No consistent themes run through the binding studies and the expression studies have not reproduced the degree of increased γ gene expression seen in vivo.[151,163–168]

Several of these γ promoter mutants have been tested in transgenic mice and recapitulate the human phenotype to varying degrees.[127,148,149,169,170]

* Data not necessarily complete for all individuals; extreme outliers omitted.

** α Thalassemia not excluded in all cases; some results obtained after sample had been in transit.

† This mutation in the $^{A}\gamma$ gene is the same as that occurring as a polymorphism in the $^{G}\gamma$ gene.

†† Only described in combination with HbS.

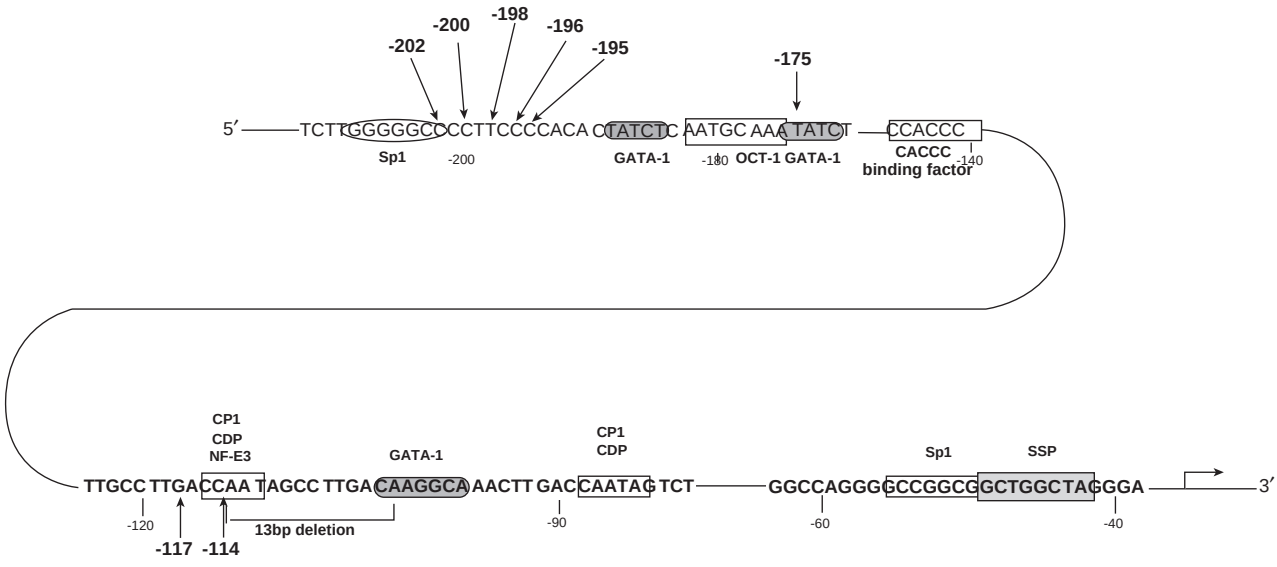

Figure 16.7. Transcription factor binding sites in the promoters of the γ-globin genes; $^{A}\gamma$ and $^{G}\gamma$ genes are identical in this region. The positions of mutations that result in nondeletion HPFH are indicated.

COMPETITION BETWEEN γ AND β GENES IN NONDELETION HPFH

Individuals with γ promoter mutations have balanced globin chain synthesis and a normal MCH (Table 16.5). When combined with a β^S or β^C gene in *trans*, the hemoglobin in the $^{G}\gamma$ −200 and −175 mutations and the $^{A}\gamma$ −175 and −114 to −102 deletion mutants has a composition of approximately 25% HbF, 25% HbA, and 50% HbS or HbC. This indicates that the combined output from the γ and β^A genes on the affected chromosome is approximately normal. The mild anemia seen in compound heterozygotes for β thalassemia and the $^{A}\gamma$ −196 and −117 mutations may indicate that the total γ + β chain output from the HPFH chromosome in these cases is slightly less than normal. Nevertheless, it would appear that the increased γ chain production is matched by a decrease in β chain output and that this reciprocity only occurs in *cis*. This reciprocal relationship could be explained if there was competition between these two genes for access to the β LCR. Altered binding of transcription factors to the γ gene promoter as a result of the base substitutions might well alter the balance of association with the β LCR, resulting in a more stable binding than would normally occur in adult red cells. It is known that during the normal developmental switch from γ to β gene expression, both genes are transcriptionally active in the same cell and that there is continual alternation of activation of the two genes.[171] Decreased binding of a repressor protein or increased binding of an activator to the γ gene promoter could therefore increase the gene's competitiveness. Different mutants would result in different probabilities of a productive interaction with the β LCR, hence the variability in the amount of HbF produced.

HPFH UNLINKED TO THE β-GLOBIN CLUSTER

A number of families have been reported in which an inherited increase in the level of HbF, usually demonstrated in an interaction with β thalassemia or sickle cell disease, apparently segregates independently of the β-globin gene cluster.[172–179] Genetic analysis of these cases is made difficult by the possibility that there is genetic heterogeneity and that there may be incomplete penetrance. Furthermore, the distribution of HbF levels in these families may be continuous, making phenotypic identification of normal and affected individuals difficult. Thus the pattern of inheritance is rarely clear in these families and examples of autosomal, sex-linked, dominant, codominant, or recessive patterns have all been reported.

X-linked. Analysis of HbF levels in healthy Japanese adults led to the suggestion that an X-linked gene was involved in increasing HbF levels with a frequency of 11% of males affected and 21% of females being carriers.[180] Support for the possibility of an X-linked locus affecting HbF levels came from analyses of the F reticulocytes in male and female sickle cell patients and from sibling-pair studies in the same population. Dover et al.[181] suggested that a codominant, biallelic F cell production locus (with high and low alleles) resided on the A chromosome and showed linkage to markers at Xp22.2–22.3. Furthermore, it was proposed that this locus accounts for 40% of the variability in sickle cell HbF levels, an effect of much greater magnitude than β-globin haplotype, age, sex, or α gene status, which together could only account for approximately 10% of the variability.[182]

Chromosome 6–linked. The value of a single large family in the study of unlinked HPFH has been dramatically demonstrated.[179] Starting with an Asian Indian patient

homozygous for β^0 thalassemia who had an extremely mild course, with 10 g/dL–12g/dL HbF, a family study was performed that showed clear-cut evidence for an HPFH-like gene unlinked to the β-globin cluster. The family study was extended until more than 200 members were accumulated. The pattern of inheritance in this family was initially unclear and assignments of phenotypes were made difficult by not only the interacting β thalassemia but also α thalassemia. Nevertheless, by using statistical analysis to take account of the influence of α and β thalassemia, $^{G}\gamma$ −158 status, age, and sex, it was possible by multiple regression analysis to demonstrate the presence of a major gene affecting F cell levels in this family.[183] By using polymorphic markers covering the whole genome it proved possible to localize this gene to a small area of chromosome 6, 6q22.3-q24,[172] which was further refined to a 1.5-Mb region containing five coding genes (*AH11*, *MYB*, *ALDH8*, *HBS1L*, and *PDE7B*) and four noncoding RNAs.[184]

Chromosome 8–linked. Further analysis of the Asian Indian kindred showed an F cell quantitative trait locus at 8q that was conditional on the *Xmn*1-$^{G}\gamma$ polymorphism.[185] This linkage was confirmed in a study of twin pairs,[186] raising the possible action of an unlinked gene on 8q on the globin gene locus itself.

Chromosome 2–linked. Genome-wide association mapping of individuals with contrasting F cell values (F cell levels above 95th or below the 5th percentile points) from a panel of 5,000 individuals identified not only the β-globin locus (probably the *Xmn*1 −158 polymorphism) and chromosome 6 locus but also a quantitative trait locus influencing Fcell production on chromosome 2.[187] It mapped to a zinc-finger protein, BCL11A, previously implicated in leukemias.

The mechanism by which the chromosome 2-, 6-, 8-, or X-linked genes affect HbF levels and F cells remains unknown. It is possible that these loci code for *trans*-acting factors that bind within the β-globin gene cluster and directly affect gene transcription. It is equally plausible that there are genes that act much more indirectly, perhaps by altering the kinetics of erythropoiesis and mimicking the increased HbF seen in stress erythropoiesis.

OTHER SEQUENCE DIFFERENCES WITHIN THE β-CLUSTER AFFECTING HbF PRODUCTION

Within the β-cluster there are numerous polymorphisms affecting either single nucleotides or oligonucleotide motifs. Associations have been noted between the inheritance of some of these alleles and higher HbF levels, usually only under conditions of erythroid expansion such as in sickle cell disease or β thalassemia. The best known of these is the C→T polymorphism at position −158 of the $^{G}\gamma$ promoter, creating an *Xmn*1 restriction site.[188–190]Normal individuals who are homozygous for T at −158 may have a slight increase in F cells and individuals with a $^{G}\gamma$-$^{G}\gamma$ gene arrangement (as a result of a gene conversion event) in which both genes have the T at −158 have HbF levels of 2%–6%.[191] Among sickle cell disease and β thalassemia patients, those with −158 T tend to have higher HbF levels and a higher proportion of $^{G}\gamma$ chains. Additional differences within the cluster also influence HbF levels in these patients because even among haplotypes that contain the −158 T residue, there are haplotype-linked differences.

Other polymorphic regions within the cluster associated with variability in HbF levels in sickle cell and β thalassemia include an $(AT)_x(T)_y$ polymorphism upstream of the β-globin gene promoter,[192] substitutions upstream of the $^{G}\gamma$ gene and in $^{G}\gamma$ IVS2,[193,194] and a $(AT)_xN_{12}(AT)_y$ polymorphism within the HS2 element of the β LCR.[195–197] In none of these cases is there direct evidence from functional studies that different alleles at these sites are responsible for altering γ gene expression and the possibility remains that they are markers in linkage disequilibrium with as yet unidentified elements.

δβ THALASSEMIA AND HPFH CONCLUSIONS

The discovery that HPFH homozygotes with 100% HbF are clinically unaffected promoted the idea that reactivation of HbF production in adult life would be an effective therapeutic strategy for the severe disorders of the β-globin gene such as β thalassemia and sickle cell disease. It was hoped that an understanding of the natural mutations that cause HPFH might provide sufficient insight into the regulation of the γ and β genes to allow manipulation of the hemoglobin switching process. Although considerable progress has been made to identify the molecular basis of many of the HPFH conditions, a complete understanding of how these lead to persistent HbF still eludes us. Among the deletion conditions, the influence of the newly apposed sequences may be responsible for maintaining the γ genes in an active state in some cases but remains to be proven and other mechanisms have not been excluded.

Many of the nondeletion conditions are due to base substitutions in the promoters of the γ genes, altering the binding of transcription factors and preventing suppression of these genes in adult life. The lack of any consistent pattern to these protein binding site changes suggests that the developmental regulation of these genes is a complex multifactorial process and additional investigations are required to provide a more detailed understanding of the way these disruptions enable the mutant γ genes to compete with the β genes in adult erythroid cells.

Identifying the genes that influence adult HbF levels but are not linked to the β-globin cluster may identify other players in the process of γ- and β-globin gene regulation. Positional cloning has localized at least three such genes, but whether they have more than minor modifying roles awaits elucidation.

To date, the knowledge we have gained about the molecular basis of HPFH and δβ thalassemia mutations has considerably increased our understanding of the regulation of

the globin genes. It is to be hoped that continued progress in this understanding will ultimately allow us to manipulate the expression of these genes for the benefit of patients with severe hemoglobinopathies.

Clinical Aspects of β Thalassemia and Related Disorders

Nancy F. Olivieri and David J. Weatherall

INTRODUCTION

Clinically, either alone or through their interactions with β-globin structural hemoglobin variants, the β thalassemias are by far the most important forms of thalassemia. Their control and management will pose a major drain on health care resources in the new millennium, particularly in emerging countries in which improvements in sanitation and public health measures have dramatically reduced the number of infant deaths from malnutrition and infection, and hence in which babies with these forms of thalassemia increasingly will survive long enough to present for diagnosis and treatment.[1]

In this chapter we describe the clinical and laboratory features of the severe, transfusion-dependent forms of β thalassemia and their carrier states, and discuss what is known of the diverse family of disorders that fall between these extremes, the β thalassemia intermedias. Readers who wish to learn more about the historical development of this field are referred to the monograph of Weatherall and Clegg.[2] The public health and economic aspects of the thalassemias in the developing countries are discussed in detail by Weatherall et al.[3]

CLASSIFICATION, NOMENCLATURE, AND GENOTYPE/PHENOTYPE RELATIONSHIPS

Despite our increasing knowledge of the molecular pathology of the β thalassemias, it is still useful to retain a broad classification based on their clinical manifestations. The severe, transfusion-dependent forms are designated β thalassemia major, or Cooley anemia, and the symptomless carrier states, thalassemia minor. The term thalassemia intermedia is retained for want of anything better to describe the broad spectrum of different forms of thalassemia in which the clinical manifestations lie between these extremes.

Because of the wide variability of the hemoglobin constitution in all the severe forms of β thalassemia, it has been necessary to resort to describing the different subtypes by the more consistent findings in carriers, particularly the level of HbA_2. Most of the common forms of β thalassemia are associated with increased levels of HbA_2 in heterozygotes. There are, however, varieties in which it is in the normal range. These "normal" HbA_2 varieties of β thalassemia are further subdivided into those in which carriers have typical thalassemic morphology of their red cells, and those in which there are no hematological changes, the "silent" β thalassemias. Other forms of β thalassemia have been identified in which carriers have unusually high levels of HbF or HbA_2. Finally, there is a group characterized by a dominant rather than the usual recessive from of inheritance. A classification based on this descriptive approach to defining the different forms of β thalassemia is shown in Table 17.1.

β Thalassemia major usually results from the compound heterozygous state for two different β-globin gene mutations, or less commonly and usually in populations with a high frequency of consanguineous marriages, from the homozygous state for the same mutation. The majority of the β thalassemias are caused by mutations at the β-globin gene loci, which result in no output of β-globin chains, β^0 thalassemia, or a reduced output β^+ thalassemia. Hence compound heterozygotes may be heterozygous for both β^+ and β^0 thalassemia or for two different forms of either β^0 or β^+ thalassemia. The term β^{++} thalassemia is sometimes used to describe β thalassemia with a particularly mild reduction in β-globin chain synthesis.

Because many different mutations underlie the β thalassemias, and those that cause β^+ thalassemia vary in their overall effect on β-chain synthesis, it is not surprising that either alone or through their interactions with structural hemoglobin variants or with α thalassemia, they generate a wide variety of different clinical phenotypes. In the sections that follow the main clinical, laboratory, and diagnostic features of these different forms of β thalassemia are described.

THE SEVERE TRANSFUSION-DEPENDENT FORMS OF β THALASSEMIA: β THALASSEMIA MAJOR

The major forms of β thalassemia are defined as genetic disorders of β-globin chain synthesis in which life can only be sustained by regular blood transfusion.

The early descriptions of severe thalassemia by Cooley and others, reviewed by Weatherall and Clegg,[2] present a picture of the disease as it was and unfortunately still is seen in children who have either not been transfused at all or given inadequate transfusion. If children are adequately treated in this way many of the "typical" features of thalassemia do not appear in early childhood and most of the clinical problems that occur after the first decade are the result of iron accumulation. For this reason it is necessary to consider this disease in two settings: the inadequately

treated child and the child who has been transfused from early in life.

General Clinical Features and Course

Age and Symptoms at Presentation

Because β-chain synthesis replaces γ-chain synthesis during the first months of life it might be expected that β thalassemia would become manifest at approximately that time. This is usually the case. Severe forms of β thalassemia commonly present during the first year. For example, Kattamis et al.[4] noted that the mean age at presentation was 13.1 months (±8.1 months), with a range from 2 to 36 months. In reviewing 121 patients, Modell and Berdoukas[5] found that 60% presented within the first year; the mean age at presentation was 6 months (Table 17.2). Similarly, Cao[6] found that, comparing a group of transfusion-dependent with nontransfusion-dependent β thalassemics, the mean age of presentation of the former was 8.4 ± 9.1 months whereas in the latter it was 17.4 ± 11.8 months. The mean hemoglobin level at presentation in the transfusion-dependent group was 8.28 g/dL compared with 9.16 ± 1.2 g/dL in the group with milder disease.

Table 17.2. Age at presentation of infants with thalassemia major or intermedia

Age (y)	Thalassemia major	Thalassemia intermedia
<1	75 (62%)	4 (11%)
1–2	35 (29%)	11 (30%)
>2	11 (9%)	22 (59%)
Total	121	37

From ref. 5.

Some infants with severe β thalassemia present later than the first year. Their hemoglobin values are in the 6–9 g/dL range and it is not clear whether they are going to fall into the major or intermediate category. After observation for several months it is apparent that they are failing to thrive or not growing adequately, and it is clear that they require regular transfusion. The same reasoning applies to even older children who have been categorized as having thalassemia intermedia but in whom poor growth or the development of other complications indicate that they are transfusion dependent.

A wide variety of symptoms may alert the parents to the fact that the child has a serious illness. Frequently, infants fail to thrive and to gain weight normally and become progressively pale. Feeding problems, diarrhea, irritability, recurrent bouts of infection, progressive enlargement of the abdomen due to splenomegaly, or failure to recover from an infective episode are common presenting symptoms. Less usual presentations include the incidental finding of an enlarged spleen, a fever of unknown origin, or the mother noticing that the infant's urine stains the napkin (diaper) pink or brown.[5] At this stage the infant may look pale but otherwise there may be no abnormal signs. On the other hand, splenomegaly may already be present. Thus an accurate diagnosis depends on the hematological findings described later in this chapter, together with the demonstration of the β thalassemia trait in both parents.

If a firm diagnosis is made at this stage and the infant is started on a regular blood transfusion regimen, subsequent growth and development may be relatively normal over the next decade. If the child is not adequately transfused, however, the typical clinical picture of β thalassemia major develops over the next few years.

Diagnostic Difficulties at Presentation

When babies with β thalassemia major present with failure to thrive and anemia, whether or not splenomegaly is already present, the diagnosis is usually made from the appearance of the peripheral blood film, the finding of an unusually high level of fetal hemoglobin, and the demonstration of the carrier state in both parents. Infants often present with an acute infective episode and it is not clear the extent to which their anemia reflects infection rather than severe thalassemia. Although the blood picture can be examined first it is often necessary to transfuse them to tide them over this acute episode. All too often the infant is then assumed to be transfusion dependent, and labeled as having the major form of the illness. It is very important to stop transfusions, either immediately or after an interval to allow the child to recover fully and to observe the steady-state hemoglobin off transfusion. Only in this way is it possible to identify the milder, intermediate forms of the disease that have been exacerbated by intercurrent illness.

Figure 17.1. A child with β thalassemia maintained on a low-transfusion regimen. There is massive hepatosplenomegaly and marked wasting of the limbs. The peculiar stance with arching of the back is typical of this condition. (From ref. 2 with permission.)

Although the diagnosis of β thalassemia major is usually fairly straightforward we have observed a number of cases, particularly in the developing countries, in which difficulties arose. For example, the disease may present with an acute illness, and there are certain infections that can mimic β thalassemia. Malaria causes anemia and splenomegaly, and although the peripheral blood findings are quite different it may be necessary to administer antimalarial agents and carefully reexamine the child to see if the spleen has regressed, and to assess the hematological findings, before the diagnosis of β thalassemia is confirmed. Occasionally, the anemia and splenomegaly associated with leukemia may superficially resemble β thalassemia; juvenile chronic myeloid leukemia, particularly because of the associated high level of fetal hemoglobin production, may sometimes cause confusion. Severe iron deficiency can usually be diagnosed from the hematological picture together with the low serum iron and ferritin values, whereas the blood pictures associated with other congenital hemolytic anemias are sufficiently different to make them unlikely to be confused with β thalassemia. We have seen several patients with congenital dyserythropoietic anemia who were thought to have β thalassemia; although the blood pictures are quite different the associated splenomegaly and dyserythropoiesis may cause confusion.

Course Through Childhood in Inadequately Transfused Patients

The undertransfused thalassemic child may be growth retarded; some are noticeably smaller than their normal siblings, although, in general, slowing of growth is more marked as puberty approaches. There is pallor of the mucous membranes and skin, a variable degree of icterus, and the dirty gray-brown pigmentation, first noticed by Cooley in his early descriptions of the disease. These children fail to thrive and show features of a hypermetabolic state, including poor musculature, reduction in body fat, recurrent fever, poor appetite, and lethargy; the neglected child with β thalassemia, with the characteristic protuberant abdomen, poor musculoskeletal development, and spindly legs looks very much like a child with malignant disease (Fig. 17.1). There is a variable degree of hepatosplenomegaly together with skeletal changes that produce a characteristic facial appearance, with bossing of the skull (Fig. 17.2), hypertrophy of the maxilla that tends to

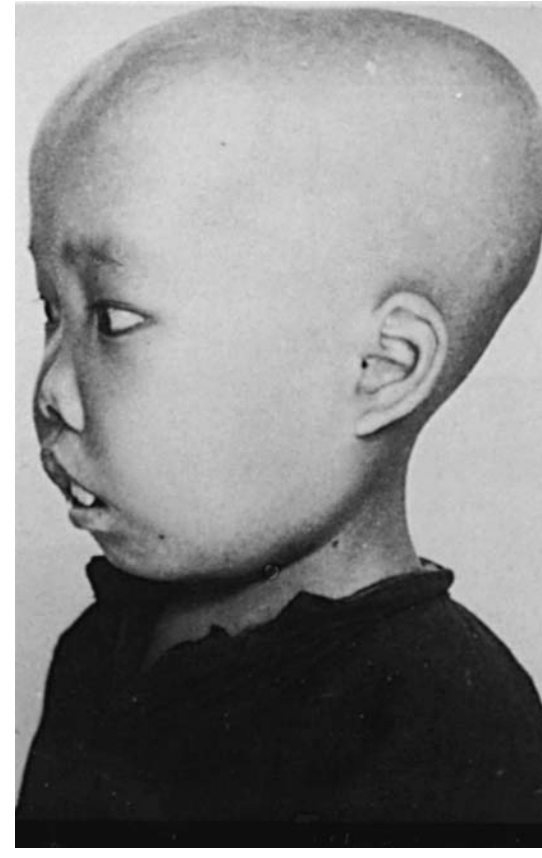

Figure 17.2 Changes in the skull in a child with thalassemia major. (From ref. 2 with permission.)

expose the upper teeth, prominent malar eminences with depression of the bridge of the nose (Fig. 17.3), puffiness of the eyelids, and a tendency to a mongoloid slant of the eyes. There may also be proximal muscle weakness and a genu valgum. Recurrent ulceration of the legs may occur at any time throughout childhood.

The skeletal changes are mirrored by characteristic radiological changes of the skull, long bones, and hands. The skull shows dilatation of the diploic space, and the subperiosteal bone grows in a series of radiating striations, giving a typical "hair on end" appearance (Fig. 17.4). There is cortical thinning of the long bones with porous rarefaction; similar changes are found in the small bones of the hands and feet (Fig. 17.5). These radiological changes, noted as early as 1930 by Voght and Diamond, have been the subject of many reviews.[7–9] Pathological fractures are also a major feature of inadequately transfused children.[10]

Figure 17.4. The skull in homozygous β thalassemia showing the typical "hair on end" appearance.

Figure 17.5. Radiological changes in the bones of the hands in thalassemia major.

The early childhood of these patients is interspersed with numerous complications. They include recurrent infections associated with worsening of the anemia, compression syndromes due to progressive bone deformity, folate deficiency, a bleeding tendency, increasing hypersplenism, gallstones, leg ulcers, and a variety of neurological conditions due to tumor masses resulting from extramedullary hematopoiesis. If they survive to puberty they often develop similar complications to children who, because they have been adequately transfused, have had a relatively trouble-free childhood.

The Well-transfused Thalassemic Child

Well-transfused thalassemic children often remain asymptomatic until early puberty. Their future course then depends on whether they have received adequate iron chelation. If not, they begin to show signs of hepatic, endocrine, and cardiac disturbances resembling those seen in adults with familial hemochromatosis. The first observable changes are often a failure or reduction of the pubertal growth spurt, sometimes associated with delayed sexual maturation. Throughout their teenage life these children suffer from a variety of complications due to different

endocrine deficiencies and they nearly all develop cardiac symptoms in the latter half of the second decade.

Children who are adequately transfused and are fully compliant with respect to iron chelation may grow and develop normally, enter puberty, and become sexually mature. Even within this group, however, there is a disappointingly high frequency of growth retardation and retarded sexual maturation.

This subdivision of the course of severe β thalassemia is, of course, rather artificial; many patients are encountered who fall between one or the other group. In the sections that follow we consider the major complications of the severe β thalassemias; in many cases they are also relevant to the intermediate forms, described later in this chapter.

Complications

The frequency and severity of the complications of β thalassemia depend to a large extent on the way that patients are managed, particularly with respect to their steady-state hemoglobin level and effectiveness of chelation therapy. They can all be related to the primary defect in globin-chain synthesis (Fig. 17.6).

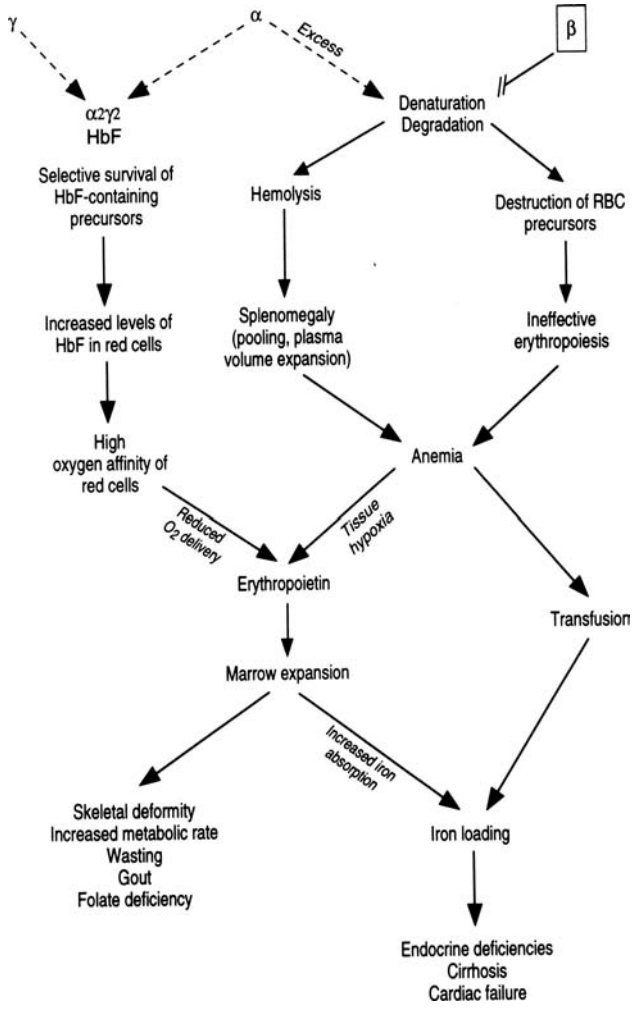

Figure 17.6. The pathophysiology of β thalassemia.

Hypersplenism and Plasma-Volume Expansion

All the early literature on thalassemia stresses the occurrence of progressive splenomegaly in the major form of the illness (see Weatherall and Clegg[2]). Splenectomy for the treatment of thalassemia has also been practiced from the time that the disease was first identified.

As soon as there was sufficient experience with children who had been maintained at relatively high hemoglobin levels it became apparent that marked splenomegaly and hypersplenism were being seen much less frequently.[11,12] In a series of careful measurements of the annual blood requirements of her patients, Modell demonstrated that it was possible to calculate an average annual transfusion requirement to maintain a mean hemoglobin level of approximately 10 g/dL. Patients who exceeded this figure by 50% or more almost invariably returned to their "ideal" transfusion requirements after splenectomy.[5,11,13] These observations were confirmed by others, who found that children who need more than 200–250 mL of packed cells/kg body weight/year to maintain average hemoglobins at approximately 10 g/dL have significant hypersplenism, and that splenectomy significantly reduces these requirements.[14] More recent experience suggests that hypersplenism may usually be avoided by early and regular transfusion and that many patients reaching adolescence after following a regimen of this type do not require splenectomy.[15]

Splenic enlargement may cause a variety of complications. Occasionally, there is physical discomfort simply due to the size of the spleen. The formed elements of the blood may be trapped in the splenic pool, producing anemia, thrombocytopenia and some degree of neutropenia. The anemia of hypersplenism has a complex pathophysiology. Several early studies reported red cell mass and survival data in thalassemic children with large spleens.[16–19] There is invariably some shortening of the autologous red cell survival, trapping of a proportion of the red cells in the splenic red cell pool, and a marked expansion of the total blood volume. In the study of Blendis et al.[16] the trapped cells in the splenic pool accounted for between 9% and 40% of the total red cell mass. There is marked expansion of the plasma volume, which has the effect of worsening the anemia and, incidentally, producing a greater load on the myocardium. The reasons for the changes in plasma volume, which occur in patients with splenomegaly associated with other diseases, is not entirely clear. It is not due entirely to splenomegaly or hepatosplenomegaly; the plasma volume may remain significantly expanded after splenectomy for many months.[16] One factor that has been incriminated is expansion of the bone marrow, which may act as a vascular shunt, a mechanism that is thought to result in plasma volume expansion in a number of other settings.

Finally, it should be remembered that a very large spleen constitutes an extensive mass of ineffective hematopoietic tissue. Thus, as it enlarges, it increases the metabolic demands of the growing child while, at the same time, causing hemodilution and plasma volume expansion.

Iron Overload

Iron overload has been a recognized feature of severe forms of thalassemia since the first autopsy reports.[20] The mechanisms of iron toxicity, its tissue distribution, and the way that it causes organ failure are discussed in Chapter 29, and the methods by which the total body iron burden can be assessed are discussed later in this chapter. Here, we outline the main features of iron accumulation as a background to the description of its effects on individual organs that follow.

It was quite apparent from the results of the first iron absorption studies, and the transfusion histories of thalassemic children in the days before high transfusion regimens were instituted, that iron loading was the result of increased absorption and transfusion, however inadequate. When assessing the results of higher transfusion regimens, Modell[11] estimated that by the time children maintained asymptomatic at a relatively high hemoglobin level reached the age of 11 years they would have accumulated approximately 28 g of iron. She suggested that it was only at approximately this level of iron loading that patients begin to show signs of hepatic, cardiac, and endocrine disturbance.

Because iron overload was to become the major cause of death in thalassemia it was clearly important to attempt to derive more accurate approaches to assessing the level of iron accumulation that would render patients at risk from life-threatening complications. Letsky et al.[21] found that there was a good correlation between the serum-ferritin and liver-iron concentrations in β thalassemics maintained on high transfusion regimens. The values in most of their older patients were extremely high and well within the range seen in untreated hereditary hemochromatosis. These workers noticed that during the period over which the first 50–100 U of blood was transfused there was a steep rise in ferritin levels, after which the rate of increase was less marked. Later studies also indicated that the correlation between transfusion load and serum ferritin may not be so clear-cut.[22] Indeed, Worwood et al.[23] found that a maximum plasma ferritin concentration of approximately 5,000 μg/L probably reflects the upper physiological limit of the rate of its synthesis; higher concentrations are now thought to be caused by the release of intracellular ferritin from damaged cells. Several other factors probably determine the level of circulating ferritin, including ascorbate deficiency, infection, hepatic damage, hemolysis, and ineffective erythropoiesis. [24,25]

Unequivocal evidence that the serum ferritin level cannot be relied on as an accurate assessment of total body iron burden was reported by Olivieri et al.[26] who found that over a wide range of serum ferritin levels and hepatic iron values, there was a wide scatter and, indeed, that the 95% prediction intervals in hepatic-iron concentrations for a given plasma ferritin were so broad as to make determination of plasma ferritin a poor predictor of body iron stores.

Later work, reviewed by Olivieri and Brittenham,[15] provided more accurate information about the levels of hepatic iron at which patients are at risk of serious complications of iron overload. These studies, which extrapolate from data obtained from patients with genetic hemochromatosis, showed that patients with hepatic iron levels of approximately 80 μmol iron/g liver, wet weight, which is approximately 15 mg iron/g liver, dry weight, are at an increased risk of hepatic disease and endocrine organ damage. Patients with higher body-iron burdens are at particular risk of cardiac disease and early death. Recently, noninvasive approaches to assessing these critical liver-iron concentrations using magnetic resonance imaging have been developed[27] (see later section).

Although in the following sections we shall focus our attention on the consequence of iron loading of the heart, endocrine glands, and liver, it is likely that excess body iron has other, less dramatic pathological consequences. For example, it is responsible for the curious gray pigmentation that has been a well-recognized feature of the severe forms of thalassemia ever since they were first described. The complex relationship between iron loading and increased susceptibility to infection will be considered further later in this chapter.

Cardiac Complications

The cardiac complications of β thalassemia are the most important factors in determining the survival in both transfused and untransfused patients. Although they have been recognized for decades, many aspects of cardiac disease in β thalassemia are still poorly understood. It is clear that they are multifactorial, reflecting chronic anemia, iron overload, the consequences of pulmonary disease, myocarditis, pericarditis, and probably many other mechanisms.

Mechanisms. Many of the cardiological changes observed in undertransfused children with severe thalassemia are part of the adaptive changes to hypoxia that occur in all forms of anemia. They include enhanced left ventricular contractility, an elevated cardiac output, left ventricular hypertrophy, and ultimately, dilation, and, in cases of profound anemia, all the manifestations of congestive cardiac failure.

The advent of high transfusion regimens rescued many thalassemic children from these distressing complications in early life but, until the development of effective chelation regimens, only bought time until they died of a cardiac disease or other complications of iron loading toward the end of the second decade of life.[28] There is now good evidence

Table 17.3. Cardiac complications of β thalassemia

* Thought to be due to platelet aggregation, particularly postsplenectomy in intermediate forms of thalassemia.

that effective chelation may protect transfusion-dependent patients from developing cardiac disease. Because many patients do not adhere sufficiently strictly to their chelation programs, and because their expense precludes their use in many developing countries, cardiac disease remains a major challenge in the management of patients with severe forms of thalassemia.

It should be emphasized that the cardiological complications of thalassemia are not restricted to the effects of anemia and iron loading, although they are by far the most important factors (Table 17.3). For example, it has been recognized that, at least in some countries, patients with thalassemia major may be unusually prone to myocarditis.[29] In addition, some patients with severe forms of β thalassemia have an additional burden of right-heart strain due to chronic pulmonary hypertension.[30] It has been suggested that this too may be related to iron overload (see later section), but it may also follow recurrent, small pulmonary emboli. Unfortunately, except for data from Thailand on the frequent occurrence of this type of complication in splenectomized patients with HbE–β thalassemia,[31] there have been few studies that have pursued this possibility. Hoeper et al.[32] have suggested that there is an increased risk of pulmonary hypertension in patients who have undergone splenectomy for any cause; autopsy data showed abundant pulmonary thrombotic lesions. The relationship of these changes to persistent thrombocytosis and an increased propensity to thromboembolic disease is discussed later in this chapter.

Children with severe β thalassemia were also prone to recurrent attacks of pericarditis. Smith et al.[19,33] first reported that a benign, transient pericarditis often develops after splenectomy. This complication was later well documented by others.[34,35] Engle[28] also observed this complication but could find no causal or temporal relationship with splenectomy and suggested that these events may coincide toward the end of the first decade of life. Several workers, notably Orsini et al.,[34] examined the relationship between pericarditis and iron loading but could find no convincing evidence that the two are connected. Over recent years this complication has been seen less frequently.

Pathology. Most of the information on the pathology of the myocardium in β thalassemia comes from autopsy studies, many of which were published in the era before the introduction of iron chelation therapy. In most cases a diffuse, rust-brown staining of the myocardium was observed, together with right and left ventricular hypertrophy, dilation, and a greatly increased cardiac weight (see Engle[28]). In most of the early series, evidence of pericarditis was found.[28,36] Interestingly, an autopsy series of 19 patients with cardiac iron loading and anemia due to causes other than thalassemia did not mention pericarditis.[37]

Estimations of the iron content of the myocardium have shown gross elevations to as much as 20 times normal. They have also underlined the marked variation in cardiac iron content, in two studies, from 0.9 to 9.2 mg/iron/g of heart, dry weight, for example.[37,38] In an extensive examination of iron-loaded hearts in patients who had received transfusions for conditions other than thalassemia,[37] iron was present in myocardial fibers as well as in the connective tissue. The endocardium was reported to have an iron concentration equal to less than 50% of that in the epicardium; iron was concentrated in the left ventricular septum and free wall, with maximal concentration in the left ventricular epicardium. The preferential deposition of iron in the epicardium, only later involving the remainder of the myocardium, may explain the preservation of systolic ventricular function early in the course of the disease. Attempts to relate cardiac function to the degree of iron overload suggest that high concentrations of iron correlate reasonably well with the degree of dysfunction, although, surprisingly, in many patients iron deposition in the conduction system appears to be relatively mild, even in those who die of cardiac arrhythmias.[37,38]

Other changes that have been observed at autopsy include extensive myocardial fibre disruption and variable fibrosis.[38–40] Witzleben and Wyatt reported findings in two children aged 8 and 10 years, respectively. There was prominent right ventricular hypertrophy and pericarditis, but cardiac fibrosis was absent or minimal, despite the presence of hepatic cirrhosis. Although these studies suggested that iron deposition alone might not be enough to produce a fibrotic reaction, later work showed that iron loading is probably the major factor in generating these changes.[41] Endomyocardial biopsies have demonstrated that interstitial fibrosis correlates reasonably well with persistent electrophysiological disturbances, at least in primary hemochromatosis.[42]

Pathophysiology. It is clear from the concentrations observed in autopsy studies that the heart can accommodate less iron load than the liver, possibly because cardiac cells have a relatively small amount of storage protein and may be more sensitive to free-iron–induced oxygen radicals. There is some evidence that very low levels of myocardial iron may interfere directly with diastolic function,[43] a process that resembles the effect of hypercalcemia, and

which is characterized by inadequate relaxation, spontaneous early depolarization, and subsequent failure of contractility.[44] The generation of free hydroxyl radicals may result in damage to the lysosomal membrane of cardiac cells and lead to the disruption of the sarcolemmal membrane and inhibition of the mitochondrial respiratory chain.[45–47] The effects of iron may be augmented by a number of variables, including the reduction of ferric to ferrous iron and the addition of low concentrations of ascorbic acid; conversely, the effects of iron may be inhibited by high concentrations of ascorbic acid, α-tocopherol, and desferrioxamine.[45,48] More recent studies, reviewed by Wood et al.[49] have emphasized the role of nontransferrin-bound iron (NTBI) in the pathogenesis of cardiac damage due to iron loading. In culture, NTBI uptake into myocytes is rapid and may be increased by prior exposure to iron. Both the level and duration of NTBI exposure are important components of cardiac iron uptake. Once NTBI enters the myocyte it is rapidly buffered by ferritin, hence limiting its potential for redox damage. Ferritin–iron complexes enter intracellular siderosomes, where they are stored. Because these buffering systems have a limited capacity, or may be disrupted by other factors, free-iron levels increase within the myocyte. Through the Haber–Weiss reaction, iron catalyses free-radical production, leading to widespread oxidative damage, mitochondrial dysfunction, impairment of cellular energy production and to a wide variety of alterations in cardiac gene expression. Cardiac arrhythmias may be potentiated by the direct action of ferrous iron with the ryanodine-sensitive calcium channel in the sarcoplasmic reticulum. Intracellular iron also impairs function of membrane-bound fast-sodium channels.

In inadequately transfused patients, the magnitude of the body-iron burden is the chief factor in the development of cardiac disease.[15] This appears to be true even though lung disease and myocarditis may aggravate iron-induced cardiac disease, as shown in a 5-year study of more than 1,000 thalassemic patients, of whom approximately 5% developed serious cardiac disease secondary to myocarditis with no evidence of iron overload.[29] Although the low incidence of iron-induced cardiac disease in this young and well-treated population is not surprising, it should be emphasized that infectious myocarditis may play a role in the development of cardiac disease and, conversely, that iron-promoted free radical formation may contribute to the pathogenesis of infectious myocarditis.

Clinical presentations. Considering this complex pathology it is not surprising that the clinical presentation of cardiac disease in thalassemia is extremely variable. It should be anticipated in any patient over the age of 15 years who has been inadequately transfused and chelated, who has been maintained at a high hemoglobin level with inadequate chelation, and, in particular, who has a hepatic iron concentration in excess of 15 mg/g liver dry weight[15] or an equivalent value as assessed by magnetic resonance imaging (MRI).[27]

The clinical descriptions of recent years have never bettered those of Engle,[28] who described a progressive staging for cardiac disease in irregularly transfused patients. In the first stage, observed at approximately the age of 10 years, asymptomatic but progressive cardiac enlargement was noted. This was often followed by attacks of pericarditis at a mean age of approximately 11 years, sometimes associated with large pericardial effusions. This complication was observed in nearly half the patients; no infective cause could be found. The third stage was characterized by the appearance of first-degree heart block, occasional atrial premature beats, and abnormal T waves. Finally, the typical signs of congestive cardiac failure appeared, with features of both right and left ventricular failure in parallel with serious disturbances of rhythm and conduction. The peak incidence of the final stage was between 10 and 15 years. The duration of life after the onset of failure was less than 3 months in more than half the patients, and one-third died within a month of the appearance of cardiac failure.

This general pattern of progression of cardiac disease is still observed, although, as mentioned earlier, pericarditis is seen much less frequently. Occasionally the picture may be predominantly of right heart failure.[28,50,51] As pointed out by Jessup and Manno,[52] in older, adequately chelated patients who are often asymptomatic there may be more subtle abnormalities of both systolic and diastolic function that are multifactorial in origin.

The clinical diagnosis of iron-induced cardiomyopathy is extremely difficult. The symptoms parallel that of left ventricular function, but there may be no abnormalities until the rapid onset of overt cardiac failure. Palpitations may simply be related to anemia or other cardiac abnormalities. Similarly, a poor exercise tolerance may also be related to anemia.

Detection of cardiac dysfunction. The investigation of cardiac function in thalassemia remains problematic. Conduction/rhythm abnormalities correlate poorly with conduction–tissue iron infiltration in autopsy sections of patients who have died of cardiac arrhythmias. Moreover, the subendocardial iron concentration is much less than that found in the epicardial region, so that endomyocardial biopsy may underestimate the degree of iron deposition.[53] There is no particular electrocardiographic finding indicative of iron-induced cardiac dysfunction, although serial tracings may be useful in that a significant change is often indicative of a process other than increased iron deposition. Holter monitoring has been shown to be of little value in predicting the onset of cardiac disease.[54] There is a large literature on the value of echocardiography in the diagnosis of iron loading of the myocardium. In general, systolic function, cardiac dimensions, and myocardial wall thickness are normal until there are unequivocal symptoms of cardiac failure. Measurements of resting ejection

fraction by radionuclide angiography or MRI are, on the other hand, more effective approaches to identifying early systolic dysfunction.[49,58] As pointed out by Wood et al.,[49] because of the complex cardiac physiology in thalassemic patients, including the reduced afterload consequent on anemia, the expected cardiac parameters for patients who are not iron loaded remain poorly characterized.

Early approaches to the assessment of the risk of cardiac disease by imaging of tissue iron were reviewed by Olivieri and Brittenham.[15] Reasonable correlations between MRI were observed in a thalassemic mouse model,[59] and MRI changes consistent with a reduction of cardiac iron, paralleled by improvement in cardiac function, were reported in individual patients.[60] More recently the MRI-related parameters T2 and T2* have been investigated for their ability to assess iron levels in the heart.[49,61] It appears that myocardial T2 and T2* shorten in patients with thalassemia; those with normal T2* values have normal function, but the relative prevalence of myocardial dysfunction and arrhythmias increases at lower T2* values. Several uncertainties about the myocardial T2* technique have been raised and its calibration against myocardial iron levels has not yet been carried out. As pointed out by Wood et al.,[49] like many other biomarkers, abnormal T2* conveys only a relative risk; many patients with high iron burdens are asymptomatic at the time of study. The predictive value of abnormal T2*, though implied, has not yet been demonstrated. Recent studies have shown limited or no correlation between cardiac T2* values and hepatic iron levels and have suggested that cardiac dysfunction may occur in the absence of increased hepatic iron.[62,63] It is difficult to understand these findings in the light of the extensive data relating the marked reduction in cardiac disease in patients whose body iron burdens have been maintained at a low level (see later). Clearly a great deal more work is required to clarify these issues, a topic to which we will return later in this chapter.

The measurement of serum atrial natriuretic peptide levels has been reported to be of value in the identification of preclinical cardiac involvement,[64] although further experience of this approach is still required. Decreased antioxidant activity of apolipoprotein E, related to the frequency of the apolipoprotein E4 allele, has been proposed as a genetic risk for left ventricular failure in thalassemia.[65]

In a critical review of the current state of assessing cardiac function in iron-loaded patients, Jessup and Manno[52] emphasized that none of the methods that have been used to assess early myocardial impairment have been rigorously tested in a prospective manner. They suggested that the combined information obtained from the patient's transfusion record, serial serum ferritin levels, details of their adherence to a chelation regimen, and, most important, hepatic iron concentration, provides as much predictive power as any of the noninvasive tests. Although some progress has been made more recently toward improving the latter, given the complexity of the pathophysiology of cardiac disease in thalassemia more prospective studies involving these new noninvasive approaches to assessing cardiac function are still required.[49]

Changing pattern of cardiac disease. With the advent of adequate chelation therapy there was a major change in the frequency of cardiac disease.[15] Two long-term trials showed quite unequivocally that the effective use of desferrioxamine results in long-term survival and the absence of cardiological complications. In one, which used the serum ferritin as a measure of iron loading, those who maintained concentrations of less than 2,500 μg/L had an estimated cardiac-free survival of 91% after 15 years; patients in whom most of the serum ferritin concentrations exceeded this figure had an estimated cardiac disease–free survival after 15 years of less than 20%.[66] The other study assessed chelation therapy in terms of hepatic iron storage; values of 80 μmol of iron/g liver weight (15 mg iron/g liver, dry weight) were used as a cut-off point above and below which patients were classified as having received ineffective or effective chelation therapy, respectively. The probability of survival to at least 25 years was only 32% among patients above the threshold.[67] These findings have been confirmed more recently in a long-term follow-up study involving seven Italian centers.[68]

Lung Disease and Pulmonary Hypertension

Over the last three decades there has been an increasing recognition of the occurrence of chronic lung disease in β thalassemia, which may aggravate cardiac disease.

A variety of functional abnormalities have been reported, including small airway obstruction, hyperinflation, and hypoxemia, possibly as the result of several different pathological processes.[30,69–71] Other studies have described a primarily restrictive pattern of lung disease, with abnormalities consistent with obstructive airways disease.[30,72–75] Studies of total lung capacity have given inconsistent results, as have the effects of transfusion on pulmonary function.[71,75]

These abnormalities have been related to autopsy findings, which have shown massive accumulation of hemosiderin in alveolar phagocytes in the perivascular and supporting framework.[40,73] In some but not all series, fibrosis was noted in the majority of cases. In addition, sclerotic vascular lesions and thromboemboli have been observed and have been attributed to platelet thrombi.[76,77] A variety of mechanisms have been proposed to account for this pathology. They include tissue damage due to the generation of free hydroxyl radicals secondary to iron deposition, ferrugination of connective tissue resulting in reduced capillary compliance, and other less well-defined abnormalities of the alveolar capillary membrane.[78,79] Abnormal growth and development of the alveolus, secondary either to intrinsic disease or due to frequent transfusions, has also been proposed as a contributing factor.[79]

Pulmonary hypertension and right heart failure is being recognized increasingly frequently, particularly in patients with β thalassemia major who have been inadequately treated or in those with β thalassemia intermedia. Although structural changes in the lung may play a role, the pathophysiology is multifactorial and extremely complex (reviewed by Aessopos and Farmakis[80]). There is increasing evidence that pulmonary hypertension may occur in a variety of chronic hemolytic states as a result of erythrocyte release of arginase coupled with liberation of cell-free hemoglobin leading to dysregulated arginine metabolism and decreased nitric oxide availability. Vascular damage, reflected in a diffuse elastic tissue defect that resembles pseudoxanthoma elasticum, has been observed in patients with β thalassemia, especially thalassemia intermedia. The endothelial dysfunction resulting from these mechanisms may also be involved in in situ thrombus formation within the pulmonary vascular bed. These changes may be enhanced in patients with β thalassemia due to oxidative stress resulting from iron overload and the structural changes outlined earlier. In addition, as outlined in the next section, the hypercoagulable state that occurs in patients with thalassemia intermedia may lead to extensive thromboembolic disease, which leads to further right-heart strain. Finally, chronic hypoxia tends to lead to further vasoconstriction and increase in pulmonary vascular resistance. In short, the complex interaction of increased cardiac output and chronic pulmonary vascular resistance combine to produce chronic pulmonary hypertension and right heart failure.

Thromboembolic Disease

There is clear evidence that patients with β thalassemia are at increased risk of thromboembolic disease. In a 1989 study conducted in Italy that examined the causes of death in thalassemia major, it was found that thromboembolism was the primary cause in four of 159 thalassemic patients.[51] In Israel, Michaeli et al.[81] reported thromboembolic events, either recurrent arterial occlusion or, more commonly, pulmonary thromboembolism, in 4% of patients with thalassemia major. Borgna-Pignatti et al.[82] identified 32 patients with thromboembolic episodes of a total of 735 patients with β thalassemia, 683 with thalassemia major and 52 with thalassemia intermedia. The most common variety was stroke, which made up half of their cases. Other manifestations included pulmonary embolism, mesenteric or portal thrombosis, and deep venous thrombosis in either the upper or lower limbs. In an analysis of more than 8,000 patients in Italy it was found that the total number of thrombotic events was 1.65%, with a prevalence in those with thalassemia major of 0.9% and with thalassemia intermedia of 4%. There was a significant increase in the prevalence in splenectomized patients.[83]

The mechanisms that underlie the increased risk of thromboembolic disease in patients with β thalassemia are complex and multifactorial.[83,84] They include endothelial activation and vascular occlusion, as evidenced by elevated levels of endothelial adhesion proteins, vasoconstriction through a nitric oxide–mediated mechanism as outlined in the previous section, thrombocytosis, and, in particular, the procoagulant properties of the thalassemic red cells. The latter appears to be the result of an increased expression of anionic phospholipids such as phosphatidylserine. This phenomenon may be more marked in splenectomized patients or in those with thalassemia intermedia because of the higher frequency of abnormal red cells in the circulation. These damaged red cells may exhibit alterations of the phospholipid in a "flip-flop" mechanism, favoring exposure of negatively charged procoagulant phospholipids. Furthermore, other factors, both genetic and acquired, may contribute toward an increased likelihood of thromboembolic disease (reviewed by Weatherall and Clegg[2]). For example, as mentioned earlier, thalassemic patients with heart failure have a higher risk of thrombosis if they carry the apolipoprotein E4 allele.[65] It has also been observed that thalassemic patients with hepatitis C may have an increased frequency of anticardiolipin antibodies and lupus anticoagulant and that this may also be associated with an increased risk of thromboembolic events.[85]

Endocrine Dysfunction

It was recognized many years ago that the iron loading of the tissues that occurs in severe forms of β thalassemia has a particular predilection for the endocrine organs. The early literature on this topic is reviewed by Weatherall and Clegg.[2] Although these studies were conducted in very heterogeneous populations of patients it became apparent that the most common endocrine abnormalities are hypogonadotropic hypogonadism, growth hormone deficiency, and diabetes mellitus; the frequencies of hypothyroidism, hypoparathyroidism, and adrenal insufficiency seem to be much lower.

Retarded growth and development. The early literature on thalassemia major frequently emphasized defective growth and development (see Weatherall and Clegg[2]). Later studies confirmed these observations and suggested that linear growth rates and final heights are related to the hemoglobin levels that have been maintained throughout early life.[86] Growth disturbances associated with low transfusion regimens are characterized by lack of weight gain and, in particular, a reduced muscle mass, which often gives the limbs a characteristic sticklike appearance and limits exercise tolerance through weakness. Modell and Berdoukas[5] observed that undertransfused patients have a much lower level of creatinine excretion in their urine than those maintained on higher transfusion regimens. Because approximately 2% of muscle creatine is broken down to creatinine each day, and this provides the only source of urinary creatinine, these studies were compatible with the

Table 17.4. Some suggested mechanisms of defective growth in β thalassemia

Inadequate transfusion
Iron overload
Selective central hypogonadism
Defective production of insulin-like growth factor 1
Impaired growth hormone response to growth-hormone releasing hormone
Abnormal growth hormone secretion
Abnormality of growth hormone receptor
Reduced secretion of adrenal androgen
Zinc deficiency
Free-hemoglobin-induced inhibition of cartilage growth
Desferrioxamine toxicity

concept that a low-transfusion regimen is associated with a reduced muscle mass and development.

The introduction of high-transfusion regimens for thalassemic children did not entirely solve the problem of growth retardation, however. Indeed, as pointed out by Modell[11,87] one of the first indications of tissue damage due to iron overload is a failure of the normal pubertal growth spurt. This is not the whole story because even children who are well transfused and adequately chelated, and apparently who have normal sexual development, may still show some degree of growth retardation and a reduced final height.[5,88,89]

The reasons for growth retardation in well-transfused children are extremely complex, multifactorial, and not entirely understood (Table 17.4). Undoubtedly, iron accumulation due to variability in the effectiveness of chelation therapy plays a major role. Here again, several mechanisms may be involved. Delayed pubertal growth has been attributed to iron-induced selective central hypogonadism[90–93] or interference by iron with the production of insulin-like growth factor (IGF-1).[94–96] Other mechanisms that have been proposed include impaired growth hormone (GH) response to growth hormone–releasing hormone (GH-RH),[97] abnormalities in GH secretion[98] and, because GH reserves appear to be normal in many patients[99–101] a defect in its receptor, although it has not been possible to demonstrate a lesion of this kind in hepatic tissues.

Several reported studies underline the complexities of these issues. In one, nearly half of a group of patients, most of whom had received regular transfusions and chelation therapy from an early age, had evidence of reduced GH reserve and low IGF-1 levels, with a substantial proportion also demonstrating reduced levels of IGF-BP3, the predominant IGF-1 binding protein, which prolongs the serum half-life of IGF peptides, and which is GH dependent. However, the reduction in GH reserve was not shown to be correlated with short height or delay in bone age.[102]

In a similar analysis of 32 patients with thalassemia major, 14 of whom were short in stature, Roth et al.[103] investigated 13 of the group who exhibited a particularly short stature or reduced growth rate. The stimulated GH secretion in 10 was in the normal range. However, studies of their spontaneous GH secretion during the night revealed that they had markedly reduced amplitudes of their GH peaks (see next section). Low IGF-1 levels were also seen in growth-retarded patients. Stimulation tests showed a marked increase in both IGF-1 and IGF-BP3 levels, indicating intact IGF-1 generation by the liver. After priming with gonadotrophin-releasing hormone (GnRH), no change in either estradiol or testosterone levels or in LH or FSH response was observed, suggesting a severe degree of pituitary gonadotrophin insufficiency. These results indicate that low GH secretion and low levels of IGF-1 in thalassemic patients are related to severe neurosecretory dysfunction rather than liver damage. In short, it was apparent that hypogonadotrophic hypogonadism was a major factor, particularly in the growth-retarded patients who had impaired sexual development.

Evidence has also been presented for the existence of a state of partial growth hormone insensitivity due to a postreceptor defect in growth hormone action, which can be overcome with supraphysiological doses of exogenous GH.[104,105] Other factors that may play a role include a reduced level of secretion of adrenal androgen,[106,107] zinc deficiency,[108] and free-hemoglobin-induced inhibition of cartilage growth.[109] It has also been recognized that short stature, related primarily to disproportionate truncal growth and loss of sitting height, may be caused by desferrioxamine [86,110] and may reflect its damaging effect on spinal cartilage.[26,111]

It is clear, therefore, that growth retardation in thalassemia is both multifactorial and extremely common (Table 17.4). In inadequately transfused patients it seems likely that hypoxia plays a role, while in those who are well transfused but inadequately chelated, iron-mediated damage to the hypothalamic/pituitary axis is the main factor. Because of the extreme sensitivity of some of the endocrine organs to iron excess, and the fact that chelating agents such as desferrioxamine in therapeutic doses can inhibit fibroblast proliferation and collagen formation and chelate other metals, even for thalassemic children who have, by all other criteria, received ideal treatment the potential for growth retardation is still considerable.

Delayed puberty and defective function of the hypothalamic/pituitary axis. Arrest or failure of puberty occurs in approximately 50% of both male and female patients. In one large series secondary amenorrhea was documented in 23% of females and 2% of males, and arrested puberty was observed in 16% of males and 13% of females. Oligomenorrhea or irregular menstrual cycles were reported in approximately 13% of females.[112] Although a conflicting literature has accumulated regarding the overall effects of iron chelation on sexual maturation, most studies have observed an improvement, with significantly reduced

serum ferritin concentrations in those who achieve a normal puberty.[112,113] However, there have been no studies of this type involving patients whose body iron loads have been assessed by hepatic biopsy.

Although in inadequately treated patients hypogonadism may be a reflection of chronic anemia, deficiency of IGF-1 secondary to liver dysfunction, cirrhosis, diabetes, and low adrenal-androgen production, there is now abundant evidence that, in those who are more adequately managed, the major mechanism involved in failure of sexual maturation is selective central hypogonadism.[91–93,114–116] Some males tend to have a low baseline testosterone level but their response to human chorionic gonadotrophin is usually normal. Although defective ovarian function has been reported in some cases,[115] patients who show retarded sexual development usually demonstrate blunted responses to GnRH rather than to FSH.

The hypothalamic/pituitary axis appears to be particularly vulnerable to the effects of iron loading. This is supported by histological studies showing selective deposition in pituitary gonadotropes [117] and the observation of loss of anterior pituitary volume in iron-loaded patients, demonstrated by MRI.[118]

Over recent years the importance of linking the function of endocrine organs to circadian cycles has been emphasized. One of the most extensively studied systems is the pulsatile secretion of LSH and FSH, which reflects the intermittent release of GnRH from the hypothalamus. In a long-term prospective study of thalassemic women with secondary amenorrhea, it was found that all of them developed gonadotrophin-pulse abnormalities together with evidence of GnRH-gonadotrophin secretory insufficiency;[114] over the 10-year period there was a progressive deterioration of hypothalamic pituitary function, and 66% of the patients became apulsatile with marked reduction in the levels of GnRH-stimulating gonadotrophin. The different approaches to the diagnosis of gonadotrophin deficiency are discussed by Chatterjee and Katz.[119]

These studies emphasize the importance of studying the hypothalamic/pituitary axis in patients with amenorrhea or other evidence of failure of sexual development. Although there were early reports of testicular and ovarian iron loading,[120] it seems likely that, with improvements in the management of β thalassemia, end-organ unresponsiveness will play a relatively small role in problems of sexual maturation and function in the future.

Thus, although there has been an increase in fertility in men and women with thalassemia over the last decade, it is disappointing that secondary amenorrhea may eventually develop in approximately one-quarter of thalassemic women. This suggests that the anterior pituitary may be particularly susceptible over time to iron-induced damage and that, unlike the heart and liver, the consequences of iron deposition may be irreversible. There are no reports in the literature describing improvement in potency, fertility, or normalization of testosterone levels and sperm counts after reduction of iron load in thalassemia major, although this may occur in primary hemochromatosis. It has been suggested that body iron burdens corresponding to a hepatic iron concentration between 9 and 30 mg/g/liver, dry weight, may be associated with a high risk of development of pituitary failure.[121] Further studies to quantitate body iron and anterior pituitary function in patients from early in life should provide more secure conclusions with respect to the threshold of risk.

Diabetes mellitus. Diabetes is relatively common in children who have been inadequately iron chelated and is also observed in those who have been well-transfused and chelated; in an extensive study of transfused and chelated patients it occurred in 4%–6% of cases.[112] It has been attributed to impaired secretion of insulin secondary to chronic pancreatic iron overload.[122–127] There have also been a number of reports of insulin-resistant diabetes,[128–131] although the mechanism is not absolutely clear. It has also been linked temporally to episodes of acute viral hepatitis.[123,132]

It appears, however, that iron-mediated damage to the pancreas is the major factor in producing diabetes in iron-loaded children; there is a good relationship between the development of diabetes and the severity and duration of iron overload.[123,133] This conclusion is strengthened by consecutive studies over a long period that have shown early and progressive loss of pancreatic β-cell mass, manifested by decreased insulin release in response to secretagogues before the development of significant insulin resistance or diabetes.[134,135] In addition, there appears to be a reduction in the frequency of diabetes in patients who have been more adequately chelated.[67]

Hypothyroidism. Mild abnormalities of thyroid function were described in some iron-loaded patients with β thalassemia by Lassman et al.[136] and Flynn et al.[137] These findings have been substantiated in later studies,[138,139] including patients who had been well managed by transfusion and iron chelation. Grundy et al.[140] described two adolescents with moderately reduced levels of plasma thyroxine and marked elevations in thyroid-stimulating hormone; both had clinical features of hypothyroidism. In the study of Jensen et al.[113] there was a strong correlation between serum ferritin concentrations and the presence of thyroid dysfunction. Although it appears that hypothyroidism is relatively uncommon in transfusion-dependent thalassemia[141] because its clinical onset is so insidious it is very important to bear this complication in mind.

Hypoparathyroidism. Defective parathyroid function has been well documented for many years[90,137,142,143] and florid, clinical hypoparathyroidism has been described in a few cases.[106,137,144,145] The symptoms and signs are all attributable to hypocalcemia and hyperphosphatemia. The early signs, which are nonspecific, include neuromuscular

irritability, paresthesiae involving the face, fingers, and toes, and abdominal cramps. The full clinical picture of acute irritability, emotional ability, memory impairment, lethargy, and convulsions has been rarely reported in thalassemia. The diagnosis is easily made by the finding of hypocalcemia and hyperphosphatemia, together with a reduction in the level of plasma parathyroid hormone (PTH). In a study of 113 transfusion-dependent cases, 12.4% showed subnormal PTH levels, suggesting that subclinical hypoparathyroidism may be relatively common.[146]

Adrenal insufficiency. The limited information about functional adrenal insufficiency in thalassemic patients suggests that it is uncommon and that, although there may be measurable abnormalities of adrenal function,[125] they are rarely associated with the clinical picture of adrenal failure.[106,120,141,147] Interestingly, there seems to be some dissociation of the different adrenal hormone functions in cases in which defects have been observed. For example, Sklar et al.[107] observed low levels of adrenal androgen secretion with a normal glucocorticoid reserve. Early suggestions that part of the skin pigmentation in thalassemia might be due to the melanophore-stimulating effect of raised plasma ACTH levels were not confirmed.[90]

It is clear, therefore, that one of the relative failures of high transfusion and adequate chelation that has otherwise changed the lives of thalassemic patients has been the persistence of endocrine dysfunction, particularly involving the hypothalamic/pituitary axis. Although the reasons are not clear, it is possible that the pituitary is particularly sensitive to even mild degrees of iron overload, and that even chelation regimens that are adequate to retain the function of other organs may simply not always be good enough to protect it.

Bone Disease

The bone changes in inadequately transfused thalassemic children were described earlier in this chapter. As soon as the high transfusion regimens were instituted in the mid-1960s it became apparent that the gross skeletal deformities that had been seen earlier could be prevented.[148,149] It seems likely, therefore, that they reflect expansion of the bone marrow mass, a process that can lead to a variety of other distressing symptoms, particularly pathological fractures.[150,151] Similarly, poor dentition[152] and attacks of recurrent sinusitis due to inadequate drainage[153] are much less common.

The pathophysiology of bone disease in thalassemia is not well understood. Although it is clear that marrow expansion plays a major role in inadequately treated patients, the osteoporosis that occurs in many patients who have been reasonably well transfused, but in whom there is severe iron loading, may be related to hypogonadism.[154,155] Indeed, it is apparent that even in well-transfused patients with thalassemia major there may be a relatively high frequency of osteoporosis, at least in part due to this mechanism.[156–158]

Jensen et al.[159] investigated 82 transfusion-dependent patients of both sexes, with a mean age of 27 years. The incidence of osteoporosis was 51%. Multivariate analysis showed that hypogonadotropic-hypogonadism, sex, and diabetes were significant risk factors. There was no association between ethnic group, smoking, exercise, calcium supplementation or age at starting chelation therapy or, indeed, the serum ferritin concentration. This study also highlighted some features of osteoporosis in thalassemia that are different from those in the postmenopausal variety. In thalassemia, men are more commonly and more severely affected and their lumbar vertebrae and femoral necks are involved, whereas in women osteoporosis mainly involves the spine. This is surprising because most of the women in this study were receiving hormone replacement therapy. Many of these patients were symptomatic with varying degrees of bone pain. This study, which confirms the earlier findings of Fabri et al.,[155] Giuzio et al.,[160] and Anapliotou et al.[154] in incriminating hypogonadism as an important factor in the development of osteoporosis in thalassemia, further underlines the importance of pituitary failure, even in patients who have been treated adequately.

There has been considerable interest in the possibility that there may be subsets of individuals who are genetically susceptible to developing osteoporosis.[161] Rees et al.[162] found that there was a significant correlation between homozygosity of the SS polymorphism of vitamin D receptor and the likelihood of developing osteoporosis of the femoral neck but not the lumbar spine. Jensen et al.[159] could find no relationship between osteoporosis and polymorphisms of the gene for the estrogen receptor. Hanslip et al.[163] found a correlation between osteoporosis and a promoter polymorphism of the COLIAI gene in males but not in females. A more recent study was unable to find any correlation between osteoporosis and the candidate genes; curiously, although the study found correlations with diabetes, chronic hepatitis, and other parameters, it did not find a correlation between hypogonadism and osteoporosis in males, although the methods for assessing gonadal function were not given.[164]

It is possible that these genetic associations of osteoporosis will vary between different ethnic groups; further work is required to test this hypothesis. Although there seems little doubt that hypogonadism is a major factor underlying osteoporosis, further work is required to clarify these complex issues. Suspicions that β thalassemia minor might be a risk factor for osteoporosis have not been confirmed.[165]

Infection

The notion that thalassemic children are particularly prone to infection has been an accepted part of the thalassemia

literature for many years. As symptomatic management improved this concept was questioned[166] and it was suggested that the incidence of infection in early childhood had been markedly reduced in children maintained at an adequate hemoglobin level.[11] In recent years, although there is still an awareness of the dangers of infection, particularly after splenectomy, there has been a major change in emphasis toward concerns about blood-borne infection, notably hepatitis B and C, human immunodeficiency virus (HIV), and malaria. Recent studies of the patterns of infection in thalassemia are reviewed by Vento et al.[167] and Rahav et al.[168]

Patterns of infection with changing management. In an extensive retrospective study of the patterns of infection in thalassemic children maintained at different hemoglobin levels, Modell and Berdoukas[5] concluded that the most serious infections were pneumonia, pericarditis, the sequelae of streptococcal infections, meningitis, peritonitis, and osteomyelitis. Further analysis suggested that pneumonia and septicemia were significantly associated with splenectomy and a low transfusion regimen, and that in patients who had been maintained at a satisfactory hemoglobin level these infections had almost disappeared. They also observed that other serious infections including meningitis, peritonitis, and osteomyelitis are only seen in splenectomized patients and that they have no obvious relationship to anemia. Finally, they noted that pericarditis is also unrelated to anemia and splenectomy but is very clearly related to age, occurring in childhood or later. They suggested that this might reflect a relationship between iron overload and pericarditis. Modell and Berdoukas also provided some comparative information from other countries, indicating that this overall pattern of infection is common in most thalassemic populations. These observations were in keeping with the earlier studies of the dangers of infection in splenectomized thalassemic children[169,170] and, indeed, in any child who has had the spleen removed early in life.[171,172] In this case the most important organisms are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Neisseria meningitis*.

The widespread use of prophylactic penicillin and appropriate immunization after splenectomy has undoubtedly reduced the frequency of severe infections in splenectomized thalassemic children.

Organisms that attack iron-loaded patients. Although, as discussed earlier, there has been a great deal of controversy as to whether the frequent attacks of pericarditis in thalassemic children are related to iron loading, no organism has ever been implicated. The only pathogens that have been shown quite unequivocally to occur with an increased frequency in iron-loaded patients are those of the *Yersinia* genus, which normally have a low pathogenicity and an unusually high requirement for iron. They do not secrete siderophores but have receptors for ferrioxamine and become pathogenic in the presence of iron bound to desferrioxamine.[173] There are numerous reports of severe infections in thalassemic patients due to infections with *Yersinia* spp.[173–176] These infections are usually characterized by severe abdominal pain, diarrhea, vomiting, fever, and sore throat. They may also be associated, on occasion, with rupture of the bowel.[177]

HEPATITIS B VIRUS. It is estimated that approximately 350 million people worldwide are persistent carriers of hepatitis B virus (HBV). The virus persists in approximately 10% of infected immunocompetent adults. Approximately 25% of all patients with chronic hepatitis progress to cirrhosis, approximately 20% of whom develop hepatocellular carcinoma. During the first phase of chronicity, virus replication continues in the liver; markers of this stage include HBV DNA and a soluble antigen, hepatitis Be antigen (HBeAg). In most persons there is immune clearance of infected hepatocytes associated with seroconversion from HBeAg to anti-HBe.

Because HBV is primarily a blood-borne infection, transfusion-dependent thalassemic children are at particular risk, depending on its prevalence in their community and the effectiveness of donor screening programs. The early experience in Europe was summarized by Schanfield et al.[178] and by Modell and Berdoukas.[5] At that time, in British, Cypriot, Sardinian, and Greek populations the frequency of antibody positivity ranged from 30% to 90% with an appropriately low level of those with persistent antigen positivity. Later studies from Greece demonstrated how the application of adequate screening and vaccination programs results in a major fall in the frequency of HBV infection.[179] Although the frequency of HBV infection is now very low in countries in which screening and immunization programs have been established, HBV-related hepatitis is still seen frequently in parts of the world where these precautions are not taken. The diagnosis of chronic active hepatitis depends on the presence of abnormal liver function tests, particularly elevated transaminases, the appearances on liver biopsy, and, in the early stages, the presence of HBeAg antigens and, later, the presence of anti-HBe. In the early phase there is an HBe-positive viremia that usually becomes negative as the disease progresses.

HEPATITIS C VIRUS. Following the identification of hepatitis C virus (HCV) it soon became clear that this infection is widespread and presents a serious risk to patients with transfusion-dependent thalassemia. The prevalence of anti-HCV in patients with thalassemia major varies in different parts of the world, ranging from 11.7% in Turkish Cypriots, through 30% in Malaysians and Chinese to nearly 75% in Italians.[180–186]

An initial HCV infection is almost invariably anicteric and can only be diagnosed by screening for elevated serum transaminases; jaundice is rare. Unfortunately, only 50% of patients recover, and the remainder develop persistent viremia with hepatitis. Of these approximately one in five develops cirrhosis and run the risk of hepatocellular carcinoma. Antibodies to structural and nonstructural proteins of the virus can be detected at various times after infection. Viremia is detected by polymerase chain reaction (PCR), which can identify HCV-RNA. Patients with chronic active hepatitis are invariably HCV-RNA positive and also have IgG anti-HCV, which is also present after recovery. There is some evidence that the liver damage associated with persistent HCV infection, or response to therapy, may be modified by the presence of excess iron.[187–189]

Clearly, therefore, any patient with persistently raised serum transaminases must be screened for HCV antibody and by using PCR to identify HCV-RNA. If this test is positive it is important to proceed to a liver biopsy to identify those who have histological changes of chronic active hepatitis. The liver histology shows predominantly chronic persistent hepatitis with a low incidence of periportal, piecemeal necrosis and lobular hepatitis.

OTHER FORMS OF VIRAL HEPATITIS. Hepatitis D virus (HDV) only replicates in patients already infected with HBV. Infection is common among HBV carriers in the Mediterranean region and may occur at the same time as HBV. The clinical course is that outlined earlier for HBV infection. Hepatitis E virus (HEV) is enterically transmitted and, like HAV, although it may produce acute hepatitis is not associated with persistent infection. Evidence of infection with HEV was obtained in 2.4% of transfusion-dependent thalassemic patients in Athens[190] and in 10.7% of a similar population in Saudi Arabia.[191]

Hepatitis G virus (HGV) was discovered in 1995 (reviewed by Stransky[192]). It produces a mild form of hepatitis but there is little evidence that patients go on to develop chronic hepatitis. It can be diagnosed by the demonstration of HGV-RNA by PCR in a similar way to HCV. Its prevalence in U.S. blood donors is approximately 1.5%. In a study of 40 Italian transfusion-dependent β thalassemics, HGV-RNA was detected in 22% of cases. In patients who were also viremic for HCV the clinical manifestations of the co-infection were no different from those of patients with HVC alone. The authors concluded that although HGV is highly prevalent among Italian polytransfused individuals there is no evidence for a clinically significant role in liver disease.[193] Similar conclusions came from a study of Chung et al.[194] in Taiwan, where the prevalence of HGV-RNA positivity was 14%; again the presence of the virus did not seem to be associated with significant hepatitis. In a further follow-up of Italian patients with HGV it was concluded that in over 25% of cases the infection resolved within 6 years.[195] Similar conclusions were reported by Zemel et al.,[196] who found an incidence of HGV infection of 19.4% in a population in Tel Aviv; follow-up studies suggested that there is persistent viremia but no significant biochemical evidence of liver damage. The frequency of HGV infections in southeast Asia seems to be even higher, with reports of frequencies in transfusion-dependent thalassemic children of 32%.[197]

All these studies suggest that HGV infection, although very common, does not seem to be associated with a serious form of hepatitis or long-term liver damage. A more recent review of HGV and its strain variant, GBVC, also suggests that this is the case, although more data are required.[198]

HUMAN IMMUNODEFICIENCY VIRUSES. The HIVs HIV-1 and HIV-2 belong to the lentivirus subfamily of retroviruses. They can both give rise to the acquired immunodeficiency syndrome (AIDS). Globally, HIV-1 is responsible for the worldwide pandemic of AIDS, although HIV-2, though mainly confined to western Africa, also spread rapidly, notably in India. It is estimated that by the end of 2005 40 million people worldwide were living with HIV infection or disease, a notable rise from the 35 million in 2001, whereas sub-Saharan Africa remains the most severely affected region the virus is still spreading rapidly in parts of Asia and eastern Europe.[199]

It should be remembered that most people in the world with HIV infections are asymptomatic. Prospective studies of cohorts of infected people with known dates of seroconversion have suggested that 50% to 60% of them will develop symptoms and signs of disease within 10 years of infection. During the asymptomatic phase many individuals show abnormal laboratory tests such as low CD4 lymphocyte counts and hypergammaglobulinemia. It is beyond our scope to deal with the various symptom complexes of AIDS, which have been classified by the Centers for Disease Control and Prevention (CDC) into several subgroups (Table 17.5).

Table 17.5. Centers for Disease Control classification for HIV infection

Group I	Acute infection
Group II	Asymptomatic infection
Group III	Persistent, generalized lymphadenopathy
Group IV	Other disease
Subgroup A	Constitutional disease (1 or more of: fever for more than 1 month; weight loss >10% baseline; diarrhea for more than 1 month
Subgroup B	Neurological disease
Subgroup C	Secondary infection
	C1 As specified by CDC surveillance definition
	C2 Others
Subgroup D	Secondary cancers
Subgroup E	Other conditions

It is not surprising, therefore, that HIV infection has become a major concern for multitransfused patients with thalassemia[200] In the mid-1980s, when it was becoming apparent that HIV infection would pose a serious problem for children who had received regular blood products, a European–Mediterranean WHO Working Group on Hemoglobinopathies together with the Cooleycare Group established a program to coordinate data collection. Work from this group and others has provided valuable information about the change in prevalence of HIV infection after donor screening was established and about the course of the illness in those who were affected[201] Early prevalence figures from Italy and Greece ranged from 2.3% to 11%,[202–204] and the infection rate in transfused thalassemic patients in the United States was reported to be approximately 12%.[205] The European–Mediterranean WHO Working Group carried out a further study of 3,633 patients in 36 centers from 13 countries and found an overall frequency of HIV positivity of 1.56%. Further data collected after establishment of screening (reviewed by Girot et al.[201]) revealed a sharp fall in the number of HIV-positive patients, although there is still a very low level of transmission from HIV blood obtained from seronegative donors.[206] In the period after 1988 an analysis of nearly 3,000 patients in 13 European centers found no HIV-1-positive patients.

The same WHO Working Group started a follow-up study of 75 seropositive thalassemic patients to observe the natural history of HIV infection in thalassemic children.[207] The median follow-up period was 4 years 11 months. At the end of the study, 43 patients were CDC stage II, 23 CDC stage III, and 13 CDC stage IV, including seven patients with AIDS, of whom three had died. The rate of progression to AIDS was not associated with intercurrent infection, splenectomy, age, or sex. For the group, a cumulative AIDS incidence rate of 1.4% was observed at 3 years, and of 9% at 5 years.

The situation in other parts of the world, where screening started later, is much less encouraging. In a study of 203 children in New Dehli, Sen et al.[208] reported a frequency of 8.9% for HIV positivity. Kumar et al.[209] found a frequency of 8.9% in a transfusion clinic in Manapur, India. These data provide some indication of the magnitude of the problem that will be posed by HIV infection in thalassemic children in many parts of the world unless urgent steps are taken to institute donor screening. This problem was highlighted by Kumar and Khuranna,[210] who reported on a prospective analysis of the outcome of pregnancies in 123 women with transfusion-dependent β thalassemia, of whom 81 were HIV positive; using the CDC classification, 39 were stage CII and 42 stage All (see Table 17.5). All 22 preterm babies of mothers with stage CII had positive viral cultures for HIV-1 within 1 week of birth; 10 of these neonates died of AIDS by 8 weeks, and the remaining 12 by 15 months of age. Of 39 CII-stage pregnancies, five infants died undelivered at 32 weeks gestation due to fulminating *Pneumocystis carinii* pneumonia.

Currently, the effectiveness of HIV control measures, including screening of blood donors, vary widely in different developing countries. The present position, together with a detailed analysis of the public health approaches to the prevention of blood-borne HIV infection, is summarized by Bertozzi et al. [199]

MALARIA. Following early hopes on the part of the WHO that malaria was being contained in many parts of the world, events of the last few years have proved just how unpredictable the control of an important infection can be. The disease has returned to many countries from which it seemed to have disappeared and, even more frighteningly, drug resistance is now widespread. Children with severe forms of thalassemia are subject to attacks of acute malaria like any other child; the protective effect of thalassemia trait against malaria, reviewed by Weatherall and Clegg,[2] is relative; no form of thalassemia protects any individual completely against the infection. Chronic malaria, as well as exacerbating the anemia of thalassemia, may also increase the degree of splenomegaly.

Thalassemic children are particularly at risk from blood-borne malaria. For example, in a study from India of the blood of children immediately after transfusion, Choudhury et al.[211] found that in 6.4% of cases there was evidence of transfusion-transmitted malaria infection. Thus it is clear that there must be a high frequency of chronic malaria in blood donors in endemic regions.

Another important question regarding malarial infection in thalassemic children relates to the effects of splenectomy on the course of the disease. This complex issue was reviewed by Looareesuwan et al.[212] Although there have been anecdotal reports suggesting that malaria may be particularly severe in those who have been splenectomized, he could not find convincing evidence that this is the case. Recent studies of patients with HbE–β thalassemia in Sri Lanka suggest that they are more prone to malarial infection than normal controls and that, furthermore, there is a highly significant increase in the serological evidence of previous infection in those who have been splenectomized.[213] These observations suggest that, at least in the case of patients with β thalassemia intermedia, there may be an increased susceptibility to malaria, part of which is related to splenectomy.

Severe *P. falciparum* malaria is not always associated with high parasitemias. Therefore, in any thalassemic child in a malarious area who presents with fever, drowsiness progressing to coma, renal failure, hemoglobinuria, hypoglycemia, or simply a rapidly worsening anemia, a diagnosis of malaria must be considered, regardless of the number of parasites in the peripheral blood. Similarly, because *P. vivax* malaria, due to persistent parasites in the liver, may cause recurrent infections, any child in a malarious area who presents with recurrent fevers and increasing enlargement of the spleen should be investigated for this condition by thin and thick blood-film studies.

Liver disease

In young adults with thalassemia major liver disease remains a common cause of morbidity. Although it has been realized for many years that iron overload, acquired through transfusion and increased gastrointestinal absorption, is a major factor in the generation of liver disease, more recently, with the increasing recognition of blood-related viral hepatitis, it has become clear that the pathogenesis of liver damage is extremely complex.

Mechanisms of liver damage. Iron produces cellular injury with progression to fibrosis and cirrhosis (Fig. 17.7). This may be mediated in several ways. It promotes free-radical mediated lipid peroxidation and mitochondrial dysfunction.[48,214–216] The deposition of hemosiderin in lysosomes may lead to fragility and subsequent rupture of their membranes. Iron-promoted catalysis of collagen synthesis or decreased collagen breakdown due to lysosomal blockade following iron overload may promote excess collagen deposition; a similar mechanism has been observed in other storage diseases.[217] Furthermore, iron overload may potentiate further iron loading; upregulation of the transport of nontransferrin-bound iron has been observed in cultured hepatocytes.[218]

As mentioned earlier, blood-borne viral infection is another major factor in the high frequency of liver disease in thalassemic patients, and iron may potentiate the effects of viral hepatitis. Agents such as alcohol may act synergistically in accelerating the development of liver damage. Clearly, therefore, hepatic pathology in patients with thalassemia is extremely complex and many questions about the mechanisms of tissue damage and its pattern of progression remain to be worked out.

Assessment of iron loading and liver damage. The methods for assessing body-iron burden in general, and the level of liver iron in particular, are discussed later in this chapter.

Early findings in inadequately treated patients. Over the last five decades, as survival has extended, severe hepatic fibrosis and siderosis have been regular findings at autopsy.[39,40,124,219] In the absence of adequate chelation therapy it is an inevitable consequence of iron overload; in most patients fibrosis develops during childhood and progresses to frank cirrhosis during the second decade.[116,217,220–222]

It appears that pathological changes in the liver occur very early during the course of the disease. In an early series of studies, the relationship between liver iron content and liver damage was examined in babies of younger than 2 years of age.[217,223–225] Hepatic fibrosis of varying degree was reported in five of these 16 babies, although the liver iron content was not reported. Importantly, screening tests were of limited clinical value and there was no biochemical evidence of hepatic damage. Consecutive histological and electron-microscopic changes in liver pathology in early childhood are reported by Iancuet al.[217]

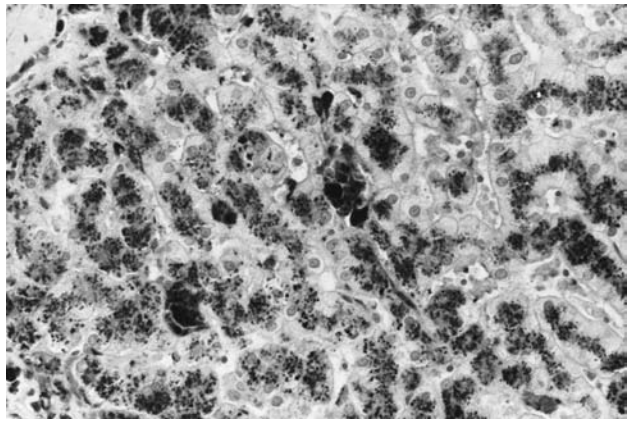

Figure 17.7. A liver biopsy obtained at autopsy from a child with thalassemia major, showing extensive iron loading (Perl's stain x510).

Early studies in older children[20,40,124,219,224,226,227] suggested that fibrosis and cirrhosis were common in transfused, nonchelated children after the age of 3 years. The age and iron content at which significant fibrosis and cirrhosis are likely to develop is still unclear. The relationship between liver-iron concentration and transfusional iron overload was best expressed as an exponential, nonlinear function of the transfused iron load.[228] In these early studies the imperfect correlation between the amount of iron administered by transfusion and the development of fibrosis may be accounted for, in part, by the fact that many children were maintained on low-transfusion regimens that would not have substantially reduced gastrointestinal iron loading.

Later studies of factors influencing the rate of development of liver disease. Age, the iron content of the liver, associated hepatitis, and, possibly, splenectomy may all play roles in determining the time at which liver disease is established.

Risdon et al.[222] suggested that the severity of fibrosis is related to age in a normal linear fashion, but that even when iron accumulation is rapid, severe fibrosis may not be expected before 10 years of age. This pattern of fibrosis does not seem to have been consistent between series of transfused, poorly chelated children with thalassemia. One study reported fibrosis as early as 3 years of age, and cirrhosis as early as 8 years; by the age of 16 years, almost all children showed cirrhosis.[221] Liver biopsies obtained in 51 regularly transfused patients, aged 5–36 years (mean 18 years), showed that only six did not have some degree of fibrosis; in five, cirrhosis was fully developed.[220] Similarly, of 16 patients aged 3–17 years, all but two, both aged 3 years at the time of the biopsy, had moderate to massive fibrosis or cirrhosis; three older patients, aged 4 and 5 years, already demonstrated a severe degree of hepatic fibrosis.[116] Angelucci et al.[229] found that fibrosis was

established in approximately 50% of transfused, irregularly chelated patients younger than the age of 6 years, and in 90% of similarly treated children older than the age of 5 years, an observation that has been confirmed in more recent studies of poorly chelated patients.[230]

It has been suggested that, following splenectomy, the iron content of the liver may increase and fibrosis may be accelerated.[40] Studies of the iron content of spleens in iron-loaded patients have given inconsistent results. Furthermore, Risdon et al.[222] could demonstrate no increase in fibrosis in splenectomized patients. Thus, although the question of the relationship between splenectomy and iron loading remains open, the balance of evidence is against this being an important mechanism for potentiating liver damage.

There is extensive evidence that the major factor in the development of fibrosis is the concentration of iron in the liver. Risdon et al.[222] noted an exponential relationship between iron content and fibrosis in a series of 52 liver biopsies in 19 patients studied over 13 years. The relationship between tissue iron concentration and hepatic cirrhosis was explored in children maintained on a high transfusion regimen who did, or did not, receive intramuscular desferrioxamine, and demonstrated a clear reduction in the degree of fibrosis in the former.[228] In early attempts to establish a threshold of hepatic iron associated with the development of hepatic damage, it was observed that fibrosis was only present in patients in whom the iron levels exceeded 7.6 mg/g dry weight.[40] Later, De Virgillis et al.[231] reported chronic persistent hepatitis, or chronic active hepatitis with periportal lesions, but only in patients with liver-iron concentrations exceeding 10 mg/g dry weight. Aldouri et al.[220] found a mean hepatic-iron concentration of approximately 12.5 mg/g dry weight, in patients with moderate or severe fibrosis, although fibrosis was observed in the presence of lower concentration of hepatic iron.

As mentioned earlier, the first clear evidence that fibrosis can be arrested by iron-chelating therapy was obtained by Barry et al.[228] This effect was observed at a dose that would now be considered inadequate, and at a liver-iron concentration in excess of 20 mg/g dry weight, a level that was subsequently shown to be associated with a heightened risk of cardiac disease and early death.[232] Arrest of fibrosis was observed in several other small studies.[116,220]

In the absence of prospective clinical trials to evaluate life-long therapy for the prevention of tissue damage in thalassemia, guidance about the risk of hepatic fibrosis has had to be derived from the clinical experience with hereditary hemochromatosis.[15] Minor iron loading develops in approximately a quarter of heterozygotes for this condition, although their body iron stores do not seem to increase beyond two–fourtimes the upper limit of normal, that is, up to approximately 7 mg/g dry weight. In contrast, homozygotes who have iron burdens exceeding 7 mg/g dry weight have a definite increased risk of hepatic fibrosis.

It is clear, however, that the toxic manifestations of iron overload do not depend entirely on the amount of excess iron in the liver. They are also modified by the rate of iron accumulation, the duration of exposure to increased iron, the partition of the iron load between relatively harmless sites in macrophages and more hazardous deposits in parenchymal cells, ascorbate status, which may help to determine this partition effect, the extent of internal redistribution of iron between macrophages and parenchymal sites, and noniron-related factors, particularly viral hepatitis. In early studies of patients with hepatitis C liver damage associated with persistent infection, or response to therapy, was considerably modified by the presence of excess iron,[187–189] although this was not observed in a more recent series.[233] Early experience with the oral chelating agent deferiprone suggested that it may result in progression of hepatic fibrosis.[234] In a small retrospective study it was observed that cirrhotic changes appeared to reverse after marrow transplantation.[235]

Assessment of liver function. Given the extremely complex and multifactorial nature of liver disease in β thalassemia, assessment of liver function and determining the reasons for abnormalities of liver function tests may be extremely difficult. As mentioned earlier, there may be significant liver damage due to iron excess without any changes in standard liver function tests. Most patients with β thalassemia, unless their bone marrow is suppressed by transfusion, have elevated serum bilirubin levels, reflecting both ineffective erythropoiesis and a shortened red cell survival. The level of bilirubin is extremely variable and, as mentioned later in this chapter, it is becoming apparent that some patients who remain deeply jaundiced may have an additional genetic defect in bilirubin conjugation. Hepatocellular damage is reflected by a rise in the activity of serum aspartate aminotransferase and alanine aminotransferase (ALT). Because these enzymes are not specific for the liver, elevated levels must be assessed with caution. Because gallstones occur quite frequently in patients with β thalassemia, particularly of the intermediate variety, a typical picture of obstructive jaundice may occur, with raised levels of serum alkaline phosphatase, 5′ nucleotidase, and γ-glutamyl-transferase.

In assessing patients with suspected liver disease an estimation of the size of the liver may be helpful. A moderate degree of hepatomegaly is quite common in patients who have been maintained at a relatively low hemoglobin level. A large, tender liver should raise the suspicion of an underlying hepatitis or, in grossly iron-loaded patients, cardiac failure. An elevation of the liver enzymes should always be investigated, particularly if the level is rising with time. It is essential to screen for the different forms of hepatitis, as discussed earlier. A liver biopsy should be performed and, when possible, the liver-iron level estimated chemically. The liver should be examined histologically with

appropriate stains to demonstrate iron, collagen, and, where applicable, hepatitis antigen.

Exocrine Pancreas

As well as diabetes, described earlier in this chapter, there is increasing evidence that iron may also cause damage to the exocrine pancreas.[236] In a combined ultrasonographic and pancreatic enzyme determination study, the frequency of exocrine pancreatic damage was assessed in 39 consecutive patients with β thalassemia and iron overload. Most of them had markedly increased echogenicity of the pancreas, with decreased size of the gland, as compared with controls. These changes showed a significant correlation with age and the duration of transfusion. Serum concentrations of trypsin and lipase were significantly lower in patients than controls. The lowest values were found in older patients with a longer duration of transfusion therapy, who also had the most marked sonographic changes. Although the functional significance of these findings is not clear, it is possible that in cases of extreme damage to the exocrine pancreas malabsorption may occur.

Folic Acid and Vitamin B_{12} Deficiency

The early literature on thalassemia offered clear evidence that in inadequately treated patients folate deficiency is relatively common.[237–239] These findings were confirmed in studies conducted in Thailand.[240] Chanarin[241] pointed out that the bone marrow may not show features that are absolutely typical of a megaloblastic anemia in patients with thalassemia and coexistent folate deficiency. In several of the early reports it was noted that severe bone pain may follow the administration of folic acid to folate-deficient patients. Folate deficiency is seen less commonly in well-transfused patients although it is still an important problem in those with the intermediate forms of thalassemia.

Vitamin B_{12} levels are usually normal or elevated.[242]

Other Vitamin and Trace Metal Deficiencies

A variety of deficiencies of vitamins and trace metals have been reported in all forms of β thalassemia.

Ascorbic acid. Early studies suggested that leukocyte ascorbic acid concentrations are significantly reduced in patients with severe forms of β thalassemia.[87,243] Subsequent work confirmed that low ascorbic acid levels are found in iron-loaded thalassemic patients.[244–246] It seems likely that ascorbic acid, because of its role as a biological reducing agent, may well be utilized in combating some of the complex free-radical damage that is mediated by excess iron in the tissues. Its role in this process, and how this may differ at varying tissue concentrations of ascorbate, is reviewed by Gutteridge and Halliwell.[215] Although clinical scurvy must be unusual in iron-loaded patients,[245] ascorbate deficiency is of great importance in determining the response to chelating agents such as desferrioxamine. Although the mechanism is uncertain, it seems likely that this effect is mediated by expansion of the chelatable iron pool to which desferrioxamine has access.[246–248]

Vitamin E deficiency. It has long been established that severe β thalassemics may be vitamin E depleted.[87,249] Hyman and her colleagues found that baseline serum DL-α-tochophoral levels and vitamin E stores were low, and that serial biopsies of skin, liver, thyroid and testes showed increased deposits of lipofuscin, which are associated with vitamin E deficiency. These findings were corroborated by Rachmilewitz,[250] who suggested that, because of the continual process of peroxidation of thalassemic red cell membranes, low serum vitamin E levels reflect its consumption as an antioxidant rather than a primary defect in vitamin E absorption or metabolism. The antioxidant properties of vitamin E are discussed by Gutteridge and Halliwell.[215] In their studies of the effects of vitamin E supplementation, Rachmilewitz et al.[251] showed that it was possible to produce a fourfold increase in both serum and red cell vitamin E levels, that the serum vitamin E level dropped rapidly after discontinuation of therapy, that there was a reduction in oxidant stress in red cells due to reduced peroxidative damage, and that in three of seven patients treated there was a significant increase in red cell survival. These findings, although they confirmed the function of vitamin E as an antioxidant in thalassemic red cells, did not define its role, if any, in the treatment of β thalassemia.

Trace metal deficiencies. There have been conflicting reports about the levels of certain trace metals in the blood of thalassemic patients, and even less is known about their significance. Erlandson et al.[252] found increased serum copper and decreased magnesium levels. Prasad et al.[253] also reported increased serum copper levels and Hyman et al.[254] confirmed that at least some patients have decreased serum magnesium levels. The significance of these observations is not clear although Hyman et al. suggested that markedly reduced magnesium levels might have a deleterious effect on cardiac function.

Prasad et al.[253] reported a reduction in serum zinc levels. Again the mechanism is not clear although it appears to be a general feature of hemolytic states, including sickle cell anemia. Low levels of serum zinc were also found in a study in Thailand by Silprasert et al.[255] Incidentally, this study also confirmed the earlier findings of elevated levels of serum copper, although there was no correlation between copper and zinc levels. These authors point out that, at least in experimental animals with zinc and vitamin A deficiency, there is lack of response to vitamin A that can be corrected by zinc supplementation. Zinc deficiency has also been

incriminated in growth retardation, although this has not been documented in thalassemia.

Overall, we know very little about the significance of these changes in the levels of trace elements. Because many chelating agents remove metals other than iron, and even desferrioxamine is not entirely specific for iron, trace metal deficiency may also be exacerbated by treatment.

Gallstones

Gallstone formation is common in undertransfused β thalassemic patients and in thalassemia intermedia.[256]

Secondary Gout

Because of the rapid turnover of red cells in their bone marrow, many patients with β thalassemia who are maintained on a low transfusion regimen are hyperuricemic. Secondary gout has been well documented[257] and gouty arthropathy has been reported.[258]

Neuromuscular Abnormalities

Neuromuscular complications of thalassemia are not common. Logothetis et al.[259] summarized their studies on 138 consecutive patients with thalassemia major who had been maintained on only a moderate transfusion regimen. They noted that walking was delayed beyond 18 months in approximately one-third of the patients, whereas speech and intellectual development appeared to proceed normally. Twenty-six of their patients developed a curious myopathic syndrome with proximal weakness, mostly in the lower extremities, and a myopathic electromyographic pattern. This complication was associated with severe skeletal stigmata, suggesting that it occurred in inadequately transfused patients. It does not seem to be a feature of adequately transfused thalassemic children.

In the series of Logothetis et al. 27 patients had histories of episodes suggesting cerebral ischemia, with focal neurological episodes. Similar episodes were described by Sinniah et al.[260] Neurosensory deafness has been noted by McIntosh,[106] who described improvement in hearing after commencement of regular blood transfusion and, in the same article, noted that deafness was relatively common in inadequately transfused young thalassemics. This complication was also reported by Hazell and Modell.[153] There is no doubt that severe cranial deformities resulting from massive expansion of the bone marrow can result in symptoms of this kind, or involvement of the optic nerve, but these complications are only seen in patients who have been maintained at extremely low hemoglobin levels.

The increased incidence in thrombotic strokes, particularly in patients with thalassemia intermedia and in those who have been splenectomized, was discussed earlier in this section. It is becoming clear however that there is also an elevated risk for subclinical infarction, or silent stroke, in patients with thalassemia intermedia or β thalassemia major. For example, Manfre et al.[261] found evidence of silent infarcts in 37.5% of individuals with thalassemia intermedia compared with 52% in those with HbS–β thalassemia. Those with thalassemia showed milder atrophy and a greater number of single lesions than those with HbS–β thalassemia. These findings were confirmed in a more recent study.[262] It seems likely that these lesions reflect the hypercoagulable state as defined earlier in this chapter. Their neurocognitive significance is considered below.

We discuss the various neurological syndromes that can follow compression by hematopoietic cell tumor masses when we describe the complications of thalassemia intermedia. There are several neurological and sensory complications of desferrioxamine therapy; these are also discussed later.

Intelligence and Behavioral Patterns

Logothetis et al.[263] evaluated the status of 138 consecutive cases of thalassemia major in Greece. Intelligence testing revealed no difference from normal children of the same age and social group. A trend to lower IQ scores was found in those subjected to less vigorous transfusion regimens. Abnormalities of behavior and character were noted in 96 cases and abnormal emotional responses, mainly depression and anxiety, were observed in 67 of the children. In summarizing their experience these workers concluded that their findings were similar to those in any group of children with chronic disease.

More recent studies have used the modern techniques of psychology and psychiatry to assess the behavioral and emotional problems of young children with thalassemia. For example, Tsiantis[264] assessed a group of Greek children by using the methods that were pioneered by Rutter and colleagues[265] for studying the reliability and validity of psychiatric assessment of children. Using these strict criteria it was found that approximately 40% of the thalassemic children, compared with approximately 30% of a control group of chronically sick children, had an emotional or behavioral disorder that would be classified as requiring some kind of psychiatric help. Problems relating to denial and displacement, which are considered to be maladaptive mechanisms, were particularly common. In a further study of group interactions with the parents of thalassemic children a number of factors were defined that may have contributed to the children's problems: death anxiety; denial; overprotective behavior; and, surprisingly, excessive pressure on the sick child to achieve.

Because of growing concerns about these problems the WHO undertook a large multicenter study in 1985 to evaluate the psychosocial aspects of thalassemia and sickle cell anemia. As an approach to data collection they produced an extremely complex questionnaire. To make this more useful for studying thalassemic populations a simpler and more practical program was developed by Ratnip (quoted by Klein et al.[266]). In particular, this attempts to define major psychosocial burdens, but also

tries to put them into perspective as seen through the very different eyes of patients and parents. A pilot study carried out on the Toronto thalassemic population using this questionnaire showed just how dangerous it is to generalize about psychosocial problems based on studies in any one group of patients or their relatives. For example, it found that the clinical and psychosocial burdens were not correlated between parents and their children, parents' perception of their child's psychological burden correlated well although the child was young but not when they reached adulthood, the burden experienced by children was affected by that felt by their parents and vice versa, and although the overall psychosocial burden was similarly perceived by children and their parents, the value placed on individual aspects may differ considerably among family members.

The neurocognitive implications of the silent infarcts, which have been demonstrated frequently in patients with different forms of β thalassemia are discussed by Armstrong.[267] He points out that most of the current studies of neurocognitive function in children with hemoglobin disorders have been restricted to the sickle cell syndromes. Their chronic anemia has been associated with a decline in neurocognitive function, even in the absence of structural changes on MRI. Currently, it is unclear to what extent the presence of silent infarcts are associated changes in neurocognitive function. He emphasizes the importance of carrying out well-controlled studies of this type on children with different forms of thalassemia, particularly with the increasingly good prognosis for patients with these conditions.

Pregnancy

Until the era of adequate transfusion and chelation, pregnancy was not observed in patients with severe forms of β thalassemia. Many patients are now passing through a relatively normal puberty and most centers that look after large numbers of thalassemic patients have had some experience of managing pregnancy in those who are on regular transfusion and chelation therapy.

Several series of successful pregnancies in transfusion-dependent β thalassemic patients have been reported. They have included both spontaneous pregnancies, twin pregnancies, and pregnancies following in vitro fertilization.[268,269] Presumably because pregnancy would only be likely to occur in women who had been adequately chelated, and therefore in whom it is unlikely that there would be serious hepatic, cardiac, or endocrine complications, most of these pregnancies seem to have gone to term and there have been no major problems. Deaths due to cardiac failure have occurred and it is essential that pregnancy be avoided in women with evidence of cardiac iron loading. The patients have maintained their usual hemoglobin levels by regular transfusion. There are limited data on the outcome of pregnancies in which desferrioxamine has been administered in the first trimester.[270] It is currently suggested that, if indicated, it is restricted to later than 16 weeks gestation until one week before delivery. It should be avoided during breastfeeding. Because of lack of data, the use of oral chelators (see later section and Chapter 29) should be avoided during pregnancy.

Autopsy Findings

With one notable exception the recent literature of the thalassemia field has, like that of the rest of medicine, completely neglected the value of the autopsy. The exception is the beautifully illustrated atlas produced by Sonakul.[271]

There are, however, many excellent descriptions of the morbid anatomy of thalassemia in its earlier literature.[20,124,272–274] Perhaps the most valuable information to come from these reports is the distribution of iron among the different organs. Extensive data, together with the weight of iron per organ, were summarized by Modell and Matthews.[274] Most of the findings at autopsy reflect the various pathologies that have been described in different sections of this chapter. The most striking finding in all these reports is the widespread deposition of iron with varying degrees of organ fibrosis. As might be expected the organs most affected include the liver, spleen, endocrine glands, pancreas, heart, and kidneys. The degree of fibrosis varies widely, and is most marked in the liver and least noticeable in the thyroid gland. The spleen is enlarged and congested with thickened reticulum. It may contain Gaucher-like cells similar to those seen in the marrow. Detailed studies of the myocardium and conductive tissues are reported by Buja and Roberts[37] and Modell and Matthews[274] (see earlier section). As shown most elegantly in the atlas of Sonakul,[271] there may be extensive extramedullary hematopoiesis. This work is also notable for the illustrations of obliterative changes in the small vessels of the lungs seen in some Thai patients with HbE thalassemia and pulmonary hypertension.

Hematological Findings

Peripheral Blood and Marrow

There is always a severe degree of anemia that is typically hypochromic and microcytic with a low mean cell hemoglobin (MCH) and mean cell volume (MCV). Presumably because of the marked changes in the shape and size of the red cells, red cell indices derived from electronic cell counters do not always reflect the degree of hemoglobinization of the red cells as judged from an inspection of the peripheral blood film. They show marked anisocytosis and poikilocytosis, with many misshapen microcytes, occasional macrocytes, and variable numbers of target cells. Erythroblasts are always present and may reach extremely high levels after splenectomy (Fig. 17.8). The appearances of the red cells are different in splenectomized patients. In particular, large hypochromic cells are found together with small piscine forms that are little more than fragments of

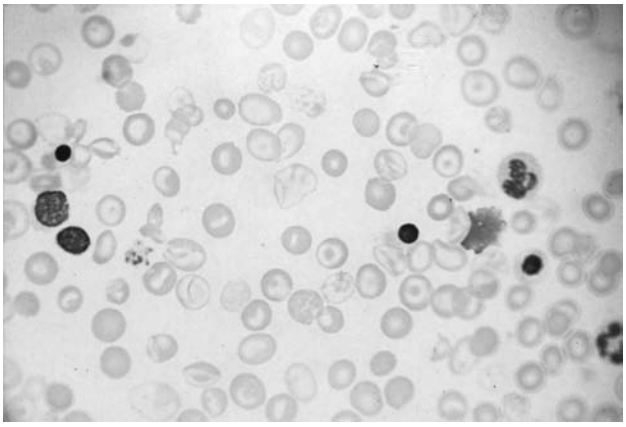

Figure 17.8 The blood smear of a patient with thalassemia major showing the typical morphological changes (Wright's stain, x438).

stroma. Ragged inclusion bodies can be seen in the cytoplasm of both nucleated and nonnucleated red cells after incubation with methyl violet. Their ultrastructural characteristics have been described in several studies.[275–278] The absolute reticulocyte count is rarely high although it tends to increase after splenectomy. The total white cell count and differential is usually normal but may also increase after splenectomy. A reduction in white cell count, particularly if there is a shift to the right with hyperlobulation of the neutrophils, is indicative of folate deficiency. Severe neutropenia may occur occasionally as part of the picture of hypersplenism. The platelet count is usually normal or slightly elevated, particularly after splenectomy; thrombocytopenia usually reflects hypersplenism or folate deficiency.

The bone marrow shows marked erythroid hyperplasia with a reversal of the myeloid/erythroid ratio. Iron staining reveals an abundance in the reticuloendothelial elements and also in the red cell precursors. On incubation of the marrow with methyl violet it is always possible to demonstrate inclusion bodies in the erythroblasts.[279] Their identification as precipitated α chains, kinetics of precipitation, distribution in red cell precursors at different stages of maturation, and ultrastructure, together with the pathophysiological consequences of α-chain precipitation, are reviewed in detail by Weatherall and Clegg[2] (see Chapters 9 and 11).

The cytoplasm of thalassemic erythroblasts contains an accumulation of glycogen, most marked in the G1 phase of early polychromatic erythroblasts.[280] It has been suggested that this reflects the storage of unused energy in cells that are blocked in this phase of the cell cycle. The marrow also shows intense phagocytic activity, with the presence of large foamy cells resembling Gaucher cells.[281]

Red Cell Survival and Metabolism

Red cell survival is reduced, with published figures ranging from 7 to 22 days. Several studies have shown that there are two populations of red cells, one that is rapidly destroyed and another with a longer survival.[282–284] The short-lived population appears to be low in HbF and to contain predominantly small amounts of HbA or α-chain precipitates.[285] Although external scanning suggests that some red cell destruction occurs in the spleen, the main effect of increasing splenomegaly is to trap a large number of red cells with consequent hypervolemia and hemodilution.[16,286]

There are several distinctive metabolic abnormalities of the red cells; the mechanisms and relationship to red cell membrane damage by excess α chains are discussed elsewhere in Chapter 9. The red cell osmotic fragility is markedly decreased. The metabolic changes reflect the marked heterogeneity of the different red cell populations in the peripheral blood. After centrifugation, cells from the "younger," upper layers contain more inclusion bodies, have a lower hemoglobin content, and show a remarkable increase in the rate of flux of potassium, with higher rates of glycolysis and lactate formation and low and unstable levels of adenosine triphosphate (ATP).[275,287,288] These changes are less marked in the "older," HbF-rich population, underlining the protective effect of increased γ-chain synthesis on both red cell metabolism and survival. Changes in other red cell enzymes and porphyrins are reviewed by Weatherall and Clegg.[2]

Iron Metabolism

As discussed earlier, iron loading is a constant feature of transfusion-dependent β thalassemia. Although the majority of the iron load is derived from blood transfusion, there may, in certain circumstances, be increased gastrointestinal absorption. As will be described later in this chapter, this is certainly the case in the intermediate forms of β thalassemia.

Iron Absorption

The inconsistent results of some iron absorption studies almost certainly relate to the transfusional status of the patients at the time of study. Heinrich et al.[289] found that inorganic-iron absorption was markedly increased 64–300 days after transfusion, whereas it fell into the normal range if performed 3–17 days after transfusion. Presumably, therefore, the level of iron absorption is related to the degree of ineffective erythropoiesis and erythroid hyperplasia; if this is reduced by transfusion iron absorption is also reduced.

Serum Iron

Serum iron is elevated in children with severe β thalassemia, and in older patients the iron-binding capacity is fully saturated. The serum of such patients contains 2–7 μmol/L of nonspecifically bound iron that is dialyzable and can be bound by transferrin from normal sera.[290]

Serum Ferritin

The measurement of plasma or serum ferritin is the most commonly used estimate of body iron stores in thalassemia. As discussed earlier, it has serious limitations, particularly in severely iron-loaded patients. The wide fluctuations that may occur at high ferritin levels may reflect a variety of mechanisms that alter the concentration independently of body iron load. These include ascorbate deficiency, acute and chronic infection, liver damage, hemolysis, and ineffective erythropoiesis. The 95 prediction intervals for hepatic iron concentration, related to the serum ferritin, are so broad that it is not possible to use the serum ferritin levels as a reliable predictor of body stores[15] (see earlier section).

Hepatic Iron Concentration

Until recently the hepatic iron concentration has been the most effective guide to assessing body iron stores, and the likelihood of tissue damage. The main disadvantage of this approach is, of course, that it is invasive; there is also the possibility of sampling error, particularly in livers that are involved by increased fibrosis of frank cirrhosis. There is now increasing evidence that adequately calibrated MRI techniques can enable safe and accurate non-invasive measurement and imaging of liver iron concentrations. The technique is based on the measurement and imaging of proton transverse relaxation times (R_2) in the liver. This approach has been reviewed recently by St. Pierre et al.,[27] who provide a comparison of the sensitivity of MRI data with different values of hepatic iron concentration. The only other approach that provides data equivalent to the latter is magnetic susceptometry using a super-conducting quantum interference device.[15]

Ferrokinetics and Erythrokinetics

Ferrokinetic and erythrokinetic studies in severe β thalassemia show a marked degree of ineffective erythropoiesis.[291,292] On the one hand there is evidence of increased red cell production as judged by bone marrow hyperplasia, plasma iron turnover, and fecal urobilinogen production, although effective red cell production as assessed by the hemoglobin level, absolute reticulocyte count, and iron incorporation is not increased, indicating an extreme degree of intramedullary destruction of red cells.

Hemoglobin Constitution

The red cells in all the severe forms of β thalassemia contain increased amounts of HbF. Homozygous β^0 thalassemics have only Hbs F and A_2; HbA is absent. The level of HbF in β^+ thalassemia homozygotes or compound heterozygotes is variable but is always elevated above normal after the first few months of life. Hemoglobin-A_2 levels are variable and of no diagnostic value. The only other abnormal finding is the presence of free α chains, which can sometimes be demonstrated using appropriate electrophoretic techniques.

Hemoglobin F

The complex and still ill-understood mechanisms for the production of HbF in β thalassemia are reviewed in detail by Weatherall and Clegg.[2] In short, it seems to reflect marked erythroid expansion, which may favor γ-chain synthesis in the postnatal period, together with selective survival of red cell precursors and mature red cells that have relatively higher levels of γ-chain production. This latter mechanism reflects the extreme heterogeneity of the level of γ-chain synthesis between different red cell precursors after birth; those that produce relatively more γ-chains, and hence in which the degree of globin-chain balance is less, come under intensive selection in the marrow and blood. By these routes alone, together with the major expansion of the total red cell precursor mass, it is possible to account for between 2 and 4 g/dL HbF without the necessity of invoking other mechanisms. This hypothesis received some experimental verification when it was observed that in patients with HbE–β thalassemia who were regularly transfused at a hemoglobin level of approximately 10 g/dL, and hence in whom there was limited erythroid expansion and endogenous erythropoiesis, there was virtually no synthesis of HbF; only HbE production could be identified. Yet the steady state HbF in untransfused patients with this condition, and hence with expanded marrows and anemia, is in the 30%–40% range.[293]

Despite some reports to the contrary, it is clear that from studies of the hemoglobin constitution of young patients with β^0 or β^+ thalassemia major before their first transfusion, that the predominant form of hemoglobin produced in all the severe forms of β thalassemia is HbF. The $^{G}\gamma/^{A}\gamma$ ratios of HbF in severe thalassemia has been reported by Schroeder and Huisman[294] and Huisman et al.[295] There was a broad scatter with a mean of approximately 3:2, regardless of the findings in the parents.

Hemoglobin A_2

The difficulties in interpreting HbA_2 levels in severe forms of β thalassemia are similar in many ways to those in interpreting the level of HbF. In a series of pretransfusion patients described by Kattamis et al.,[4] the HbA_2 level in 54 homozygotes, of whom 11 were of the β^+ variety, was 3.0 with a range from 0.8% to 5.5%. Several differential centrifugation studies have shown that the absolute level of HbA_2 in the HbF-rich population is much lower than that in cells that contain predominantly HbA (reviewed by Weatherall and Clegg[2]). Thus, it is clear that the distribution of HbA_2 is uneven and that the level that is measured in the peripheral blood is an average of cells with widely differing amounts; it is of no diagnostic value.

In Vitro Hemoglobin Synthesis

In vitro globin-chain synthesis studies have provided a clear picture of hemoglobin production in the severe forms of β thalassemia.[296–300] In nonthalassemic reticulocytes α- and β-chain synthesis is almost synchronous and there is only a small pool of free α chains. In reticulocytes or marrow cells from patients with severe β thalassemia there is always marked globin-chain imbalance, with published α/β + γ production ratio ranging from 1.5 to 30. Imbalanced globin-chain synthesis leads to substantial number of free α chains in the cells, which can be demonstrated by both gel filtration and DEAE cellulose chromatography.[299,300] The α chains in this pool exist both as monomers and dimers, and either combine with newly made β and γ chains to produce Hbs A and F, respectively, are destroyed by proteolysis, or form hemichromes and become associated with the red cell membrane.

The problems and pitfalls with this approach to measuring globin-chain production in β thalassemia have been reviewed in detail.[2] It should be remembered that the excess of α chains that are produced in β thalassemia are unstable and hence in order to obtain an estimate of the absolute amount of globin chain produced in radioactive labeling experiments it is necessary to carry out a time course experiment and extrapolate to zero time. Furthermore, many of the early discrepancies that were reported in α/β+γ-chain production ratios between the peripheral blood and bone marrow were the result of artifacts caused by the contamination of globin chains with nonglobin radioactive proteins produced in the bone marrow.

In short, because of the rapid destruction and turnover of excess α chains, particularly in the bone marrow, and the heterogeneity of cell populations with respect to γ-chain synthesis, the measurement of globin-chain synthesis in the marrow and blood at a single time point does not give information about the absolute rates of synthesis of individual chains. Nevertheless, it provides a reasonable indication of the overall severity of the defect in β-globin production. Provided that the various pitfalls associated with the measurements of total counts or specific activities, as outlined in detail by Weatherall and Clegg,[2] are taken into consideration, this approach can be used for diagnostic purposes, or to monitor the effects of different forms of therapy designed to augment γ-chain synthesis, or other modalities, to a reasonable degree of accuracy.

β THALASSEMIA INTERMEDIA

It has been apparent since the earliest descriptions of thalassemia that there are forms characterized by moderate anemia, jaundice, and splenomegaly that, although not as severe as the transfusion-dependent varieties, are clearly worse than the carrier states. In the extensive Italian literature on this subject these conditions have been variously described as La Malattia-di-Rietti-Greppi-Micheli (reviewed by Bannerman[301] and Weatherall[302]), the anemic form of the Mediterranean hematological disorder,[303] microcitica costituzionale,[304] and thalassemia intermedia.[305] Over recent years it has been apparent that this clinical picture can result from the interaction of many different thalassemia alleles, either one with another or with those for structural hemoglobin variants. Hence, the term is simply a descriptive title for a particular clinical disorder and has no clear-cut genetic meaning. Because we are still not at a stage at which we can always describe precisely the genetic interactions that can produce this clinical picture, it seems useful to retain it.

Thalassemia intermedia has been the subject of a number of articles and reviews that focus either on the molecular pathology and pathophysiology in general,[2,306,307] the molecular basis in certain populations,[308–314] or the clinical features.[2,315–317]

How is β Thalassemia Intermedia Defined?

There is no adequate definition of β thalassemia intermedia. As discussed later in this chapter, the hematological findings in heterozygous β thalassemia are remarkably uniform, and are characterized by a mild degree of anemia; splenomegaly is extremely unusual. Hence, any thalassemic patient with a hemoglobin level persistently below 9–10 g/dL, particularly if there is associated splenomegaly, falls into the intermediate class of β thalassemias. It is at the more severe end of the spectrum that the difficulty in definition arises. Some children survive early life with hemoglobin levels in the 5–6 g/dL range. Although they are often classified as having thalassemia intermedia, particularly if they present relatively late, many do not thrive or develop normally, and may grow up with gross skeletal deformities. It is now believed that these children should be transfused to avoid these distressing complications. Whether they should be classified as having severe thalassemia intermedia or thalassemia major is, therefore, a question of semantics that is of little importance.

Some children with β thalassemia have hemoglobin values between 6 and 9 g/dL. They grow and develop reasonably well, and reach adult life, and it is also useful to retain the term thalassemia intermedia for this type of patient. It should be remembered that they may become transfusion dependent if complications such as hypersplenism develop, or if the disorder is complicated by other factors such as folate deficiency or intercurrent infection. Clearly, the term thalassemia intermedia can cover a broad and shifting clinical spectrum, from almost complete health to a condition characterized by severe growth retardation and skeletal deformity that requires transfusion therapy; it is a diagnosis that can be made only after a considerable period of observation and that often requires revision.

Table 17.6. Thalassemia intermedia

1. Mild deficit in β-globin chain production
   - Homozygous mild β^+ thalassemia
   - Compound heterozygosity for severe β^0 or β^+ and mild β^+ thalassemia
   - Interactions of β^0 with 'silent' β thalassemia
   - Homozygosity for 'silent' β thalassemia
2. Reduced globin chain imbalance due to coinheritance of α and β thalassemia
   - Homozygous or compound heterozygous β^0 or β^+ thalassemia with 2 or 3 α gene deletions
   - Homozygous or compound heterozygous severe β^0 or β^+ thalassemia with nondeletion α2 gene mutation
   - Homozygous or compound heterozygous severe β^+ thalassemia with 1 or 2 α gene deletions
3. Severe β thalassemia with increased capacity for γ-chain synthesis
   - Homozygous or compound heterozygous β^0 or β^+ thalassemia with heterocellular HPFH
   - Homozygous or compound heterozygous β^0 or β^+ thalassemia with particular β-globin RFLP haplotype
   - Mechanism unknown
4. Deletion forms of δβ thalassemia and HPFH
   - Homozygous $(\delta\beta)^0$ or $(^A\gamma\delta\beta)^0$ thalassemia
   - Compound heterozygosity for β^0 or β^+ and $(\delta\beta)^0$ or $(^A\gamma\delta\beta)^0$ thalassemia
   - Homozygosity for Hb Lepore (some cases)
   - Compound heterozygosity for Hb Lepore and β^0 or β^+ thalassemia (some forms)
   - Compound heterozygosity for $(\delta\beta)^0$, $^G\gamma\beta^+$ or $^A\gamma\beta^+$ HPFH and β^0 or β^+ thalassemia
   - Compound heterozygosity for $(\delta\beta)^0$ thalassemia and $(\delta\beta)^0$ HPFH
5. Compound heterozygosity for β or δβ thalassemia and β-chain structural variants
   - Hb S, C, E/β or δβ thalassemia
   - Many other rare interactions
6. Other β thalassemia alleles or interactions
   - Dominant β thalassemia
   - β thalassemia trait associated with ααα or αααα globin gene duplications
   - Highly unstable β-globin chain variants

Genetic Interactions that Result in the Phenotype of β Thalassemia Intermedia

The main interactions that are known to modify the phenotype of β thalassemia are summarized in Table 17.6 and Figure 17.9. Other conditions that produce the clinical picture of thalassemia intermedia, the interactions of the β thalassemias with structural hemoglobin variants, the δβ thalassemias and their interactions, and so on, are considered elsewhere in this book. It is still difficult to predict phenotypes from genotypes with certainty; some guidelines are summarized in the following sections.

Interactions of "Silent" or "Mild" β

Thalassemia Alleles. It is customary to divide the mild β thalassemia alleles, which can interact with one another or with more severe alleles to produce thalassemia intermedia, into the "silent" and "mild" β^+ thalassemias. Although useful in practice, this is a somewhat artificial classification. Although many of the so-called silent alleles show no hematological changes in individual cases, if large numbers are studied it is apparent that some of them have slightly reduced MCV or MCH values, and slightly elevated HbA_2 or α/β-globin chain synthesis ratios. There is so much overlap with normal values, however, that for practical purposes it is reasonable to classify these extremely mild alleles as "silent," not in the least because they would not be identified by standard screening techniques to detect β thalassemia carriers. We shall return to this question later in this chapter. It is now apparent that interactions of both silent and mild β thalassemia alleles may be responsible for some forms of β thalassemia intermedia.

Several of the "silent" β thalassemia alleles, when coinherited with more severe β thalassemia alleles, have been shown to produce the picture of β thalassemia intermedia. For example, the β-101 C→T allele has been observed in the compound heterozygous state with a variety of different β thalassemia alleles, including codon 39 (C→T), IVS-1-110 (G→A), IVS-1-1 (G→A), IVS-2-745 (C→G), codon 44 (–C–C), and others.[312,318–320] All these interactions result in mild

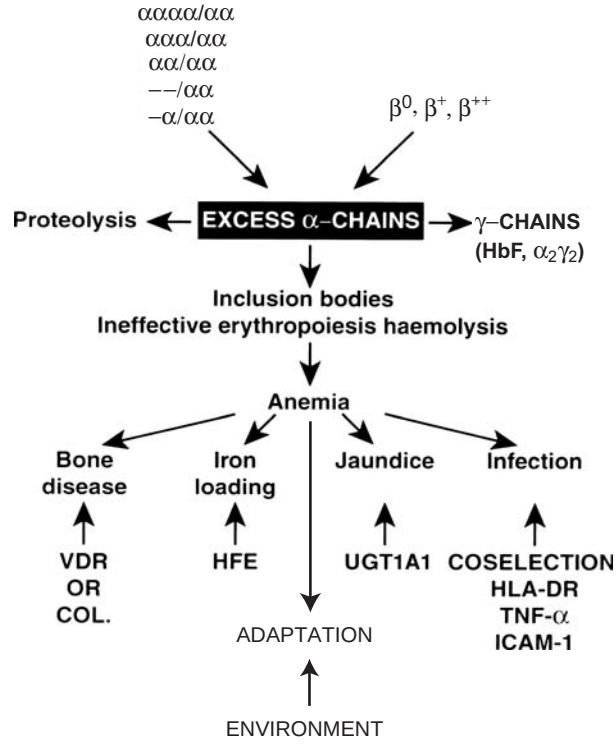

Figure 17.9. Some of the factors that modify the phenotype of β thalassemia. They include variable output from the β-globin genes, different forms of α thalassemia, variation in the level of fetal hemoglobin production, and a variety of secondary genetic modifiers. VDR, vitamin D receptor; OR, estrogen receptor; COL, collagen genes; HFE, primary hemochromatosis gene; UGT1A1, glucuronosyl transferase. Coselection indicates a number of genetic polymorphisms that are, like the thalassemias, modified by malaria resistance.

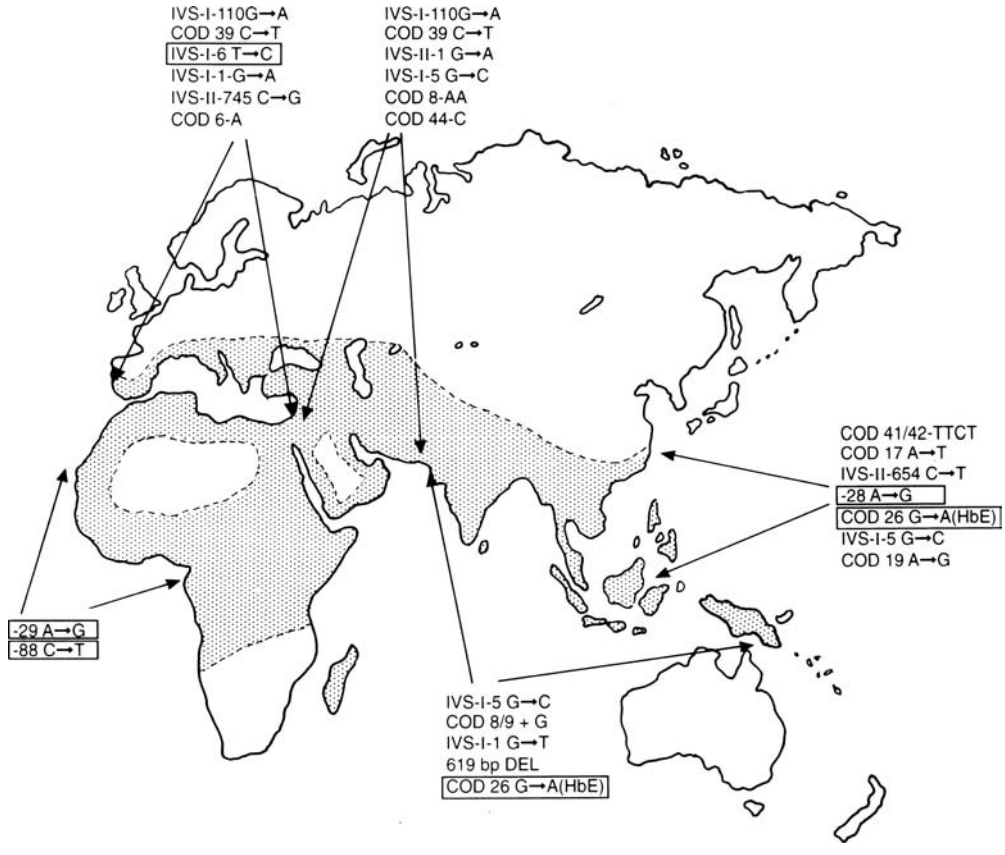

Figure 17.10. The world distribution of the thalassemia alleles. The common mild alleles are shown in boxes. In these populations, many of the intermediate forms of β thalassemia result from the different interactions of these milder alleles. (From ref. 2 with permission.)

forms of β thalassemia with steady-state hemoglobin values in the 9–12 g/dL range, a marked reduction in the MCV and MCH, elevated HbA_2 levels of 4.5–6.0, and HbF values ranging from 10% to 45%. They are a very common cause of β thalassemia intermedia in Mediterranean populations.

Other silent β thalassemia alleles that interact with more severe alleles to produce β thalassemia intermedia include β CAP+1 (A→C),[321] β 5′ UTR+10 (–T),[322] β CAP+33 (C→G),[323] and IVS-2-844 (C→G).[324]

These silent mutations produce the clinical picture of β thalassemia trait in their homozygous state. In families in which they interact with severe alleles to produce β thalassemia intermedia it is usual to find one parent with typical β thalassemia trait, although the other shows no hematological abnormality.

Interactions of Mild β Thalassemia Alleles

There are many mild β thalassemia alleles. For most of them there are very few published data about their hematological characteristics or about the results of their interactions with more severe β thalassemia alleles (Fig. 17.10).

The β-88 (C→T) allele is relatively common among Africans and African-Americans.[325,326] Its heterozygous phenotype is typical of β thalassemia trait. The homozygous condition is characterized by a relatively mild form of β thalassemia intermedia, with hemoglobin values in the 9–12 g/dL range, HbA_2 values in the 4%–8% range, and surprisingly high levels of HbF, in the range 40%–72%. In the compound heterozygous state with the other common promoter allele in this racial group, β-29 (A→G), the phenotype is also an extremely mild form of β thalassemia intermedia.

The β-87 (C→G) allele has been observed in Mediterranean populations, particularly in Italy and Turkey. The homozygous state is characterized by a mild form of β thalassemia intermedia.[327,328] This mutation has been observed in the compound heterozygous state with several β thalassemia alleles including codon 39 (C→T),[329] IVS-1-110 (G→A).[314] The best characterized of these interactions are with the codon 39 nonsense mutation; these patients have thalassemia intermedia with steady-state hemoglobin levels of approximately 10 g/dL and fetal hemoglobin values in the 30%–80% range.

There have been a few reports of individuals homozygous for the β-31 (A→G) and β-30 (T→A) alleles.[330,331] These conditions have not been observed in their compound heterozygous state with other β thalassemia alleles; their homozygous states are characterized by extremely mild forms of β thalassemia intermedia.

The β-29 (A→G) mutation is probably the most common form of β thalassemia in African populations. The homozygous state is characterized by a mild form of β thalassemia intermedia and there have been no reported transfusion-dependent cases.[325,332] Steady-state hemoglobin values range between 10 and 12 g/dL and HbF values between 50% and 70%. In the compound heterozygous state with the β codon 24 (T→A) allele, the clinical picture is again a mild form of β thalassemia intermedia, with hemoglobin values in the 9–13 g/dL range and HbF levels in the 25%–70% range.

In view of the mildness of the promoter mutations it is surprising that the β-29 (A→G) allele, observed in a Chinese family, is described as having a severe, transfusion-dependent phenotype.[333] Although it has been suggested that the different phenotype to that observed in Black populations with the same mutation may reflect the fact that, in the latter, it is on a chromosome carrying the Xmn-1 $^{G}\gamma$ polymorphism, although this is not the case in the Chinese patient, it is not clear whether this difference alone is sufficient to explain the wide difference between the phenotypes in different populations.

Mutations in β codons 19, 26, and 27, in addition to reducing β-globin output, are also associated with the production of the structural hemoglobin variants, Hbs Malay, E, and Knossos, respectively. The homozygous states for Hb Malay and Knossos are characterized by mild forms of thalassemia intermedia, with hemoglobin values in the 9–12 g/dL range and moderately elevated levels of HbF. Because of its common occurrence in the Mediterranean region, Hb Knossos has been found in the compound heterozygous state with several severe β thalassemia alleles.[314,334,335] All these interactions are associated with the clinical picture of a mild to moderate form of β thalassemia intermedia. In the case of compound heterozygosity for Hb Knossos and the IVS-1-110 G→A allele, the disorder has been severe enough to require occasional blood transfusions, and splenectomy. The clinical phenotypes of the many HbE interactions are described in Chapter 18.

The β IVS-1-6 (T→C) splice mutation, sometimes called the Portuguese β thalassemia variant, is widespread among the Mediterranean population. Unlike the other mild forms of β thalassemia, the homozygous state for this condition is not always associated with a mild phenotype.[312,314,336–339] In the first descriptions of this condition, and in the extensive study of Efremov et al.,[336] it was found that homozygotes had a relatively mild form of thalassemia intermedia; none had required regular transfusion. On the other hand, in a later report from Israel, Rund and her colleagues describe a much more variable clinical phenotype. At one extreme nine patients had baseline hemoglobin levels of 10–11 g/dL, none had been splenectomized, and transfusions had either been rare or never required. At the other extreme, however, there were nine patients with baseline hemoglobin levels of 6–7 g/dL who were transfused either infrequently or regularly, even though they had undergone splenectomy. This latter group also had growth retardation, pronounced bone changes and thalassemic bone changes, absent puberty, and evidence of iron overload. The reasons for this remarkable clinical heterogeneity are not clear. Because this mutation is so common there have been numerous opportunities for studying its interaction with other β thalassemia alleles, particularly the more severe forms that are common in the Mediterranean population. The most extensive data relate to interactions with the IVS-1-110 G→A and codon 39 C→T alleles. Overall, it appears that the interactions with β^0 thalassemia alleles are more severe and result in a picture at the most severe end of the spectrum of β thalassemia intermedia. On the other hand, those with β^+ mutations are more varied in their phenotype, some of them being described as moderately severe, others mild; many of the latter cases may have, in addition, one or more α thalassemia alleles.[314]

Finally, there are several different mutations that involve the poly-A addition site of the β-globin gene. From the limited number of interactions that have been described it seems likely that these are fairly mild alleles. A homozygote for the AATAAA→AACAAA allele, first described by Orkin et al.,[340] has been encountered (Dr. J. Old, personal communication). This patient has never required transfusion and has a mild form of β thalassemia intermedia with moderate splenomegaly and no skeletal deformities. His steady-state hemoglobin level is approximately 7–8 g/dL, with HbF and HbA_2 values of 13.3% and 9.2%, respectively. Other interactions of this family of β thalassemia alleles are summarized by Weatherall and Clegg.[2]

Interactions between α and β Thalassemia

The extensive literature on the ameliorating effect of the co-inheritance of α thalassemia on the different forms of β thalassemia has been reviewed.[2] The concept that defective α-chain synthesis might reduce the severity of β thalassemia by lessening the degree of globin-chain excess was suggested both by biosynthetic studies[341] and by direct gene analysis.[342] It was later confirmed by larger population studies.[310,313,343–346] From these investigations it was possible to determine, at least in outline, how different α and β thalassemia alleles can interact to produce forms of β thalassemia intermedia of varying severity. It appears that, overall, there is a reasonable correlation between the homozygous states for β^0 or β^+ thalassemia, together with the homozygous state for α^+ thalassemia, and a mild phenotype. On the other hand, the loss of a single α-globin gene seems to have minimal phenotypic effect on homozygosity for β^0 thalassemia, except for a slightly later presentation, and an unpredictable effect on compound heterozygosity for β^+ or β^0 thalassemia or homozygosity for β^+ thalassemia. Reports of the occurrence of homozygous β thalassemia in association with a genotype of HbH disease in the same individual suggests that this rare

interaction produces the clinical picture of a severe form of β thalassemia intermedia.[347,348]

Unusually High Levels of HbF Production in Generating β Thalassemia Intermedia

It has long been realized that variation in the ability to produce HbF in the postnatal period must be a major factor in the generation of the phenotype of β thalassemia intermedia. Although many threads of evidence have pointed in this direction, some of the most convincing were early reports of individuals apparently homozygous for β^0 thalassemia who ran relatively mild clinical courses.[318,349–352] In the families of some of these patients a determinant for heterocellular hereditary persistence of fetal hemoglobin (HPFH) appeared to be segregating. Detailed studies of the HbF of parents and relatives, however, sometimes did not show any evidence for a second determinant of this type.[352] Later studies, relating HbF production to particular restriction fragment length polymorphism (RFLP) haplotypes in the β-globin gene cluster, together with detailed family studies, suggest that some of the determinants that are associated with an unusually high level of HbF production in β thalassemia lie within the β-globin gene cluster, whereas others segregate quite independently. Although this work has gone some way to explaining the heterogeneity of HbF production in β thalassemia, in many cases the reasons for unusually high levels of HbF are not clear (see Chapter 16).

Determinants for Increased HbF Production within the β-Globin Gene Cluster

A variety of studies have suggested that the β-globin gene RFLP haplotypes associated with the Xmn-1 $^{G}\gamma$ polymorphism associated with a C→T change at position-158 in the $^{G}\gamma$-globin gene are associated with an increased propensity for HbF production in β thalassemia.[310,353,354] In both African-Asian and Italian populations this has been the only change found in a number of patients homozygous for β^0 thalassemia whose clinical course has been that of a moderate to severe form of β thalassemia intermedia. This conclusion was strengthened in later comparisons of the β-globin gene RFLP haplotypes of patients with thalassemia major and intermedia.[309,314]

A word of caution is necessary, however. In all these studies there has been a wide spectrum of phenotypes associated with homozygosity for the $^{G}\gamma$ polymorphism. Overall, homozygotes for β^0 of β^+ thalassemia who are also homozygous for this polymorphism have a milder disease, manifested by a late presentation and the picture of a moderately severe form of β thalassemia intermedia. This is not always the case, however, and some of them subsequently become transfusion dependent in later life or even have severe disease from early in childhood. In the study of Ho et al.[314] there was a wide variation in the phenotypic severity, even among those who fell into the β thalassemia intermedia category. It is also apparent that certain β thalassemia mutations are, themselves, associated with an increased propensity for fetal hemoglobin production. Although this relates particularly to promoter mutations it is also observed in the rare deletional forms of β thalassemia that remove the 5′ end of the β-globin gene (reviewed by Thein[355]).

Determinants for Increased HbF Production Not Encoding in the β-Globin Gene Complex

Several families have been reported in which there is very good evidence that homozygotes or compound heterozygotes for β thalassemia produce unusually high levels of HbF and have the phenotype of β thalassemia intermedia, due to the coinheritance of a gene for heterocellular HPFH.[356,357] In both the families described in these reports subsequent studies showed that the genetic determinant for heterocellular HPFH did not segregate in the β-globin gene cluster.[357,358] Later studies indicated that the determinant in the large family described by Thein and Weatherall showed strong linkage to chromosome 6, whereas that in the family originally described by Cappellini et al. does not. Further families have been reported by Ho et al;[314] again it is clear that heterocellular HPFH is an important factor in the generation of β^0 thalassemia intermedia. It appears, therefore, that there are a number of determinants for a form of heterocellular HPFH that can modify the β thalassemic phenotype; one is on chromosome 6, but this form of heterocellular HPFH is quite heterogeneous and other varieties exist that are encoded on other chromosomes (see Chapter 16). The role of the locus on the X chromosome, which seems to be involved in setting the level of F cells in adults[359] in determining the level of HbF in β thalassemia is still not clear.

Heterozygous β Thalassemia with an Unusually Severe Phenotype

There are two mechanisms whereby heterozygous β thalassemia can be associated with the phenotype of β thalassemia intermedia. First, there are cases in which β thalassemia is complicated by the inheritance of chromosomes carrying more than the usual number of α-globin genes, ααα or αααα. Second, there are particular β-globin gene mutations that, because of the unusual properties of their products, give rise to severe phenotypes in heterozygotes. The latter are usually referred to as the dominant β thalassemias.

The extensive literature on the ααα and αααα interactions is summarized in detail by Weatherall and Clegg[2] and by Premawardhena et al.[360] It is clear that the inheritance of triplicated or quadruplicated α-globin gene arrangements, either in homozygous or heterozygous states, can, together with the heterozygosity for β^0 or β^+ thalassemia,

produce a wide spectrum of phenotypes ranging from extremely mild to quite severe forms of β thalassemia intermedia.[314,315,319,360–364]

Families with dominantly inherited forms of β thalassemia were first described by Weatherall et al.[365] and Stamatoyannopoilos et al.[366] Their relationship to exon 3 mutations is described elsewhere in this book. This condition is characterized by a form of thalassemia intermedia of varying severity together with typical thalassemic changes in the blood and bone marrow. The most striking feature is the presence of inclusion bodies in the marrow and, after splenectomy, in the peripheral blood. It seems likely, although it has not been firmly established, that these consist of excess α chains and quite possibly the unstable β chain products.

There is one remarkable characteristic of the forms of β thalassemia intermedia associated with heterozygosity for β thalassemia. In all these conditions there are unusually low levels of HbF for the β thalassemia intermedia phenotype. This observation was emphasized in the recent description of the homozygous state for the quadruplicated α-globin genes associated with heterozygous β thalassemia. The phenotype was a moderately severe form of β thalassemia intermedia yet the fetal hemoglobin level was only 4.6%.[360] The degree of globin chain imbalance in this patient was similar to that in other forms of β thalassemia intermedia associated with extremely high levels of HbF. In reviewing the literature on both varieties of β thalassemia intermedia associated with β thalassemia trait it was clear that a low level of HbF in these conditions is nearly always found. Whether this reflects a requirement for defective β-globin synthesis in both *cis* and *trans* for the production of high levels of HbF, or some more subtle effect whereby red cell precursors that contain relatively mild HbF do not come under selection in these conditions is not clear. But there is no question that the low level of HbF is characteristic of all of them.

Summary

Considering the remarkable heterogeneity of the various interactions that can produce the clinical phenotype of β thalassemia intermedia, it is not surprising that this condition has a remarkably variable clinical course. Although hitherto ignored, it should be remembered that other factors including adaptation to anemia may play an important role in this diversity. For example, patients with HbE–β thalassemia, the most common form of thalassemia intermedia globally, are able to grow and develop normally at hemoglobin levels which would be associated with a much more severe phenotype in other genetic forms of thalassemia intermedia. Recent studies suggest that this relates to the level of HbF and hence the oxygen affinity of the red cells of patients with these different conditions; the relatively low levels of HbF in HbE–β thalassemia compared with other forms of thalassemia intermedia allow much better adaptation to anemia (unpublished observations), and the action of environmental factors, notably malaria, may have a profound effect on phenotypes of these intermediate forms of thalassemia in many of the developing countries. It is also apparent that much remains to be learnt about the genetic factors that are involved in HbF production in these conditions. Given these factors, it is not surprising that it is difficult to predict the clinical course for any particular form of thalassemia intermedia, even when the genetic basis is apparently well established.
