One of the hallmarks of β thalassemia intermedia is its late presentation compared with transfusion-dependent forms of the disease.[4–6] Although there is considerable individual variation, overall it is usual for transfusion-dependent patients to come to medical attention in the first year of life, whereas those with thalassemia intermedia tend to present during the second year or later. There are few good published data on the hemoglobin levels over the first few years of life. Although some children maintain a steady-state hemoglobin value that seems to vary little, others do not. Although it has been suggested that a fall in hemoglobin over the first few years may reflect increasing hypersplenism[5] it is not clear whether this is always the case. From our own experience many children with intermediate forms of β thalassemia do not reach a steady-state hemoglobin level for several years, and it is very important not to draw conclusions about their likely prognosis without a long period of observation.

The clinical manifestations are extremely variable. In some cases the disorder presents early in life with relatively severe anemia, while in others it may not appear until later due to a complication such as hypersplenism. Many patients have been found to have this condition on routine clinical examination. Growth and development may be normal or there may be a similar pattern of retardation as occurs in undertreated transfusion-dependent β thalassemia. The most common symptoms are those of anemia and mild jaundice. There is always some degree of splenomegaly. Bone changes are variable and range from none at all to the severe skeletal deformities characteristic of transfusion-dependent β thalassemia. Some infants, who have presented relatively late with hemoglobin values in the 7 g/dL range, are clearly destined for transfusion from the beginning. When observed over a few months there is failure to thrive, listlessness, proneness to infection, and a poor appetite. Sequential studies over even a short period make it clear that these infants are not developing normally and that they should be considered to have thalassemia major, and treated accordingly. The course for infants who, despite their relatively low hemoglobin levels, are fully active and thriving, is usually one of chronic well-compensated anemia that may be exacerbated during periods of infection or folate deficiency or with increasing hypersplenism.

Complications

Hypersplenism

Increasing splenomegaly leading to hypersplenism is a relatively common feature of β thalassemia intermedia. In most of the larger series cited earlier, a significant proportion of the patients had undergone splenectomy for worsening of their anemia, thrombocytopenia, or neutropenia.

Iron Loading

There is increasing evidence that although the rate of iron loading is much slower than in transfusion-dependent β thalassemia, patients with β thalassemia intermedia do iron load and this may become of clinical importance in adult life. Bannerman et al.[367] described a 41-year-old Sicilian patient with β thalassemia intermedia who had gross iron loading with associated cardiac failure, diabetes mellitus, and hypopituitarism. On the other hand, Erlandson et al.[368] did not consider that iron loading was a major problem in this disorder. In a later study Pippard et al.[317] examined the rate of iron loading in 15 patients with this condition. There was a highly significant increase in plasma ferritin levels with age and the majority of patients older than 20 years had totally saturated iron-binding capacities. Liver biopsies of three of the older patients showed excessive iron deposition associated with portal cirrhosis in each case. Iron absorption studies, described in a later section, showed that the rate of iron loading from the gastrointestinal tract was approximately three–four times normal.

Later studies confirmed these observations. Cossu et al.[369] reported an increasing serum ferritin level with age and increased urinary iron excretion in response to desferrioxamine. Fiorelli et al.,[370] in attempting to explain some of the variability in the degree of iron loading among 38 adult patients with β thalassemia intermedia, described significant differences between patients who had undergone splenectomy compared with those with intact spleens; the iron burden was considerably greater in the former. This may simply reflect the greater severity and hence more marked marrow expansion and higher rate of iron absorption of these children. Although these data are limited, there seems little doubt that iron loading is an important feature of β thalassemia intermedia. It can undoubtedly lead to liver damage and cirrhosis and to other complications of iron excess. It is not clear how often it causes cardiac damage; as discussed later, there are very few data relating to the cardiac status of older adult patients with this condition.

Endocrine Function

The fact that in many of the larger series of patients with β thalassemia intermedia cited earlier there was a history of a normal puberty and menarche, even though the latter was sometimes delayed, suggests that overall endocrine function is often maintained up to and beyond puberty. From such limited data as there are it appears that by the time these patients reach the third or fourth decades there is a significant incidence of diabetes mellitus, and other endocrine deficiencies. Of the 15 patients reported by Pippard et al.[317] one was frankly diabetic and three showed a reduced first-stage insulin response associated with a high-normal fasting plasma glucose concentration during standard glucose tolerance tests, findings that suggest impairment of pancreatic β-cell function. Similar results were obtained in three of 11 patients studied by De Sanctis et al.[132] In the series reported by Pippard et al.[317] all had normal thyroid-stimulating hormone reponses to thyroid-releasing hormone, and a normal fasting prolactin concentration, but two had a reduced luteinizing hormone response to luteininzing hormone–releasing hormone. Plasma cortisol response to synacthen was normal in four of five patients tested. McIntosh[106] described a woman with multiple endocrine deficiencies; replacement therapy was followed by a normal pregnancy.

Cardiac Function

Because of the slower rate of iron loading in β thalassemia intermedia than in transfusion-dependent forms of the disease it would be expected that, if cardiac complications occur at all, they would only be manifest in adult life. Although there have been single case reports of cardiac failure associated with iron loading in this disorder,[367,371] there is very little information about the dangers of iron loading of the myocardium in this condition.

In the series of patients reported by Pippard et al.,[317] a high proportion complained of exertional dyspnea, palpitations, or both. The electrocardiogram showed only minor abnormalities in a few cases; there were inverted T waves over the right ventricular leads in one, and evidence of left-ventricular hypertrophy in four of the older patients. Holter monitoring over a 24-hour period revealed marked abnormalities in eight of the nine patients studied. These included periods of bradycardia and tachycardia, and supraventricular extrasystoles. This was in marked contrast to the absence of rhythm abnormalities in nine cases of well-transfused patients with β thalassemia major, including five older than the age of 14 years. Echocardiography showed that four of the older patients with thalassemia intermedia had enlarged diastolic dimensions. Both the ejection fractions and fractional shortening, however, were normal in all eight cases studied. Fiorelli et al.[316] described the cardiac status of 18 patients with thalassemia intermedia in Italy. All had cardiomegaly and systolic flow murmurs compatible with the degree of anemia. Their electrocardiograms showed some modifications of the QRS complexes compatible with ventricular hypertrophy. No consistent abnormalities of rhythm or conduction were observed. In five of the patients, echocardiography showed enlarged diastolic dimensions and some rather nonspecific functional alterations. Most of these changes could be ascribed

to moderate to severe anemia and none were characteristic of iron loading of the myocardium.

Olivieri et al.[372] reported detailed studies on a 29-year-old Italian man who, although he had not received transfusions after the age of 5 years, nevertheless presented with hepatomegaly, abnormal liver function tests, an elevated serum ferritin level, and marked iron loading of the liver as judged by biopsy and quantitative MRI. Before treatment the left ventricular ejection fraction was 60% at rest, with no increase at peak exercise, and there was mild right ventricular dilation and abnormalities in diastolic function. These changes did not alter after intensive chelation therapy, except that there was some improvement in the atrial contribution. Although these are relatively mild changes the fact that they altered after treatment suggests that there may have been some functional cardiac anomalies secondary to iron loading.

Clearly, it will be important to try to follow larger series of adult patients with β thalassemia intermedia with consecutive studies of cardiac function; currently there is no way of knowing what proportion of older patients with this condition are at risk from cardiac disease.

Over recent years there has been considerable interest in the syndrome of pulmonary hypertension and right heart failure in patients with HbE–β thalassemia, particularly those who have undergone a splenectomy (see Chapter 18). This complication has also been reported in β thalassemia intermedia.[373] In seven patients who presented with congestive cardiac failure and pulmonary hypertension after splenectomy, there was dilation of the main pulmonary artery with cardiac enlargement, signs of right ventricular hypertrophy, and a dilated right ventricle, but good left ventricular function as judged by echocardiography. Right heart catheterization showed markedly raised pulmonary pressure with increased pulmonary vascular resistance. Whether this picture results from platelet aggregation in the pulmonary circulation, as suggested in the case of HbE–β thalassemia, remains to be determined.

Gallstones

Probably as a result of both ineffective erythropoiesis and hemolysis there is a high frequency of pigment stones.[316,368,374]

Folic Acid Deficiency

There are many well-documented cases of folate deficiency occurring in patients with β thalassemia intermedia.[5,367,368] The degree of anemia may be profound and patients may present in cardiac failure.

Skeletal Deformities and Bone and Joint Disease

As mentioned earlier, some patients with β thalassemia intermedia develop severe skeletal deformities, similar in every way to those seen in the undertreated transfusion-dependent forms of the disease. Pathological fractures are also a major feature, particularly in older patients. There is also a particularly distressing complication involving the bones and joints that has been called "thalassemic osteoarthropathy."[375] This takes the form of a curious periarticular disease characterized by dull aching pains in the ankles, exacerbated by weight bearing and relieved by rest. Radiological changes include widening of the medullary spaces, thin cortices with coarse trabeculation, and evidence of microfractures in the region of the joints. Histological analysis confirmed the presence of the latter and, in addition, showed osteomalacia and increased osteoblastic surface areas with iron deposition in the calcification front and cement lines. We have observed this complication in a number of adult patients with β thalassemia intermedia, at least one of whom required an arthrodesis of the ankle joint for relief of intractable pain. Acetabular protrusion has also been reported in patients with severe bone involvement.

Extramedullary Erythropoiesis

The generation of tumor masses composed of extramedullary erythropoietic tissue is a frequent complication.[368,376,377] The most common site is in the paraspinal region. Alam et al.[378] give a valuable summary of the radiological characteristics of these lesions. Although they do not usually cause symptoms there have been well-documented case reports of spinal cord compression,[379,380] cauda equina lesions,[381] and hemorrhage causing a massive hemothorax.[382]

Although these masses are usually identified by conventional radiography,[378] the diagnosis can be confirmed, particularly if they are in an unusual site, by both computed tomography (CT) and MRI analysis.[383] They produce a low-intensity signal similar to that of adjacent marrow of the thoracic spine and are surrounded by a characteristically high-intense rim attributed to a layer of fat surrounding the masses.

Total body CT analyses of adults with β thalassemia intermedia suggest that some degree of extramedullary erythropoiesis is probably quite common; it was detected in 65% of patients by Sergiacomi et al.[384] It seems likely that at least some of these lesions may undergo fatty transformation with time, particularly if the hemoglobin level is raised by splenectomy.[385]

Infection

Although it is suspected that patients at the severe end of the spectrum of β thalassemia intermedia have increased susceptibility to infection, there are very few supporting data. Such that there are suggest that the pattern of infection is similar to that outlined for transfusion-dependent β thalassemia earlier in this chapter. As is the case in thalassemia major, severe *Yersinia* infection associated with iron chelation, and aplastic or hypoplastic episodes due to parvovirus infection have been recorded.[386] There is

increasing evidence that those patients who require occasional transfusion are prone to contract hepatitis B and C.[387] Although there have been attempts at defining specific abnormalities of neutrophil function or of the immune system, as in the case of the more severe forms of β thalassemia there have been no consistent findings. The problem of infection in thalassemia intermedia is discussed in more detail by Weatherall and Clegg.[2]

Hyperuricemia and Gout

Although in several reported series patients with β thalassemia had elevated uric acid levels, secondary gout seems to be uncommon.[375]

Leg Ulcers

This is a relatively common complication of β thalassemia intermedia.[5,315,316] The cause is unknown; the possible relationship to the rheological properties of the red cells is discussed by Gimmon et al.[388]

Pregnancy

Because many patients with thalassemia intermedia pass through a normal puberty, pregnancy is not uncommon.[389,390] In most of these reports it is stressed that these patients may become quite profoundly anemic during pregnancy, but if they are maintained at a relatively normal hemoglobin level there seems to be no increased rate of fetal loss.

Thromboembolic Disease

The "hypercoagulable state" associated with platelet activation, which correlates with abnormal red cell phospholipid exposure, is reviewed by Ruf et al.[391] In fact, much of the experimental work that underlies this concept was performed on the blood of patients with β thalassemia intermedia. In a review of thromboembolic complications of β thalassemia from Italy Borgna-Pignatti et al.[82] discussed earlier in this chapter, five of the 32 affected patients had thalassemia intermedia. There have been occasional reports of severe thromboembolic disease following splenectomy, but in the series described by Skarsgard et al.[392] several nonthalassemic patients presented with the same complication. From these limited data it is not possible to assess the overall risk of thrombotic disease, nor is it clear whether it is related to the occurrence of recurrent priapism following splenectomy in patients with this type of thalassemia.[393]

Hematological Findings

There is a variable degree of anemia, with hemoglobin values in the 5–10 g/dL range. The red cell indices are typically

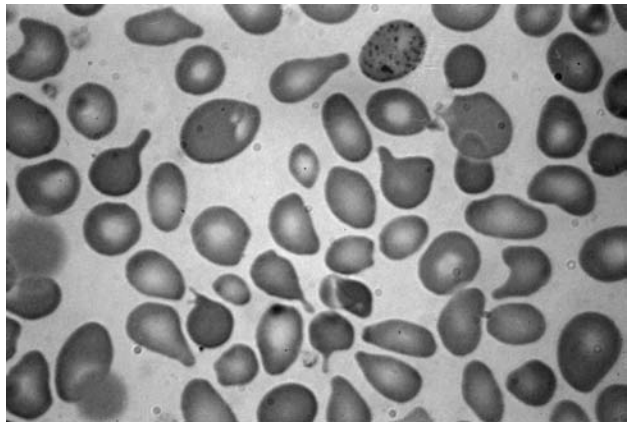

Figure 17.11. A peripheral blood smear from the propositus from the first family to be reported with dominantly inherited β thalassemia.[365] Hypochromia is not a major feature but there is a remarkable degree of poikilocytosis and heavy basophilic stippling.

thalassemic and the peripheral blood findings are indistinguishable from those of the more severe forms of β thalassemia. In some of the dominantly inherited forms of β thalassemia, hypochromia is less marked, and poikilocytosis is the main feature (Fig. 17.11). Except when there is hypersplenism the white cell and platelet counts are usually normal. The reticulocyte count is elevated and, following splenectomy, on staining with methyl violet nucleated red cells show ragged inclusions similar to those observed in thalassemia major. The bone marrow shows marked erythroid hyperplasia and, again, many of the red cell precursors contain inclusion bodies.

Red Cell Survival, Ferrokinetics, and Erythrokinetics

Red cell survival studies have shown a moderate reduction in survival times, with $^{Cr}51$ T1/2 values ranging from 10 to 16 days.[368,394]

Iron-absorption studies have shown an increase in the rate of iron accumulation.[289,317,395–397] In the studies of Pippard et al. the patients were in positive balance of between 2.6 and 8.6 mg iron per day. Cavill et al.[398] found that the marrow turnover was approximately six times normal but that most of this increase in activity was ineffective. Similar results were reported by Najean et al.[399] The serum-transferrin-receptor level has been used to assess the degree of erythroid expansion. In a study by Dore et al.[400] of untransfused patients with a steady-state hemoglobin level of 9.6 g/dL the mean basal transferrin receptor level was 30.3 compared with 12.8 in a series of age-matched healthy controls.

There have been several studies of serum erythropoietin (Epo) levels in β thalassemia intermedia.[401,402] Although overall elevated levels were found, and there was evidence of a reciprocal relationship with the hemoglobin level, in one study there appeared to be inappropriately low Epo levels for the degree of anemia. Because of the increased

oxygen affinity of red cells with high levels of HbF, erythropoietin levels may be particularly high in patients with HbF levels in excess of 50%.[403] More extensive data on Epo response in HbE–β thalassemia are discussed in Chapter 18.

Hemoglobin Constitution

Considering the extraordinarily diverse genotypes that underlie the phenotype of β thalassemia intermedia, it is not surprising that it is characterized by a wide range of different hemoglobin constitutions, particularly with respect to the levels of HbF. In the intermediate forms of the β^0 thalassemias the hemoglobin consists entirely of HbF, with HbA_2 values in the low-normal range. There is a wide range of HbF levels in the β^+ thalassemia intermedias and it is possible only to make some broad generalizations about how these relate to the underlying genotypes.

In the β^+ thalassemia intermedias that reflect the homozygous state for mild β^+ thalassemia mutations the level of HbF tends to be low compared with those that result from the interaction of two severe alleles. This is exemplified in the homozygous state for the common Mediterranean mutation, IVS-1-6 (T→C), in which the fetal hemoglobin level tends to be in the region of 20% of the total, although even here there is considerable scatter.[404] The exception to this rule is the homozygous or compound heterozygous states for promoter mutations of the β-globin gene. In this case there tends to be an unexpectedly high level of fetal hemoglobin, usually in excess of 50% of the total.[325] In both these conditions homozygotes have, as a rule, increased levels of HbA_2.

In interactions between homozygous or compound heterozygous states for β^+ or β^0 thalassemia and the heterozygous states for α^+ or α^0 thalassemia, the hemoglobin pattern does not seem to alter from that found with the β thalassemia mutations alone. In the interactions between these forms of β thalassemia and the genotype of HbH disease there is quite a different pattern. In this case, although the amounts of Hbs A and F do not differ significantly from those seen with β^+ or β^0 thalassemia alone, there is an unusually high level of HbA_2 and traces of Hb Bart's can be demonstrated.[347,348] The unusually low levels of HbF in the forms of thalassemia intermedia associated with β thalassemia trait were discussed earlier in this chapter.

Hemoglobin Synthesis

Early studies that provided data on α/non-α-globin-chain synthesis ratios in patients with β thalassemia intermedia showed that, overall, the degree of imbalance of globin-chain synthesis was less than that observed in the more severe forms of β thalassemia.[394,405] Although there have been sporadic reports none have related the degree of globin-chain imbalance to the underlying molecular pathology in sufficient numbers to be able to offer any firm conclusions about the degree of globin-chain imbalance associated with the different combinations of mutations that underlie the intermediate forms of β thalassemia.

THE HETEROZYGOUS FORMS OF β THALASSEMIA

The heterozygous states for the different forms of β thalassemia are summarized in Table 17.1. The most common varieties are associated with an elevated level of HbA_2 and normal or slightly elevated levels of HbF. There is another group that is characterized by normal levels of HbA_2. This is subdivided into Type 1, in which there are no hematological changes; this corresponds to the "silent" β thalassemias. In Type 2, the hematological changes are indistinguishable from the β thalassemia trait with elevated levels of HbA_2. There are other rare groups characterized by unusually high levels of Hbs A_2 or F, or by a much more severe course.

The Common Forms of Heterozygous β Thalassemia

The heterozygous states for most forms of β thalassemia are characterized by mild anemia, characteristic changes in the MCV and MCH, an elevated level of HbA_2, and normal or only slightly elevated levels of HbF.

Clinical Features

Patients heterozygous for β thalassemia are believed to be symptom-free; the condition is diagnosed as part of a family study, as an incidental finding during an intercurrent illness, or as part of a population survey. Recently, however, a population study that compared the symptoms and quality of life of adult patients with thalassemia trait with age-matched controls found that the former had a highly significant increase in symptoms attributable to mild anemia and, possibly, increased rates of infection.[406] Occasionally, and particularly during pregnancy, the mild anemia may bring a carrier to the notice of the physician.

There are no characteristic clinical findings, and palpable splenomegaly is most unusual.

Hematological Findings

The larger reported series, when adequately analyzed by sex and age, have shown that although there is a considerable scatter in hemoglobin levels, most heterozygous β thalassemics have a significant degree of anemia compared with controls drawn from the same population.[351,407,408] The red cell indices are a valuable diagnostic feature. There is a relatively high red cell count but the cells are small and poorly hemoglobinized and the MCH and MCV are markedly reduced. On the other hand, the MCHC is usually in the normal range or only moderately reduced. There may be a slightly elevated reticulocyte count. The red cells show characteristic morphological changes; there is

microcytosis and hypochromia with variation in the size and shape. The presence of target cells, much stressed by early workers, is very variable and although some are usually found their absence is of little diagnostic value. Basophilic stippling is a frequent finding, particularly in patients with more severe β thalassemia alleles.

Completely normal hematological findings in heterozygous β thalassemia are very unusual. They are usually found in individuals with β thalassemia trait who have coinherited one or other forms of α thalassemia. These interactions, and their implications for screening programs, are discussed by Weatherall and Clegg.[2]

The bone marrow shows a variable degree of erythroid hyperplasia, in which polychromatic and pyknotic normoblasts predominate. The cytoplasm of the red cell precursors is often ragged and shows basophilic stippling. Iron is usually plentiful and is distributed normally between the reticuloendothelial elements and the red cell precursors. On incubation of the marrow with methyl violet, a few of the red cell precursors show small inclusions, similar to those seen in abundance in homozygous individuals.[409]

Red Cell Survival, Iron Metabolism, and Ferrokinetics

The ^{51}Cr T1/2 of the red cells have given mean values just below the normal range in several reported series.[292,410–412] Serum iron and ferritin estimations have shown that, although there is considerable variability, the mean values are little different from normal.[351,412–416]). Iron loading, as evidenced by increased serum iron or ferritin levels, or iron deposition in the tissues, is unusual. In the series described by Knox-Macaulay et al.,[351] five females and four males had iron-binding saturations of 50% or more; one 68-year-old woman, who had received oral iron intermittently for 15 years due to a mistaken diagnosis of iron-deficiency anemia, had a totally saturated iron-binding capacity and clinical evidence of iron overload. There have been other reports of iron loading in heterozygous β thalassemics.[417,418] In addition to these isolated case reports, Fargion et al.[419] described a group of Italian males with very high serum ferritin levels. Whether some of these patients were also carrying genes for hereditary hemochromatosis is not known.

The rate of iron absorption is either normal or slightly elevated [367,420] Iron is rapidly removed from the plasma, the rate of plasma iron turnover is increased, but it appears in red cells relatively slowly. In an extensive series of ferrokinetic studies, Pippard and Wainscoat[412] found that the overall efficiency of erythropoiesis is significantly reduced, with a mean of 76 ± 17 standard deviations of normal. Serum erythropoietin levels are slightly elevated, more so in females than males, but there appears to be no correlation with the hemoglobin level.[421]

These findings suggest that there is a mild degree of ineffective erythropoiesis in β thalassemia carriers and that the anemia is predominantly due to intramedullary destruction of red cell precursors rather than hemolysis.

Complications

Most patients heterozygous for β thalassemia go through life without any manifestations that can be ascribed to the disease. The only complication of any importance is worsening of the anemia during pregnancy.

Pregnancy. Although it is clear that the hemoglobin level falls to a greater degree during pregnancy than in normal women, the resulting anemia is usually mild; most of the reports of more severe forms of anemia in pregnancy probably reflect the added complications of either iron or folic acid deficiency.[351,422,423]

In normal women there is an increase in both plasma volume and red cell mass that commences at the end of the first trimester. Schuman et al.[424] found that pregnant thalassemic women are unable to increase their red cell mass to the same degree as normal women; there is no difference between them in the degree of expansion of the plasma volume. On average, the decrease in the hemoglobin level between the first and second trimester is comparable with that of normal women, in the range of 7%–10%. In the large series of White et al.[423] and Landman[422] there were minimal changes in the red cell indices during pregnancy. From these studies it is clear that any pregnant β thalassemia carrier with a hemoglobin value of less than 8–9 g/dL should be investigated for other causes for anemia. Because of the unreliability of serum iron and iron-binding capacity estimations in pregnancy, it is helpful to assess the patient's iron status by the serum ferritin level.

Folic acid deficiency. Folic acid deficiency has been reported in heterozygous β thalassemia in nonpregnant persons, but this must be extremely rare.[425,426]

Failure of diagnosis. In populations in which β thalassemia is not common the trait may be misdiagnosed as iron-deficiency anemia or attract a number of other diagnostic labels. This can lead to a variety of unnecessary investigations, considerable anxiety, and inappropriate treatment with iron.

Life Expectancy

In one extensive study aimed at defining the lifespan of individuals heterozygous for β thalassemia, no significant differences were found between β thalassemia heterozygotes and normals.[427] Surprisingly, in a prospective study of 4,401 subjects in Ferrara over a 7-year period of observation by the same group, it was concluded that male β thalassemia heterozygotes show a significant degree of protection against myocardial infarction.[428] At first sight these observations seem contradictory although it is possible that the relatively small effect on cardiac disease was masked in the life expectancy survey. A more recent study in Greece also has found a significant degree of protection against

cardiac disease, and suggests that the lipoprotein and blood rheology profiles may be the underlying cause of the protective effect.[429]

Hemoglobin Constitution

The cardinal finding in the common forms of heterozygous β thalassemia is an elevated level of HbA_2. In most of the larger series the HbA_2 levels ranged from 3.5% to 7% with a mean of approximately 5% (reviewed by Weatherall and Clegg[2]). By relating the percentage of HbA_2 to the MCH it is clear that this reflects an absolute increase in δ-chain production. Studies of patients with β thalassemia trait who are also heterozygous for δ-chain variants have shown that the increased output is both cis and trans to the β thalassemia gene.[430–433] The level of HbA_2 may be reduced in association with coexistent iron deficiency, but although it has been reported that it may fall into the normal range and is restored to its elevated level after iron therapy,[415,434] this must be unusual. What usually happens is that the level falls but it remains elevated in the β thalassemia trait range.[435]

In most large series the HbF level is elevated in approximately 50% of cases, in the range 1%–2%.[436] The distribution of HbF within the red cells, as judged either by acid elution or fluorescent antibody techniques, is heterogeneous.

In all the larger reported series of HbF levels a few individuals fall outside the distribution of normal to 2%–3%, and have values ranging between 4% and 15%. Knox-Macaulay et al.[351] showed that at least some of them have, in addition, determinants for heterocellular HPFH. In one family it was possible to demonstrate independent segregation of β thalassemia and HPFH genes. Similar families have been reported by Mazza et al.[408] Wood et al.,[437] and Thein and Weatherall.[357] It seems likely, therefore, that the majority of β thalassemia heterozygotes with unusually high levels of HbF carry one or more genes for heterocellular HPFH.

There is no evidence that acquired factors alter the level of HbF to any significant degree; the only one that has been adequately documented is pregnancy, during which the normal rise in HbF that occurs at midterm is mirrored in heterozygous β thalassemias by an increase at approximately the same time. It returns to its basal level some time toward the end of pregnancy.[438] The level of HbF is not modified by coexistent iron deficiency.[415]

Red Cell Metabolism

One of the characteristic changes of the red cells in β thalassemia heterozygotes is their decreased osmotic fragility, which in contrast to normal red cells, becomes even more marked after sterile incubation for 24 hours.[439] These altered osmotic properties have formed the basis for several population screening tests.

There have been a variety of studies of membrane function.[440–443] Using radioactive tracers it has been shown that there is an increased flux of K^+, an effect that is accentuated when the cells are incubated for 24 hours at 37°C. This increased permeability to K^+ appears to occur in cells of all ages, although it may be slightly more marked in younger cells. ATP levels are normal or slightly reduced, but on sterile incubation the red cells lose ATP more rapidly than normal; this can be reversed by glucose. It appears that heterozygous β thalassemic red cells can compensate for their increased cation loss by upregulating the transport-regulated component of glycolysis, and hence can maintain normal ATP levels, but when they are stressed by in vitro incubation this mechanism breaks down.

In some of the studies cited previously similar membrane function abnormalities were found in other hypochromic anemias such as iron deficiency. It is likely, therefore, that these abnormalities reflect an underhemoglobinized red cell as well as globin-chain imbalance. In favor of this concept is the observation that similar changes have been described in cells of α/β thalassemics in which there is minimal globin-chain imbalance.[444]

These observations suggest a possible mechanism for the further increase in osmotic resistance on sterile incubation of β thalassemic red cells. With successive loss of K^+ and water, and cellular dehydration, there must be a decrease in red cell volume and hence in osmotic activity. If glucose is added to the incubation this probably provides adequate energy for ATP regeneration and hence for maintaining the Na^+-K^+ pump to counteract excessive loss of K^+ and water from the cells. Further evidence that this is the case is derived from the observation that the increased osmotic resistance can be demonstrated, even in the presence of glucose, by inhibition of the Na^+-K^+ pumps by ouabain or ethacrynic acid.[442]

Globin-Chain Synthesis

In vitro hemoglobin synthesis studies indicate that α/β-globin-chain production ratios range from approximately 1.5–2.5, both in the bone marrow and in peripheral blood. Reports of more balanced globin-chain synthesis in the bone marrow[410,445,446] were later found to be based on artifacts produced by the presence of radioactively labeled nonglobin proteins that cochromatograph with β-globin chains.[447,448] Hence the measurement of globin-chain synthesis, particularly if peripheral blood reticulocytes are used, provides a valuable confirmatory test for heterozygosity for β thalassemia in cases in which the diagnosis is uncertain.

Developmental Changes in Hematological Findings and Hemoglobin Constitution

The changes in the red cells of infants heterozygous for β thalassemia over the first few months of life are of considerable importance with respect to the diagnosis of the condition over this period. Because of the alterations that

occur both in the red cell indices and in the hemoglobin pattern of normal infants over the first year, studies that set out to describe these changes in β thalassemia heterozygotes must be carefully controlled with a population of normal infants at exactly the same stage of development. Data of this kind have been reported by Galanello et al.[449] and Wood et al.[450] Galanello et al.[451] have produced useful percentile curves for the red cell indices in β thalassemia heterozygotes in infancy and childhood. Further information on these changes is reported by Metaxatou-Mavromati et al.[452]

From these studies it is apparent that the hemoglobin values and red cell indices of heterozygous β thalassemic newborns do not differ significantly from normal. By the age of 3 months, however, clear differences emerge, which become highly significant by 6 months and remain so during the rest of development. It appears, therefore, that carrier screening by MCV or MCH determination is feasible from approximately 3 months onward. Similarly, there is clear distinction in HbA_2 values by 3 months. In all these studies it was observed that the rate of decline of HbF is retarded in β thalassemia heterozygotes and does not reach its adult level until well into childhood.

Phenotypic Characteristics in Relationship to Different Molecular Forms of β Thalassemia

Limited data have been published that relate the hematological findings and HbA_2 and F levels to particular mutations in β thalassemia heterozygotes.[325,453–455] Although there is some overlap, it is evident that the common, mild β thalassemia mutations, IVS-1-6 T→C, β-29 A→G, β-87 C→G, and β-88 T→G, for example, have slightly higher hemoglobin levels and, more important, higher MCH and MCV values than the more severe β^0 or β^+ thalassemia alleles. Other mild alleles for which sufficient data are available, including the forms of β thalassemia associated with Hbs E, Malay, and Knossos, are also associated with MCH and MCV values that are either normal or only slightly reduced. Indeed, the pattern that is emerging is of a continuous spectrum of hematological findings, ranging from the typical characteristics of β thalassemia trait associated with severe β^0 or β^+ thalassemia alleles, through milder changes associated with less severe alleles, to complete normality in the "silent" alleles. There are insufficient data to make it possible to be dogmatic about what is a "typical" set of red cell indices for a particular allele.

The HbA_2 levels in relationship to underlying mutations were reviewed by Huisman.[456] Overall, and although there is considerable overlap, several groups can be defined. Carriers of β^0 or severe β^+ thalassemia alleles have HbA_2 levels between 4.5% and 5.5%, whereas those with mild β^+ alleles have values between 3.6% and 4.2%. There are exceptions, however. Carriers of β-globin gene promoter mutations tend to have relatively high levels of HbA_2, even though these are mild β thalassemia alleles. The highest HbA_2 values in heterozygotes appear to be associated with deletional forms of β thalassemia (see later section and Chapter 16).

The relationship between the underlying mutation and HbF levels in β thalassemia heterozygotes has been reviewed by Kutlar et al.[457] These analyses are complicated by the presence or absence of the C→T polymorphism at $-158^{G}\gamma$, which is known to modify both the $^{G}\gamma/^{A}\gamma$ ratio of the HbF and, probably, its level under conditions of erythropoietic stress. It appears that β thalassemia heterozygotes with certain mutations, notably –88 (C→T), –29 (A→G), and IVS-1-1 (C→A), appear to have relatively higher levels of HbF that are independent of the C→T polymorphism at $-158^{G}\gamma$. Carriers of mutations such as IVS-1-6 (T→C), IVS-1-110 (G→A), codon 24 (T→A), codon 39 (C→T), and codons 41–42 (-TCTT) tend to fall into two groups, that is, with high $^{G}\gamma$ and low $^{G}\gamma$ varieties of HbF; neither is associated with high HbF values.

Association with Other Genetic Disorders

Because the heterozygous state for β thalassemia is so common, it is not surprising that it has been found in association with a variety of other genetic disorders.

In many populations glucose-6-phosphate dehydrogenase (G6PD) deficiency and β thalassemia are found at high frequencies and hence they are not infrequently encountered together in the same individual. This interaction was analyzed in Sardinia by Piomelli and Siniscalco.[458] The mean hemoglobin levels in hemizygous G6PD-deficient males was 14.1 g/dL, thalassemic males 13.6 g/dL, and males with both conditions 12.5 g/dL. The red cell indices in the thalassemic males were not altered by coexistent G6PD deficiency. In a later study Sanna et al.[459] found no interaction between the two traits.

Another common occurrence is the co-inheritance of the genetic determinant for Gilbert syndrome.[193,460] There is a polymorphic variation in the promoter of the bilirubin UDP-glucuronosyl transferase gene (UGT1A1); the particular motif is a $A(TA)_n$ TAA. Some individuals with Gilbert syndrome have an additional TA, that is, the arrangement $A(TA)_7$TAA rather than the more usual $A(TA)_6$TAA. It has been found that the expanded variety of promoter polymorphism is found commonly in heterozygous β thalassemics with unusually high bilirubin levels. Interestingly, homozygosity for the $(TA)_7$ motif is not always associated with an elevated bilirubin in otherwise normal persons and hence it is likely that the increased production of bilirubin as a result of the ineffective erythropoiesis in β thalassemia heterozygotes is sufficient to cause unusually high blood levels.

Several families have been reported in which the genes for hereditary elliptocytosis (HE) and β thalassemia were segregating.[461–463] In these cases there did not seem to be any summation of the effects of the two disorders, although in the family reported by Perillie and Chernoff[464] there may have been some interaction. Similarly, there have been

reports of the interaction of β thalassemia trait and hereditary spherocytosis (HS.[465–468] Although it has been reported to cause relatively severe hemolysis it is difficult to determine whether this is a true summation effect; HS is very variable in its expression even within members of the same family. Similarly, in the few reported instances of the coinheritance of β thalassemia and pyruvate kinase deficiency, the red cell enzyme deficiency has not had any deleterious effect on the phenotype of β thalassemia trait [469,470]

Variant Forms of Heterozygous β Thalassemia

The more unusual forms of heterozygous β thalassemia are summarized in Table 17.1. The most common and most important are the normal HbA_2-β thalassemias.

Normal HbA_2–β Thalassemia

Based on the hematological findings it has been useful to divide the normal HbA_2–β thalassemias into Type 1, in which there are minimal red cell abnormalities and in which the thalassemia allele is clinically "silent," and Type 2, in which the hematological changes are indistinguishable from those of heterozygous β thalassemia with an elevated level of HbA_2.[471]

"Silent" β Thalassemia *(Normal HbA_2–β thalassemia type 1).* As described by Schwartz[472] and discussed earlier in this chapter, the importance of the "silent" β thalassemias is that they can interact with more severe β thalassemia alleles to produce β thalassemia intermedia. Their molecular basis is described in Chapter 16 and the clinical consequences of their interaction with different β thalassemia alleles are summarized earlier in this chapter. There are no significant hematological abnormalities but on globin-chain synthesis analysis there is mild imbalance, with α/β-chain production ratios in the 1.2–1.3/1 range.

Normal HbA_2–β thalassemia type 2. This condition is heterogeneous. One of the most common causes is the compound heterozygous inheritance of both δ and β thalassemia.[473] A variety of different forms of δ^0 or δ^+ thalassemia mutations have been found, either in cis or trans to β thalassemia mutations, and in some cases β haplotypes containing β and δ thalassemia genes in *cis* have been disseminated throughout populations. For example, in the mild form of β thalassemia, Hb Knossos, carriers have minimal hematological changes and low levels of HbA_2. This phenotype results from a mild β^+ thalassemia mutation (β27 G→T) together with a deletion of an A in codon 59 of the δ gene in *cis*, which completely inactivates it.[335] The same δ^0 59 (-A) mutation has been found in *cis* to the β^0 39 and β^+ IVS-1-110 mutations in Mediterranean populations[474] and δ+27 (G→T) has been reported in both *cis* and *trans* to the β^+ IVS-2-745 mutation.[475,476] Although on average, the HbA_2 levels fall into the normal range, there is considerable scatter and in some cases values in the 3–3.7 range are observed.

Although the diagnosis of coexistent β and δ thalassemia is best made by analysis of the respective globin genes, some clues can be obtained from family studies. Where the two mutations exist in *cis*, the condition will be transmitted both vertically and laterally. On the other hand, if the two thalassemia mutations are in trans they will separate and individuals with both high HbA_2– and normal HbA_2–β thalassemia may be found in different generations.

When considering the differential diagnosis of normal HbA_2–β thalassemia, and if different forms of δ thalassemia have been excluded, it is important to remember that there are certain unusual phenocopies of this condition. For example, some forms of εγδβ thalassemia, which involve long deletions of the β-globin gene complex, are characterized by a picture that is indistinguishable from normal HbA_2–β thalassemia in heterozygotes. Similarly, the Corfu form of δβ thalassemia, in which a 7.2-kb deletion involves the δ gene but leaves the β gene intact is also associated with this phenotype. This is because the β gene in *cis* to this deletion carries an additional β thalassemia mutation.

Heterozygous β Thalassemia with Unusually High Levels of HbA_2 or HbF

There is a rare group of β thalassemias in which levels of HbA_2 in excess of 5%–6% are observed. They all seem to result from deletions of the β-globin gene, which remove its 5′ promoter region, including sequences from –125 to +78 relative to the CAP site; in each case the promoter boxes are lost (reviewed by Thein[355]). The HbA_2 levels associated with these β thalassemias may be as high as 8%–9% (see Chapter 16).

These deletion forms of β thalassemia are also associated with unusually high HbF levels in heterozygotes. The first variety to be described, which became known as the Dutch form of β thalassemia,[477] was found in a large kindred with 13 heterozygotes; their HbF levels ranged from 5.1% to 14.4% with a mean value of 8.3%. Similar values have been reported in heterozygotes for several other deletional forms of β thalassemia.

Isolated Elevated HbA_2 Levels: Heterozygous β Thalassemia with α Thalassemia and Related Conditions

Occasionally, during population screening or family studies, individuals are encountered who have elevated HbA_2 levels in the absence of the usual hematological findings of heterozygous β thalassemia. Because the coinheritance of α^+ or α^0 thalassemia with β thalassemia may result in normalization of the red cell indices and balanced globin-chain synthesis, leaving a raised HbA_2 as the sole abnormality, it seems likely that many of the reported cases of isolated HbA_2 elevation reflect these interactions.[478,479]

Several families have been described in which there were otherwise normal individuals with raised HbA_2 levels in whom detailed analyses of the α-, β-, and δ-globin genes showed no abnormalities.[480]

Heterozygous β Thalassemia with an Unusually Severe Clinical Course

There are two main mechanisms whereby heterozygous thalassemia may run a more severe course. First, there is the coinheritance of a chromosome containing additional α-globin genes, either ααα or αααα. The forms of β thalassemia intermedia associated with these genotypes were discussed earlier in this chapter. Second, there are the dominant β thalassemias, which result from mutations that give rise to products that are able to form inclusion bodies in the red cell precursors.[365,366] These conditions, which give rise to a wide spectrum of forms of β thalassemia intermedia of varying clinical severity, together with the underlying molecular mechanism, are described in Chapter 16.

β Thalassemia Unlinked to the β-Globin Gene Complex

Several families have been reported in which a form of β thalassemia trait appears to segregate independently from the β-globin gene complex.[481–484] Although subsequent analyses have shown some problems of interpretation in one of these families there seems little doubt from the study of Thein et al. that there is a form of phenotypically characteristic heterozygous β thalassemia that segregates independently of the β-globin genes. It seems likely that this reflects the action of a mutant *trans*-acting factor that is involved with β-globin gene regulation. The red cell indices, HbA_2 levels, and globin-chain synthesis findings are indistinguishable from the forms of β thalassemia trait associated with mutations in the β-globin genes.

Other β Thalassemias of Unknown Cause

Most laboratories that have sequenced large numbers of β-globin genes during their studies of families with the phenotype of β thalassemia have amassed varying numbers of cases in which no abnormality has been found. For example, Kazazian[485] reported that this was the case in nine of the 100 alleles that his laboratory had sequenced in detail. Because in many cases it has not been possible to conduct the kind of genetic studies required, it is quite possible that at least some of these undefined disorders reflect the type of unlinked forms of β thalassemia described previously.

The Problem of Borderline Red Cell Indices or HbA_2 Levels

In heterozygotes for very mild β thalassemia alleles, or those for severe alleles who have coinherited α thalassemia, the red cell indices may be almost normal. The usual levels of the MCH and MCV below which further study is advised, less than 27 pg and 80 fl, respectively, may miss these conditions in screening programs.

In clinical practice it is also not infrequent to encounter individuals with HbA_2 levels that appear to be very marginally raised, that is, in the 3%–3.5% range. These cases pose considerable diagnostic and counseling difficulties. What action should be taken? Probably the first thing to do is to repeat the estimation, but if similar values are obtained again, the finding cannot be ignored.

Galanello et al.[486] have analyzed 125 individuals with HbA_2 values in this range. In 37 cases they were able to detect an underlying molecular defect in the β-, δ-, or α-globin genes. Twenty-three were carriers of mild β-thalassemia alleles, 16 were compound heterozygotes for δ and β thalassemia, two had triplicated α-globin genes, and two had single α-globin gene deletions. The finding of this relatively high percentage of abnormalities, and the fact that many of them can interact with β thalassemia to produce severe phenotypes, suggests that in any screening program, particularly when an individual who has a borderline HbA_2 is planning to have a child with a partner with typical β thalassemia trait, it is important to investigate the cause for the marginally elevated HbA_2 level.

AVOIDANCE AND POPULATION CONTROL

Because of the changing demography of disease in many countries the thalassemias will be a major health problem in the new millennium.[1,2,487] As populations become richer, and standards of nutrition and public health improve, there is a fall in childhood mortality. Hence, an increasing number of babies with genetic diseases such as thalassemia will survive the early months of life and present for treatment. It is essential, therefore, that some form of program for the population control of these diseases is initiated.

It is beyond the scope of this chapter to deal with the complex ethical, economic, and organizational problems of establishing screening programs for the thalassemias. They must be backed up by adequate facilities for counseling and each individual society has to decide whether it wishes to try to reduce the frequency of births of children with serious forms of thalassemia by counseling and marital advice or by establishing a program of prenatal diagnosis. These complex issues are discussed in detail by Weatherall and Clegg[2] and Weatherall et al.[3] and the extensive experience gained from the successful population programs that have been carried out over the last 20 years in the Mediterranean island populations are reviewed by Cao et al.[488] The methods that are currently established for prenatal diagnosis of β thalassemia are described in Chapter 28 and Weatherall and Clegg.[2]

MANAGEMENT

Advances in the management of thalassemia major have greatly improved the prognosis for patients over recent

years. Although bone marrow transplantation, for those with appropriate donors and in countries in which the facilities exist, now offers the possibility of curing the condition, the mainstays of treatment are still adequate transfusion, backed up with iron chelation therapy and the judicious use of splenectomy. Some of these topics are dealt with in detail in other chapters. Here we simply outline the principles of management. The broader population, social, and psychological aspects are reviewed elsewhere.[2]

It is very important before embarking on any form of treatment to establish the particular variety of β thalassemia and to obtain a full blood group genotype of the patient. It is also essential to assess the patient carefully over the first few months after the diagnosis is established and not to embark on a transfusion regimen too hastily. Many patients with intermediate forms of β thalassemia, who may not need regular transfusion, embark on a life of unnecessary treatment of this kind, particularly if they present with an unusually low hemoglobin level during a period of intercurrent infection. The important indications for transfusion are not the steady-state hemoglobin level, but the child's well-being, particularly with respect to activity, growth, development, and the early appearance of skeletal changes.

Transfusion and Splenectomy

Transfusion Regimens. Long-term transfusion programs form the cornerstone of treatment for most patients with thalassemia major[149] (see Chapter 29). Avoidance or reduction of the frequency of transfusions in an effort to ameliorate iron loading does not prevent this complication; when erythropoietic activity is increased more than fivefold, as it may be in severe thalassemia, the amount of iron absorbed surpasses iron loss, resulting in an increase in body iron.[489] The goals of transfusion, therefore, include not only correction of the anemia but also suppression of erythropoiesis and inhibition of increased gastrointestinal absorption of iron. Both "hypertransfusion" and "supertransfusion" regimens, in which pretransfusion hemoglobins are maintained above 10 and 12 g/dL, respectively, prevent most complications of anemia and ineffective erythropoiesis[490] but are associated with substantial iron loading. The maintenance of pretransfusion hemoglobin concentrations that did not exceed 9.5 g/dL were found to reduce transfusion requirements and body iron loading, as estimated by serum ferritin concentrations; in parallel, marrow activity did not increase more than threefold over normal, and a lower incidence of endocrine and cardiac complications was observed.[491]

Type of Red Cell Concentrates

Most centers still use washed or filtered red cells. Early clinical experience of the use of neocytes, young red blood cells separated from older cells by density centrifugation,[492] suggested that a modest extension of the transfusion interval could be achieved.[493] Later studies, which used a simpler method of preparation,[494] confirmed these findings.[495] A more recent report observed that the reduction in total annual transfusional iron load during neocyte transfusions varied widely: from less than 10% to greater than 25%[496] The cost–benefit relationship of neocyte transfusions is unclear; the benefits of reduced iron administration are offset by an up to fivefold increase in preparation expenses over those of standard concentrates.[497]

Further details of the practical aspects of transfusion therapy are discussed in Chapter 29 and by Weatherall and Clegg.[2]

Splenectomy

In the past, it was quite common to observe an increase in transfusion requirements at approximately the age of 10 years. In many cases it was apparent that this reflected the effects of hypersplenism (see Modell and Berdoukas[5]). More recent experience, however, suggests that many patients who have received adequate transfusion therapy from an early age do not show this phenomenon and hence splenectomy is now required less often.[15] Splenectomy has been recommended when transfusion requirements exceed 250 mL[498] or 200 mL packed cells/kg body weight.[14] Concerns that it may be associated with acceleration of iron loading in other organs[499,500] are not supported by one study that reported that the spleen is not a significant repository of transfused iron.[501] Because of the risk of infection, splenectomy should be delayed until the age of 5 years. Splenic embolization[502] and partial splenectomy[503,504] have been used to preserve splenic function, but an early response has often been followed by recurrence of hypersplenism, and these approaches are not generally recommended.

At least 6 weeks before splenectomy, patients should be vaccinated with pneumococcal, *Haemophilus influenzae* type B and meningococcal vaccines, and after surgery, daily prophylactic penicillin should be administered, at least during childhood and probably indefinitely. Erythromycin may be substituted for those who are allergic to penicillin. Antimalarials should be given to those traveling to countries in which malaria is endemic and to those who live in these regions.

Iron Chelation

Background. In the absence of iron chelating therapy, transfusional iron overload is progressive and ultimately fatal.[15] For many years, cardiac iron loading has been the leading cause of death in transfusion-dependent thalassemia patients and it is still observed at the present time. The beneficial effects of iron chelation therapy with the agent desferrioxamine mesylate on survival and the prevention of cardiac disease are reviewed earlier in this chapter. In

short, two extensive studies reported the influence of effective long-term use of desferrioxamine mesylate on the prevention of cardiac disease,[66,232] findings that were later confirmed by a multicenter study in Italy.[68] As well as providing clear evidence of the efficacy of desferrioxamine in compliant patients these studies also provided evidence about the level of body iron that should be maintained to maintain transfusion-dependent thalassemic patients in good health.[15]

Assessment and Maintenance of Body Iron Levels

Methods for the assessment of body iron levels were discussed earlier in this chapter and are also summarized in Chapter 29. Data that have accumulated over the past 10 years permit a quantitative approach to the management of iron overload and provide guidelines for the control of body iron burden in chelated patients. Chelating therapy should not be aimed at maintenance of a normal body iron (~0.2–1.6 mg iron/g liver dry weight), as this greatly increases the probability of desferrioxamine toxicity.[505] By contrast, maintenance of hepatic iron concentrations exceeding 15 mg iron/g liver dry weight is associated with a greatly increased risk of cardiac disease and early death.[232] Slightly lower iron burdens (between ~7 and 15 mg iron/g liver dry weight) are associated with an increased risk of other complications of iron overload, including hepatic fibrosis, in homozygotes for hereditary hemochromatosis.[506,507]

It has been proposed therefore that a conservative goal for chelating therapy is the maintenance of hepatic storage iron concentrations of approximately 3–7 mg iron/g liver dry weight[15] in the range found in asymptomatic heterozygotes for hereditary hemochromatosis.[508] If measurement of hepatic iron by liver biopsy or MRI is not feasible, the serum ferritin provides an alternative but less reliable means of determining whether the body iron is within an optimal range. A serum ferritin level of 2,500 μg/L, maintained over a period of more than 10 years, may reflect a threshold of increased risk of cardiac disease and early death.[66] Recent studies using MRI approaches to the assessment of myocardial iron levels (reviewed by Pennell[61]) have suggested that there may not be a clear cut relationship between hepatic iron or serum ferritin levels and cardiac iron. The current status of these new approaches to the assessment of cardiac iron was discussed earlier in this chapter and is considered in more detail in Chapter 29. Until more is known about the clinical efficacy of this new technology, particularly from prospective studies, and given the overwhelming evidence for the prolonged survival of patients who are compliant to chelation therapy, it is essential that monitoring of transfusion-dependent patients continues to be carried out by assessment of body iron burden by hepatic MRI or direct iron measurements.

The initiation of desferrioxamine therapy. The adverse effects associated with desferrioxamine, and the balance between its effectiveness and toxicity, are reviewed by Olivieri and Brittenham.[15] It has been recommended that initiation of desferrioxamine should be guided by the concentration of hepatic iron, obtained by liver biopsy under ultrasound guidance, after approximately 1 year of regular transfusions. If a liver biopsy is not possible at the start of therapy, subcutaneous infusions of desferrioxamine, not exceeding 25–35 mg/kg/day, should be initiated after approximately 1 year of regular transfusions. Titration of hepatic iron, as above, should avert the potential toxic effects of desferrioxamine.[505] If the hepatic iron concentration is not regularly assessed, a "toxicity" index, defined as the mean daily dose of desferrioxamine (mg/kg) divided by the serum ferritin concentration (g/L) should be calculated for each patient every 6 months and should not exceed 0.025.[505] Doses of desferrioxamine should not usually exceed 50 mg/kg/day, and all patients should undergo regular examination for ophthalmological or auditory complications and abnormalities of growth (see Chapter 29).

Alternatives to subcutaneous infusions. Regimens of continuous ambulatory intravenous desferrioxamine infused through implantable subcutaneous ports, in which the infusion site cannot be manipulated by the patient, overcome the disadvantages of drug preparation and self-administration, eliminate the irritation associated with subcutaneous infusions, and improve compliance.[60] Because this system requires that the site be changed weekly by medical personnel at a clinic visit, it is not popular with many patients. Those unwilling to visit the clinic frequently, and those for whom standard pumps are unwieldy, may benefit from systems in which the desired concentrations of continuous subcutaneous or intravenous desferrioxamine can be infused using a lightweight, disposable, silent balloon infuser (Baxter) that produces continuous pressure without a battery or other mechanical device.[509,510]

Desferrioxamine "allergy". Reactions to desferrioxamine include acute inflammation, itching, and edema at the site of infusion, increasing in severity, to wheezing, tachypnea, tachycardia, hypotension, and coma. Although these reactions suggest an allergic mechanism, evidence supporting an immunological basis for this is lacking; direct, IgE-independent activation of dermal mast cells by desferrioxamine has been demonstrated.[511] These severe reactions may be effectively managed using rapid intravenous desensitization similar to protocols recommended for penicillin-allergic individuals,[512–514] followed by long-term, continuous, subcutaneous or intravenous infusion.

Rescue of patients with severe iron loading and organ damage. There is limited evidence that it is possible to improve both liver and cardiac function in patients who are heavily iron loaded and in whom there is evidence of defective organ function. These patients are best managed by the

administration of desferrioxamine intravenously through implantable venous ports, although scrupulous attention has to be paid to the care of access sites. Because of the dangers of high-dose desferrioxamine administration it is recommended that the drug is given by continuous infusion at a dose of up to 50 mg/kg/day. Further details of this topic are reviewed by Davis and Porter[515] and Weatherall and Clegg.[2]

Orally active iron chelators. The expense and inconvenience of desferrioxamine, and problems with compliance, have led to a search for orally active iron chelators. The pharmacology and clinical experience with these agents is discussed in detail in Chapter 29. Here we summarize only particular issues of their use in patients with severe forms of thalassemia.

The most extensive experience has been obtained with deferiprone (L1). Although support for a long-term open label study and randomized trial of deferiprone and desferrioxamine was terminated prematurely by the corporate sponsor, follow-up of hepatic storage iron concentrations in both cohorts indicated that in approximately one-third of the deferiprone-treated patients the hepatic iron stabilized at, or increased concentrations that would have placed patients at risk for cardiac disease. Despite the fact that compliance was better in the deferiprone-treated group,[26,516,517] these findings, and subsequent studies[518] suggested that long-term therapy with deferiprone might not provide adequate control of body iron in a significant proportion of patients with thalassemia major.[519] The administration of deferiprone is also associated with a number of side effects including neutropenia, gastrointestinal upset, and painful arthritis; importantly, the latter seems to vary in frequency between different racial groups and has been reported as occurring in between 30% and 50% of patients on the Indian subcontinent, although in many cases the arthritis is transient in some there has been both clinical and radiological evidence of destructive joint disease.[520] The reasons why a proportion of patients do not maintain iron balance while receiving deferiprone, and why there are differences in the frequency of complications in different ethnic backgrounds remain unexplained (see Chapter 29).

Recent uncontrolled retrospective studies, or short-term prospective studies, have suggested that deferiprone might be more effective in reducing the level of cardiac iron loading than desferrioxamine.[521,522] Until the results of longer-term prospective controlled studies are available, the potential role for deferiprone, alone or combined with desferrioxamine in the management of cardiac iron loading, remains unclear.[523]

The more recently developed oral tridentate chelator, Deferasirox (ICL670, Exjade) has also shown promise in early clinical trials[524,525] (see Chapter 29). So far the effects on maintaining iron balance look promising and the side effects have been restricted to abdominal discomfort, rashes, and a mild increase in the creatinine level.

Clearly the current position regarding the place for the use of oral chelating agents compared with the well-proven gold standard of desferrioxamine remains uncertain. It is absolutely vital that new agents are subjected to long-term prospective controlled studies; the natural history of iron loading and its associated toxicity renders short-term observational studies completely inadequate. This is of particular importance with respect to the problem of thalassemia in developing countries in which the cost of any therapeutic agents is in competition with drugs required for the major communicable diseases. In these populations it is particularly difficult to monitor patients regularly for potential side effects and until the true place of these agents has been determined by adequate studies their widespread use in the developing world should be monitored with extreme caution.

Other novel oral chelating agents that are being developed are considered in Chapter 29.

Blood-Borne Infections

As discussed earlier, liver disease due to transfusion-transmitted viruses, hepatitis B, C, HIV, and malaria are now a major cause of morbidity and mortality in patients with β thalassemia. HBV infection is still the most important worldwide, while HCV is a major problem in Europe, North America, and Japan. Since the introduction of HIV donor screening, the risk of acquisition of HIV by transfusion has been greatly reduced in Europe and the United States. In patients becoming HIV seropositive the risk of progression to AIDS appears to be approximately 9% at 5 years. It is beyond our scope to discuss the treatment of HIV infections. Here we will focus on the management of HCV, because this is an important and increasing problem in patients with β thalassemia. The prevention and management of blood-borne malaria has been reviewed recently.[526]

Hepatitis C. Iron overload and infection with HCV are cofactors in the evolution of chronic liver disease, a common cause of death after age 15 years in thalassemia major.[51]

When recombinant α-interferon was the only effective therapy for chronic infection with HCV,[527] a study of the long-term efficacy of α-interferon in patients with thalassemia major[528] reported a complete response, defined as both sustained normalization of serum ALT and clearance of HCV-RNA from serum, in 40% of patients over a mean follow-up period of 3 years. The rate of relapse was much lower in thalassemic (18%) than in nonthalassemic individuals (50%). This suggested that in most patients with thalassemia, α-interferon should not be stopped after 3–6 months, but should be continued at least until the serum ALT level declines to normal. This and other studies[187,529] also highlighted the importance of compliance with desferrioxamine during α-interferon therapy. When it was found that responses to α-interferon were improved by its

coadministration with ribavirin,[530,531] concerns were raised about the effect that the hemolytic complications of ribavirin administration might have on the anemia of thalassemic patients. Recent studies suggest that, although transfusion requirements may increase, it is possible to treat successfully thalassemic patients with interferon in combination with ribavirin although the results of more extensive trials are required to confirm the efficacy and safety of this type of regimen.[532]

Other infections. Although in the past infectious complications were a major problem in thalassemic children, this seems to be less common in those who are maintained on an adequate transfusion and chelation regimen. The one important exception is infections with the *Yersinia* genus of bacteria. The pathophysiology and clinical features were described in a previous section. Treatment with desferrioxamine should be stopped, stool cultures examined for *Yersinia* spp, and appropriate antibiotic treatment started, either an aminoglycoside or cotrimoxazole. The management of other infections in patients with thalassemia is reviewed by Vento et al.[167]

Bone and Endocrine Disease

The mechanisms of the reduction in bone density in β thalassemia were discussed earlier. It is recommended that bone densitometry, using dual-energy x-ray absorptiometry or in vivo neutron activation, is included in the evaluation of thalassemia patients to guide treatment.[533] Appropriate hormonal replacement therapy in hypogonadal patients, exercise programs, and the administration of elemental calcium and vitamin D may be of benefit. The value of bisphosphonates, calcitonin,[534] and fluoride remains to be determined.

Other endocrine disorders are discussed in detail earlier in this chapter. They should be managed by appropriate replacement therapy.

Bone Marrow Transplantation

Bone marrow transplantation is now an important option for transfusion-dependent patients with β thalassemia who have appropriate donors. This topic is discussed in full in Chapter 32.

Thalassemia Intermedia

Patients who are growing and developing adequately without transfusion, and who fall into the β thalassemia intermedia category, should be maintained on folate supplementation and have regular assessment of their iron status, with appropriate chelation therapy if there is evidence of iron loading. In the face of a falling hemoglobin level and progressive splenomegaly, splenectomy may be indicated, although the results are unpredictable. Symptomatic extramedullary hematopoietic masses have been treated successfully with various combinations of hypertransfusion, x-ray therapy and the administration of hydroxyurea.[2,535]

Other issues relating to the management of the complications of thalassemia intermedia are discussed in detail by Weatherall and Clegg.[2]

Experimental Therapies

As well as work directed toward the development of new chelating agents (Chapter 28) the major areas of research toward improvements in the management of the thalassemias include attempts to increase the level of fetal hemoglobin production (Chapter 30), the development of noninvasive approaches for prenatal diagnosis (Chapter 32) and the application of somatic gene therapy (Chapter 33). Other approaches at the molecular level, including the use of RNA interference technology, homologous recombination and therapeutic cloning, antisense messenger RNA and others, have been reviewed recently.[536]

Global Health Issues

Although the β thalassemias and different interactions are of increasing importance in richer countries, their major public health impact is in the poorer countries of the Middle East, the Indian subcontinent, and south and east Asia. It is beyond the scope of this Chapter to discuss the economic aspects of the control and management of the thalassemias, particularly in the developing countries. These issues, together with some recommendations for the future control of these conditions in the developing world have been summarized recently.[3]

It should be remembered that any form of treatment and particularly pharmacological approaches, are in direct competition with the costs of managing the major killers in the developing countries, notably AIDS, malaria, and tuberculosis. Hence, in assessing therapy for thalassemia in these countries, the "better than nothing" approach to drug therapy is simply not possible; treatment has to be of genuine proven value if it is to compete with some of the costs of the major killers in these countries.

Because research into more effective management or cure of the thalassemias is still at an early stage, and even if some of it comes to fruition it is likely to be extremely expensive, the more conservative approaches to the prevention and management of the β thalassemias outlined in this chapter are likely to be the major approach that is possible in many countries of the world for the foreseeable future. Given the heavy pressures on healthcare provision in the developing world it is absolutely critical that the richer countries take every opportunity to fully confirm the efficacy of any new forms of investigation or treatment, even if they appear to be cost-effective, before they are introduced into the developing countries.

FORMS OF THALASSEMIA RELATED TO β THALASSEMIA

There are several forms of thalassemia or thalassemia-like disorders that are related to the β thalassemias. They include the δβ, εγδβ and δ thalassemias and hereditary persistence of fetal hemoglobin (HPFH). The molecular basis and hemoglobin constitution of these conditions are described in detail in Chapter 16 and original references to their clinical manifestations are given in detail in Weatherall and Clegg.[2] Here, their major clinical manifestations are summarized briefly.

The δβ Thalassemias

The δβ thalassemias are subdivided into the $(\delta\beta)^+$, $(\delta\beta)^0$, and $(^A\gamma\delta\beta)^0$ thalassemias. There is considerable clinical variation associated with these different conditions and their various interactions with structural hemoglobin variants.

$(\delta\beta)^+$ Thalassemia

These disorders are also known as the hemoglobin Lepore thalassemias because they are associated with the production of δβ fusion variants. Over 20 individuals have been reported as being homozygous for different molecular forms of Hb Lepore. Despite the fact that they synthesize no normal β or δ chains these patients have a remarkably diverse series of clinical phenotypes, ranging from conditions that are very similar to the homozygous state for β^0 thalassemia to relatively mild forms of β thalassemia intermedia.[2] Many of the reports of these patients did not include studies to search for ameliorating factors such as the coexistence of α thalassemia or heterocellular HPFH and where these factors had been looked for, and excluded, the phenotype has usually been similar to the homozygous state for β^0 thalassemia.[537]

The heterozygous states for the Hb Lepore thalassemias are symptomless and the hematological changes are similar to those of heterozygous β thalassemia except that the level of HbF is significantly higher. There is an extensive literature on the interaction of this condition with the β and $(\delta\beta)^0$ thalassemias.[2] These conditions also show remarkable clinical diversity which, in the case of the β thalassemia interactions, seems to depend mainly on whether they are between β^0 or β^+ thalassemias; in the former case the phenotype is of severe β thalassemia major, whereas in the latter the phenotype is in the more severe spectrum of β thalassemia intermedia.[538] Compound heterozygosity for hemoglobin Lepore and $(\delta\beta)^0$ thalassemia also produces the phenotype of thalassemia intermedia. The hemoglobin Lepore thalassemias have also been found in compound heterozygotes for Hbs S, C, and E. Here again, the clinical phenotypes have been extremely variable but, overall, resemble those of Hbs S, C or E–β thalassemia (see Chapters 18, 19, and 21). Except when coinherited with other hemoglobin variants or β thalassemia, the anti-Lepore hemoglobins are not associated with any clinical abnormalities. The rare interactions between the anti-Lepore hemoglobins and β thalassemia have been associated with very mild forms of β thalassemia intermedia.

$(\delta\beta)^0$ and $(^A\gamma\delta\beta)^0$ Thalassemia

The homozygous states for these conditions, that are associated with 100% HbF production, usually result in the phenotype of a variable form of β thalassemia intermedia with hemoglobin values in the 7–9 g/dL range. Compound heterozygotes for these conditions and β thalassemia are also characterized by β thalassemia intermedia of widely varying severity; those with $(^A\gamma\delta\beta)^0$ thalassemia seem to be at the more severe end of the spectrum of this phenotype.

The $(\delta\beta)^0$ thalassemias have been observed in the compound heterozygous state with a variety of hemoglobin variants, including Hbs S, C, and E. The combination with HbS produces a relatively mild sickling disorder and in some cases there has been no history of sickle cell crises. Again, however, there is considerable heterogeneity and at least one family has been reported in which children with sickle cell $(^A\gamma\delta\beta)^0$ had a condition which was similar to sickle cell disease.[539] From the limited amount of data it appears that HbC–$(\delta\beta)^0$ thalassemia is a milder condition than HbC disease or HbC–β^0 thalassemia. Similar, HbE–$(\delta\beta)^0$ thalassemia is characterized by a very mild phenotype, which is significantly less severe than HbE–β thalassemia.

Finally, the phenocopies of δβ thalassemia that arise from the acquisition of two different mutations in the β-globin gene cluster that involve the γ gene promoters, the β genes or the δ genes, Sardinian δβ thalassemia and Corfu δβ thalassemia for example,[540,541] behave clinically in the same way as the other forms of δβ thalassemia.

δ Thalassemia

Although the δ thalassemias are clinically and hematologically silent, they may cause problems for genetic counseling. They may occur in *cis* or *trans* to a β thalassemia mutation, and produce the hematological phenotype of normal Hb A_2–β thalassemia trait. Although the gene frequencies have not been determined it appears that δ thalassemia may occur in *trans* with a variety of different β thalassemia mutations in the Mediterranean population.[542]

$(\varepsilon\gamma\delta\beta)^0$ Thalassemia

This rare condition is characterized by a complete absence of output from the β globin gene cluster and therefore, in the homozygous state, would not be compatible with survival. Although this disorder results from two distinct forms of molecular pathology (see Chapter 16), the clinical features in heterozygotes are similar although remarkably

variable even within the same family. In newborn babies there is a moderate degree of anemia, with hemoglobin values in the 7–10 g/dL range. As these patients get older the anemia becomes less severe and in adult life the disorder behaves like the heterozygous state for normal Hb A_2–β thalassemia trait. But the clinical variability after birth is quite remarkable. In some patients there is pallor, jaundice and splenomegaly whereas others, in the same family, may go through completely uneventful postnatal periods. The reasons for this clinical diversity have not been determined.[2,543]

Hereditary Persistence of Fetal Hemoglobin

A classification together with the molecular pathology of these conditions is described in Chapter 16. Overall, they fall into two main groups depending on whether they result from deletions or point mutations. They are further classified into whether the distribution of HbF in the red cells is pancellular or heterocellular. Their clinical importance is related mainly to their interaction and modifying effect on other β-globin disorders.

$(\delta\beta)^0$ Hereditary Persistence of Fetal Hemoglobin

These conditions have been observed in the homozygous state and in the heterozygous state, either alone or in combination with other disorders of β globin.

There have been a number of detailed descriptions of the homozygous state for $(\delta\beta)^0$ thalassemia including the underlying pathophysiological mechanisms.[2,544] These individuals have no clinical disability or abnormal physical signs. The characteristic hematological finding is a moderately elevated red cell count, probably reflecting a low P_{50} due to the very high level of HbF. The hemoglobin levels are normal or slightly elevated and the red cell indices show moderately reduced MCV and MCH values. These findings, with biosynthetic studies showing a mild defect in non-α-chain synthesis, indicate that HbF production is not quite sufficient to compensate for an absence of β-chain production and hence the phenotype of β thalassemia trait. Heterozygotes, apart from an increased level of HbF and a slightly reduced MCV, show no hematological abnormalities. They have significantly reduced HbA_2 levels.

There are extensive data on the clinical and hematological changes in compound heterozygotes for $(\delta\beta)^0$ HPFH and HbS. These individuals are not anemic and have very few episodes suggestive of sickle cell crises, although occasional mild bone or joint pains have been reported. Splenomegaly has not been a regular feature of this condition in the US, although it has been observed in approximately 40% of cases in West Africa. There have been occasional reports of aseptic necrosis of the femoral heads. Clearly, the uniform distribution of approximately 25% HbF in the red cells of these patients protects them from most of the deleterious effects of the sickle cell gene. Compound heterozygotes for $(\delta\beta)^0$ HPFH and HbC are usually symptomless and show normal or slightly reduced hemoglobin levels with minimal reticulocytosis. A small proportion of patients show mild splenomegaly. Compound heterozygotes with HbE also have an extremely mild phenotype with no anemia or other hematological changes. Compound heterozygotes with β thalassemia are also very mildly affected, if at all. Their hemoglobin levels are similar to those of heterozygous β thalassemia, as are the red cell indices, and splenomegaly is extremely rare. There have been occasional exceptions however. For example in one well-documented family that described the interaction of the Indian form of $(\delta\beta)^0$ HPFH, or HPFH 3, the three affected children had a relatively severe form of thalassemia intermedia with hemoglobin values in the 5–9 g/dL range.[545] Presumably these cases reflect the inability of the level of HbF to compensate for defective β-globin production.

Nondeletional HPFH

As described in Chapter 16 these heterogeneous conditions are divided into those in which there is a mutation in either the $^{G}\gamma$- or $^{A}\gamma$-gene promoters, and a group of conditions that are characterized by persistently low levels of HbF that is heterogeneously distributed among the red cells. As a group, they have very little clinical implication except for their interactions with other β-globin gene abnormalities.

$^{G}\gamma\beta^{+}$ HPFH results from a number of different mutations at the $^{G}\gamma$ locus. It has only been observed in the homozygous form in Tunisian $^{G}\gamma\beta^{+}$ HPFH. These individuals have approximately 50% HbF but are clinically and hematologically completely normal. Many different varieties have been found in the heterozygous state but in no case has there been any hematological abnormalities. Similarly, in the compound heterozygous state with HbS or β^0 thalassemia there have been no clinical or hematological changes; in the latter interaction the patient had a hemoglobin level of 13.1 g/dL and red cell indices typical of β thalassemia trait, although the HbF level was 64%.

The $^{A}\gamma\beta^{+}$ forms of HPFH, also heterogeneous at the molecular level, have also been observed in the homozygous and heterozygous states, either alone or in combination with β thalassemia or structural hemoglobin variants. The homozygous state was identified in the Greek form. These individuals showed no clinical abnormalities and were not anemic although at least in one case there was a slightly reduced MCV and MCH. The HbF value was approximately 24% which is twice that found in heterozygotes for this particular mutation. There are no clinical or hematological abnormalities in the heterozygotes. In compound heterozygotes with β thalassemia there appears to be no clinical disability although there is usually pallor, icterus and splenomegaly. There is mild anemia with hemoglobin values in the 9–11 g/dL range and the red cells

show typical thalassemic red cell indices. Fetal hemoglobin levels range from 25%–45%. Similarly, in homozygotes for the British form of $^{A}\gamma\beta^{+}$ HPFH both homozygotes and heterozygotes show no clinical or hematological abnormality. The compound heterozygous states for Black $^{A}\gamma\beta^{+}$ HPFH together with HbS or HbC are also associated with no significant clinical or hematological changes.

Heterocellular HPFH

Heterocellular HPFH is undoubtedly a heterogeneous condition in which there are relatively low levels of persistent HbF production distributed in a heterogeneous fashion among the red cells. Although genetic linkage studies have shown that this condition is quite heterogeneous at the molecular level, none of the genes involved have been identified with certainty. Heterozygotes have approximately 5%–10% HbF heterogeneously distributed among their red cells with no associated clinical or hematological abnormalities. It is clear, however, that the coinheritance of this condition with β thalassemia or the sickle cell genes can modify the phenotypes of their associated diseases quite considerably by increasing the output of HbF.[2] They are usually ascertained when one or other heterozygous parent of a patient with these disorders has an unusually high level of HbF; an extended family study may demonstrate other normal individuals with an elevated HbF. It is important, therefore, to carefully measure the level of HbF in heterozygous members of families in which there are patients with either β thalassemia intermedia or sickle cell anemia with unusually mild features.

The Diagnostic Value of the Cellular Distribution of Hemoglobin F in δβ Thalassemia and HPFH

In $(\delta\beta)^{0}$, $^{G}\gamma\beta^{+}$ and $^{A}\gamma\beta^{+}$ HPFH HbF is uniformly distributed among the red cells. There is one exception. In the British form of $^{A}\gamma\beta^{+}$ HPFH HbF is quite heterogeneously distributed, both in homozygotes and heterozygotes.[2] In all these conditions the red cell indices are normal.

In the δβ thalassemias and heterocellular HPFH the HbF is heterogeneously distributed. They can be distinguished by the higher levels of HbF (greater than 10% in heterozygotes) and reduced MCH and MCV in δβ thalassemia. In heterocellular HPFH the HbF level rarely exceeds 5% and the red cell indices are normal.

Hemoglobin E Disorders

Suthat Fucharoen and David J. Weatherall

INTRODUCTION

Hemoglobin E (HbE) is the most common abnormal hemoglobin in Southeast Asians, especially among the Khmer, Laotians, and Mon/Khmer speaking people, the Zhuang in Guangxi, People's Republic of China, and in India, Bangladesh, and Sri Lanka. The occurrence of HbE is most concentrated at the border of Thailand, Laos, and Cambodia, an area dubbed the HbE triangle.[1–4] The gene frequency of HbE is between 0.05 and 0.10, reaching 0.5 in certain parts of Cambodia and the northeast of Thailand. It is estimated that 30 million Southeast Asians are heterozygous for HbE and 1 million are homozygous. The maintenance of so high a gene frequency indicates that the HbE variant somehow improves fitness. Correlation of HbE frequency with the incidence of malaria has been noted, suggesting the action of a balanced polymorphism.[5] Studies of malaria and HbE are detailed in Chapter 26.

CLASSIFICATION OF HbE DISORDERS

In 1954, HbE became the fourth abnormal hemoglobin to be identified by electrophoresis,[6] and a substitution of lysine for glutamic acid at position 26 of the β-globin chain was found in 1961.[7] Many different syndromes are observed when HbE is variously combined with different α and β thalassemias and with other abnormal hemoglobins (Fig. 18.1). They can be classified into asymptomatic and symptomatic forms (Table 18.1).

Asymptomatic Forms

HbE Heterozygotes. HbE heterozygotes are clinically normal with minimal changes in blood counts and erythrocyte indices. Red cell morphology is similar to that in thalassemia minor with normocytic or slightly microcytic red cells (mean corpuscular volume [MCV] 84 ± 5 fL). A few target cells may be present in the blood smear. Osmotic fragility curves may be within normal limits or moderately shifted to the right, indicating slightly decreased osmotic fragility. Hemoglobin electrophoresis reveals both HbA and HbE. Quantifying the amount of HbE is crucial for the diagnosis of various HbE syndromes that occur from the interaction of HbE with other genetic hemoglobin abnormalities and nongenetic factors (Table 18.2). HbE constitutes 25%–30% of the hemolysate in HbE trait and with double heterozygosity for HbE and α^+ thalassemia ($-\alpha/\alpha\alpha$). HbE–α^+ thalassemia trait cannot be differentiated from simple HbE trait by hematological screening. The amount of HbE is reduced by coexistent α thalassemia. Lower levels of HbE suggest concomitant inheritance of the α^0 thalassemia (--/αα) gene.[8,9] In double heterozygotes for α^0 thalassemia and HbE, the amount of HbE ranges between 19% and 21%. A marked decrease of HbE to 13%–15% is observed in individuals who are double heterozygotes for HbH disease and HbE and have the HbAE Bart's disease syndrome.[10–12] Interactions between HbE and various α thalassemia genes are illustrated in Figure 18.2. HbE levels of 30% or above suggest the interaction of HbE with β thalassemia.[13–16] HbE heterozygotes who have iron deficiency anemia may have lowered amounts of HbE and further reduced MCV and mean corpuscular hemoglobin (MCH) values, depending on the degree of anemia.[17] The changes in the hematological parameters and amount of HbE in compound heterozygotes of HbE with other abnormal hemoglobins are summarized later in this chapter.

Homozygous HbE. Homozygotes for HbE usually have normal hemoglobin levels but some may be mildly anemic; clinical symptoms are rare. Most patients are not jaundiced and the liver and spleen are usually not enlarged. Reticulocyte counts are consistently normal, and nucleated red cells are not seen in the blood. Bone marrow examination shows a normal cellular pattern or minimal erythrocytic hyperplasia. Bone changes are not present. Osmotic fragility studies show a marked increase in the resistance of erythrocytes to hypotonic saline, indicating decreased osmotic fragility. In addition to a slightly reduced hemoglobin level and microcytic, poorly hemoglobinized red cells[18–20] (Table 18.2), the most unique finding is the red cell morphology, with 20%–80% target red cells (Fig. 18.3). Hemoglobin analysis reveals approximately 85%–95% HbE with the remainder HbF. There is defective β^E-globin chain synthesis in all HbE homozygotes with an average α/non-α biosynthesis ratio of 2, equivalent to the ratio found in β^+ thalassemia heterozygotes.[18–21] Defective β^E-chain synthesis is due to decreased β^E mRNA production, a result of abnormal RNA splicing caused by the HbE mutation[22–24] (see Chapter 16).

Symptomatic Forms

HbE–β Thalassemia. Generally, HbE–β thalassemia disease is a thalassemia syndrome of intermediate severity, although the clinical spectrum can be very heterogeneous.[14,16] Two types of HbE–β thalassemia disease have

Table 18.1. Summary of the common HbE syndromes in Thailand

Phenotype	Genotype	Anemia	Distinguishing features
Asymptomatic			
HbE heterozygote	β^A/β^E	No	Hbs E (25–30%) + A
HbE $-\alpha^+$ thalassemia heterozygote	β^A/B^E -$\alpha/\alpha\alpha$	No	Hbs E (25–30%) + A
HbE $-\alpha^0$ thalassemia heterozygote	β^A/B^E $--/\alpha\alpha$	No	Hbs E (19–21%) + A
HbE homozygote	β^E/β^E	No	only HbE
HbE homozygote -α^+ or α^0 thalassemia heterozygote	β^E/β^E -$\alpha/\alpha\alpha$ or $--/\alpha\alpha$	No	only HbE
HbE/Hb C	β^E/β^C	No	HbE (32%) + Hb C(56%)
Symptomatic			
HbE homozygote-Hb CS homozygote	β^E/β^E -$\alpha^{CS}\alpha/\alpha^{CS}\alpha$	Mild	Hbs E ($\alpha_2\beta_2{}^E$) + $\alpha_2{}^{CS}\beta_2{}^E$
β^0 Thalassemia/HbE	β^o/β^E	Moderate–severe	Hbs E + F
$\beta+$ Thalassemia/HbE	$\beta+/\beta^E$	Mild	Hbs E + F + A
EA Bart's			
- HbH disease with HbE heterozygote	$-\alpha/--$ β^A/β^E	Moderate	Hbs E + A + Bart's
- HbH-CS disease with HbE heterozygote	$\alpha^{CS}\alpha/--$ β^A/β^E	Moderate	Hbs CS + E + A + Bart's
EF Bart's			
- HbH disease with HbE homozygote	$-\alpha/--$ β^E/β^E	Moderate–severe	Hbs E + F + Bart's
- Hb H-CS disease with HbE homozygote	$\alpha^{CS}\alpha/--$ β^E/β^E	Moderate–severe	Hbs CS + E + F + Bart's
- HbH disease with β thal/HbE disease	$-\alpha/--$ β^o/β^E	Moderate–severe	Hbs E + F + Bart's
- HbH-CS disease with β thal/HbE disease	$\alpha^{CS}\alpha/--$ β^o/β^E	Moderate–severe	Hbs CS + E + F + Bart's

CS = Hb Constant Spring.

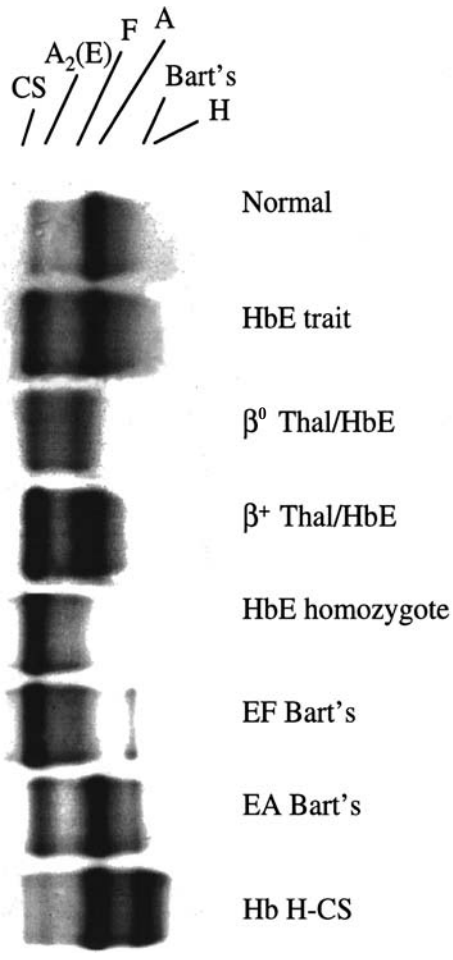

Figure 18.1. Hemoglobin types of various HbE syndromes performed by electrophoresis in an alkaline pH buffer.

been described that depend on the presence or absence of HbA. In HbE–β^0 thalassemia, β^A-globin chains are not present. This genotype results in HbE–β^0 thalassemia disease characterized by HbE and HbF without detectable HbA (Fig. 18.1). HbE constitutes between 40% and 60% of the hemolysate with the remainder HbF (Table 18.2). Clinically, HbE–β^0 thalassemia and homozygous HbE are quite different; the latter is asymptomatic and the level of HbF much lower. In exceptionally rare cases the amount of HbE in HbE–β^0 thalassemia and homozygous HbE may overlap, requiring family studies and further investigation to define the genotype. In HbE–β^+ thalassemia, some HbA is detected in addition to HbE and HbF. Different β^+-thalassemia genes result in a variable severity of disease because of different levels of HbA.[25]

HbAE Bart's Diseases. Because α chains appear to have a lower affinity for β^E chains than β^A chains, HbE heterozygotes who inherit different forms of α thalassemia, and in whom α chain synthesis is decreased, tend to have relatively lower levels of HbE than in unaffected HbE heterozygotes. This particular thalassemia syndrome is characterized by the presence of HbA, HbE, and Hb Bart's and results from the interaction of the genotype of HbH disease with heterozygous HbE.[10–12] Two common subtypes of HbAE Bart's disease have been observed: α^+ thalassemia/α^0 thalassemia –β^A/β^E and α^0 thalassemia/Hb Constant Spring – β^A/β^E. The latter disorder has a more severe clinical syndrome than the former type of HbAE Bart's disease. Usually the HbE level ranges from 13% to 15% (Table 18.2). Small amounts of Hb Bart's are always present in this genotype and intraerythrocytic inclusion bodies (HbH inclusions) can be demonstrated in approximately 5% of the

erythrocytes, indicating the presence of small amounts of HbH (β_4); this amount is insufficient to be resolved by electrophoresis.

HbEF Bart's Disease. HbEF Bart's disease is characterized by HbE, HbF, and Hb Bart's.[10] HbE constitutes 80% and HbF 10% of the hemolysate, with the remainder Hb Bart's. The presence of Hb Bart's indicates that there is excess γ-globin chain; however, no inclusion bodies or HbH are present, probably because the abnormal β^E-globin chains do not form tetramers. Four genotypes of HbEF Bart's disease can be found. These result from the interaction between the genotype for HbH disease, either α^0 thalassemia/α^+ thalassemia or α^0 thalassemia/Hb Constant Spring, with either homozygous HbE or HbE–β thalassemia.[26] Hb Constant Spring and small amounts of HbA may be observed in patients with the α^0 thalassemia/Hb Constant Spring and HbE–β^+ thalassemia genotype. To differentiate among these genotypes, family studies and further investigation by DNA analysis are required.

Homozygous HbE–Homozygous Hb Constant Spring Syndrome. It is difficult to identify the existence of the α thalassemia gene in homozygous HbE without DNA analysis. Individuals have been encountered who were homozygous for HbE and homozygous for Hb Constant Spring. They had thalassemia intermedia with a mild degree of anemia, jaundice, and splenomegaly. Their MCV ranged from 75 to 80 fL, and their MCH was between 23 and 25 pg (Table 18.2). Compared with homozygous HbE alone there were minimal red cell changes. This may be due to the interaction of α thalassemia with the β thalassemia–like reduced globin synthesis typical of HbE.

HEMOGLOBIN E–β THALASSEMIA

Because of the extremely high gene frequency for HbE and the widespread occurrence of β thalassemia, in many Asian countries HbE–β thalassemia is the most common form of severe thalassemia in the population. For example, in parts of India, Bangladesh, Myanmar, Thailand, and Indonesia it is the most common severe form of β thalassemia. In these countries it is causing an increasingly serious burden on healthcare resources and, because of its extraordinary phenotypic diversity, presents particular management problems.[16,25]

Pathophysiology

Individuals homozygous for HbE are usually clinically normal but compound heterozygotes with HbE–β thalassemia may have thalassemia major.[14] The abnormal β^E gene results in reduced amounts of β^E-mRNA and β^E-globin chains, leading to a mild β^+ thalassemia phenotype.[21,23] This occurs because the G→A mutation in codon 26 (Glu→Lys) of the β^E-globin gene activates a cryptic splice site at codon 25, leading to alternative mRNA splicing with reduced β^E-globin chain production[22] (see Chapter 16). A reduction in β^E-chain synthesis results in α/β synthesis ratios from 1.2 to 2.1 in HbE heterozygotes. In addition to the reduction of β^E-globin chains, the tertiary conformation of the HbE molecule is also affected. This is because the inhibitory effect of the β-26 substitution on the α1β1 contact may lead to the exposure of certain sulfhydryl groups and precipitation under conditions of oxidative stress.[27] The phenotypic implications of the inherent instability of HbE are not clear and require further investigation. Finally, the low percentage of HbE may also be partly attributed to the defective assembly of α_2 $\beta^E{}_2$ tetramers[28] (see Chapter 4).

The pathophysiology of HbE–β thalassemia therefore reflects both the reduced output of HbE together with the added globin-chain imbalance consequent on the coinheritance of β thalassemia. Hence the pathophysiology of this condition has many features in common with that of the intermediate forms of β thalassemia (see Chapter 17). As well as the deleterious effects of excess α globin chain production the inherent instability of HbE, as described previously, undoubtedly contributes to the overall damage to erythroid precursors and red cells. On the other hand, patients with this condition appear to be able to adapt more effectively to their anemia than those with other forms of β thalassemia intermedia at similar hemoglobin levels. This may reflect the relatively lower levels of HbF that are produced in HbE–β thalassemia and hence the lower oxygen affinity of the red cells.[16] Recent studies have also suggested that developmental changes in erythropoietin response to severe anemia in this condition may have important pathophysiological implications. It was found that hemoglobin levels and age are independent variables and that, for a given hemoglobin level, the erythropoietin response decreases with increasing age. Hence the hematopoietic drive, with resultant erythroid expansion, is greater in very young children with this condition, possibly explaining some of the phenotypic instability during early life.[29]

Genotype–Phenotype Interaction

Definition of Severity. Despite seemingly identical genotypes, compound heterozygotes for β thalassemia and HbE have remarkably variable phenotypes. Notable are variations in anemia, growth, development, hepatosplenomegaly, and transfusion requirements (Fig. 18.4). A novel scoring system based on six independent parameters – hemoglobin level, age at disease presentation, age at receiving first blood transfusion, requirement for transfusion, spleen size, growth and development – was able to separate patients into three distinctive severity categories: mild, moderate and severe courses. The scoring system consisting of six clinical criteria scored as 0, 0.5, 1 or 2, according to clinical presentation. HbE–β thalassemia patients with total scores ranging from 0 to 3.5, 4 to 7, and 7.5 to 10 are grouped as mild, moderate, and severe cases, respectively. The severe patients are very anemic and are usually transfusion dependent; some may have marked growth retardation and skeletal deformities, whereas the mild cases have mild anemia and usually have normal growth and development.[30] A spectrum of severity with hemoglobin levels from 2.5 to 13.5 g/dL, in the steady state, was found in 803 patients with HbE–β^0 thalassemia.[14] Because β^0 thalassemia is associated with an absence of β-globin chain synthesis, the causes of phenotype heterogeneity in these patients is likely to be a result of factors other than reduced β-globin chain synthesis.

As suggested by recent studies in Sri Lanka, the application of a clearly defined scoring system for severity

Figure 18.4. A group of β-thalassemia patients with variation of anemia and clinical phenotypes.

combined with a long period of observation and genetic analysis[31] may help us to understand the factors that determine the severity of anemia in HbE–β^0 thalassemia. Analysis of concordance and discordance of hemoglobin levels in 216 sibling pairs from 98 families showed a remarkable skew toward the lower values with a mode at 0–0.5 g/dL.[32] Concordance of hemoglobin levels between sibling pairs greatly exceeded discordance, indicating that severity of anemia in these patients is determined by polygenic factors, rather than a single gene effect. The factors that influence the severity of anemia are discussed later.

β *Thalassemia Mutations.* Although β^0 thalassemia is caused by many mutations, all result in absence of β-globin chain production by the abnormal gene (see Chapter 16). β^0 Thalassemia is usually more severe than β^+ thalassemia, in which a wide range of β-globin chain production is observed. Some β^+ thalassemia mutations may produce only very small amounts of β-globin chains and have a phenotype similar to that of β^0 thalassemia (e.g., C→T in IVS-II-654) (see Chapter 16). Alternatively, interaction between HbE and mild β^+ thalassemia, such as A→G at position –28 or A→G in codon 19 of the β-globin gene usually results in a mild thalassemic phenotype. Table 18.3 shows the hematological data and hemoglobin analysis, in the steady state, in mild HbE–β^+ thalassemia compared with homozygous HbE and severe types of HbE–β^+ thalassemia.[25] In mild HbE–β^+ thalassemia, HbE formed approximately 60% of total hemoglobin and HbF levels were approximately 3%–10%, which is the same effect produced by the mutation in codon 19 (Hb Malay, β19(B1) Asn→Ser). HbF is minimally increased in the absence of severe hemolytic stress. In a few cases, the hemoglobin phenotype was "HbE + HbA" with 60% HbE. In contrast, in the two types of severe HbE–β^+ thalassemia shown in Table 18.3 with mutations at IVS-II-654 and IVS-I-5, the mutations lead to severe hemolytic stress with HbF increased to a similar degree as in HbE–β^0 thalassemia. Therefore, these severe HbE–β^+ thalassemias are similar to HbE–β^0 thalassemia. Compound heterozygotes for β^+ and β^0 thalassemia genes also show variable severity similar to HbE–β^0 thalassemia (see Chapter 16). We can conclude that 1) patients with mild β^+ thalassemia and HbE have mild disease; and 2) patients with severe β^+ or β^0 thalassemia alleles and HbE have moderate to severe disease. These observations suggest that additional factors may be involved in determining disease severity.

Coinheritance of α Thalassemia. Concomitant inheritance of α thalassemia or Hb Constant Spring may be responsible for mildness of anemia in β or HbE–β thalassemia.[31,33–35] HbE–β^0 thalassemia patients who have coinherited α^+ thalassemia have hemoglobin levels of 7.4 g/dL or above, whereas those without detectable α thalassemia have hemoglobin levels higher or lower than 7.4 g/dL. Coinheritance of α^0 thalassemia with HbE–β^0 thalassemia may lead to so mild a condition that the individuals do not have a clinical abnormality that requires medical attention.[33] This effect is more evident in the

Association with Increased HbF. Coinheritance of determinants that increase HbF expression can ameliorate the severity of β thalassemia. Inheritance of a β thalassemia chromosome with the *Xmn*-1 cleavage site at position –158 5′ to the $^{G}\gamma$-globin gene is associated with increased HbF and milder anemia.[34] Two copies of this allele are necessary to produce a significant clinical effect. Hemoglobin levels of patients with an *Xmn*-$1^{+/+}$ genotype were greater than 8.5 g/dL, whereas those of patients with the *Xmn*-$1^{-/-}$ genotype were less than 7 g/dL. Increased expression of the $^{G}\gamma$-globin gene was also detected in the *Xmn*-$1^{+/+}$ patients. This increase of γ-globin gene activity helps to reduce the overall globin-chain imbalance and thus ameliorates the anemia. A similar effect, however, is not seen in individuals heterozygous for the *Xmn*-l site polymorphism. Patients with a single copy of the *Xmn*-l-positive allele have a variable clinical course and a wide range of hemoglobin levels and HbF production.

The association between the *Xmn*-$1^{+/+}$ genotype and a highly significant increase in the absolute level of HbF and a milder phenotype has also been observed in patients with HbE–β thalassemia in Sri Lanka.[31] In this study, it was clear that there must be other genetic determinants in the population that are responsible for an elevation of HbF, although so far these have not been identified.

Table 18.4 shows the effect of the type of β-thalassemia mutation, α thalassemia, and the *Xmn*l restriction site in determining severity in 80 Thai HbE–β thalassemia patients. The presence of a mild β thalassemia mutation, α thalassemia, and homozygosity for the *Xmn*l restriction site was associated with a mild phenotype in 17 of 27 (63%) patients. Although two cases were *Xmn*l negative, one had HbE–β^+ thalassemia and the other had the Hb Constant Spring gene. These findings suggest that the three factors can account for the mildness of the disease in 21% of cases. In severe cases, none had coinherited α thalassemia or an Hb Constant Spring gene and 3 of 11 cases (27%) were also *Xmn*l negative. Six of 42 patients with moderate severity also lacked an *Xmn*l restriction site.

Amount of Alternative Spliced β^E-Globin mRNA. An underproduction of β-globin chains from the β^E-globin gene strongly suggests that alternative RNA splicing is of physiological significance. The percentage of alternative spliced β^E globin mRNA was determined by the reverse transcriptase polymerase chain reaction technique in 14 patients with the same β thalassemia mutation.[36] Variation in clinical phenotype and degree of anemia were present. Preliminary results showed abnormally spliced β^E globin mRNA in patients with severe symptoms and low hemoglobin levels between 2.9% and 6.1%, whereas those with higher hemoglobin levels had values from 1.6% to 2.6%. The majority of patients with the *Xmn*l-negative genotype had more severe anemia and a higher percentage of abnormally spliced β^E globin mRNA. This indicated that the amount of alternatively spliced β^E globin mRNA was a more predominant factor in determining severity of anemia than the pattern of *Xmn*l polymorphism or the level of HbF. If confirmed, β-globin mutations resulting in abnormal pre-mRNA processing should result in variable degrees of gene expression and greater severity of anemia. Further investigation is needed to clarify this point.

Pyrimidine 5′ Nucleotidase Deficiency. In one Bangladeshi family, an individual homozygous for both HbE and pyrimidine 5′ nucleotidase deficiency was found. The patient had a severe hemolytic anemia in contrast with HbE homozygotes. Globin–chain synthesis experiments showed that the mechanism underlying the interaction between these two genotypes was a marked decrease in the stability of HbE in pyrimidine 5′ nucleotidase–deficient red blood cells. In these cells, free α-globin chains but not β^E-globin chains accumulated on the membrane. It was hypothesized that the marked instability of HbE in the enzyme-deficient cells resulted from oxidant damage to mildly unstable HbE.[37] Clearly this interaction also has the potential to modify the phenotype of HbE–β thalassemia.

Severe jaundice. In Sri Lanka, and probably in other regions of the Indian subcontinent, patients with HbE–β thalassemia are encountered quite commonly who have severe and persistent jaundice in the absence of definable liver disease. It turns out that this is due to the homozygous inheritance of the $TA_{(7)}$ allele of the promoter of the glucuronyltransferase 1 gene, a polymorphism that is particularly common in this population.[38] These patients have a highly significant increase in the incidence of gallstones. Homozygosity for the $TA_{(7)}$ allele occurs in 10%–25% of

some populations of Africa and the Indian subcontinent but at a much lower frequency in Southeast Asia.[39]

Conclusion. The genotypic factors that can be used to predict a mild phenotype in HbE–β thalassemia are mild β^+ thalassemia mutations, the coinheritance of α thalassemia, and the homozygosity for *Xmn*-l restriction site 5′ to the $^{G}\gamma$ globin gene. The *Xmn*-l-$^{G}\gamma$ site may not consistently predict the phenotype of HbE–β thalassemia. It is also clear that the complications of the disease, severe jaundice for example, may be affected by genetic modifiers.

Clinical Manifestations

HbE–β thalassemia is an important cause of childhood chronic disease in Southeast Asia. In contrast to thalassemia patients in developed countries, and for economic reasons, most Southeast Asian patients do not undergo transfusion or the transfusion is suboptimal, and iron chelation is uncommon. Patients show remarkable variability in the clinical expression of HbE–β thalassemia, ranging from a mild form of thalassemia intermedia to transfusion-dependent conditions clinically indistinguishable from homozygous β^0 thalassemia (Fig. 18.4). Approximately half of the patients have the thalassemia intermedia and half have the thalassemia major phenotype. In 803 HbE–β thalassemia patients, hemoglobin levels ranged from 3 to 13 g/dL and averaged 7.7 g/dL in the steady state.[14] As discussed earlier this remarkable variability in severity reflects the heterogeneity of β thalassemia mutations present with HbE and other modulating factors. A similar degree of phenotypic heterogeneity is also well characterized in patients living in Sri Lanka[31,40] and in immigrants, mainly from Bangladesh, living in the United Kingdom.[16,41]

At birth, infants with severe HbE–β thalassemia are asymptomatic because HbF levels are high. As HbF production wanes and is replaced by HbE at 6–12 months of age, anemia with splenomegaly develops. In the more severe phenotypes, almost without exception signs of impaired health are noted during the first decade of life. Clinical data in 378 patients with HbE–β thalassemia in Thailand are shown in Table 18.5. The initial complaints varied from patient to patient, and several symptoms usually appeared simultaneously. Most common was the development of a mass in the left upper quadrant and pallor. With time and without transfusions, anemia, jaundice, hepatosplenomegaly, retardation of physical development, and thalassemic facies evolve. Absence of secondary sexual development is common and chronic leg ulcers are sometimes observed. These clinical manifestations are secondary to decreased oxygen delivery to tissues, ineffective erythropoiesis and iron overload, and resemble those of untreated β thalassemia major (see Chapter 17).

The milder, nontransfusion-dependent phenotypes of HbE–β thalassemia also show considerable heterogeneity. Some patients grow and develop normally with only modest splenomegaly, despite having hemoglobin levels that are only 2–3 g/dL higher than those with more severe disease. Yet some of these patients pass through a normal puberty with good growth and sexual development, whereas others who have been asymptomatic through early childhood have delayed puberty with or without defective growth. Detailed studies in a group of children with HbE–β thalassemia in Sri Lanka, performed over 10 years,

have emphasized the instability of the phenotype during early development.[31,40,42]

Complications

Expanded Erythropoiesis. Erythrpoiesis is massively increased to 10–15 times normal because anemia stimulates erythropoietin production. Extensive erythropoiesis can be found in the liver, spleen, and bone and in extramedullary sites. Erythropoietic masses in the spinal canal can cause spinal cord compression and paraplegia, and when they occur intracranially convulsions may result.[43–45] Massive erythropoiesis leads to fragility and distortion of the bones and decreases bone density because of osteoporosis and osteomalacia, as observed in irregularly transfused thalassemia major patients.[46] Bone marrow expansion also increases blood volume, leading to high-output cardiac failure.

Iron Overload. Iron overload occurs without exception.[47] Excessive iron accumulates because of blood transfusions and enhanced gastrointestinal absorption.[48] The skin is darkened and iron deposition occurs in the bone marrow, liver, spleen, heart, pancreas, and elsewhere.[49–51] Arrhythmias are not as frequently encountered as in thalassemia major and although liver fibrosis from iron overload is common, ascites and other signs of cirrhosis are very rare. Diabetes mellitus secondary to iron deposition in the pancreas frequently develops in untreated adult patients if they live long enough.[52] We have observed a terminal wasting stage in some patients who lived into their third and fourth decades. These patients developed more skin pigmentation, poor appetite, weight loss, and increasing anemia, and eventually died. This is believed to result from organ failure caused by uncontrolled tissue oxidation from chronic, severe iron overload. As iron overload is a constant complication of thalassemia and iron is a strong oxidant, reduced levels of antioxidants such as vitamins C and E are common in these patients.[53]

Heart Disease. Half of the patients with HbE–β thalassemia in Thailand die of heart failure. This is associated with failure of other organs, delayed growth and sexual maturation, hepatomegaly, and endocrinopathies. Organ failure results from iron deposition in the heart and other tissues.[49–52] Myocardial iron deposition is mostly slight, occurring primarily as small granules in perinuclear areas, with later accumulation throughout the fibers, predominantly subepicardial, occasionally subendocardial.[54] The small amount of iron deposited in the heart is in marked contrast to enormous iron deposition in the liver and pancreas. Other causes of death are anemia, infection, constrictive pericarditis, and pulmonary artery occlusion. Cardiomegaly is proportional to the severity of anemia and systolic murmurs are frequently present.[55–57]

Chronic pericarditis following upper respiratory tract infection is frequently encountered, more so in splenectomized patients. A pericardial rub may be detected, often transiently. Intractable pericardial effusion may follow, causing cardiac tamponade and failure, and requires aspiration. In a very few cases chronic constrictive pericarditis develops, requiring surgical intervention. Histological examination of the pericardium shows nonspecific pericarditis.[54] Viral infection has been suspected as the cause of this pericarditis but has not been proven.

Infections. Prospective studies showed increased susceptibility to viral, bacterial, and fungal infection that may be causes of death in severe HbE–β thalassemia.[58–61] In splenectomized patients, septicemia can be very acute and overwhelming, leading to death in a short period. Gram-negative and Gram-positive bacteria are frequent causes of septicemia. Fungal infection with *Pythium* can lead to arterial occlusion and gangrene of the legs.[60,61] Investigators have not yet pinpointed the mechanisms that cause increased susceptibility to infections but iron overload and severe anemia may be involved.

Recent studies have suggested that patients with HbE–β thalassemia may be more prone to infection by both *Plasmodium falciparum* and *Plasmodium vivax* malaria and that those who have undergone splenectomy may be even more susceptible. The clinical significance of these findings remain to be determined.[62]

Jaundice and Gallstones. Stones are found in approximately 50% of patients.[63] As discussed earlier, they occur most frequently in a genetic subset of individuals with very high bilirubin levels in some populations.[38,39] For the detection of biliary calculi, ultrasonography is more sensitive than oral cholecystography and plain abdominal films. Cholecystitis and ascending cholangitis may occur with abdominal pain, fever, and increasing jaundice.[64] Antibiotics alone are usually not effective and cholecystectomy is necessary.

Hypertension, Convulsions, and Cerebral Hemorrhage. After multiple blood transfusions some patients in Thailand developed hypertension, convulsions, and cerebral hemorrhage after transfusion of 2 U or more of blood and many of them died.[65] This complication may develop as late as 2 weeks after multiple transfusions, suggesting that blood volume overload is not the cause of hypertension. Monitoring blood pressure during and after blood transfusions with prompt antihypertensive intervention has reduced deaths from this complication. This complication has not been reported in other populations.

Hypoxemia. A great majority of splenectomized HbE–β^0 thalassemia patients in Thailand develop hypoxemia with low arterial pO_2.[66] Platelet counts in splenectomized thalassemia patients are double that of nonsplenectomized patients; young and larger platelets are also observed in the absence of the spleen. Platelet microaggregates have been detected in the circulation of these splenectomized patients.[67] One hypothesis for the pathogenesis of hypoxemia in HbE–β^0 thalassemia is that platelets increase in

number, are younger and more active after splenectomy, and aggregate in the circulation and in the pulmonary vasculature. Substances released during platelet aggregation may cause constriction of the terminal bronchioles leading to decreased oxygenation and hypoxemia. A canine model showed that induction of platelet aggregation in the circulation reproduced the hypoxemia observed in splenectomized thalassemia patients.

Administration of aspirin to inhibit platelet aggregation reduces the degree of hypoxemia in the majority of cases,[68] suggesting that these agents should be routinely given to splenectomized patients with HbE–β thalassemia.

Interestingly, the combination of pulmonary hypertension and consequent hypoxemia has not been observed so frequently in other populations, suggesting that other factors may be involved in the Thai population.

Thromboembolism. Autopsy findings in a large number of patients with HbE–β thalassemia revealed striking pulmonary artery occlusion. Serial sections of the lungs revealed in some patients as many as 24 lesions/cm^2, the distribution of which indicated an embolism.[69,70] Thromboembolism in HbE–β thalassemia seems to involve platelets, a reactive thalassemic red cell surface, coagulation factors, and abnormal endothelium, but this problem is still under study.

Autoimmune Hemolytic Anemia. Some patients develop autoimmune hemolytic anemia with worsening anemia and a positive Coombs' test.[71] The condition is responsive to corticosteroids. Studies of HbE thalassemia patients with this condition showed that their red cell surface is an active site of complex immune reactions that are likely to be associated with many pathophysiological phenomena.[72]

Treatment

Because HbE–β thalassemia has such a variable phenotype and patients with this disorder, probably because they have relatively lower levels of HbF and reflecting the oxygen affinity of HbE, are able to adapt to anemia better than patients with other forms of β thalassemia intermedia, it is vital to observe young children with this condition after presentation for a reasonable period before deciding on the best approach to management. It is important to remember that they may present with a particularly low hemoglobin level consequent to a recent infection and it is particularly important therefore not to establish them on a regular transfusion until their steady-state hemoglobin level and level of growth and degree of splenomegaly has been assessed. Particularly in areas where malaria is endemic it is important to exclude chronic *P. vivax* infection as a possible cause of rapidly progressive splenomegaly.

The hemoglobin level alone should not be the major factor in initiating transfusion. Rather, the broader picture should be taken into account with particular attention to growth failure, lack of activity, and the earlier appearance of skeletal change. If it is clear that the patient will require regular transfusion the regimen to be followed, including chelation, is similar to that for the management of β thalassemia major (see Chapter 17). Those who do not require transfusion should be maintained on folic acid supplements and advised about the early treatment of infective episodes. Although some patients with increasing splenomegaly and evidence of hypersplenism may benefit from splenectomy, this should be avoided when possible because of the particularly high risk of infection.

Patients who do not require regular transfusion have serum ferritin estimations at least twice per year. Increased iron levels should be controlled by intermittent courses of chelating agents to maintain safe ferritin levels (see Chapter 17).

Hydroxyurea therapy may increase HbF levels,[73] although recent studies in other populations have shown that this effect is not great, even when combined with erythropoietin.[74] For those who present early with severe disease bone marrow transplantation remains an important option[75,76] (see Chapters 31 and 32).

Rapidly expanding extramedullary hemopoietic masses, particularly involving the brain or spinal cord, require urgent treatment by blood transfusion, hydroxyurea, or possibly, radiotherapy. Limited experience in those with profound jaundice due to genetic inability to conjugate bilirubin suggest that at least in some cases very low doses of phenobarbitone may be helpful.

Conclusions

HbE-β thalassemia is a major public health problem in Southeast Asia and in other Asian countries. Although some progress has been made toward a better understanding of its pathophysiology and clinical management a great deal remains to be learned. Recent work has made it absolutely clear that there must be other genetic modifiers to be discovered that are responsible for the variable phenotype. A better approach to predicting the phenotype is urgently required, particularly if prenatal diagnosis is to be widely used for the control of this condition and, even more so, if experimental forms of gene therapy become available in the future.

Because it may be some time before there are more definitive forms of treatment it is important to utilize the information that we already have more effectively. For example, in malarious areas it will be very important to conduct trials of malaria prophylaxis with particular respect to the phenotype of patients with this condition early in life. Because recent evidence suggests that the erythropoietin response to anemia tends to decline with age, the possibility of transient periods of transfusion during maximum erythroid expansion should be seriously considered.[29] Because genetic evidence indicates that the phenotype in this condition may be improved quite dramatically with only a modest increase in steady-state hemoglobin level,

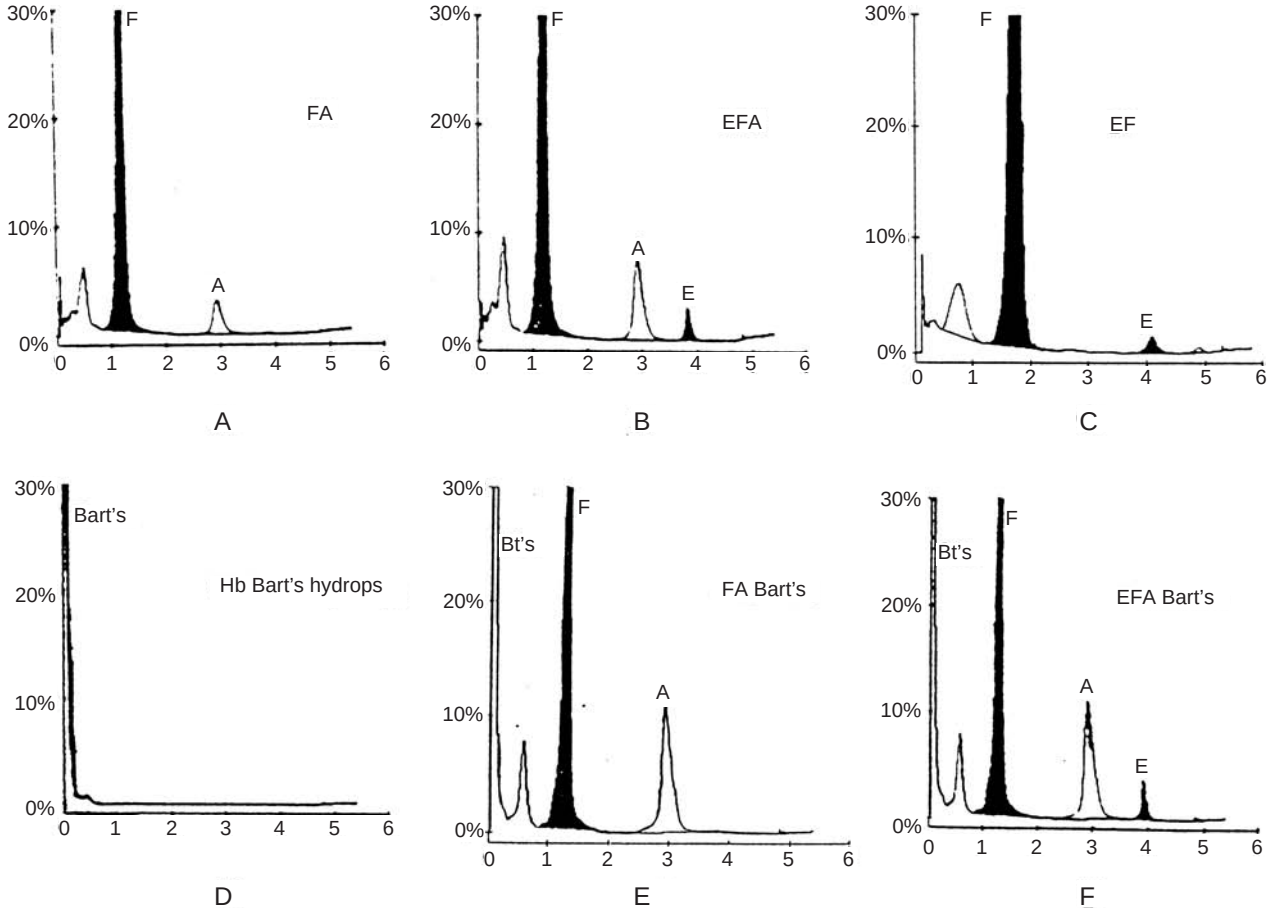

Figure 18.5. Chromatograms of newborns with HbE syndromes detected by automated HPLC. **(A)** Healthy newborn; **(B)** newborn with HbE trait; **(C)** newborn with HbE–β thalassemia; **(D)** newborn with Hb Bart's hydrops fetalis; **(E)** newborn with HbH disease; **(F)** newborn with HbAE Bart's disease.

more efforts should be directed at trying to raise the HbF level in these patients.

NEONATAL AND PRENATAL DIAGNOSIS

The amount of HbA_2 in normal newborns is lower than in adults and usually is not visualized by hemoglobin electrophoresis. Pootrakul et al.[77] observed a "slow" hemoglobin component at the position of HbA_2 that proved to be HbE. The mean HbE level, quantitated by cellulose-acetate electrophoresis, was 3.7%. An automatic high-performance liquid chromatography (HPLC) system (Variant™, Bio-Rad) was used to study various HbE disorders in cord blood (Fig. 18.5). HbE concentrations in homozygous HbE ranged between 3.9% and 14.9%. In HbE heterozygotes, HbE was between 2.1% and 10.3% with a mean of 4.5% (Table 18.6).[78] These data suggest that newborns with homozygous HbE have a tendency to have higher concentration of HbE than those with heterozygous HbE, but some overlap occurs. Furthermore, both homozygous HbE and HbE–β^0 thalassemia patients had similar chromatograms composed of HbE and HbF with similar amounts of HbE. DNA analysis is necessary to differentiate between these two syndromes.

Diagnosis of HbE syndromes can also be performed prenatally by cordocentesis at the gestational ages of 16–24 weeks.[79] The chromatograms obtained from cordocentesis using the automatic HPLC system were similar to those of the cord blood specimens. In the HbE heterozygote, 0.8%–1.5% of HbE was detected in addition to HbA. HbA was not present in fetuses homozygous for HbE or with HbE–β^0 thalassemia (Table 18.7). These two conditions were distinguished only by DNA analysis. Prenatal diagnosis of Hb–β thalassemia is now performed, if requested, by chorion-villus sampling and DNA analysis.

LABORATORY DIAGNOSIS IN ADULTS

The diagnosis of HbE is based on the electrophoretic or chromatographic separation of hemoglobins from peripheral blood. In alkaline buffer (pH 8.6), HbE migrates like HbA_2 on cellulose-acetate membranes but can be distinguished from HbA_2 by its higher concentration, more than 10% of the total hemoglobin. HbE also migrates like HbA_2 on HPLC columns.[78] Variable concentrations of HbE may reflect the genotypes of HbE disorders. In general, as

mentioned previously, HbE is 25%–30% of the hemolysate from heterozygotes and lower amounts of HbE are found with coinheritance of α thalassemia (Table 18.2) or with coexistence of iron-deficiency anemia. Lower proportions of HbE in heterozygotes indicate a concomitant inheritance of the more pronounced defects of α-globin chain synthesis as in HbAE Bart's disease.[10–12] In contrast, the amount of HbE is higher in HbE–β thalassemia and HbE levels of 85%–95% of total hemoglobin are found with homozygous HbE. Compound heterozygotes with HbE and HbC also appear to have very high HbE levels because HbC ($\alpha_2\beta^{6Glu\rightarrow Lys}{}_2$) coelectrophoreses with HbE ($\alpha_2\beta^{6Glu\rightarrow Lys}{}_2$) in the standard alkaline buffer. These two variants can be distinguished by agar gel electrophoresis at acid pH, or by reverse phase HPLC, and by the presence of approximately 45% HbC in the heterozygous state.[80]

The blue dye dichlorophenolindophenol can be used as a screening test for HbE, which has a weakened $\alpha_1\beta_1$ contact and precipitates on incubation with the dye at 37° C.[27] Homozygous HbE produces heavy sediments at the bottom of the tube whereas heterozygous HbE, HbH disease, and HbE–β thalassemia produce a cloudy or evenly distributed particulate appearance.

INTERACTIONS OF HEMOGLOBIN E WITH OTHER β-GLOBIN CHAIN VARIANTS

As well as the common interactions of hemoglobin E with the α and β thalassemias described in this chapter there have been occasional reports of interactions between HbE and other β-chain structural hemoglobin variants (Table 18.8). Although most of these interactions result in a

relatively mild clinical phenotype, because of their rarity they may cause difficulties in both diagnosis and for genetic counseling, particularly if prenatal diagnosis is being considered.

The interaction of HbE with HbS, HbSE disease, has been accounted occasionally in India and Sri Lanka and in other populations. The clinical features of this rare condition are discussed in Chapter 23.

The interactions between HbE and Hb Malay are of particular interest. Hb Malay occurs not uncommonly in Malaysia and Thailand and, like HbE, results from a mutation (β codon 19 AC-AGC; β19 Asn-Ser) that creates an alternative splice site, in this case between codons 17 and 18 (see Chapter 16). Hence it is synthesized at a slightly reduced rate and has a phenotype of the mild form of β thalassemia. From the limited amount of published data it appears that this interaction is associated with a relatively mild phenotype similar to that described earlier for the milder forms of HbE β thalassemia (see Weatherall and Clegg[16] and Table 18.8). Similarly, although the number of reported cases is too small to make any dogmatic statements, as shown in Table 18.8 interactions of HbE with unstable hemoglobin variants, Hb Dhonburi for example,[81] also seem to have been associated with mild phenotypes, and the same seems to apply to the few reported interactions with different forms of Hb Lepore.

SECTION FIVE

SICKLE CELL DISEASE

Martin H. Steinberg

PATHOPHYSIOLOGY

A β-hemoglobin gene mutation results in the synthesis of the sickle β-globin chain. Sickle hemoglobin (HbS) polymerizes when deoxygenated, and polymer-associated injury to the sickle erythrocyte is the proximate cause of sickle cell disease. The principal pathophysiological features of this disease are shown in the figure and can be grouped as vasoocclusive/blood viscosity related and hemolysis/vasculopathy related. This complex pathophysiology involves diverse molecular and cellular defects that include abnormal erythrocyte volume regulation, impaired nitric oxide bioavailability, reperfusion injury and inflammation, altered hemostasis, defects of intercellular interactions, endothelial cell damage, leukocyte and platelet activation, and in all probability, other perturbations of normal physiology.

DIAGNOSIS

Sickle cell disease is a constellation of similar but not identical disorders, all of which have at least 50% HbS in the blood. The phenotype of sickle cell disease is caused by several common and some less common genotypes; homozygotes for the HbS gene are said to have sickle cell anemia; common compound heterozygous forms of disease include HbSC disease and HbS-β thalassemia. The cornerstone of the clinical laboratory diagnosis is the detection and quantification of HbS. Depending on the context of the diagnostic situation, direct detection of the HbS and other globin gene mutations can be warranted. Sickle cell trait is clinically benign and not considered a form of sickle cell disease.

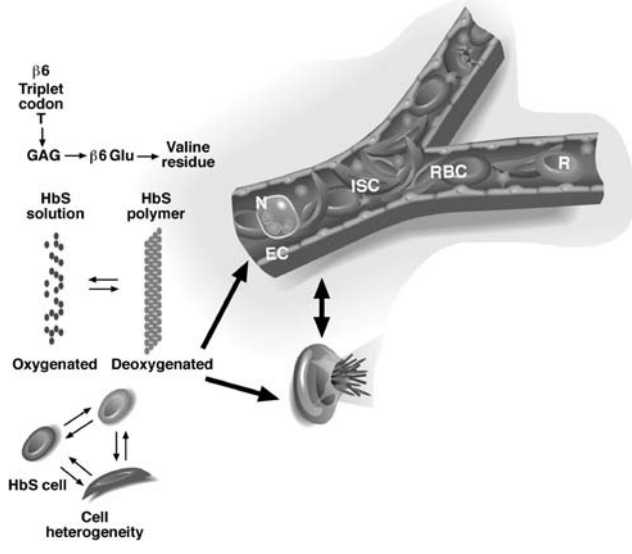
CLINICAL FEATURES

The complications of sickle cell disease can occur acutely, producing dramatic clinical findings, or they can be chronic, disabling, and cause premature death. For example, pulmonary hypertension is usually silent but is associated with a grave prognosis. The clinical features of sickle cell disease are heterogeneous. Fetal hemoglobin, α thalassemia, and compound heterozygosity for other variant hemoglobins such as HbC or β thalassemia are well-known determinants of the phenotype.

Acute painful episodes are the most common clinical events. Most often they begin with little warning. In some patients it is difficult to distinguish among new episodes of acute pain, chronic pain with acute exacerbations, therapy-induced pain, and pain made worse by major psychosocial issues. Insufficient doses of opioid analgesics, given at infrequent intervals, is the most common deficiency in pain treatment.

The acute chest syndrome, with fever, chest pain, cough, hypoxia, and lung infiltrates affects more than half of all sickle cell anemia patients. It is most common but least severe in young children, in whom it is often secondary to infection. In adults, pain often precedes this event, and mortality is higher than in children. Fat embolism from necrotic bone marrow is a common cause of the most severe acute chest events. Sometimes, fat embolization is accompanied by dramatic falls in the hemoglobin and platelet levels, marked leukocytosis, and multiorgan failure. Recognizing acute chest syndrome is critical because aggressive treatment with oxygen, blood transfusions, bronchodilators, and antimicrobials can be lifesaving.

Strokes occur in approximately 10% of children with sickle cell anemia and are more rare in other genotypes.



Pathophysiology of sickle cell disease. The nucleotide and amino acid substitution of HbS leads to the replacement of a glutamic acid residue by a valine residue. On deoxygenation, HbS polymer forms, causing cell sickling and damage to the erythrocyte membrane. Some cells adhere to the endothelium and cause vasoocclusion. Other cells are destroyed within the circulation, releasing hemoglobin and arginase and depleting bioavailable nitric oxide (Chapters 10 and 11).

Prophylactic blood transfusion can prevent a stroke in high-risk individuals. A current focus is how better to predict who will have clinically significant cerebrovascular disease and how this might best be managed. Survival decreases and the risk of stroke increases as blood pressure increases, even though it is within the "normal" range.

Osteonecrosis, seen in approximately half of all patients, most often affects the heads of the femur and humerus. In some individuals, it culminates in a severely painful or a useless joint that requires surgery.

Pulmonary hypertension affects approximately a third of adults with sickle cell anemia. Although usually mild, when defined in terms of pulmonary artery systolic pressure, its presence portends a poor prognosis as at least a quarter of patients die within 2 years of its detection.

Other severe complications are leg ulcers, priapism, nephropathy with renal failure and severe anemia with advancing age, and sickle retinopathy, especially in HbSC disease and liver disease. Infections are common and major causes of death in children and adults.

Treatment. Treatment for sickle cell disease is evolving and many clinical trials of new agents are in progress. With the exceptions of transfusions to prevent stroke, hydroxyurea for prevention of painful episodes, and prophylactic penicillin for prevention of pneumococcal disease in children, controlled clinical trials have not established the superiority of any treatment modality. Nevertheless, much can be done to promote better health of the individual, including good nutrition and avoidance of extremes of temperature and dehydration, genetic counseling for couples at risk for having affected children, and neonatal screening to identify infants with sickle cell disease and directing their parents toward comprehensive care programs that provide recommended immunizations and prophylactic penicillin.

The following five chapters discuss in detail the topics outlined previously.

19

Clinical and Pathophysiological Aspects of Sickle Cell Anemia

Martin H. Steinberg, Kwaku Ohene-Frempong, and Matthew M. Heeney

INTRODUCTION

Many authors have recounted the history of sickle cell disease in Africa and its first recognition in the United States[1–3] Sickle-shaped red cells were first described in 1910 in the blood of a sick, anemic student from Grenada.[4,5] Sickle hemoglobin (HbS) was identified in 1949 and the mechanism of inheritance of sickle cell anemia was established afterward.[6–8] A single amino acid difference was found to distinguish the sickle β-globin chain from the normal one.[9] The breadth of clinical and laboratory manifestations of sickle cell disease and its multitudinous complications still challenge the pediatrician, internist, general surgeon, obstetrician, orthopedist, ophthalmologist, psychiatrist, and subspecialists in each of these disciplines.

The features of sickle cell anemia change as life advances. Life's first decade, with declining fetal hemoglobin (HbF) levels, is typified by a risk of severe life-threatening infection, dactylitis, acute chest syndrome, splenic sequestration, and stroke; pain is often the torment of adolescence. If the worst of childhood and adolescent problems are survived or escaped, young adulthood can be a time of relative clinical quiescence, but sickle vasculopathy is likely to progress despite producing few symptoms. Chronic organ damage leading to pulmonary hypertension, deteriorating pulmonary function, renal failure, and late affects of previous cerebrovascular disease, including neurocognitive impairment, become paramount as years advance. Sickle cell anemia is noted for its clinical heterogeneity (Chapter 27). Any patient can have nearly all known disease complications; some have almost none, but die with a sudden acute problem. Some skip one or more phases of the disease but suffer intensely from others.

For convenience, when discussing the most common clinical events of sickle cell anemia, we have grouped these by the age group in which a complication is most likely to occur, although nearly every complication can occur at any age. As in other chapters, because of space constraints, many early references are omitted to allow inclusion of new material. Most of these citations can be found in the first edition of this book.[10]

PREVALENCE OF DISEASE AND LABORATORY DIAGNOSIS

Prevalence

Outside Africa, the prevalence of HbS depends primarily on gene flow from Africa to the Middle East, Asia, Europe, and the New World, modulated by genetic admixture with indigenous populations. Variations in the prevalence of HbS from within a country or geographic region are due to the presence of malaria, population isolates, altitude, and miscegenation. Although HbS is widely distributed in Caucasian populations, this is usually not the result of selection, but of ancient wars and migration, the slave trade, and generations of genetic admixture. In India, Greece, Turkey, Italy, and elsewhere in the Old World, HbS, excluding recent migrants from Africa or the Caribbean, is found mainly in Caucasians. In the United States, the prevalence of HbS in Caucasians varies according to the population examined, but it is usually less than 0.1% and is invariably found with African or Arab–Indian β-globin gene cluster haplotypes (Chapter 27). Table 22.1 in Chapter 22 shows the prevalence of the HbS gene in some African locations and throughout the world.

In African Americans, the incidence of sickle cell anemia at birth was estimated to be approximately 1 in 600 and the incidence of all genotypes of sickle cell disease approached 1 in 300.[11] These estimates and the distribution of disease in the United States have surely changed because of new immigrants from the Caribbean region, Central and South America, the Middle East, Africa, and India. In Paris, 1 in 900 newborns has sickle cell disease and in Salvador, Bahia, Brazil, approximately 1 in 500 newborns is affected. Although the treatment of complications of sickle cell disease differs little among its genotypes, knowing the genotype is critical for genetic counseling.

Diagnosis

Imprecision defining sickle hemoglobinopathies has permeated the medical literature. Sickle cell disease is a phenotype, expressed in patients with different genotypes. We use the following definitions:

- Sickle cell disease – at least half the hemoglobin is HbS and patients have distinguishing clinical and hematological features
- Sickle cell trait (HbAS; Chapter 22) is clinically benign and blood counts are normal, so it is not a form of sickle cell disease
- Individuals homozygous for the HbS gene (*HBB*, glu6val) are said to have sickle cell anemia

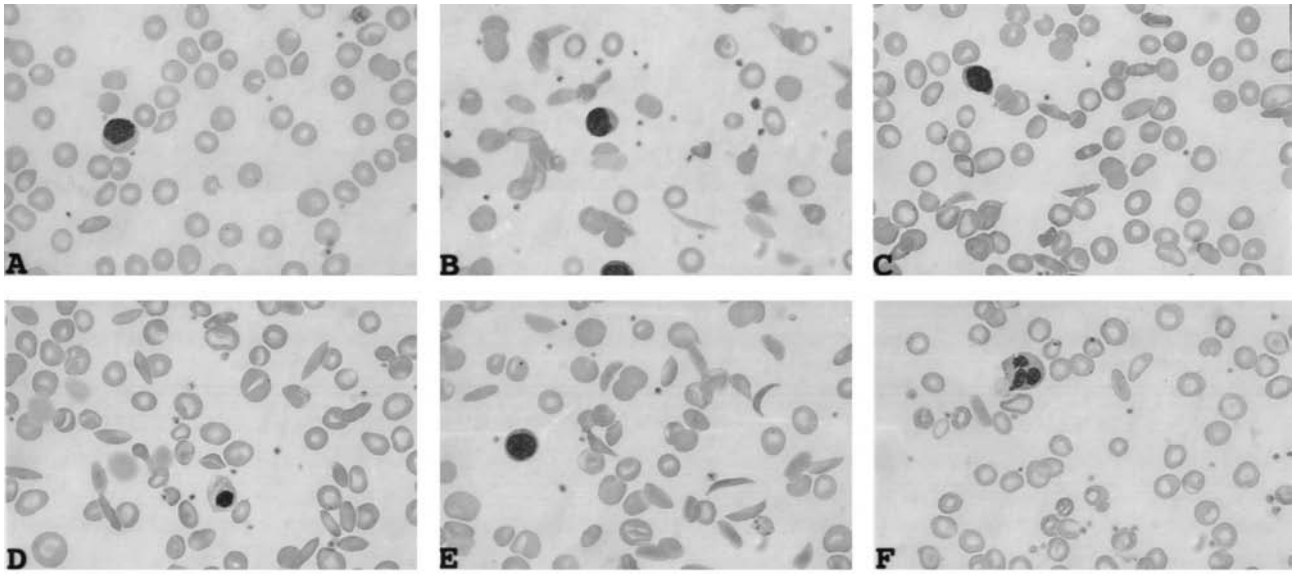


Figure 19.1. Blood films in patients with sickle cell anemia and average or low HbF levels. HbF in these patients are **A**-0.5%, **B**-1%, **C**-4%, **D**-5%, **E**-7%, and **F**-10%. Patients C and F were taking hydroxyurea. Although some of these patients have more ISCs than patients depicted in Figure 19.2 who have high HbF concentrations, note that patient A with the lowest HbF level has very few sickled cells. See color plates.

- Compound heterozygous forms of sickle cell disease include HbSC disease (*HBB* glu6val, glu6lys), HbS-β thalassemia (*HBB* glu6val and a β thalassemia mutation), and less common types (Chapters 21 and 23).

Diagnosing sickle cell disease is not difficult but determining the correct genotype can be problematic if family studies and access to molecular diagnostic methods are not available. Examining the blood of parents or siblings of affected patients is the least costly way of establishing the genotype and can be done with simple combinations of blood counts and quantitative studies of hemoglobin fractions.

Blood Counts and Erythrocyte Indices

In sickle cell anemia, the erythrocytes are normocytic or macrocytic, depending on the reticulocyte count and the presence or absence of confounding conditions such as iron or folic acid deficiency and coincident α thalassemia (Chapter 23). Microcytosis in a suspected case of sickle cell anemia can be seen very early in life before erythropoiesis has fully matured, when iron deficiency has developed or when α thalassemia is present. HbS–β^0 thalassemia, a phenocopy of sickle cell anemia but with microcytosis, and sickle cell anemia–α thalassemia are addressed in Chapter 23. These two conditions are very alike hematologically and clinically and their distinction from each other is difficult lacking genetic testing or family studies. In an individual, they cannot be separated using hemoglobin analysis or blood counts alone. Typical blood counts and erythrocyte indices in these genotypes are shown in Table 23.2 of Chapter 23.

Blood Films

Sickled cells are nearly always seen in sickle cell anemia and HbS–β^0 thalassemia but are less common in other genotypes. Typical blood films from patients with sickle cell anemia with high, average, and low HbF concentrations are shown in Figures 19.1 and 19.2. Some patients have many irreversibly sickled cells (ISCs), nucleated red cells, Howell–Jolly bodies, and polychromatophilic cells, whereas others have far fewer. In adults, ISCs remain relatively constant over time, although their percentage increases early in a painful episode (Chapter 20).[12]

Detecting HbS and Measuring Hemoglobin Fractions

From neonatal life through early adult life, there is a slow but continual fall in HbF, whereas HbA_2 levels increase until ages 1–2 years. With few exceptions, the hemoglobin fractions present at age 1 year are sufficiently stable to be relied on for diagnosis. In untreated sickle cell anemia, HbS nearly always forms more than 80% of the hemolysate, except in infancy when the γ- to β-globin gene switch is incomplete. HbS can be detected by isoelectric focusing, hemoglobin electrophoresis, or high-performance liquid chromatography (HPLC). Hemoglobin fractions are best measured by HPLC or capillary electrophoresis. Sickling hemoglobins can be detected chemically because they are insoluble and precipitate in high-molarity phosphate buffer when

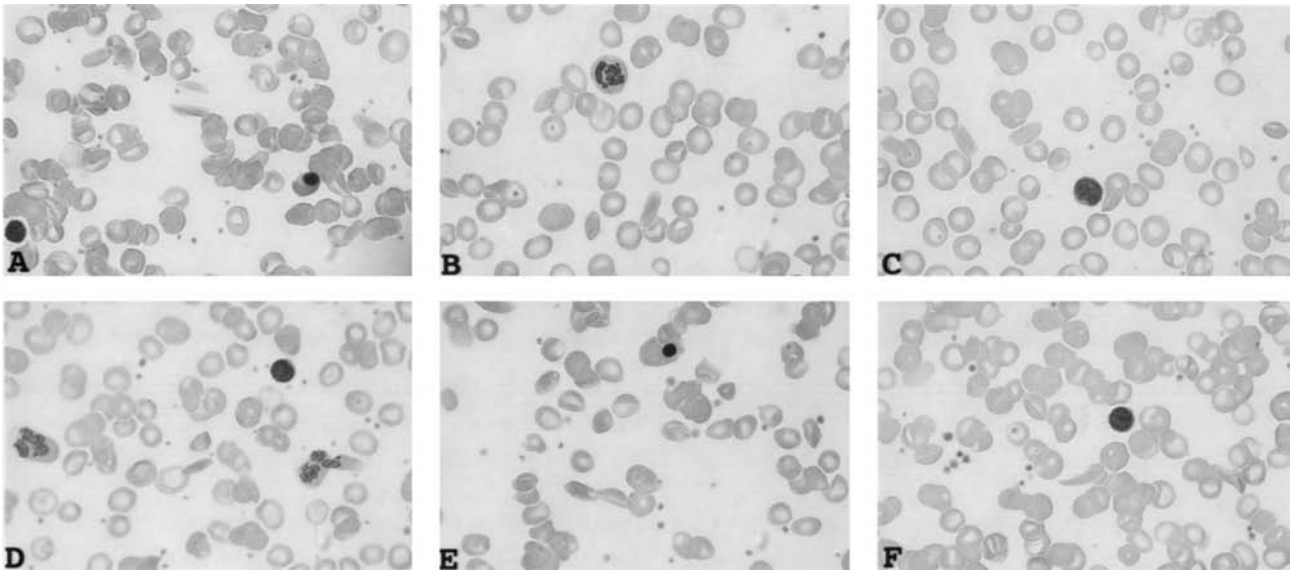

Figure 19.2. Blood films in patients with sickle cell anemia and high HbF levels. HbF in these six patients are **A**-19%, **B**-18%, **C**-19%, **D**-21%, **E**-20%, and **F**-23%. All patients were receiving hydroxyurea. All still have sickled cells in the blood and these are particularly prominent in patient A. Also note nucleated red cells in A and E. (See color plate 19.2.)

reduced with sodium dithionite, but these sickle solubility tests should not be used as the sole means of detecting HbS or other sickling variants because their results are not quantifiable and they cannot reliably distinguish among genotypes of sickle cell disease and HbAS. DNA-based methods of detecting the HbS mutation are now widely available and are definitive (Chapter 28).

PATHOPHYSIOLOGY

Major features of the pathophysiology of sickle cell disease such as HbS polymer, erythrocyte membrane abnormalities, sickle vasculopathy, and hemolytic anemia are discussed in Chapters 6, 8, 9, 10, and 11. Sickle vasoocclusion and hemolytic anemia are the two major features of disease pathophysiology. Reappraisals of the contributions of hemolysis and sickle vasoocclusion to the phenotypes of the disease and novel insights into the role of nitric oxide (NO) in sickle vasculopathy have led to new pathophysiological insights (Chapters 10 and 11).

A New View of Sickle Cell Pathophysiology: Hemolysis and Viscosity–Vasoocclusive Phenotypes (for a more detailed discussion, see Chapter 11)

Hemolysis, long discounted as a critical measure of sickle cell disease severity when compared with sickle vasoocclusion, might be the proximate cause of some severe disease complications and a major predictor of mortality. Hemolytic anemia is most severe in patients with sickle cell anemia, less severe in individuals with sickle cell anemia and concurrent α thalassemia, and least severe in patients with HbSC disease and HbS–β^+ thalassemia. Even within a single genotype, the hemoglobin concentration is variable because of different rates of hemolysis.[13–17]

Intravascular heme reduces NO bioavailability. NO binds soluble guanylate cyclase, which converts guanosine triphosphate to cyclic guanosine monophosphate (cGMP), relaxing vascular smooth muscle and causing vasodilation. A state of reduced endothelial NO bioavailability in sickle cell disease impairs downstream homeostatic vascular functions of NO, such as inhibition of platelet activation and aggregation and transcriptional repression of the cell adhesion molecules, vascular cell adhesion molecule (VCAM)-1, intercellular adhesion molecule (ICAM)-1, P-selectin, and E-selectin. Hemoglobin, heme, and heme iron catalyze the production of oxygen radicals, further limiting NO bioavailability and activating endothelium. Lysed erythrocytes also liberate arginase that destroys L-arginine, the substrate for the NO synthases. Reactive oxygen species, generated at high rates in patients with sickle cell anemia, also consume NO. The normal balance of vasoconstriction to vasodilation is therefore skewed toward vasoconstriction, endothelial activation, and proliferation. Both hemolysis and splenectomy are associated with red cell membrane damage, phosphatidylserine exposure at the red cell membrane surface, activation of tissue factor, and thrombosis. Chronic anemia and tissue ischemia might also contribute to a proliferative vasculopathy via activation of hypoxia inducible factor (HIF)-1α–dependent factors such as inducible nitric oxide synthase (iNOS), erythropoietin, and vascular endothelial growth factor (VEGF).[18]

Clinical studies suggest a close association of hemolysis with the subphenotypes of pulmonary hypertension, priapism, leg ulceration, and perhaps ischemic stroke.[19–26] Individuals with the highest rates of hemolysis also had a

greater risk of death.[27] The frequency of painful episodes has also been associated with mortality.[28] Perhaps this association is mediated by increased hemolysis during painful episodes with a rise in pulmonary artery systolic pressure.[29] Hemolysis-related complications occur less often in patients with HbSC disease and sickle cell anemia–α thalassemia. HbF appears to have a lesser effect in modulating these phenotypes compared with the viscosity–vasoocclusive phenotypes of painful episodes, acute chest syndrome, and osteonecrosis.

Hemolysis might also be linked to vasoocclusive disease via the adhesive properties of the sickle reticulocyte. Sickle reticulocytes, whose numbers reflect in part the bone marrow response to hemolysis, adhere to endothelium and to leukocytes and are the most adherent of the heterogeneous population of sickle erythrocytes. Sickle erythrocyte adherence varies according to the hemoglobin genotype being most manifest in sickle cell anemia. Even among patients with this genotype, adherence varies approximately 20-fold. Because most of the endothelial cell adhesion molecules that bind sickle reticulocytes are normally suppressed by NO, decreased NO bioavailability might also contribute to sickle erythrocyte adherence.

Distinct from the hemolysis-related phenotypes are ones associated with increased blood viscosity and vasoocclusion, such as osteonecrosis, acute chest syndrome and painful episodes. Adversely affected by α thalassemia, their prevalence is directly associated with hemoglobin concentration; high HbF levels have a protective effect.

Hemolytic anemia–induced phenotypes are likely to be improved by transfusion, by agents that increase NO bioavailability and drugs that reduce intravascular hemolysis, but helped to a lesser extent by drugs that induce HbF expression.[30,31] Drugs that induce the production of HbF appear to reduce the incidence of painful episodes and acute chest syndrome.[32,33]

Hemolytic and viscosity–vasoocclusive phenotypes must have substantial areas of overlap and HbF is likely to play a role in all disease complications. Nevertheless, this dichotomization of pathophysiology helps place subphenotypes of sickle cell disease into a new context with implications for therapeutics, for example, by devising drug combinations that target multiple limbs of the pathophysiological tree.[18] One can envision combining a drug or drugs that induce HbF expression with agents that reduce sickle erythrocyte density, adhesive interactions of sickle cells, and the inflammatory response.[34]

Chronic activation of the hemostatic system has also been considered part of the pathobiology of sickle cell disease and might be the consequence of the exposure of aminophospholipids in the sickle erythrocyte, endothelial dysfunction with thrombin generation, and platelet activation, among other factors.[35,36] Platelet activation was correlated with the severity of pulmonary hypertension and also with reticulocyte count but not with lactate dehydrogenase (LDH). When exposed to cell-free hemoglobin, basal- and agonist-stimulated platelet activation was increased. In patients, sildenafil reduced platelet activation. These findings suggested a possible interaction among hemolysis, decreased NO bioavailability, and pathological platelet activation that might contribute to thrombosis and pulmonary hypertension.[37]

CLINICAL FEATURES OF SICKLE CELL ANEMIA

In the following discussion of the clinical features of sickle cell anemia complications are grouped by the age at which each is paramount. Painful episodes and their management are discussed separately in Chapter 20. Two large observational studies, one in Jamaica and the other in the United States, have provided much of our most reliable information on the clinical course and complications of sickle cell disease in developed countries. The Cooperative Study of Sickle Cell Disease (CSSCD) followed nearly 4,000 patients, including a newborn cohort of 694 patients, over a span of 20 years.[38–40] In Jamaica, a newborn cohort of more than 300 individuals and their matched controls, have been followed even longer.[41] Both studies have substantial patient numbers, longitudinal data collection, and biological sample repositories that can be used for genetic studies and measurement of newly developed disease markers. The inclusion of newborn cohorts in these studies eliminated the bias of studying only patients seeking medical care. Nevertheless, these studies are now decades old and their databases do not include complications of disease that were more recently recognized and do not report current methods of clinical and laboratory testing. Newly ascertained patient databases with their associated biological samples are needed.

Few controlled clinical trials of the treatment of the complications of sickle cell anemia are published and progress in this area has been slow. There were a number of questions posed in the first edition of this book: How should acute chest syndrome be managed? Is exchange transfusion superior to simple transfusion? Can preoperative transfusion sometimes be avoided? Do angiotensin-converting enzyme inhibitors delay sickle nephropathy? How is priapism best managed? How aggressively should blood pressure be lowered to decrease the chance of stroke? These questions have yet to be answered.

We will summarize recent information about the complications of sickle cell disease and provide explicit recommendations for treatment based on controlled clinical trials, in the few instances where they are available. In most cases, however, lacking the results of such studies, we will recommend management strategies based on experience with similar problems in other diseases, data from observational studies, expert opinion, and our understanding of the pathophysiology of sickle cell disease.

Assessing the Severity of Sickle Cell Disease

Knowing the elements of disease that put patients at risk for selected complications, overall disease severity and death

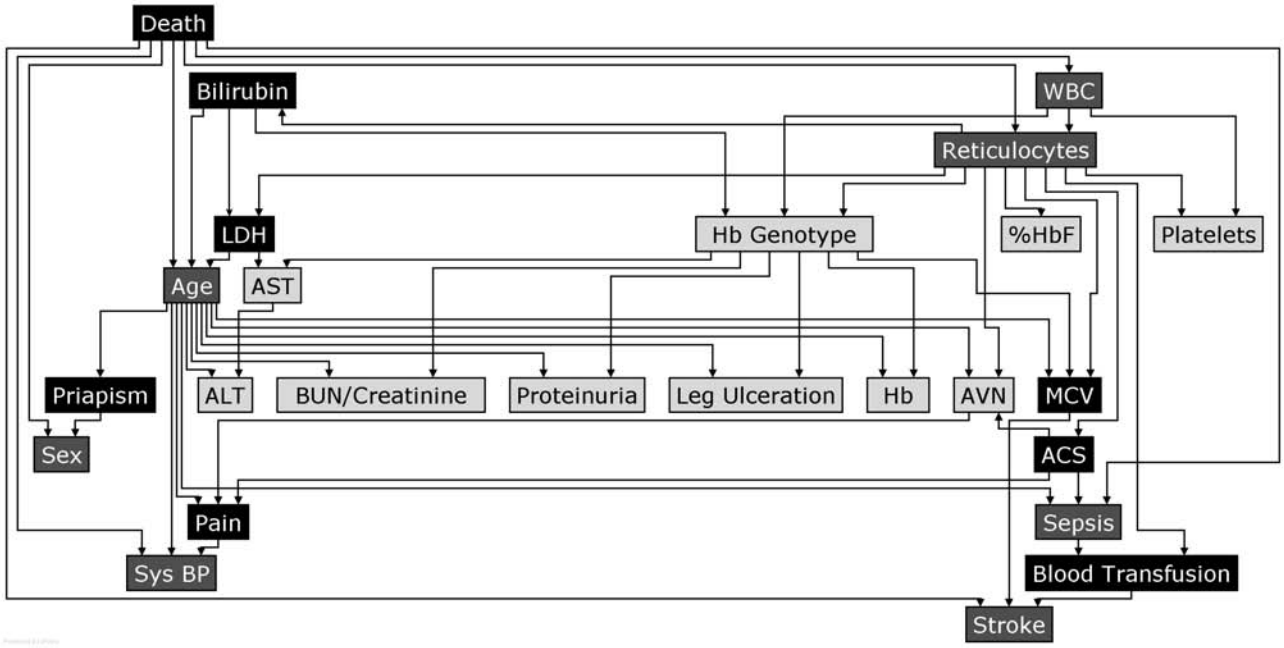

Figure 19.3. A Bayesian network model of the risk of death in sickle cell disease.[44] (See color plate 19.3.)

would have great value for patient counseling, planning therapy, and the development of novel treatments. A study was done of 392 infants with sickle cell anemia or HbS–β^0 thalassemia from the CSSCD. Nine years of clinical and laboratory data were available for analysis and an additional 115 infants were used for validation. Severe outcomes were defined as death, stroke, two or more painful episodes per year for 3 consecutive years, and one or more acute chest events per year for 3 years. Seventeen percent of the newborn cohort was identified as severe. A severe endpoint was achieved at a mean age of 5.6 ± 3.8 years. Hemoglobin levels of less than 8 g/dL, leukocyte counts more than 20,000/mm^2, an episode of dactylitis in patients aged younger than 1 year, and an elevated percentage of "pocked" red blood cells by age 1 year were significant predictors of adverse outcomes and combined identified 10.5% of the cohort, with a 0.35–0.71 probability of a severe outcome by age 10 years. Application of the severity model to the validation cohort yielded 100% positive predictive value and an 88% negative predictive value.[42] Unfortunately, in another study of children, this result could not be replicated.[43] In 168 children followed for up to 7.1 years, no relationship existed between these early clinical predictors and later adverse outcomes, with the possible exception of leukocyte count. At this moment, clinical and laboratory features seem unreliable means of making prognoses in young children.

Using Bayesian network modeling and data from 3,380 sickle cell disease patients of all ages and multiple genotypes, a severity score was constructed that estimated the risk of death within 5 years.[44] The predictive value of this score was validated in two independent patient groups: 140 adults and children in whom severity was assessed by expert clinicians and 210 adults in whom severity was also assessed by the echocardiographic diagnosis of pulmonary hypertension and death. A network of 24 variables described complex associations among complications of sickle cell disease and its laboratory variables (Fig. 19.3). In addition to known risk factors, the severity of hemolytic anemia and clinical events associated with hemolytic anemia were major contributors to risk for death. By capturing multiple effects that could be synergistic or antagonistic, according to the overall clinical presentation, the model could be used to compute a personalized measure of disease severity. A model calculator can be used to assess the clinical severity of patients with sickle cell disease, given any clinical profile (www.bu.edu/sicklecell/downloads/Projects).

This analysis suggested that the intensity of hemolytic anemia, estimated by LDH, reticulocyte count, and aspartate aminotransferase (AST), is an important contributor to death. Systolic hypertension, associated with pulmonary hypertension in patients with sickle cell disease, is an important predictor of mortality and might reflect the decrease in NO bioavailability that characterizes hemolytic anemia. Polymorphisms in key genes that modulate the pathobiology of disease that might underlie severity and the propensity to develop subphenotypes of disease are discussed in Chapter 27.

THE NEONATE

At birth and for the first few months of life, children with sickle cell disease usually do not have typical vasoocclusive complications. This is likely to be due to the persistence of very high HbF levels. The CSSCD reviewed birth outcome

Table 19.1. Incidence of major clinical events in children with sickle cell anemia in the first decade

Age (y)	Hand–foot syndrome	Painful event	Acute chest	CVA	Acute anemia		Bacteremia
					Spleen	Other	
< 0.5	14.6	2.9	6.8	0.0	1.0	2.9	1.9
0.5–1	31.3	9.5	16.4	0.0	5.5	5.0	9.9
1	20.0	24.0	26.8	0.3	6.2	1.7	6.5
2	11.0	38.3	26.3	1.3	5.3	3.3	8.7
3	3.5	42.4	34.2	0.4	2.0	5.9	4.7
4	2.0	49.6	25.5	1.5	1.5	3.9	2.0
5	0.0	40.8	22.5	0.7	1.4	2.0	0.0
6	0.0	39.2	28.9	2.1	1.0	8.3	4.1
7	0.0	41.6	20.8	1.5	0.0	3.0	1.5
8–10	0.0	37.9	15.2	0.0	0.0	1.9	0.0

Incidence rates per 100 person-years from 427 children with sickle cell anemia observed in the Cooperative Study of Sickle Cell Disease, from October 1978 to October 1988.[38]

and neonatal clinical course of 480 infants with sickle cell disease. Rates of preterm birth (aged <37 weeks), low birth weight (<2500 g) and small for gestational age were 9%, 10%, and 8%, respectively, and similar to those in all African Americans. These figures were similar among the different genotypes of sickle cell disease. Fifty-nine percent of newborns with sickle cell disease with a low birth weight were born at term compared with 41% of all African Americans with low birth weight, a significant difference.[45]

Although the onset of clinical manifestations of vasoocclusive disease can be delayed, laboratory evidence of the presence of hemolytic disease is present early. Neonatal hyperbilirubinemia has been reported at a higher rate in newborns with sickle cell disease. The prevalence of anemia in newborns with sickle cell disease in the United States is unknown because hemoglobin levels are not measured routinely on full-term, well-appearing newborns. The Jamaican cohort study reported that compared with controls, neonates with sickle cell anemia had a lower than normal hemoglobin concentration as early as age 2 weeks. In a longitudinal study on the hematological changes in children with sickle cell disease followed from birth to age 5 years, the CSSCD reported that anemia and reticulocytosis were apparent by age 10 weeks in patients with sickle cell anemia.[46] There are no physical features in a newborn with sickle cell disease that would raise the clinician's suspicion of this diagnosis. That is why screening programs are the most effective way to identify patients prior to the onset of clinical complications and at present, such programs are in place in all states (http://genes-r-us.uthscsa.edu/nbsdisorders.pdf) and in may sites in countries with a high incidence of disease.

INFANTS

The CSSCD collected data prospectively on clinical complications of disease in 694 babies.[38] Table 19.1 shows the frequency of the most common complications and their prevalence or incidence at different ages in children with sickle cell anemia up to age 10 years. With the exception of acute chest syndrome, which occurred more frequently in boys than in girls (29.1 vs. 20.1 per 100 person-years), and painful events, which had a higher incidence in girls (35.7 vs. 28.9), there were no sex differences in the occurrence of most of these complications. Constant or episodic scleral icterus and the pattern of recurrent pain in limbs and abdomen often become established in the first year of life. Splenomegaly, another manifestation of sickle cell disease in children, is present in a few infants with sickle cell anemia aged younger than 6 months. The spectrum of complications was the same in children with HbSC disease but complications occurred at lower rates and at later ages. It is evident that even at the ages when HbF levels are expected to be high, some children with sickle cell disease face increased risk for vasoocclusive complications. The high incidence of pneumococcal bacteremia in infancy is explainable by the documentation of early splenic dysfunction (discussed later).

In children not detected through newborn screening, it is difficult for unsuspecting physicians to determine the existence of sickle cell disease on the basis of physical examination alone. The earliest physical sign of the disease is often dactylitis ("hand–foot syndrome"), manifested as painful swollen hands and feet. In sickle cell anemia, anemia is present early, with a mean hemoglobin level of 9.3 g/dL at age 3 months, and remains at the same level until after age 18 months, when it falls below 9.0 g/dL. Over the same period, the mean HbF level drops from 40.4% to 17.1%.[46] It is unclear why this large fall in HbF concentration has so little effect on the degree of anemia, but it could be related to the rise (5.4%–10.4%) in mean reticulocyte count over the same period.

FIRST 10 YEARS

In the first decade of life, the most common sickle cell disease–related clinical events are painful episodes and acute chest syndrome. Pain, presumed to be caused by vasoocclusive ischemia, often starts as the hand–foot syndrome, when the feet and hands become swollen and tender because of inflammation of the metacarpal and/or metatarsal periosteum. When accompanied by fever and persistent localized tenderness and erythema, osteomyelitis should be ruled out. Beyond infancy, the pattern of recurrent pain, typical of sickle cell disease, usually becomes established. The management and pathophysiology of sickle cell disease–related pain is discussed in Chapter 20.

The Spleen in Early Childhood

The spleen undergoes immense changes in function and size in the early life of children with severe forms of sickle cell disease. In sickle cell anemia and HbS–β^0 thalassemia, splenic dysfunction begins in infancy. This has been demonstrated in a series of studies first using technetium-99m sulfur-colloid liver-spleen scans, and later by the presence of increased circulating "pocked" or "pitted" red cells as measures of splenic function. Splenic dysfunction is the primary cause of the increased incidence of and mortality from bacterial infection in young children with sickle cell disease. Splenomegaly is a common feature of sickle cell disease in early life. The onset of splenomegaly and the prevalence of splenomegaly at different ages are different among the major genotypes and among different sickle cell disease populations around the world. In the United States, splenomegaly is seen in children with sickle cell anemia who are aged 1–5 years, but it is rare in older children. Splenomegaly persists longer in patients with HbS–β^0 thalassemia and in patients with HbSC disease in whom it is present over a wider age range. In Jamaica, early splenomegaly was found to be associated with increased susceptibility to infection and low HbF concentrations. Greek patients with sickle cell anemia had persistent splenomegaly at a higher rate than did Jamaicans.

When 43 children with sickle cell disease had splenic function measured before and during treatment with hydroxyurea for a median duration of 2.6 years, six patients (14%) completely recovered splenic function and two (5%) had preserved splenic function, suggesting that hydroxyurea might help preserve or recover splenic function.[47]

Persistent gross splenomegaly, related to endemic malaria, is common in patients with sickle cell disease residing in Africa. The frequency of splenomegaly was higher in a group of Nigerian children with sickle cell anemia compared with age-matched patients from the United States. Nigerian children with persistent gross splenomegaly had more frequent episodes of acute anemia, a complication commonly associated with acute attacks of malaria. Persistent massive splenomegaly is often associated with a hematological picture of hypersplenism with lower hemoglobin levels, platelet, and leukocyte counts than expected for age and hemoglobin genotype.

Growth and Development: Nutrition

Growth, Development, and Energy Expenditure. Delayed growth and sexual development become major issues of concern to the adolescent. Growth delay starts in early childhood but becomes more apparent during adolescence when the growth spurt of normal children separates them from patients with sickle cell disease. Children and adolescents with sickle cell disease have impaired growth compared with controls.[48–51] The growth deficit tends to be greater in weight than in height, and is more severe in patients with sickle cell anemia and HbS–β^0 thalassemia compared with HbSC disease and HbS–β^+ thalassemia. Bone age is often less than chronological age in both boys and girls. In a more recent study of 148 children, 38% fell below the 5th percentile in one or more measures such as height, weight, or body mass index.[52]

In parallel with delayed growth in weight and height, adolescents with sickle cell disease are delayed in sexual maturation. There was a 1–2 year delay in attaining Tanner stages 2–5 in both males and females with sickle cell anemia, and menarche was delayed by 2–3 years. Puberty was delayed 1–2 years, and median age at menarche was 13.2 years.[52] Fortunately, sexual maturation is eventually achieved and the height, but not the weight, gap is closed by adulthood in most patients. Nevertheless, size and rate of sexual development are constant measures of comparison among adolescents and those who are delayed often face severe emotional consequences.

To see if reduced height and weight were associated with abnormalities of the growth hormone (GH)/insulin-like growth factor–I (IGF-I)/IGF-binding protein-3 (IGFBP-3) axis, 21 children with sickle cell disease were examined. Nearly half had a defective GH response to both clonidine and glucagon and they had slower linear growth velocity, lower circulating IGF-I and IGFBP-3, and either partial or complete empty sellae by computed tomography (CT) scanning. A single injection of GH produced a smaller increase in circulating IGF-I in children with or without defective GH secretion when compared with age-matched children with idiopathic short stature and children with isolated GH deficiency, suggesting partial GH resistance in the sickle cell disease group. Defective GH secretion, decreased IGF-I synthesis, and partial resistance to GH in these short children suggest that treatment with IGF-I may be superior to GH therapy.[53] Five patients treated for more than 3 years with GH had improvement in their height.[54]

Delayed growth and skeletal and sexual maturation in sickle cell disease could be a result of energy deficiency and chronic malnutrition. Children and adults with sickle cell disease had increased resting energy expenditure.[55–59] Resting metabolic rate in patients with sickle cell anemia was 19% higher than that in control subjects, and this difference was not accounted for by differences in lean body mass. Increased energy expenditure could lead to a marginal nutritional state that contributes to abnormal growth.

When basal rates of whole body protein, glucose, lipid metabolism, and resting energy expenditure were measured, resting energy expenditure was 15% greater in the patients than controls. Whole body protein breakdown and protein synthesis were 32% and 38% greater, respectively, in patients, but whole body amino acid oxidation, glucose, and lipid metabolism were similar to controls. Isotope infusions studies and indirect calorimetry reflected hypermetabolism, and suggested that hemolysis and increased cardiac workload might contribute to this.[60] Additional

energy required for the greater rates of whole body protein breakdown and synthesis contributed significantly to the observed increase in resting energy expenditure, suggesting that dietary energy and protein requirements are increased in sickle cell disease. Supplemental oral glutamine decreased resting energy expenditure and might improve growth.[61]

Voluntary energy intake in sickle cell anemia appears to be similar to that of control subjects with a normal hemoglobin genotype despite their higher resting metabolic rate. This observation suggests a suboptimal nutritional state. Patients might therefore conserve energy by reducing their physical activities. This hypothesis was tested by comparing resting metabolic rate, total daily energy expenditure, and physical activity level in postpubertal boys with sickle cell disease and in normal matched controls. Resting metabolic rate of patients exceeded that of the controls, but total energy expenditure was greater in controls. Control subjects had nearly 50% more physical activity than patients, suggesting that reducing physical activity is a compensatory mechanism for energy deficiency in sickle cell disease.[57]

Nearly all studies of energy expenditure in sickle cell disease are flawed by the difficulty of choosing appropriate controls, making their interpretation difficult. Although matching for age and sex is fine as far as it goes, controls for hemolysis or anemia are not included. Therefore, results of these studies are not specific for sickle cell disease, but compare patients with hemolytic anemia with hematologically normal controls. Ideally, to ensure that results reflect the pathophysiology of sickle cell anemia and not hemolytic anemia in general, controls should include individuals with other chronic hemolytic anemias.

Nutrition

Dietary intake of multiple vitamins and minerals, calcium, and fiber was low, and declined steeply during 3 years of observation.[62] Poor dietary intake might be contributed to by frequent hospitalizations for pain.[63] A long-standing and still unanswered question centers about the contribution, if any, of nutritional deficits to the pathophysiology of disease. In developed countries nutritional deficiencies do not seem to be a major factor in the course of the disease in most patients. No evidence exists that the many vasoocclusive complications of sickle cell disease or its hemolytic anemia are, except in extreme circumstances, affected by a patients' nutritional status or that nutritional supplementation, with the exception of the rare case of megaloblastic arrest of erythropoiesis due to folic acid deficiency, can change the course of disease.

Zinc deficiency has been found in some patients with sickle cell anemia and treatment with supplemental zinc has been claimed to reverse the sexual immaturity of some patients, promote the healing of leg ulcers, reduce infections, and have some effect on the sickling process. The relationship between zinc deficiency and delayed growth and sexual development in children with sickle cell disease has been confirmed.[64]

Several lines of evidence indicate that tissue zinc deficiency is present in some patients with sickle cell anemia but there are some inconsistencies in the data. Among most experienced practitioners, supplemental zinc has not been widely used. Whether or not zinc deficiency plays an important role in the pathophysiology of well-nourished patients with sickle cell anemia is doubtful, but this has not been the subject of many controlled trials. One trial of 130 patients compared the effects of zinc with a placebo in the reduction of painful episodes. After 18 months of observation, approximately half as many episodes occurred in the zinc-treated group compared with the placebo-treated patients.[65] As zinc deficiency adversely affects helper T cells and cell-mediated immunity, the role of supplemental zinc for preventing infection was studied in 32 patients with sickle cell disease, aged 19–49 years.[66] Twenty-one zinc-deficient patients were divided in two groups: 11 subjects were observed for 1 year, following which they received, for 3 years, 50–75 mg of elemental zinc daily, as oral zinc acetate; and 10 patients were observed for 1 year, following which they received placebo for 1 year and then switched to zinc supplementation for 2 years. A third group of 11 patients were zinc sufficient and not treated. Zinc supplementation increased lymphocyte and granulocyte zinc, and increased in interleukin-2 production. Documented bacteriologically positive infections, hospitalizations, and number of vasoocclusive pain episodes were significantly decreased.

Vitamin A status, estimated by a reduced serum retinol level, was less than normal in 66% of children with sickle cell anemia. This was associated with increased hospitalizations, poor growth, and lower hemoglobin concentration.[67] Among 65 children with sickle cell anemia, aged 5–18 years, 65% had reduced levels of vitamin D (25 OHD), and this was associated with season of the year and dietary intake.[68] Bone metabolism in sickle cell disease is discussed later.

Because of the relationship between plasma homocysteine concentration and folate status, plasma homocysteine concentrations were measured in 120 children with sickle cell anemia who had never received supplemental folic acid.[69] Plasma homocysteine levels in sickle cell anemia patients and controls were similar. In 34 children, simultaneous serum folate, red cell folate, and total homocysteine concentrations were measured and their serum folate and red cell folate concentrations were normal. There was no correlation of plasma homocysteine concentration with various clinical or laboratory measures or with red cell folate concentration. These children, who likely had good nutritional status, had normal folate stores in the absence of supplemental folic acid, making daily folic acid supplementation in well-nourished patients unlikely to be necessary.

Stroke, Neurological, and Neurocognitive Manifestations

Pathophysiology

One of the best examples of the vasculopathy of sickle cell disease is the extensive cerebrovascular damage that often leads to stroke and subtle neuropsychological dysfunction. Many recent reviews have discussed the pathophysiology and management of sickle cerebrovascular disease.[70–73]

Most cases of sickle cell stroke are due to stenosis and/or occlusion of major vessels of the Circle of Willis, the internal carotid arteries, and less frequently, the vessels of the vertebrobasilar system. These large arteries show fragmentation and duplication of the internal elastic lamina with extensive intimal hyperplasia encroaching on the vascular lumen. Some vessels also show aneurysmal formation. Strokes are caused by in situ occlusion or embolism from thrombi formed at the point of vascular damage or formed at areas of turbulent blood flow. Stenosis of the major vessels results in increased blood flow velocity, which can be measured with transcranial Doppler (TCD) ultrasonography.[74,75]

Gene expression profiling in blood outgrowth endothelial cells has been used to understand the biological systems that might mediate stroke in sickle cell disease.[76] In endothelial cells grown from the blood of 11 patients with sickle cell anemia at risk for stroke because of Circle of Willis disease, compared with nine patients not at risk for stroke, genes mediating inflammation were differentially expressed.

Hemorrhagic stroke is thought to be caused often by rupture of aneurysms formed in the vessels of the Circle of Willis or the fragile vessels of moyamoya disease that results from stenotic lesions of the major intracranial vessels. Angiographic studies following hemorrhagic stroke have shown the presence of multiple aneurysms, although not all cases of hemorrhage were associated with aneurysm. Bleeding is commonly subarachnoid but can be intraventricular or parenchymal.

Epidemiology

Strokes in sickle cell disease are classified into three clinical types: infarctive, hemorrhagic, and transient ischemic attacks. Although all types are seen in all age groups, infarctive strokes were generally believed to be more common in children.

The overall prevalence of stroke and incidence of a first stroke in patients with sickle cell anemia in the United States are, respectively, 4.96% and 0.61 per 100 person-years as reported in the CSSCD.[22] In HbSC disease, the rate and prevalence are 0.84% and 0.15 per 100 person-years; in HbS–β^+ thalassemia and HbS–β^0 thalassemia, these figures are 1.29% and 0.09 and 2.43% and 0.08, respectively.

Stroke is rare in infants with sickle cell disease; however beyond age 1 year, stroke incidence in sickle cell anemia patients is relatively uniform at approximately 0.5 per events per 100 patient-years until age 40 years, except for peaks of 1.02 events per 100 person-years in patients aged 2–5 years and 0.8 in patients aged 6–9 years. In 39 children with sickle cell anemia between ages 7 and 48 months without a history of clinical stroke – three had a history of seizures – who were examined with magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA), the overall prevalence of abnormalities in these "asymptomatic" children was 11%. One patient had a silent infarct observed on MRI and a stenotic lesion on MRA; three other patients had stenotic lesions on MRA. Patients with a history of seizures all had lesions consistent with infarcts on MRI. Of the patients who had psychometric testing, 1 of 18 was developmentally delayed. One of 3 patients with a history of seizures had mild developmental delay.[77] Therefore, very young children with sickle cell anemia without a history of clinical stroke can have infarction in the brain and/or stenosis of major cerebral arteries, similar to those reported in older children. The high incidence in the first decade and the absence of a direct correlation between the incidence of stroke and advancing age, suggest that cerebrovascular disease is not likely to be simply the result of cumulative damage caused by sickle cells and abnormal blood flow. Rather, those children experiencing stroke in the first decade might have an additional risk factor, genetic or acquired, which predisposes them to early stroke (Chapter 27). The risk of stroke persists throughout life for sickle cell disease patients. In sickle cell anemia, the risk of having a first stroke is 11% by age 20 years, 15% by age 30 years, and 24% by age 45 years. The absence of an antecedent or concurrent medical event associated with an initial stroke is a major risk factor for subsequent stroke in patients on a regular transfusion program.[78] Approximately 60% of patients with moyamoya and an incident stroke will have at least one recurrent cerebrovascular event despite transfusion, an incidence approximately twice that of individuals without moyamoya.[79]

The only reliable data to compare with the rates of stroke in the United States is from the Jamaican cohort study. In this study, 5.5% of 310 children with sickle cell anemia had a stroke by age 14 years.[80] This rate seems lower than that of children in the United States where approximately 8% of those with sickle cell anemia would have had a stroke by this age.

Stroke in adults can be infarctive or hemorrhagic. In the CSSCD, the incidence of stroke in patients aged 20 years or older was 0.59 per 100 person-years. Of the 27 first strokes occurring in adults, 52% were hemorrhagic, 30% were infarctive, 11% were transient ischemic attacks, and two were unclassified. The risk of hemorrhagic stroke was highest in patients aged 20–29 years, at 0.44 per 100 patient-years. In contrast, only 5 of 52 first strokes in sickle cell anemia patients younger than 20 years were hemorrhagic. Hemorrhagic stroke has a reported mortality rates of 24%–65%. In 15 children, aged approximately 10 years, compared with 29 control subjects, an increased risk of hemorrhagic

stroke was associated with a history of hypertension, recent transfusion, and treatment with corticosteroids and possibly nonsteroidal antiinflammatory drugs.[81]

Stroke is associated with a high mortality rate. In the CSSCD, 10% of patients with stroke died within 2 weeks following the incident event. All patients who died had sickle cell anemia; almost all had a hemorrhagic stroke that was associated with a mortality rate of 26%. No deaths occurred soon after infarctive stroke. In the Jamaican cohort, in which stroke is not managed routinely with blood transfusion, 6 of 15 children with presumed infarctive stroke died, two immediately after the initial stroke and four after a recurrent stroke; one of two patients with a hemorrhagic stroke died.

Several factors were identified with increased risk for stroke. In decreasing order of risk, prior transient ischemic attack, level of anemia at steady state, rate of acute chest syndrome, acute chest syndrome 2 weeks prior to the stroke event, and elevated systolic blood pressure were associated with infarctive stroke. In 95 patients aged 1–23 years, without a previous stroke, and followed for a median of 6 years, 19 patients had central nervous system (CNS) events. Mean overnight oxygen saturation and TCD velocity were independently associated with risk.[82] Risk factors for hemorrhagic stroke were anemia and elevated leukocyte count at steady state. In the CSSCD study, no association was found between stroke and the frequency of painful episodes, priapism, or transfusion therapy within 2 weeks before the stroke event. Increased level of HbF has been reported in two smaller series to be protective of stroke, an association not noted in the CSSCD.[80,83] Scant data exist on the association of stroke in sickle cell disease with either inherited or acquired thrombophilia.[84]

High homocysteine levels have been associated with stroke in one study, whereas another correlated homocysteine levels with acquired folic acid deficiency.[85,86] Correction of the folic acid deficiency led to lower levels of homocysteine. Systolic hypertension is another risk factor for stroke.[87]

Coincident α thalassemia is associated with protection from stroke, perhaps because these patients have less hemolysis and a higher hemoglobin concentration (Chapter 23). Only 20% of pediatric patients with sickle cell anemia who had a stroke had α thalassemia, whereas 35% of individuals without a history of stroke had α thalassemia. The incidence of infarctive strokes in sickle cell anemia with coincident α thalassemia was reduced by more than 50%, and none of 48 patients with homozygous α thalassemia-two had a stroke. Nevertheless, in the Jamaican study, α thalassemia was not a deterrent for stroke.[80] α Thalassemia was associated with reduced TCD flow rate and hemolysis, estimated by serum LDH, is an independent risk factor for cerebral vasculopathy.[27,88] Serum LDH correlated with TCD flow velocity in children with sickle cell anemia, supporting the notion that hemolytic anemia was a determinant of cerebrovascular disease.[89]

Diagnosis

Stroke can be diagnosed by clinical presentation or history. The most common presenting symptoms of infarctive stroke are hemiparesis, aphasia, dysphagia, seizure, and monoparesis. The diagnosis is often confirmed or defined further with brain imaging studies that are also performed to exclude hemorrhage, which could require surgical intervention. Hemorrhagic stroke often presents as severe headache with vomiting and depressed consciousness. MRI or CT scanning is able to demonstrate parenchymal infarct or hemorrhage, although changes in CT can lag behind the event by several days (Fig. 19.4). Cerebrovascular lesions can also be delineated using MRA. Traditional angiography involving catheterization and injection of radiographic dyes is used less frequently, although this method might still be a more sensitive and specific than MRA.

Positron emission tomography (PET) added to MRI can improve the detection of cerebral vasculopathy and PET excels at assessing the functional metabolic state by permitting glucose utilization and microvascular blood flow to be measured. Forty-nine children with sickle cell anemia were studied using PET and MRI, 19 who had clinically overt stroke, 20 who had life-threatening hypoxic episodes or “soft” neurological signs, and 10 who were normal based on neurological history and examination. Sixty-one percent of all patients had abnormal MRI findings, 73% had abnormal PET findings, and 90% showed abnormalities on either the MRI or the PET or both. Eighty-nine percent of patients with overt stroke had an abnormal MRI, 89% had abnormal PET, and all had either abnormal MRI or PET or both. In the 20 subjects with “soft” neurological signs, half had abnormal MRI, 65% had abnormal PET, and 85% had abnormal MRI and/or PET. Sixty percent of the 10 neurologically normal subjects had abnormal PET. Eighty-three percent of patients without an overt stroke had imaging abnormalities based on either MRI or PET or both, suggesting silent ischemia. These imaging abnormalities were associated with lower than average full-scale intelligence quotient whether there was an overt stroke or silent ischemia. Chronic red blood cell transfusion in four patients improved metabolic and perfusion status on repeated PET scans. Using both PET and MRI identified a much greater proportion of children with sickle cell anemia who had neuroimaging abnormalities, even in the absence of a history of overt neurological events. In addition, the PET lesions were more extensive and bihemispheric.[90] These data suggest that PET can be useful a tool to evaluate metabolic improvement after therapeutic interventions.

Six patients with sickle cell disease and a history of stroke, aged 10–28 years, had PET scans using ^{18}F-fluorodeoxyglucose as a tracer. MRI demonstrated that two patients had only small vessel disease and four had both large and small vessel disease. In two of four subjects with large vessel disease, PET showed a corresponding

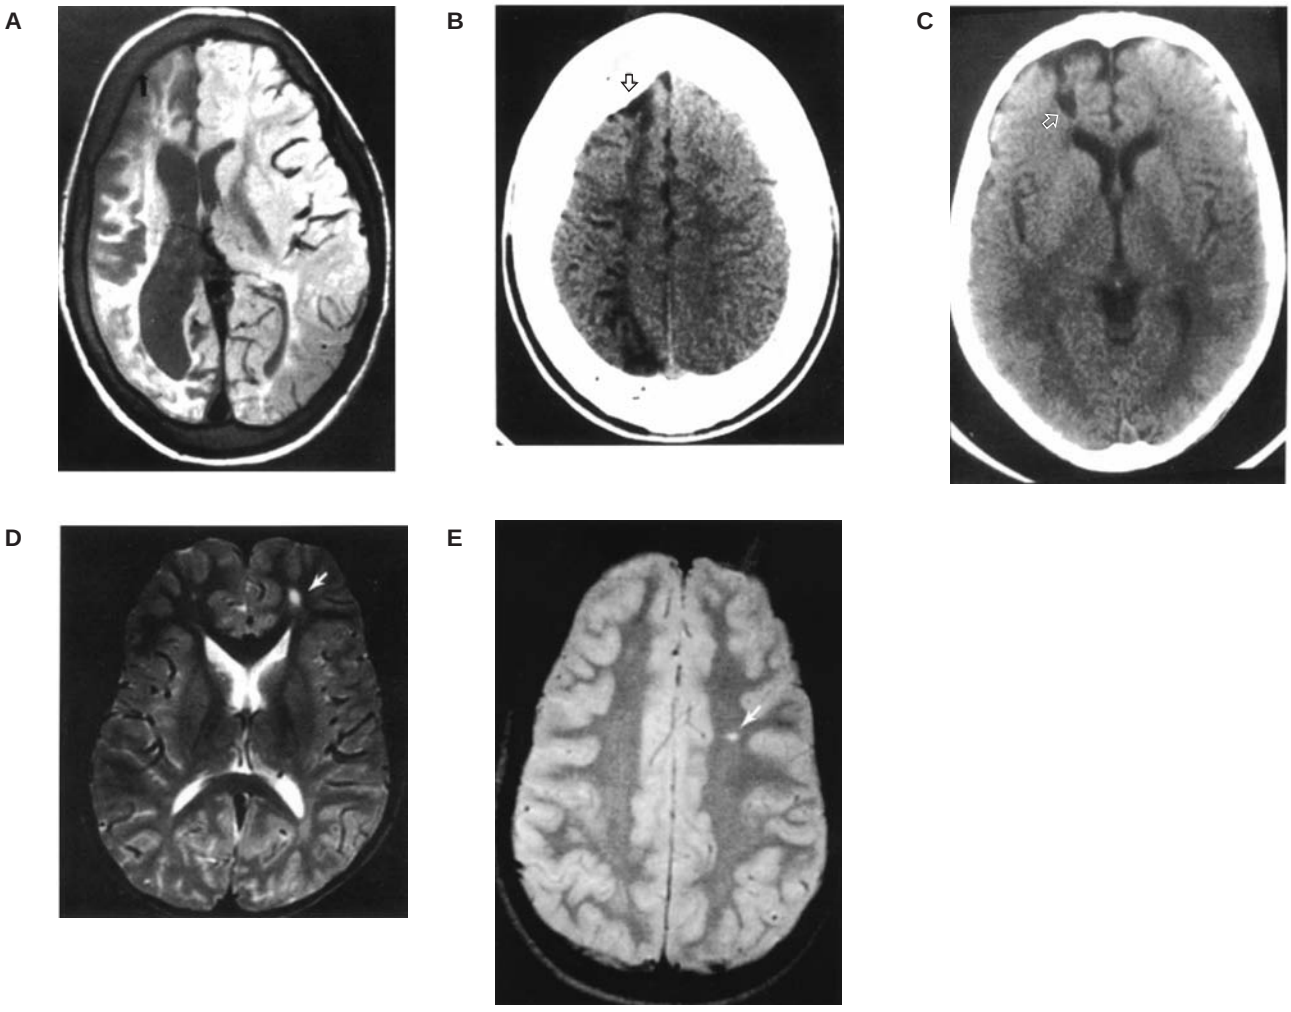

Figure 19.4. MRI and CT scans of cerebral infarction in sickle cell anemia. CT and MRI patterns of cerebrovascular disease. The left side of the photo represents the right side of the brain. **(A)** TI-weighted MRI from a 12-year-old girl who suffered a right internal carotid artery occlusion 1 year before this study. There is severe loss of cortical and subcortical brain and massive dilation of the ventricular system. The anterior cerebral (ACA) and middle cerebral artery (MCA) territories are involved. This is an example of a major vessel occlusion pattern. **(B)** CT showing a linear area (open arrow) of infarction defining the border zone between the MCA and ACA territories. This 10-year-old boy developed mild left hemiparesis. Angiography showed an occluded right internal carotid artery (ICA) with extensive collateral flow from the vertebrobasilar system. **(C)** CT demonstrating another "border zone" infarction with a wedge-shaped area of infarction extending from the cortical surface to near the frontal pole of the lateral ventricle on the right (open arrow). This 14-year-old boy had a stroke at age 10 years. When studied at age 14 years after 4 years of chronic transfusion he had bilateral border zone infarcts (only right side shown), but both carotid systems were patent on angiography. These lesions are typically seen in cases with large artery, usually the ICA, stenosis or occlusion. In this case the absence of carotid lesions could indicate another mechanism, perhaps repeated bouts of severe anemia or resolution of lesions after years of transfusion. **(D)** T2-weighted MRI showing what is also considered by some to be a border zone lesion. The area of high signal near the frontal pole of the left lateral ventricle (white arrow) is an abnormal area of ischemia in the border zone between the deep and superficial vessels. This area is often abnormal on MRI in sickle cell disease when the CT is normal, and the patient may have little if any deficit. This 10-year-old boy was neurologically asymptomatic but had this MRI because of abnormal TCD studies. **(E)** TI-weighted MRI from a 13-year-old girl who was neurologically asymptomatic except for headaches. The white arrow shows what has been called an "unidentified bright object." Similar lesions have been noted in asymptomatic elderly patients with vascular risk factors. Although not yet proven by pathological studies, it is likely that these small lesions, usually appearing in the subcortical white matter, are areas of small infarction caused by microvascular occlusion. Their presence does not imply concomitant large artery stenosis, and the risk of subsequent clinical stroke associated with these lesions is unknown. The patient whose MRI is shown in this panel remained asymptomatic without evidence of stroke 6 years after this study was performed.[74]

metabolic abnormality and also identified an area of hypometabolism extending beyond the anatomical lesion revealed by MRI. PET did not demonstrate an abnormality corresponding with small vessel disease. Detailed neuropsychological testing demonstrated cognitive dysfunction in all cases.[91] For some patients, PET might add sensitivity in detecting impaired metabolism in the area surrounding a major vessel infarct.

The magnitude of initial brain damage, degree of cerebrovascular disease, age at first stroke, type of stroke, and management determine the long-term outcome of stroke. Children with infarctive stroke often recover motor deficits, but recovery might depend on their age at the time of the first stroke. In one report, only one-third of children younger than 5 years, compared with two-thirds of those older than 5 years, recovered from motor deficits after initial stroke.[92]

In addition to motor deficits, cognitive abnormalities occur in sickle cell disease patients with cerebrovascular disease and stroke. Abnormal neuropsychometric studies are common both in the short-term and long-term periods after stroke. Brain MRI and neuropsychological evaluations were conducted to determine whether neuroradiographic evidence of infarct in children with sickle cell disease aged 6–12 years would result in impairment in cognitive and academic functioning. In 194 children, 135 of whom had sickle cell anemia, MRIs were categorized according to the presence of T2-weighted, high-intensity images suggestive of infarct and were further categorized on the basis of a clinical history of stroke. An abnormal MRI but no clinical history of cerebrovascular accident was classified as a silent infarct. Neuropsychological evaluations included assessment of both global intellectual functioning and specific academic and neuropsychological functions. Nearly 18% of all patients and 22% of patients with sickle cell anemia had MRI abnormalities. A clinical history of stroke was found only in children with sickle cell anemia (4.6%). Children with a history of stroke performed significantly more poorly than children with silent infarcts or no MRI abnormality on most neuropsychological evaluation measures, and individuals with silent infarction performed significantly more poorly than children with no MRI abnormality on tests of arithmetic, vocabulary, and visual motor speed and coordination.[93,94] Neurocognitive abnormalities in neurologically intact adults are discussed later.

It might be useful to obtain a thorough family history of stroke and other thrombotic events and to include evaluation for thrombophilia in laboratory assessment of sickle cell disease patients, particularly those with silent infarcts and stroke. Patients with hemorrhage should also be evaluated for coagulopathy.

Treatment recommendations. Initial management of infarctive stroke should include stabilization of the patient, judicious intravenous hydration, and transfusion (Chapter 29).[95] The goal of initial transfusion is to improve oxygenation and reduce the risk of further vasoocclusive and hypoxic damage. Exchange transfusion is preferable to simple transfusion because it allows a rapid decrease in the percentage of sickle cells. In a retrospective analysis, children receiving simple transfusion as an initial treatment had a fivefold greater relative risk of a second stroke during follow-up than those receiving exchange transfusion.[96]

Patients with persistent neurological deficits should be started on rehabilitation therapy as soon as possible. Long-term care centers and chronic transfusion therapy should be used to reduce the chance of recurrent stroke and management of iron overload. In untransfused patients the risk of recurrent stroke is as high as 70%, whereas it is approximately 10% in those maintained at HbS levels of less than 30% by chronic transfusion therapy.[97] In patients who remain stable neurologically, the HbS level can be allowed to rise to approximately 50% after several years at a level of 30% or less, with no added risk of a recurrent stroke.[78,98] This reduces the transfusion requirement and the rate of iron accumulation.

The duration of chronic transfusion is undetermined. In children, strokes have recurred when transfusion therapy was discontinued after 1–2 years or after 5–12 years. It is unknown whether continued chronic transfusion therapy will reduce the risk of hemorrhagic stroke later in life.

Iron overload in sickle cell disease patients receiving chronic transfusion occurs at rates similar to those in transfusion-dependent thalassemia. Iron chelation therapy, when adhered to, is equally effective in reducing iron stores (Chapter 29). Partial exchange transfusion reduces the rate of iron accumulation. This method of chronic transfusion is applicable to young children, as long as they have good venous access required for the procedure, and has eliminated iron overload in many patients receiving chronic transfusions.[99]

Although chronic transfusion therapy is effective in decreasing the rate of recurrent infarctive stroke in children, this has not been proven to be an effective measure in patients who have their first stroke in adulthood. Moreover, transfusion therapy is often stopped when children make the transition from the pediatric to the adult clinic. Hemorrhagic stroke might be a late sequela of infarctive stroke, suggesting that progressive vascular damage could eventually lead to rupture of abnormal vessels. Such bleeding has occurred even in patients maintained on chronic transfusion therapy. Encephaloduroarteriosynangiosis, to establish anastomoses between external and internal carotid arteries, has been used in patients with moyamoya and recurrent cerebrovascular events with a good outcome in a small series of patients.[100]

Management of hemorrhagic stroke includes careful hydration, nimodipine to reduce vasospasm, surgical evacuation of blood, and ligation of accessible aneurysms. Long-tem management of hemorrhagic stroke is unclear. The risk of recurrence is unknown, and the value of chronic transfusion in preventing recurrence is unproven. A high

fatality rate within 2 weeks of a hemorrhagic stroke illustrates the need for ways to prevent this complication. Routine evaluation for aneurysms is not standard practice, although surgical intervention is usually successful in the treatment of those with aneurysm.

In 35 children with sickle cell anemia and stroke, transfusions were discontinued, hydroxyurea initiated, and phlebotomy was used to reduce iron stores. Initially, patients discontinued transfusions before hydroxyurea therapy was started, but later patients overlapped transfusions with hydroxyurea until the full dose was achieved. After 3–104 months of treatment, the stroke recurrence rate was 5.7 events per 100 patient-years, but children receiving overlapping hydroxyurea therapy had 3.6 events per 100 patient-years. With more than 6 months of phlebotomy, serum ferritin decreased from a median of 2,722 to 298 ng/mL and liver biopsy showed normal histology and iron stores.[101]

Stroke prevention. It is now possible to prevent the first occurrence of stroke in most children with sickle cell anemia. TCD ultrasonography, which measures blood flow velocity through intracranial vessels, was shown to be capable of selecting children with a high risk of stroke based on blood flow velocity in the major intracranial arteries.[102] Blood flow velocity is higher than normal in stenotic vessels. In a study of children with sickle cell anemia and no history of stroke, when blood flow velocity of 170 cm/second or higher in a middle cerebral artery was defined as abnormal, 6 of 23 patients with abnormal TCD ultrasonography had a stroke compared with only 1 of 167 with normal TCD ultrasonography. In a subsequent multicenter controlled study, 130 children with sickle cell anemia and internal carotid artery or middle cerebral artery blood flow velocity of 200 cm/second or higher were randomized to chronic transfusion therapy or standard care. After 1–26 months of observation, 11 of the patients on standard care had a stroke compared with only one in the transfusion group, a risk reduction of 92%.[103,104]

On the basis of these studies, patients with sickle cell anemia and HbS–β^0 thalassemia are screened – sometimes biannually, depending on their blood velocity value – for cerebrovascular blood flow by TCD ultrasonography, and individuals at high risk of stroke are chronically transfused. Nevertheless, most high-risk patients will not have a stroke during a given year and this must be weighed in the decision to transfuse. Additional prognostic variables that could help gauge the risk of stroke are being sought. In one study, a Bayesian network was able to predict, based on clinical variables and polymorphisms in candidate genes, the likelihood of developing a stroke (Chapter 27).[105]

The question of how long these transfusions should be continued was partially answered in a follow-up study.[106] When children at high risk of stroke were transfused for 30 months or longer, and their TCD flow rates became normal, they were randomly assigned to continue or discontinue transfusion. Children with severe stenotic lesions on MRA were excluded. The study was stopped after only 79 of the planned 100 patients were randomized as high-risk TCD flow rate developed in the 14 of the 41 children in the transfusion-halted group and two had a stroke within 2.1 to 10.1 months of their last transfusion. Neither high-risk TCD flow rate nor stroke occurred in the 38 children randomized to continue transfusions. It was concluded that discontinuation of transfusion for the prevention of stroke in children with sickle cell disease results in a high rate of reversion to abnormal blood flow velocities and stroke. Interestingly, the serum LDH level increased in patients randomized to stop transfusions, suggesting that increased intravascular hemolysis and decreased NO bioavailability might play a role in stroke recurrence. It was suggested that stem cell transplantation might be one approach to recurrent stroke prevention.

Hydroxyurea can reduce TCD flow rates, sometimes to normal values, raising the possibility that it could be useful in some instances for primary stroke prevention.[107–109] In the largest of these studies that included 37 children, HbF increased from 10.3% ± 6.6% to 22.7% ± 7.9% and the maximum transcranial velocity fell from 173 ± 22 to 129 ± 20 after 1 year at maximum tolerated dose.[107] The use of hydroxyurea to prevent recurrent stroke (ClinicalTrials.gov NCT0012298) is now the subject of a randomized clinical trial. Until these results are reported, prophylactic transfusion remains the standard unless there is no possibility of successfully transfusing the patient.

Silent infarction. MRI studies have identified brain infarcts in 18%–20% of patients who have had not had a clinical stroke. These "silent" infarcts are usually located in the deep white matter in the junctional areas ("border zones") between the tributaries of the anterior and middle cerebral and the posterior and middle cerebral arteries. Patients with complete strokes usually have infarcts in the cortical regions. In an analysis of risk factors for silent infarct among the infant cohort of the CSSCD who underwent MRI studies after age 5.9 years, 18% had a silent infarct. History of seizure, lower rates of painful episodes, and lower hemoglobin level were associated with silent infarcts, as were increased leukocyte count, elevated "pocked" red cell count, and the numbers of patients with a Senegal β-globin gene haplotype.[110] Silent infarcts are associated with increased neuropsychometric abnormalities. Infants with silent infarcts on MRI performed significantly more poorly than children with no MRI abnormality on tests of arithmetic, vocabulary, and visual motor speed and coordination.[111] Children with a history of stroke scored lower than those with silent infarcts or no MRI abnormality on most neuropsychological evaluation measures.

Although clinicians suspect that "silent" infarcts are associated with increased risk of clinical stroke, this has not been proven conclusively. A broadened definition of stroke that included significant changes in neuropsychometric

studies in association with infarcts or vascular changes on brain imaging studies would identify a large number of children with sickle cell disease who might require therapy to prevent further brain damage and overt (motor) stroke. The management of children with sickle cell anemia should include annual TCD ultrasonography, starting at age 2 years, to identify those with high risk of stroke for consideration of preventive chronic transfusion therapy. Annual MRI studies might also identify those with "silent" infarcts and cerebrovascular damage.

Neuropathy. Peripheral neuropathies have been described but are not common. Most often they seem to result from adjoining bone disease and nerve entrapment, as when the mental nerve becomes entrapped in the mandibular canal due to bone infarction and in spinal radiculopathy, when bone infarction compresses a nerve root. Less often a mononeuropathy can occur.[112] One conjecture is that the richly anastomosing arteriolar and capillary network supplying peripheral nerves and the large diameter of these vessels helps preclude vasoocclusive damage. Some reports suggest that children with sickle cell anemia who become lead intoxicated are prone to peripheral neuropathy.[113]

Sensorineural hearing loss, particularly in the high-frequency 2,000–8,000-Hz range, has been encountered in up to 22% of patients with sickle cell disease.[114,115] Sometimes this has been observed in the course of a painful episode with resolution thereafter. Although the cause of this defect is uncertain it has been ascribed to vasoocclusive damage to inner and outer hair cells and the stria vascularis. Some patients also have transitory vertigo from apparent labyrinthitis. Although it is not possible to dissociate infectious causes from a vasoocclusive etiology, the latter remains a possibility.

Acute Anemic Episodes

Except for acute and usually small changes during vasoocclusive events – sometimes with severe acute chest syndrome, the packed cell volume (PCV) can fall dramatically – steady-state hemoglobin levels remain more or less constant over time unless erythropoiesis is depressed. Acute anemic episodes describe the episodic lowering of hemoglobin levels below the usual steady-state level in patients with sickle cell disease. The two common causes of acute anemia occurring in sickle cell disease, splenic sequestration and the B19 parvovirus–associated acute aplastic crisis, occur mainly in children. Other acute anemic events are seen in all age groups.

Acute Splenic Sequestration

Because it is initially enlarged, the spleen in sickle cell anemia becomes dysfunctional as early as the first 6 months of life and then begins a slow process of involution that in over 90% of patients outside of Africa culminates in a total loss of functional splenic tissue in late childhood. HbF levels determine, at least partially, the rate of splenic atrophy so that individuals with the highest levels of HbF maintain splenic function longer than those with lower levels. Some individuals with unusually high HbF levels continually have an enlarged functional spleen and these patients become susceptible to complications of splenomegaly in sickle cell anemia such as sequestration crisis, splenic infarction, intrasplenic hemorrhage, rupture, and abscess. Acute splenic sequestration, the sudden trapping of red cells in the sinuses of an enlarging spleen accompanied by severe anemia, mild thrombocytopenia, and hypovolemia has been defined by the CSSCD as a decrease of the hemoglobin or PCV of at least 20% from baseline, accompanied by an increase in palpable spleen size of at least 2 cm from baseline. Acute splenic sequestration often occurs in association with a febrile upper respiratory illness but its pathophysiology is not clearly understood. Sickle cells trapped for any duration of time in a hypoxic environment might be expected to hemolyze. It might therefore be inaccurate to describe acute splenic sequestration as trapping of sickled cells as it is neither acute nor followed by increased hemolysis and plasma is sequestered along with cells. Moreover, the "trapped" red cells are easily released into the general circulation as the acute anemia and hypovolemia are corrected when the spleen shrinks following therapeutic blood transfusion. It is more likely that blood continues to flow into the sinuses of the spleen but leaves at a much slower rate. A phenomenon causing expansion and subsequent shrinkage of the sinus vascular space within the spleen is a more likely mechanism. This could be due to hypoxic injury to the splenic microvasculature. Splenic sequestration is not always severe, and mild forms with less than 2 cm enlargement of the spleen and less than a 2-g/dL drop in hemoglobin level probably predominate. Rapid enlargement of the liver can also be associated with blood pooling and acute anemia, albeit much less often than splenic sequestration. Management of both conditions are similar (see later).

Acute splenic sequestration can occur in patients younger than 6 months. Cases of acute splenic sequestration in a 5-week-old and 2-month-old with sickle cell anemia have been reported. Although rare, acute splenic sequestration can occur in adults with sickle cell anemia and HbSC disease. Sometimes this occurs in adult patients with typical sickle cell anemia with low HbF levels and without any suggestion of having coincident α thalassemia.[116] The incidence of acute splenic sequestration in children with sickle cell anemia was 1.0 per 100 person-years by age 6 months, 6.2 by 1 year, 5.3 by 2 years, 2.0 by 3 years, and 1.0 by 6 years.[38] Acute splenic sequestration is less common in young children with HbSC disease and its peak incidence of 2.9 per 100 person-years by age 4 years is not reached as early as it is in patients with sickle cell anemia. Acute splenic sequestration in HbSC disease might occur over a broader age range and is seen in adults and

children. α Thalassemia, by its effects on the rheology of sickle erythrocytes, might help preserve splenic function into adulthood and increase the incidence of acute splenic sequestration episodes in children and adults with sickle cell anemia (Chapter 23).[16] Among French and Guadeloupean children with sickle cell disease, the incidence of splenic sequestration was approximately 13% and 29%, respectively.[117,118]

Among the CSSCD cohort of newborns, 43 of 694 patients experienced 62 episodes of acute splenic sequestration over a 10-year observation period. Many patients develop episodes of subacute sequestration with the spleen frequently showing enlargement and reduction in size associated with mild changes in hemoglobin level. In a few patients, there is a chronic hypersplenism with lower hemoglobin level, platelet, and leukocyte counts than usual. Sixteen of the 43 children experiencing acute splenic sequestration underwent splenectomy. Those who had splenectomy were aged 0.3–4.1 years (median 1.6 years) at the time of the initial acute splenic sequestration event and were splenectomized at a median age of 2.6 years (range 0.8–5.3 years). None of the splenectomized sickle cell anemia patients developed postsplenectomy invasive bacterial infection during follow-up. Early splenectomy has been performed in the management of acute splenic sequestration without apparent increased risk of postsplenectomy bacterial infection.[119] The concern that splenectomy could pose additional risk for bacterial infection in young children with sickle cell disease has led some centers to the use of partial splenectomy, although the protective value of this procedure is uncertain as overwhelming septicemia has followed partial splenectomy.

Treatment recommendations. Acute splenic sequestration is a potentially life threatening and should be managed with urgency. Deaths often result from hypovolemic shock and not from anemia. Immediate management of acute splenic sequestration should be directed toward correction of hypovolemia with volume expanders. In an autopsy-based study, approximately 7% of deaths were due to splenic sequestration.[120] Transfusion of red cells can follow restoration of blood volume and blood pressure but this should be performed with caution because an acutely enlarged spleen has a tendency to release sequestered blood, and hemoglobin levels a few hours after transfusion tend to be higher than expected from the amount of red cells transfused. Red cells should be given in small portions and allowed to equilibrate to avoid hypervolemia. One guide to transfusion for splenic sequestration is that when the observed hemoglobin level is less than 5 g/dL, the initial volume of transfused red cells should be the equal in milliliters/kilograms to the observed hemoglobin level. For example, a child with hemoglobin concentration of 3 g/dL would then receive as an initial transfusion, 3 mL/kg of packed red cells. Subsequent transfusion amounts, if clinically indicated, should be estimated based on the hemoglobin level after equilibration of the initial transfusion. The use of diuretics might be advisable in those in whom hypervolemia is imminent or present.

Long-term management for individuals with recurrent acute splenic sequestration or severe hypersplenism includes parental retraining in the palpation of the spleen – this is a part of the initial training of parents of all infants with sickle cell disease – limited-term chronic transfusion therapy, or splenectomy. In facing the issue of splenectomy following one or more episodes of acute splenic sequestration, the ease of accessibility of the child to a competent medical facility in the event of an acute event and the functional state of the spleen must be considered. In situations where it is deemed unlikely that the child can reach a competent medical facility in time, splenectomy should be performed after the first episode of acute splenic sequestration. Where medical access is not a problem, the function of the spleen can be assessed through technetium-99m sulfur colloid scan or pocked red cell counts. If the spleen is judged functional, it might be prudent to delay splenectomy through chronic transfusion therapy until the child is 3 years or older. Partial splenectomy could be an alternative solution.

In regions of the world where sickle cell anemia is accompanied by high HbF levels, such as the eastern province of Saudi Arabia, the features of splenic sequestration are different. The age of onset is later and chronic splenomegaly is often present. In 44 sickle cell disease patients who had a splenectomy, more than half had high HbF levels and hypersplenism and most had some type of sequestration crisis, which could be minor. The spleen showed histological features of fibrocongestive splenomegaly.[121] Among 134 patients with sickle cell anemia who had splenectomy, recurrent acute splenic sequestration crisis was the most common indication, followed by hypersplenism. The mean HbF level was 20.5%.[122]

Aplastic Crisis and B19 Parvovirus Infection

Beyond malaria endemic areas, the most common cause of acute anemia in children with sickle cell disease is the so-called "aplastic crisis." This is defined as a transient erythroid aplasia or hypoplasia and is usually associated with parvovirus B19 infection, an agent that preferentially attacks erythroid precursors – the P antigen of erythrocytes is its receptor – so that the bone marrow has few primitive red cells and reticulocytes might be absent. Recovery occurs in 1–2 weeks. Not every patient with evidence of B19 parvovirus infection becomes acutely anemic and the reason for this is not known. Patients who have been infected with this virus appear to develop life-long immunity due to the presence of neutralizing antibodies. Transient cessation of red cell production in the marrow, coupled with the continued rapid destruction of sickle erythrocytes in the periphery, results in a rapidly developing severe anemia. The incidence of transient erythroid aplasia has not

been determined in many sickle cell disease populations. In the 64 acute anemic episodes not due to acute splenic sequestration that occurred in 33 children aged 10 years and younger, the CSSCD did not report the specific incidence of erythroid aplasia. The largest reported series of transient erythroid aplasia comes from the Jamaican cohort study. All 91 episodes of "aplastic crisis" occurring in 308 sickle cell anemia patients were associated with parvovirus B19 and the rate of parvovirus B19 infection was the same in both the patients and their normal age-matched controls. An additional 23 sickle cell anemia patients with parvovirus B19 infection showed mild or no hematological changes. In one United States institution, parvovirus accounted for only 70% of the episodes of "aplastic crisis." Other viruses and bacteria have been associated with transient erythroid aplasia.

The clinical course of transient erythroid aplasia is usually insidious and is often discovered during evaluation of febrile children. Older children can report headache or that they are easily tired. The diagnostic hallmark of transient erythroid aplasia is reticulocytopenia (often <2%) associated with either a minimal or a clinically significant fall in hemoglobin concentration from its usual level. Usually erythropoiesis alone is affected, but concomitant neutropenia and thrombocytopenia have also been reported. Because of its relatively gradual development – in contrast, acute splenic sequestration develops rapidly – transient erythroid aplasia is often well tolerated. Hemoglobin levels of less than 4 g/dL can be seen in patients whose only complaint might be fever. In patients without evidence of previous parvovirus B19 infection and who do not have increased IgG for parvovirus B19, it is important to document whether parvovirus B19 is responsible for any episode of reticulocytopenia by obtaining antiparvovirus B19 IgM and IgG levels. Aside from searching for possible bacterial causes of the febrile illness, it is generally not useful clinically to test for other viral infections in establishing etiology of erythroid aplasia. B19 parvovirus is often asymptomatic and more than 70% of patients aged 17–21 years have IgG antibodies but less than 30% of individuals had a history of acute anemic episodes.[123] Parvovirus B19 is also associated with acute splenic sequestration, acute chest syndrome, stroke, nephrotic syndrome, encephalopathy, and myocarditis.[124–126]

The prevalence and incidence rates of B19 parvovirus infection were determined in 633 patients with sickle cell disease. Thirty percent were B19 IgG positive at intake into the study. On annual testing the incidence rate was 11.3 per 100 patient-years. In 68 patients who developed transient red cell aplasia, pain was present in 61.8%, acute splenic sequestration in 19.1%, and acute chest syndrome in 11.8%.[127] Virtually identical findings were reported from Jamaica.[128]

Acute anemia with reticulocytopenia can also accompany oxygen treatment in sickle cell disease[129,130] and bone marrow necrosis.

Treatment recommendations. The management of transient erythroid aplasia starts with awareness of whether the patient has had prior infection with parvovirus B19. Routine screening of children with sickle cell disease for parvovirus B19 IgG helps to identify patients who remain at risk and in whom parvovirus B19 infection should be considered whenever they are evaluated for a febrile illness. Patients at risk or whose parvovirus B19 status is unknown should be isolated from pregnant women until the reticulocyte count is determined because this virus might have untoward affects on the fetus of susceptible women. In the future, when a vaccine is available, patients without B19 parvovirus immunity should be recipients. Unlike normal children, children with sickle cell disease are instructed to seek medical attention for all febrile illnesses. This increases the chances of those with parvovirus B19 being exposed to medical staff. A cluster of parvovirus B19 infections in nurses traced to two sickle cell disease patients hospitalized for transient erythroid aplasia has been reported.

During the earliest phases of acute illness, antiparvovirus IgM and IgG levels can be negative. It is advisable to repeat these tests 1 week or so later for evidence of recent parvovirus B19 reflected by an increase of IgM antibody. The main therapeutic decision considered in erythroid aplasia is whether or not transfusion of red cells is required. Patients with a 25% or more drop in their hemoglobin level from baseline with reticulocyte counts that are falling or are absent and those who are symptomatic from severe anemia should be transfused early to shorten the period of the acute anemia. In a series of 80 children with strokes at the Children's Hospital of Philadelphia at least four had a stroke during a period of severe anemia due to erythroid aplasia. Transfusion should be performed cautiously similar to that described for splenic sequestration to avoid hypervolemia and complications due to a sharp rise in blood viscosity. Typically, a patient with transient erythroid aplasia begins to show nucleated red cells and reticulocytes within a week of the severe reticulocytopenia. In untransfused patients, the reticulocyte counts can rise to dramatic levels during recovery.

Hyperhemolysis

Hemolysis in sickle cell disease is discussed in detail in Chapter 11. An increase in the rate of hemolysis, in conjunction with specific clinical complications of sickle cell disease, has been called hyperhemolysis and is a third potential cause of acute anemia in sickle cell disease. Nevertheless, most experts, in the absence of malaria, have had difficulty documenting a convincing case of acute hyperhemolysis. Hyperhemolysis should be typified by an acute reduction in hemoglobin level associated with higher than usual reticulocyte counts and perhaps an unaccountable and sudden increase in LDH. In some reported cases of hyperhemolysis, the patient might have been examined

during the recovery phase of an acute erythroid aplastic episode and the reticulocytosis was not reflective of increased red cell production due to hemolysis. Other cases could be a result of extensive bone marrow necrosis, although in this instance, reticulocytopenia should be present. Acute chest syndrome is often associated with a 0.5–1 g/dL drop in steady-state hemoglobin level. Also, during hospitalization for acute painful events, the hemoglobin concentration usually falls modestly. These observations are likely to be the result of a combination of events such as blood loss due to phlebotomy, acute bone marrow suppression due to associated inflammation, and small increases in hemolysis.

There is little evidence to implicate G6PD deficiency in accelerated hemolysis and acute anemia. Although reported, the lack of a sex difference in the incidence of acute anemic events argues against such an association.

Autoimmune hemolytic anemia is found in some patients with sickle cell disease who have been transfused and can be responsible for the fall in hemoglobin concentration from baseline (Chapter 29).

Perhaps the most clinically significant cause of acute hemolysis in sickle cell disease occurs in the context of malaria infection. Acute hemolytic anemia due to malaria is the leading cause of death in children with sickle cell disease living in malaria-endemic areas of Africa.

Bacterial infection can transiently reduce erythropoiesis and worsen the usual anemia of sickle cell disease. Rarely, in developed countries, when severe anemia develops, megaloblastic arrest of erythropoiesis is present. This is usually due to marginal nutrition that causes folic acid deficiency.

Erythropoietin in Sickle Cell Disease

Serum erythropoietin levels in sickle cell anemia have been measured and are inappropriately low for the level of hemoglobin.[131] This might be explained by the right-shifted blood hemoglobin–oxygen dissociation curve in sickle cell anemia that enhances the delivery of oxygen to tissues, and the observation that red cell precursor mass appears to be an independent determinant of erythropoietin levels. An expanded erythroid marrow of sickle cell anemia would offset the reduction in peripheral red cell mass, reducing erythropoietin concentrations.[132] Erythropoietin has been used successfully to treat the severe anemia that often develops as sickle nephropathy progresses. In this case, care must be taken to avoid untoward increases in PCV so that increased blood viscosity from sickle erythrocytes does not lead to an increased incidence of vasoocclusive events.

In a review of 39 patients with sickle cell disease treated with erythropoietin or darbepoietin the median dose range was more than 200 U/kg. It was suggested that this treatment might allow more aggressive dosing of hydroxyurea in the setting of mild renal insufficiency.[133]

Treatment recommendations. Increased hemolysis in a patient with sickle cell disease should be investigated to exclude autoimmune hemolysis that is found accompanying alloimmunization in heavily transfused patients. In these patients, because of the presence of antibodies that are usually panagglutinins, finding blood compatible for transfusion is difficult. Corticosteroids can be used effectively, as in other types of autoimmune hemolytic anemia.

Judicious use of blood transfusion is warranted when anemia is severe. Hemolysis related to malaria infection must be corrected as the infection is treated. It is generally recommended that children with sickle cell disease living in malaria-endemic areas should be protected from malaria. It is unclear whether this protection should be in the form of antimalarial prophylaxis or patient/family education on how to respond to febrile illness. The widespread selection of chloroquine-resistant *P. falciparum* in Africa and elsewhere makes that drug unsuitable for routine prophylaxis. It is also unclear whether sulfadoxine-pyrimethamine preparations recommended for malaria prophylaxis during pregnancy are suitable for long-term use in patients with sickle cell disease.

Infection

Epidemiology

Infection is the major cause of mortality and morbidity in children in the first years of life, when the most common offending agent is *Streptococcus pneumoniae*. The spectrum of infection changes with age, where Gram-negative organisms acquired via the urinary, respiratory, and gastrointestinal tract become more common and indwelling venous access devices are a common locus of infection.

Prior to the institution of universal newborn screening for sickle cell disease, pneumococcal vaccination, and penicillin prophylaxis therapy, *S. pneumoniae* bacteremia was the leading cause of death in patients aged younger than 2 years in the United States. Patients with sickle cell disease lose splenic reticuloendothelial function in early life. This was demonstrated by technetium-99m sulfur colloid liver-spleen scans, which showed absence of splenic uptake in young sickle cell anemia patients even when their spleen was enlarged, an entity termed functional hyposplenism. The dysfunction of the spleen appears to be unrelated to its size fluctuation in the early years; gradual enlargement occurs until ages 3–4 years, followed by gradual regression into a contracted fibrotic, but possibly revivable organ. Splenic dysfunction is also inferred from the appearance in circulation of red cells containing Howell–Jolly bodies – remnants of nuclear chromatin, normally "culled" from red cells by the spleen – and by the rise in "pocked," more correctly, pitted, red cells in circulation. The rate of splenic regression is related to the natural reduction in HbF levels that occurs during postnatal development. Ten Saudi Arabs,

aged 4–26 years, with sickle cell anemia and mean HbF of 20% were found to have splenic abscesses. Tender, enlarged spleen, abdominal pain, and fever were common presenting features. Six patients had evidence of infection with *Salmonella* sp.

Hyposplenic patients are susceptible to infection with encapsulated bacteria such as *S. pneumoniae* and *Haemophilus influenzae*. There is also evidence of abnormal granulocyte function in sickle cell anemia. Circulating neutrophils appear to be activated in the "steady state" as they have increased activity of phospholipase A_2.[134] Although these cells might contribute to the initiation of vasoocclusion, they also respond poorly to priming by cytokines and have approximately half the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase response as control cells. An impaired response would affect killing of microorganisms requiring high levels of oxidant radicals for their death, such as *S. pneumoniae* and *H. influenzae*. Sepsis, pneumonia, meningitis, and otitis are the most frequent infections and they can progress with devastating rapidity.

The immune defect in sickle cell disease appears to be specific for certain organisms; primary among these is *S. pneumoniae*. Early studies had demonstrated a defect in opsonization of *S. pneumoniae* antecedent to phagocytosis. This opsonic defect was initially thought to reside in the alternate pathway of complement activation, but later it was shown that the opsonic defect was due to a lack of specific antibodies against pneumococci, perhaps due to early loss of splenic antibody production function. This opsonic defect is not generalized to all microorganisms.

The relatively high risk of overwhelming pneumococcal infection in patients with sickle cell disease and the associated high rate of mortality have been well documented. The incidence of bacteremia in sickle cell disease varies with age and the genotype of the disease. Overall, the rate of bacteremia seems to have declined in the United States since the early reports of children with sickle cell disease having bacteremia at 300–600 times the rate of normal children. Factors accounting for the declining rate of bacteremia include the institution of penicillin prophylaxis and the use of conjugate pneumococcal and *H. influenzae* type b vaccination. In its cohort of 427 infants with sickle cell anemia followed from 1978–1988, the CSSCD reported that bacteremia occurred in babies younger than 6 months. The peak incidence of bacteremia, 9.9 events per 100 person-years, occurred in babies aged 6–12 months, declining to less than 5 per 100 person-years after age 3 years. The second 6 months of life also saw the highest incidence of bacteremia in children with HbSC disease. The CSSCD had reported an incidence of bacteremia of 7.98 per 100 person-years for children younger than 3 years with sickle cell anemia; this declined to 2.54 in those aged 3–5 years. *S. pneumoniae* was responsible for 67% of the cases of bacteremia in those younger than 6 years but only 19% of cases in individuals older than 6 years. Twenty-four percent of children younger than 3 years with sickle cell anemia who had pneumococcal bacteremia died. In 75% of the patients who died of sepsis, death occurred within 24 hours after hospitalization.

Recent changes in management of febrile illness in young children with sickle cell disease have reduced the rate of mortality. In the CSSCD infant cohort of 427 children with sickle cell anemia, there were 62 cases of *S. pneumoniae* bacteremia with a 14.5% mortality rate, after 1,781.4 person-years of observation.

With increasing age, the cause of bacterial infection in sickle cell disease changes from the pneumococcus to Gram-negative organisms such as *Escherichia coli*, *Klebsiella* and *Salmonella* species.[135,136] Acquisition of natural antibodies, subclinical infection, and in recent years, protection offered by conjugated pneumococcal vaccination might account for the decline in relative risk of pneumococcal infection despite the permanent loss of splenic function. Until the widespread use of *H. influenza* type b vaccination, this organism was the second leading cause of sepsis and meningitis in children with sickle cell disease. As the rate of *H. influenza*e infection has declined in the general childhood population so has it declined in children with sickle cell disease, although it remains higher than that in the general population.

In addition to bacterial sepsis and meningitis, patients with sickle cell disease have increased risk of osteomyelitis. In the United States, *Salmonella* sp. are the most common cause of osteomyelitis followed by *Staphylococcus aureus*.[137] In recent literature from other parts of the world, *Salmonella* sp. are reported also as the most frequent causes of osteomyelitis in sickle cell disease patients. Other Gram-negative organisms such as *Klebsiella* and staphylococcal species are the leading causes of osteomyelitis in some regions.

Eighteen African American patients with sickle cell disease with human immunodeficiency virus (HIV)-1 infection were reported, 11 who had quantitative studies of viral load and were under treatment or follow-up. Although data are scanty, it might be that these HIV-1–infected sickle cell anemia individuals have a lower viral load and higher CD4 cell counts than HIV-1–infected control patients and include more asymptomatic long-term nonprogressors than controls. It was hypothesized that asplenia removes an important site for viral replication and accounts for a more indolent disease when HIV-1 and sickle cell anemia coexist.[138]

Prevention

Invasive pneumococcal infection was the nemesis of children with sickle cell anemia, a major contributor to morbidity and the leading cause of death in children, adolescents and young adults prior to the initiation of penicillin prophylaxis.[139] More than 20 years ago, in a randomized, controlled clinical trial, Gaston and colleagues[140] showed

that when children with sickle cell disease received penicillin prophylactically, they had an 84% reduction in pneumococcal infection. The results of this landmark study lead to a rapid medical response that improved the care of children with sickle cell disease. Prevention of mortality from pneumococcal infection is the basis for the establishment of newborn screening for sickle cell disease as these infections can occur shortly after birth. Since 2006, all states now universally screen for sickle cell disease so that affected infants can be identified and given prophylactic penicillin. When identified, infants at risk, when possible, are followed in special Pediatric programs, and in addition to being given prophylactic penicillin, a polysaccharide pneumococcal vaccine was administered, most commonly at age 2–5 years.[140] Parents should be taught to understand the importance of the appearance of fever and the need for rapid treatment should pneumococcal infection "breakthrough" the antibiotic-vaccination barrier. This approach was believed to reduce the high mortality rate of pneumococcal infection.

Nevertheless, infections continued to occur because of vaccine ineffectiveness and the lack of compliance with prophylaxis. A recent study examined the incidence of invasive pneumococcal disease before and after the introduction of the 7-valent pneumococcal conjugate vaccine.[141] The results were remarkable: an average 92% decline in infection in children younger than 5 years when the post–conjugate vaccine era was compared with the pre–conjugate vaccine era. A similar effect was not seen in older children. Only a small number of individuals developed pneumococcal disease, the surveillance had a limited geographical distribution, and all drug recipients were Medicaid enrollees, so that replication of these results is warranted.

Penicillin remains highly efficacious prophylaxis for most strains of *S. pneumoniae*. What makes this treatment a less effective approach to disease prevention is that compliance with treatment is suboptimal. Penicillin should be given twice daily and the solution used for the youngest children remains stable for only 2 weeks. In one study, only 25%–30% of Medicaid program enrollees were likely to receive prophylactic penicillin for at least 270 days per year, and this failure to achieve maximal prophylaxis seemed likely to be generalizable, at least to the Medicaid population.[141] Perhaps the financial difficulties encountered by state Medicaid programs accounted for this poor record of prophylaxis.

Although a polysaccharide pneumococcal vaccine was first introduced in the late 1940s and a 23-valent vaccine was available by 1986, the babies with sickle cell disease, who are at highest risk for infection, often have a poor antibody response. The risk of infection in children younger than 3 years might also not be reduced. The loss of splenic function in older children retards their response to this vaccine. In contrast, the conjugate pneumococcal vaccine is given in the first months of life when the risk infection in sickle cell disease begins and this immunization is associated with a superior antibody response.[142]

How long penicillin prophylaxis should be continued is unclear. A follow-up study to the prophylactic penicillin trial whose purpose was to determine the efficacy of penicillin prophylaxis in children older than 5 years with sickle cell anemia failed to show any significant difference between the penicillin and placebo groups.[143]

These results do not apply to children with a history of severe pneumococcal infection or splenectomy as they were excluded from the study. Some clinicians might conclude that penicillin prophylaxis is unnecessary for patients older than 5 years. Splenic dysfunction remains present however, and older children and adults have died of overwhelming pneumococcal infection. The decision to discontinue penicillin prophylaxis for any child should be carefully considered, taking into account parental understanding of and the ability to respond appropriately to signs of infection and the prior history of pneumococcal infection.

With effective vaccines to prevent infection with *S. pneumoniae*, the question of whether or not prophylactic penicillin is needed arises. Widespread penicillin use is not risk free. Penicillin-resistant strains of *S. pneumoniae* are increasing in number and approximately 4% of isolates in sickle cell disease have some measure of resistance; most patients taking prophylaxis harbor some resistant strains. The susceptibility of these organisms to penicillin might be declining and prophylaxis is less effective in carriers of intermediate resistance and resistant serotypes. In North America, the 7-valent conjugate vaccine protects against more than 70% of the serotypes isolated from patients in the pre–conjugate vaccine era; however, two-thirds of the serotypes not included in the vaccine were susceptible to penicillin and the use of this vaccine appeared to decrease the number of antibiotic-resistant invasive pneumococcal infections.[144] To increase vaccine efficacy a 13-valent vaccine is being developed. Although patterns of penicillin resistance and vaccine susceptibility are likely to continue to change and to differ throughout the world, until a conjugate vaccine with greater coverage is available, antibiotic prophylaxis could still be useful.[145]

Is a conjugate vaccine useful in other parts of the world where sickle cell disease is more common than in North America and where the spectrum of pneumococcal disease might be different? In developing countries, a vaccine that is affordable, deliverable, and covers the spectrum of infectious strains of the pneumococcus could have a major impact on the public's heath. Although only 32% of infected patients in an urban hospital and 23% of pneumococcus carriers from rural villages in The Gambia had serotypes represented in the vaccine, in both studies approximately twice as many individuals had serotypes related to those in the vaccine.[146,147] Despite some concerns, because of the benefits of vaccination in the general population, experts

have suggested that vaccination should start now if the obstacles to vaccine delivery can be overcome.[148] Sickle cell disease patients will be special beneficiaries of this policy. Another caveat to consider is that *S. pneumoniae* can switch capsular serotypes by conjugation and adapt to the presence of vaccine pressure. This is one mechanism by which virulent nonvaccine serotypes could arise in the face of vaccine pressure.[144]

Treatment. Young children with sickle cell disease who have a febrile illness are managed as if they have pneumococcal sepsis until proven otherwise. This practice mandates that all children with sickle cell disease with significant fever or who simply look or act ill need medical evaluation and prompt antibiotic therapy. Their evaluation should consist at minimum of a physical examination, complete blood count, reticulocyte count (to exclude erythroid aplasia), and a blood culture. Lumbar puncture should be performed if meningitis is suspected based on the examination or cannot be ruled out because of the young age of the patient. Immediately after the specimens for culture are obtained, broad-spectrum antibiotics should be administered intravenously. A chest x-ray is advisable in children younger than 3 years because physical signs of acute chest syndrome can be less obvious in young children, and because the presence of acute chest syndrome would alter the course of therapy.

Children younger than 6 years with fever, or who appeared ill were hospitalized and treated with intravenous antibiotics until bacterial cultures were negative. The standard practice has shifted to outpatient management of febrile children with sickle cell disease who are not ill appearing. Children are given ceftriaxone, a long-acting cephalosporin with excellent antipneumococcal sensitivity, watched for a few hours to ensure their continued well-being, and discharged home for outpatient follow-up. In some institutions, infants are excluded from outpatient management of febrile illness, and in others, children are given oral antibiotics for a few days following the intravenous ceftriaxone. This practice change has succeeded largely because in the era of penicillin prophylaxis, pneumococcal vaccination, and comprehensive care, the incidence of pneumococcal sepsis, bacteremia, and meningitis has become very low at major clinical centers. With good follow-up, outpatients whose cultures grow pathogenic bacteria are returned for further evaluation and appropriate treatment. An unusual fatal hemolytic reaction to ceftriaxone in a child with sickle cell disease has been reported. This underscores the need for close follow-up of those managed as outpatients after receiving ceftriaxone.

The standardized incidence rates for second and third infections in patients with sickle cell anemia were 4.8 and 15.8 times greater, respectively, than the rate of infection in the sickle cell anemia population at large. This implied that the susceptibility to infection is characteristic of a subgroup of patients and that sick patients with prior bacteremia should be assessed early and aggressively for further infection. A possible genetic basis for bacteremia is discussed in Chapter 27.

Acute Chest Syndrome

Epidemiology

Characterized by fever, chest pain, cough, and lung infiltrates, this sometimes lethal complication affects more than half of all sickle cell disease patients and is the second most common reason for hospitalization. Acute chest syndrome was defined in the CSSCD as, "the new appearance of an infiltrate on chest radiograph or, in the presence of pulmonary symptoms and negative chest radiograph, abnormalities on an isotopic scan of the lungs." This broad definition attempted to unify a condition characterized by chest pain, varying degrees of respiratory distress, fever, cough, and leukocytosis. In many instances, particularly in young children, the new pulmonary infiltrate is discovered incidentally as part of the evaluation of fever. Acute chest syndrome has its highest incidence in the more severe forms of sickle cell disease, but also occurs and can be lethal in HbSC disease and HbS–β^+ thalassemia.

In 3,751 patients who were observed for a total of 19,867 person-years, 1,085 (29.2%) had at least one episode of acute chest syndrome. Of these individuals, 56% had only one episode, whereas 6% had five or more episodes.[149] Acute chest syndrome occurred more often in sickle cell anemia (12.8/100 person-years) and HbS–β^0 thalassemia (9.4/100 person-years) than in HbSC disease (5.2/100 person-years) and HbS–β^+ thalassemia (3.9/100 person-years). Risk factors for acute chest syndrome in sickle cell anemia patients were low age, low HbF level, high total hemoglobin level, and high steady-state leukocyte count. Children aged 2–4 years with sickle cell anemia had the highest incidence of acute chest syndrome (25.3/100 person-years) The direct relationship between hemoglobin concentration level and acute chest syndrome is unexplained, but it is thought to be related to the higher blood viscosity associated with a high PCV. The role of asthma is discussed later.

Pathophysiology

The etiology of acute chest syndrome is usually not defined, and in most instances is likely to be multifactorial. Its pathogenesis is summarized in Table 19.2. Pulmonary infarction, pulmonary infection with all types of microorganisms, atelectasis secondary to rib infarction and involuntary splinting, pulmonary embolism, necrotic bone marrow emboli, and in situ thrombosis all might eventuate in acute chest syndrome. Lungs are particularly vulnerable to vasoocclusive damage in sickle cell disease. Deoxygenated sickle cells that manage to escape trapping in the peripheral microcirculation are returned to the lungs where they are

Table 19.2. Pathogenesis of the acute chest syndrome

Mechanism	Evidence
Bone infarction with atelectasis and regional hypoxia	Bone infarctions cause pain with hypoventilation, atelectasis, and subsequent hypoxia
	Incentive spirometry reduces radiographic atelectasis in patients with sickle cell anemia and vasoocclusive crisis
Fat emboli	Bone marrow embolization found in many patients
	Lipid-laden alveolar macrophages are recovered from bronchopulmonary lavage fluids in acute chest episodes
	Secretory phospholipase A_2 levels elevated and may liberate free fatty acids and promote inflammation
Infection	Seasonal predilection, pathogenic microorganisms recovered from lung and blood
Thromboembolic disease	Microvascular in situ thrombosis
	Increased adherence of erythrocytes to endothelial cells
	Pulmonary hypoxia results in entrapment of sickle erythrocytes
	Pulmonary emboli documented
Vascular injury and inflammation	Endothelin-1 levels elevated during acute chest syndrome
	Elevated levels of inflammatory mediators
	Clinical progression to acute respiratory distress syndrome

Adapted from ref. 161.

reoxygenated. It is conceivable that those cells that become fully sickled by the time they reach the lungs and before they are reoxygenated would be trapped in pulmonary precapillary arterioles, particularly in atelectatic areas, before reoxygenation and unsickling. Large and small branches of pulmonary arteries probably undergo damage similar to that seen in cerebral arteries in sickle cell disease, leading to stenosis and occlusion of the vessels and diminished blood flow and infarction in some areas of the lung. Cumulative microinfarction of the lung might lead to progressive pulmonary dysfunction and chronic lung disease with advancing age (see later). Shunting of deoxygenated and partially oxygenated red cells from the alveolar microcirculation is likely to deposit into the peripheral circulation cells that might readily sickle on further deoxygenation. Partially oxygenated sickle cells have been described in the circulation of patients with sickle cell disease.

Isolation of microorganisms in pulmonary secretions or from the blood during the course of acute chest syndrome does not necessarily establish that they are etiologically related to acute chest syndrome, and their presence might represent superinfection in damaged pulmonary tissue. It is believed that acute chest syndrome can be triggered by lung infection. Unsurprisingly, a wide variety or organisms have been associated with acute chest syndrome, and the recovery of an offending agent is greatly increased by bronchopulmonary lavage. Such agents include, *S. pneumoniae, H. influenzae, Mycoplasma pneumoniae, and Chlamydia pneumoniae.*[150] Recent data indicate that approximately 5% of acute chest syndrome episodes are associated with recent B19 parvovirus infection. In most cases of acute chest syndrome, an aggressive search for all possible causes of infections is not done. Therefore, many of the published studies on the frequency infection in acute chest syndrome underreport the possibility of such a causative linkage. A pathogen isolated from blood at the time of acute chest syndrome is often assumed to be its causative agent. Bacteremia was present in only 3.5% of the 1,772 episodes of acute chest syndrome reported by the CSSCD. The most frequent organism was *S. pneumoniae*, followed by *H. influenza*, a pathogen much less common now as a cause of serious infection in the United States than in the CSSCD report. Children were more likely to have infection-associated acute chest syndrome than were adults. In children younger than 2 years, 14% of the episodes of acute chest syndrome were associated with bacteremia and *S. pneumoniae* was the pathogen in 78% of cases. In contrast, only 1.8% of patients older than 10 years had bacteremia, and *S. pneumoniae* accounted for only 25% of the positive cultures.

Acute chest syndrome is a frequent postoperative complication of sickle cell disease. It is presumed that this is an extension of the common atelectasis that tends to follow prolonged anesthesia. The likelihood, however, that pulmonary infarction initiated by sickled red cells returning to the lungs after slow flow through anesthetized tissue cannot be discounted.

Clinical Course

The course of acute chest syndrome is variable. Fever, cough, and chest pain are the most common presenting symptoms. Children younger than 5 years presented more frequently with fever and cough, whereas older children and adults tended to also have shortness of breath, wheezing, productive cough, chest pain, and chills. Pain and fever are the most frequent acute events associated with acute chest syndrome. Thirty percent of the patients with acute chest syndrome had pain, but adults tended to have pain prior to acute chest syndrome more often than did children. Rib infarction was a common precipitating factor of acute chest syndrome. Incentive spirometry was able to reduce the incidence of acute chest syndrome following rib infarction.

Fat embolism from necrotic bone marrow is a common cause of the most severe acute chest events during which hemoglobin and platelet levels fall and the leukocyte count increases.[151] Fat embolism, with its poor prognosis, can be identified by finding lipid within pulmonary macrophages

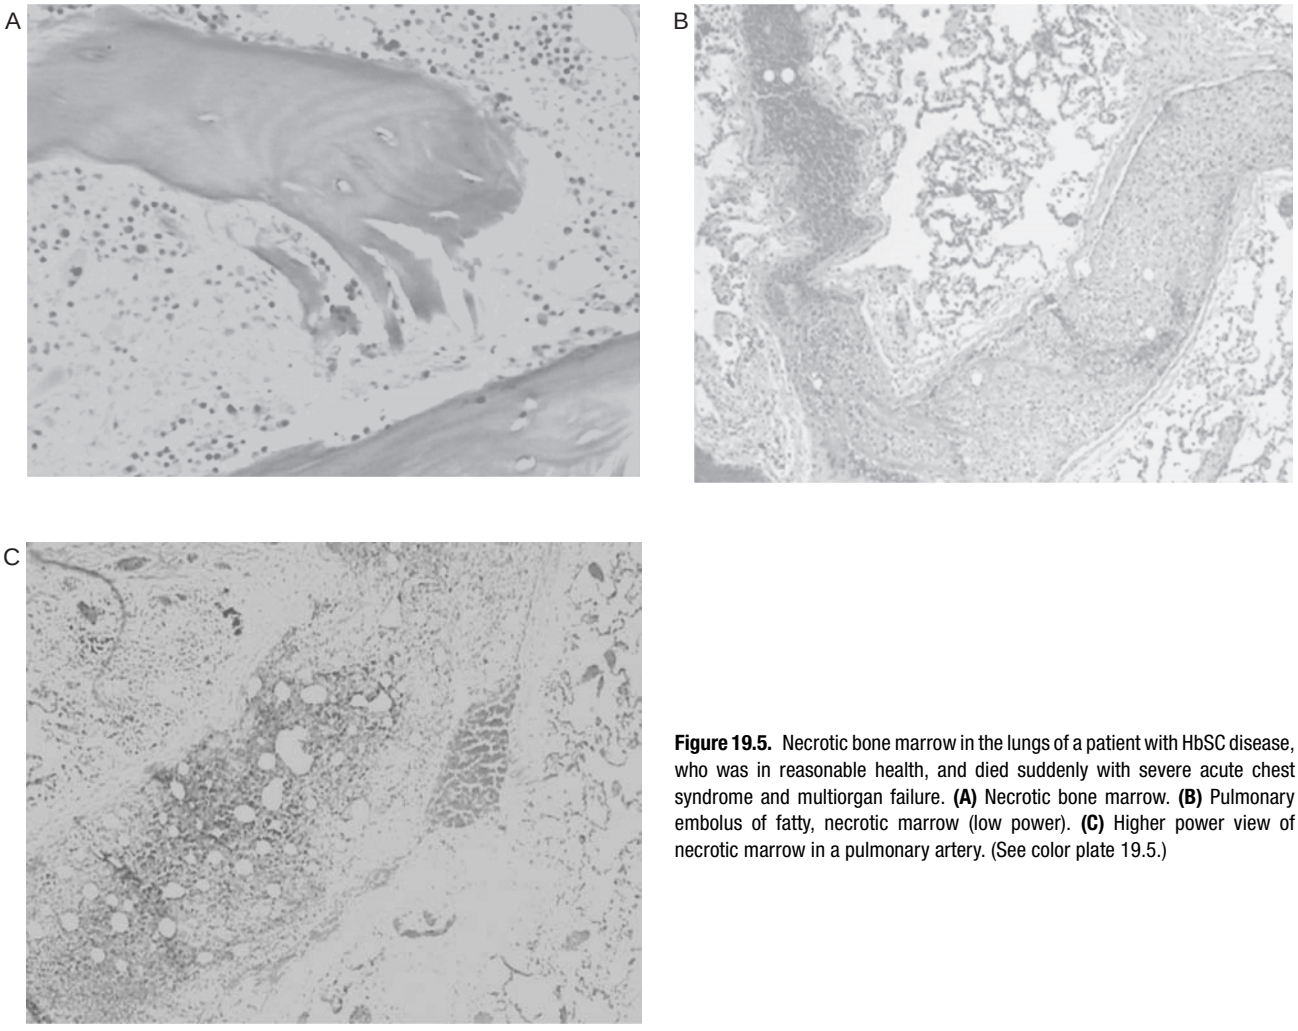

Figure 19.5. Necrotic bone marrow in the lungs of a patient with HbSC disease, who was in reasonable health, and died suddenly with severe acute chest syndrome and multiorgan failure. **(A)** Necrotic bone marrow. **(B)** Pulmonary embolus of fatty, necrotic marrow (low power). **(C)** Higher power view of necrotic marrow in a pulmonary artery. (See color plate 19.5.)

obtained by bronchopulmonary lavage; however, this test is rarely done. Fat-laden necrotic bone marrow has been found on autopsy of sickle cell disease patients dying from severe acute chest syndrome (Fig. 19.5). The detection of fat in the circulation and in pulmonary macrophages can also help make this diagnosis. Sometimes, bone marrow fat embolization causes an adult respiratory distress–like syndrome, in which maintaining adequate oxygenation is difficult and multiorgan failure develops. This is characterized by central nervous system disease including lethargy progressing to coma, renal failure, hepatic failure, rhabdomyolysis, severe anemia, thrombocytopenia, and marked leukocytosis. Fat emboli, in addition to being prominent in the pulmonary vasculature, can be seen in the brain and other organs. In the full-blown multiorgan failure syndrome, which might develop over the course of hours, death might at times be inevitable despite the rapid institution of treatment.

Although it is generally believed that repeated episodes of acute chest syndrome lead to restrictive and obstructive lung disease, to date, no longitudinal studies have confirmed this supposition. A history of acute chest syndrome was associated with lower transcutaneous oxygen saturation in one study. A similar finding was made when children older than 5 years were compared with younger children. Acute chest syndrome is often recurrent and a few patients have repeated severe episodes. Such patients and those with chronic hypoxia after surviving severe acute chest syndrome or adult respiratory distress syndrome might benefit from chronic transfusion therapy.

Prevention

Prevention of acute chest syndrome should be among the goals of managing sickle cell disease patients in pain, particularly when they are bedridden. The use of incentive spirometry in all patients should be strongly encouraged.[152] Routine assessment of oxygen saturation by using pulse oximetry at steady state should be part of general care of sickle cell disease patients. A drop of 3% or more from

baseline level at presentation with acute illness was predictive of acute chest syndrome.[153]

Elevated levels of phospholipase A_2 have been found in sickle cell disease patients in association with acute chest syndrome. Free fatty acids released from embolized fat by phospholipase A_2 were suspected of causing further damage to lung tissue. It was hypothesized that elevated levels of serum phospholipase A_2 might predict the occurrence of acute chest syndrome. In a pilot study, when patients were hospitalized with an acute painful episode, but without evidence of acute chest syndrome, they were randomized to receive either a simple blood transfusion or standard care. Five of eight patients who received standard care developed acute chest syndrome compared with none of the seven patients who were transfused. These promising results have lead to the planning of a larger clinical trial of the ability of serum phospholipase A_2 levels to predict development of acute chest syndrome and of transfusion to thwart its occurrence.[154–159]

Hydroxyurea (see Chapter 30) reduced the frequency of acute chest syndrome in adults with sickle cell anemia but it is unclear whether hydroxyurea alone will prevent recurrent acute chest syndrome.

Management

Severe acute chest syndrome is a medical emergency, as progression to hypoxia and circulatory collapse with multiorgan failure requiring intensive care can rapidly develop. Vigilance and a high index of suspicion that this can occur should dictate the management of most cases of acute chest syndrome, especially when on presentation, pain is severe, hypoxia present, the hemoglobin concentration is lower than the baseline level, the leukocyte count is elevated beyond that customary for a painful event, and the platelet count is depressed from its baseline. Repeating a previously normal chest x-ray, especially if chest pain is present, and continuous, or very frequent measurement of blood oxygenation by pulse oximetry will permit the early detection of hypoxia that might signal the need for transfusion.

Successful management of severe acute chest syndrome depends to a large degree on the experience of the intensive care unit in managing such patients. Close coordination of intensive care among internists, pulmonologists, hematologists, infectious disease experts, nursing, and respiratory therapists is necessary for achievement of a successful outcome. Response to treatment was evaluated in 671 episodes of the acute chest syndrome in 538 patients.[150] Treatment included phenotypically matched blood transfusions, bronchodilators, and bronchoscopy. Thirteen percent of patients required mechanical ventilation; 3% died and 81% recovered. As in prior studies, adults older than 20 years were more severely affected than younger patients. Transfusions improved oxygenation with a 1% rate of alloimmunization. Twenty percent of the patients treated with bronchodilators improved. Eighteen patients died, and the most common causes of death were pulmonary emboli and infectious bronchopneumonia, with infection contributing to 56% of the deaths. Regardless of its etiology, management of acute chest syndrome includes intravenous broad-spectrum antibiotics, careful hydration, aggressive respiratory therapy with bronchodilators, incentive spirometry, and maintenance of tissue oxygenation. Antibiotics are usually given although documented bacterial infection is found in less than 10% of cases. The choice of antimicrobial can be predicated on the algorithm for community-acquired pneumonia; however, some patients with sickle cell disease are frequent hospital visitors and this might modify the choice of a drug. It has become customary to add erythromycin or another agent to cover mycoplasma or chlamydiae infection. Oxygen therapy should be given when the patient is hypoxic or tachypneic with signs of respiratory distress. Hydration should be used carefully to avoid pulmonary edema and should not exceed maintenance and replacement of losses. In the context of pain management with opioid analgesics, care should be taken to balance the analgesic need and the danger of respiratory suppression.

Simple or exchange transfusion to reduce the percentage of HbS containing cells and increase the baseline hemoglobin concentration level is useful in hypoxic patients. The timing of transfusion is unclear as is whether exchange transfusion is superior to simple transfusion. Although some experts prefer the former, a controlled study of the merits of any form of transfusion for acute chest syndrome has not been conducted. It is the impression of clinicians that patients with infarctive acute chest syndrome, as opposed to infectious acute chest syndrome, if this distinction can be made, have a more rapid recovery in response to blood transfusion, suggesting that early transfusion might prevent progression to severe acute chest syndrome. This also has not been tested in a controlled study. In patients with moderate to severe acute chest syndrome, the goals of transfusion should be to maintain a hemoglobin concentration of 10 g/dL and HbS level of less than 30%, levels similar to those used in the management of stroke. Blood less than 5 days old is preferable because banked blood has low 2,3 bisphosphoglycerate levels and a high affinity for oxygen. Transfusing old blood into a hypoxic sickle cell disease patient could worsen the condition of the patient in the immediate posttransfusion period as transfused cells have a higher oxygen affinity than normal until the 24 hours that it takes to restore 2,3, bisphosphoglycerate levels passes.

Recent studies suggest that NO could be involved in the pathogenesis of acute chest syndrome and that inhaled NO could be a useful treatment (summarized in ref. 162). It must be emphasized that despite apparent responses to 80 ppm inhaled NO for 15 minutes in acute chest syndrome, with increases in pO_2 and reductions in pulmonary artery pressure, there have been no careful clinical trials of this

treatment and this treatment has not yet improved mortality in adult respiratory distress syndrome.

ADOLESCENCE

Adolescents with sickle cell disease face both the physical limitations associated with this disease and the psychological impact of a serious chronic disease. Although sickle cell disease in older children and adolescents is not fundamentally different, there are a few problems that are more or less common during adolescence. In the second decade of life patients with sickle cell anemia have a lower incidence of bacteremia, dactylitis, acute splenic sequestration, acute chest syndrome, stroke, and mortality, but higher incidence of cholelithiasis and cholecystectomy and severe pain episodes.

Psychosocial Issues

Although adolescence can be a period of relative stability medically, it is not so psychologically. In fact, much of medical literature dealing with adolescents with sickle cell disease concentrates on psychosocial issues. The management of adolescents with sickle cell disease has been reviewed.[163] Some of the major issues in adolescents with sickle cell disease include, growth and development, management of pain, the psychological impact of, and psychosocial adjustment to a chronic disease and their transition to adult care.

Psychosocial problems reported in adolescents with sickle cell disease include low social adjustment, depression, anxiety, acting out behavior, and negative body image. These are not unexpected outcomes from a chronic disease, which is associated with severe pain, physical limitations, and an unpredictable course. Adolescent boys are more vulnerable to psychosocial problems than are girls and demonstrate more difficulties coping with sickle cell disease. Older boys were more likely to be socially withdrawn and were more depressed than younger boys and girls. Family competence was associated with fewer internalizing and externalizing behaviors by the adolescent. Difficulties with medical staff often begin in adolescence and frequently revolve around issues of pain management and inpatient stay. Unpredictable painful episodes can hamper the adolescent's development of a sense of control.[163]

Psychosocial difficulties of adolescents with sickle cell disease often go unaddressed by pediatric staff who feel unqualified to handle such issues. Those unresolved difficulties become magnified when adolescents are transferred to adult care. Independent of parents, transferred patients might fail to comply with recommended medical therapy and follow-up. There is growing interest in ensuring that the transition from pediatric to adult care proceed successfully for adolescents with sickle cell disease. Programs caring for adolescents with sickle cell disease need to be aware of these psychosocial issues and adopt measures to ensure optimal physical and psychological wellness for their patients. A series of guidelines on psychosocial issues are recommended for professionals taking care of adolescents and others with sickle cell disease.[164,165]

YOUNG ADULTS

Pregnancy and Contraception

The obstetrical and gynecological issues of sickle cell disease, including recommendations for management, have been reviewed. Pregnancy in sickle cell disease is not contraindicated. Complications of pregnancy are most prevalent in sickle cell anemia and HbS–β^0 thalassemia and less common in HbSC disease and HbS–β^+ thalassemia.[166] Routine sterilization or interruption of pregnancy in women with sickle cell anemia is not medically indicated. Women with sickle cell disease appeared to be as fertile as controls, although they had a delay in menarche and for their first pregnancy. In the Jamaican study, the number of infants born to patients with sickle cell disease was less at all ages compared with controls, perhaps reflecting lesser fertility after a first pregnancy.

The Placenta

The placenta in sickle cell anemia weighs less than that of age-matched controls and shows villous sclerosis, intervillous fibrin deposits, and infarction.[167] Umbilical veins have irregularly elongated and round cells suggesting hypoxia and proliferation of the smooth muscle cells, absence of an inner elastic lamina in the tunica media, and varying thickness of the basement membrane.[168] These changes are possibly related to hypoxia-induced cytokines in the placenta and umbilical vein.[169,170]

Hazards of Pregnancy

A low birth rate may be explained in part by the anemia and vasculopathy of sickle cell disease and perhaps poor access to health care. One hundred twenty-seven deliveries in women with sickle cell anemia and HbSC disease that occurred between 1980 and 1999 were compared with a control group of 129 deliveries in African American women with normal hemoglobin. Compared with controls, deliveries among women with sickle cell disease were at increased risk for intrauterine growth restriction, antepartum hospital admission, and postpartum infection. They were also more likely to be complicated by low birth weight, prematurity, and preterm labor or premature rupture of membranes. Perinatal deaths were similar and there were no maternal deaths.[171]

The hazards of pregnancy in sickle cell anemia are many, especially for the fetus. Older medical literature suggested that pregnancy in sickle cell anemia was not worth the risk and that therapeutic abortion and early sterilization was

desirable. Modern medical management of pregnancy generally achieves good results but the rate of obstetrical complications is still higher than in normals. Among more than 9,300 African American women delivering at a single maternity center, the combined prenatal and perinatal losses in women with sickle cell anemia were 20% compared with 10% in women with HbAS or normal hemoglobin.[172] Four percent of women with sickle cell anemia had pyelonephritis (0.3% in controls); pregnancy-induced hypertension was found in 20% (9.6% in controls); caesarian sections were performed in 44% of patients (22% in controls); gestational ages were approximately 1 week less than in controls; and birth weight was 2,700 g (3,010 g in controls). Patients with sickle cell anemia have approximately twice the normal rate of multiple pregnancy, placenta previa, abruptio placentae, preterm delivery, fetal distress, and caesarean sections and a fivefold increased occurrence of toxemia.[172] Twenty-one percent of infants born to mothers with sickle cell anemia were small for gestational age when compared with the general population; the incidence in mothers with HbSC disease and HbS–β thalassemia is unknown but presumed to be less. Small-for-gestational-age fetuses are likely a result of placental insufficiency and patients with preeclampsia and acute anemic events are especially prone to this complication.[173] In a cohort individuals with sickle cell anemia residing in Jamaica and their matched normal controls who were followed from birth, patients had later menarche and age of first pregnancy by several years. Thirty-seven percent of patients had spontaneous abortions compared with 10% of controls and babies of subjects had a lower gestational age and lower birth weight. In this study, the death rate was 2.1%.[175]

Given access to modern obstetrical care, maternal mortality has been reported to range from less than 0.5% to 2.1%.[173–177] In pregnancy, the B19 parvovirus may cause fetal loss and hydrops fetalis. In the general population, parvovirus-infected patients have a 10% risk of fetal loss before 20 weeks gestation, falling to 1% afterward. The incidence and risk in pregnant sickle cell disease patients are unknown and the role of intrauterine blood transfusion and intravenous immunoglobulin has not been studied.[178,179]

Sickle cell patients have an increased risk of developing preeclampsia after 20 weeks of gestation when hypertension coexists with edema and proteinuria. The pathophysiology of preeclampsia lies in utero-placental insufficiency, which activates endothelial cells with release of oxygen free radials, endothelial reactive substances, and consumption of NO and prostacyclins. As noted in Chapters 10 and 11, sickle vasculopathy is associated with similar abnormalities.

Treatment recommendations. Pregnant patients should be seen by their obstetrician at least twice monthly and their labor closely supervised with frequent fetal monitoring. Antenatal care is best provided by an obstetrician familiar with sickle cell disease patients in conjunction with an experienced hematologist. Prenatal visits serve to collect background data, establish the hemoglobin phenotype, and catalog the existing complications of the disease. Other than HbF level, maternal steady-state hematology has little influence on fetal outcome. Pertinent data include previous pregnancies and their outcomes, previous complications during pregnancy with emphasis on spontaneous abortions, preeclampsia, low-birth weight infants, and complications from sickle cell disease such as acute chest syndrome, stroke, cardiac disease, pulmonary hypertension, and history of blood transfusions. Some patients with frequent vasoocclusive complications, renal failure, pulmonary hypertension, prior spontaneous abortions, and frequent blood transfusion warrant even more intense observation.

As a group, patients with sickle cell anemia have relative hypertension as their blood pressure is higher than expected when compared with a control group with similar levels of anemia. This is associated with an increased risk of stroke. Even “normal” blood pressure might be “abnormal,” so this should be carefully followed. Similarly, significant renal damage can be present with normal serum creatinine levels because of the very high glomerular filtration rates in young patients with sickle cell anemia (see later). Prognostically, women with the highest levels of HbF had a lower rate of fetal perinatal death.[179]

A medication profile with particular attention to hydroxyurea use should be documented. Although patients have become pregnant or fathered children while taking hydroxyurea or having taken hydroxyurea in the past, this drug is a teratogen in animals and should not be used if pregnancy is planned. Pregnancy has been reported in at less than two dozen individuals receiving hydroxyurea, usually for myeloproliferative disorders, but sometimes in sickle cell anemia.[33] In this very small experience there have been no adverse outcomes. Developmental defects have not been reported in pregnant patients who took hydroxyurea for other diseases. Contraception should be practiced by both women and men receiving hydroxyurea and the uncertain outcome of unplanned pregnancy discussed frankly. If pregnancy occurs while taking hydroxyurea there is little information on which to base a decision for continuation or termination of the pregnancy. So far, congenital defects have not been described in pregnancies followed to term and developmental defects have not been reported in infants of mothers who took hydroxyurea for other diseases. This is no cause for complacency and careful studies of this issue have not yet been reported.

Antenatal testing should include, hemoglobin fraction quantification by HPLC to establish the hemoglobin phenotype and HbF level. HPLC is also used to measure HbA and HbS concentration after transfusion. In addition to blood counts and serum chemistries, other laboratory tests should include hepatitis A, B, C, and HIV testing, electrolytes, urinalysis, urine culture, rubella antibody titer, and serum ferritin. All patients should have their red cell

phenotype recorded and alloantibodies identified so that if the need arises for blood transfusion, phenotypically matched blood can be used. When antenatal diagnosis is contemplated, the parental genotypes must be determined by DNA-based methods.

Folic acid should be taken at a dose of 1 mg/day. The decision to place a patient with sickle cell disease on iron supplementation during pregnancy depends on their iron status. For patients who are already iron overloaded, there is no indication for supplemental iron. When iron stores are low or marginal, especially in patients transfused infrequently, routine iron supplementation is advisable.

Blood transfusion during pregnancy continues to be debated and the practice of transfusion varies according to locale and individual practice customs. A common, but questioned, practice is to place all patients on a transfusion regimen. The benefits of this practice have not been proven.[180–183] Transfusions are warranted preoperatively for caesarian section, during some episodes of acute chest syndrome, during acute neurologic events and with severe anemia. Lacking a history of complicated pregnancies, prior miscarriage and frequent difficult to manage vasoocclusive events, most pregnancies can be successfully managed without regular transfusions. Multiple birth pregnancies appear to benefit from transfusion.[183,184]

The mode of delivery of the patient with sickle cell disease depends on the clinical/obstetric indications, such as fetal distress and abruptio placentae and nonobstetrical emergencies. Prior to surgery, preoperative transfusion should be used to reduce the level of HbS to less than 30% of total hemoglobin (Chapter 29). When the PCV is less than 25%, simple transfusion can be used because hyperviscosity is minimal if PCV remains below 30%. If the baseline PCV is more than 25%, exchange transfusion is preferable.

The treatment of preeclampsia and eclampsia is beyond the scope of this chapter but should include a low threshold for exchange blood transfusion and if preeclampsia progresses, careful thought should be given to delivery.

If pregnancy must be terminated, some have advised against using hypertonic saline because of the theoretical possibility of it inducing a vasoocclusive episode. Little information on the choice of method for abortion is available.

During the puerperium, the main concerns are pain control, adequate hydration, and the prevention of pulmonary complications, such as acute chest syndrome that might be favored by immobility and hypoventilation. Patients should be provided with an incentive spirometer to help lung expansion and prevent atelectasis.[173,175,176]

Any approved form of contraception is acceptable in sickle cell anemia. The dangers and the consequences of unwanted pregnancies outweigh the very small risks of contraceptive devices or drugs and the complications of these methods do not seem to exceed those in the normal population.[185]

In summary, obstetricians should establish strong lines of communication with hematologists so that care can be coordinated. In the primigravida, careful observation and intervention with transfusions only if complications such as toxemia, severe anemia, or worsening symptoms of sickle cell disease ensue is a reasonable plan. In multigravida, the experience of prior pregnancies helps guide the clinician. Uncomplicated previous pregnancies might be managed like those in primigravidae. Individuals who have lost previous pregnancies might benefit from the early use of transfusions aimed at keeping the hemoglobin level above 9 g/dL.

Surgery and Anesthesia

Surgery and anesthesia in sickle cell disease are safe, but not complication free. Precautions must be observed and the major issue is the use of preoperative blood transfusion.[152] Anesthesia in sickle cell disease has been comprehensively reviewed; the principles of best preoperative and intraoperative anesthetics should be followed.[188,189]

In an analysis of more than 700 surgical procedures in sickle cell anemia, mortality was approximately 1% with no deaths in children.[190] In this report, transfused patients undergoing moderate-risk surgery had fewer postoperative acute chest syndromes and painful episodes. Low-risk surgeries did not have any acute chest syndromes even if patients were untransfused. Nearly 90% of patients were transfused preoperatively but this was not a clinical trial of perioperative management or the effects of preoperative transfusion. Even complicated surgery including heart, liver, and renal transplantation can be accomplished.

Although common sense suggests that tourniquets be avoided and arterial cross-clamping eschewed, most reports do not indicate problems with these procedures.[191,192]

The major issue in preoperative management is the question of blood transfusion. Whether or not preoperative blood transfusion forestalled intraoperative or postoperative complications has been partially answered by a clinical trial that compared simple transfusion to a hemoglobin level of approximately 10 g/dL before surgery under general anesthesia to exchange transfusion that reduced HbS levels to 30% or less.[193] Both regimens were effective in preventing postoperative complications but simple transfusion exposed patients to half as much blood and these individuals had fewer transfusion-related complications. Regardless of the type of transfusion regimen, complications, often minor, were seen in approximately a third of surgeries and acute chest syndrome, a major problem occurred in 10%. When acute chest syndrome occurs after cholecystectomy or splenectomy it has a preference for basal lung regions and for the lung on the side of surgery.[194] In one retrospective analysis, laparoscopic cholecystectomy did not decrease the incidence of acute chest syndrome when compared with an open approach; however, preoperative transfusion was not uniformly used.[195]

What remains unclear is the complication rate of surgery without routine transfusion. The need to resolve this issue was suggested by a prospective survey of preoperative

transfusion practice in the United Kingdom where 43%, 39%, and 23% of patients, respectively, received no transfusion, simple transfusion, or exchange transfusion preoperatively. All groups had similar postoperative complication rates and sickle cell–related complication rates of 12%, 8%, and 0%, respectively. Undergoing moderate high-risk procedures was a predictor of postoperative complications.[197] In another study, 28 children with sickle cell disease had a total of 38 minor surgical procedures and no preoperative transfusions were given in 34 cases. Only minor postoperative complications occurred and the absence of postoperative acute chest syndrome suggested that minor or low-risk elective surgical procedures in children might not routinely require preoperative transfusion.[198] The authors of both studies concluded that the lack of clear benefit of transfusion confirmed the need for a randomized controlled trial of transfusion versus no transfusion.

After tonsillectomy and myringotomy, more than a third of patients had postoperative complications regardless of the method of transfusion, and a history of pulmonary disease was predictive of these complications.[199] These results were confirmed in 41 children who underwent transfusion to a hemoglobin level of 10 g/dL and underwent tonsillectomy. Postoperative complications including hypoxia, fever, and acute chest syndrome were noted in 22% of patients and the majority of patients were managed with less than 24 hours of hospitalization.[200]

Treatment recommendations. Lacking a randomized direct comparison of preoperative transfusion compared with no transfusion in sickle cell anemia, a reasonable approach would be to recommend simple transfusion to a hemoglobin level of 10 g/dL in all patients with sickle cell disease undergoing intraabdominal and thoracic surgery, tonsillectomy, and other procedures while receiving a general anesthetic with moderate or high risk. Incentive spirometry might help prevent acute chest syndrome. Minor elective procedures in children might be performed without preoperative transfusions.[201]

Venous Access Devices

Indiscriminate use of intravenous fluid therapy and blood transfusion early in life often culminates in difficulty finding venous access in teenagers and adults requiring implantable intravenous access devices. Infusion ports and central venous catheters are associated with a 5–10 times higher risk of complications in sickle cell anemia than when they are used in other diseases.[202] The risks include thrombosis, at times involving large veins and causing superior vena cava syndrome, and sepsis. Some reports found serious complications associated with more than half of the devices implanted. Infections have been estimated to occur at a rate of 1.5/1,000 catheter days depending on the indication for catheter placement.[203] In one analysis, 41% of bacteremias in adults were associated with venous access devices.[204] Another study suggested that more than 80% of bacteremias in adults were related to indwelling catheters.[205] Approximately 60% of infections were due to coagulase-positive or coagulase-negative staphylococci. Fungemia is usually associated with indwelling catheters and *Candida albicans* is the usual organism. Some experts recommend using low doses of warfarin, 2 mg daily, to retard thrombosis of implantable ports and catheters.

Treatment recommendations. Preservation of veins by using oral hydration when possible early in life and meticulous care of short-term intravenous lines should delay the destruction of veins that leads to indwelling line placement. After a line is placed, special attention should be devoted to its care. Most often, successful treatment of catheter-associated bacteremia requires that the device be removed.

Osteonecrosis

Epidemiology

Painful, often disabling, and frequently requiring surgical treatment, the age-adjusted incidence rate of osteonecrosis in sickle cell anemia is 2.5 per 100-patient years for both hip and shoulder joints.[206,207] About three-quarters of individuals with shoulder disease also have hip involvement. By age 35 years, half of all individuals with sickle cell anemia have evidence of hip and shoulder osteonecrosis and in childhood, sickle cell disease is the most common cause of this lesion. Among 1,056 patients with sickle cell anemia, 21% had osteonecrosis and the median age at diagnosis was 32 years.[208] In 64 adults with 92 symptomatic hips who were followed for a mean duration of 17 years, nearly 90% of hips collapsed within 5 years of diagnosis. The average time between the diagnosis and collapse was 42 months for stage I hips and 30 months for stage II hips.[209]

One hundred twenty-one patients with sickle cell disease and asymptomatic osteonecrosis of the femoral head contralateral to a hip with symptomatic osteonecrosis were identified by MRI and followed with annual hip x-rays for a mean duration of follow-up of 14 years. At the initial evaluation, 56 asymptomatic hips were classified as stage 0, 42 as stage I, and 23 as stage II. At the most recent follow-up, pain had developed in 110 previously asymptomatic hips and collapse had occurred in 93. Symptoms always preceded collapse. Of the 56 hips that were classified as stage 0 at the time of the initial evaluation, 47 had symptomatic osteonecrosis and 34 had collapse. Of the 42 asymptomatic stage I hips, 40 became symptomatic within 3 years and 36 had collapse of the femoral head. Of 23 asymptomatic stage II hips, all became symptomatic within 2 years and all collapsed; the mean interval between the onset of pain and collapse was 11 months. At final follow-up, 91 hips had intractable pain and required surgery. These prospectively collected data strongly suggest that osteonecrosis in sickle cell disease follows an inexorable path that ends with joint failure.[210]

Table 19.3. A modified Ficat system of grading osteonecrosis of the femoral head[211, 212]

	Imaging results	Clinical
Stage 0	MRI normal (marrow necrosis may be present histologically)	Normal
Stage I	Normal radiograph and CT; abnormal MRI with necrosis (marrow and bone necrosis)	Usually painless
Stage II	Sclerosis and lytic areas on x-ray; CT and MRI abnormal with necrosis and reactive interface	Pain not always present
Stage III	Femoral head flattening and crescent sign on x-ray; MRI, crescent sign	Pain present, especially with weight bearing, relieved with rest
Stage IV	Femoral head collapse; joint space narrowing; osteoarthritis	Pain at rest, joint stiffness and weakness; secondary arthritis

Pathogenesis

A complete understanding of the pathogenesis of osteonecrosis in sickle cell anemia is lacking but it might begin with microinfarction of the trabeculae of cancellous bone. Pressure within the marrow of the femoral head is increased when osteonecrosis is recognized clinically or by MRI, but whether or not this is a cause or a result of osteonecrosis is unclear. It has been reported in nonsickle cell disease–related osteonecrosis, that asymptomatic "normal" hips contralateral to involved hips can have increased pressure and it has been claimed that it is these, rather than "normal" hips with normal pressure, which will ultimately develop clinical disease. Patients with higher PCV and with sickle cell anemia–α thalassemia have a higher prevalence of osteonecrosis.[206,207] In studies of osteonecrosis in patients who did not have sickle cell disease, there has been some association of this lesion with low levels of protein S and protein C and hypofibrinolysis and the strong impression that coagulation plays some role in the genesis of this lesion.[211] The genetic modulation of sickle cell osteonecrosis is discussed in Chapter 27.

Clinical Aspects

Osteonecrosis of the hip, because of pain and loss of joint function, can dominate the clinical manifestation of sickle cell anemia. Presenting with pain in and about the affected joint, at times with spasm of the surrounding musculature, hip disease can also present acutely and mimic septic arthritis or synovitis.

More often, the onset of osteonecrosis is insidious. Hip necrosis is often bilateral although both hips need not develop disease simultaneously or progress symmetrically. Activity-limiting symptoms do not often accompany shoulder disease that is asymptomatic in 80% of patients when discovered.

Osteonecrosis can be detected very early in its evolution by MRI and only more advanced disease is radiographically visible (Table 19.3). MRI can be used to quantify the extent of damage to the femoral head. Hip disease can be scored by the system of Ficat, a simplification of an earlier categorization, that classifies by x-ray and MRI the progressive features of this disorder (Fig. 19.6 and Table 19.3).[212] The crescent sign, present in stage III disease, represents an intracapital fracture that begins at the interface of the necrotic lesion and subchondral bone and extends through the area of bone necrosis. Fibrous metaplasia beneath this fracture prevents revascularization and repair, making this lesion irreversible. Many other more or less complicated classification systems have been proposed, some including objective measurements of femoral head involvement and joint destruction. These more elaborate systems might be useful when evaluating and comparing new methods of treatment.[213]

Treatment recommendations. Because symptoms of hip disease often are present in children and can progress rapidly to disability, management poses a dilemma that must balance the relief of pain and avoidance of loss of joint function with the knowledge that total joint replacement is not yet a permanent "cure" and reoperation, especially of the hip, is likely to be required.

Until now, conservative treatment with bed rest and wheelchair, crutches to reduce the load on weight-bearing joints, nonsteroidal antiinflammatory drugs, and physical therapy have been the sole means of managing early disease. Pain relief is problematic, relying on joint protection, rest, heat, hydrotherapy, relaxation techniques, and analgesics. Milder analgesics are often ineffective. If not guarded against, prolonged bed rest can cause flexion contractures. Physical therapy is directed to stretching and strengthening hip adductors and other hip muscles, releasing muscle spasm, training in the proper uses of crutches, quadriceps strengthening, improving upper body strength, and posture retraining. Whether any conservative treatment delays the progression of sickle osteonecrosis is unclear, but the bulk of the evidence suggests that it does not.[214,215] As pain becomes intolerable and joint function is lost, as a final resort, joint replacement is done. Transfusions have not proved useful for pain relief or halting disease progression.[216]

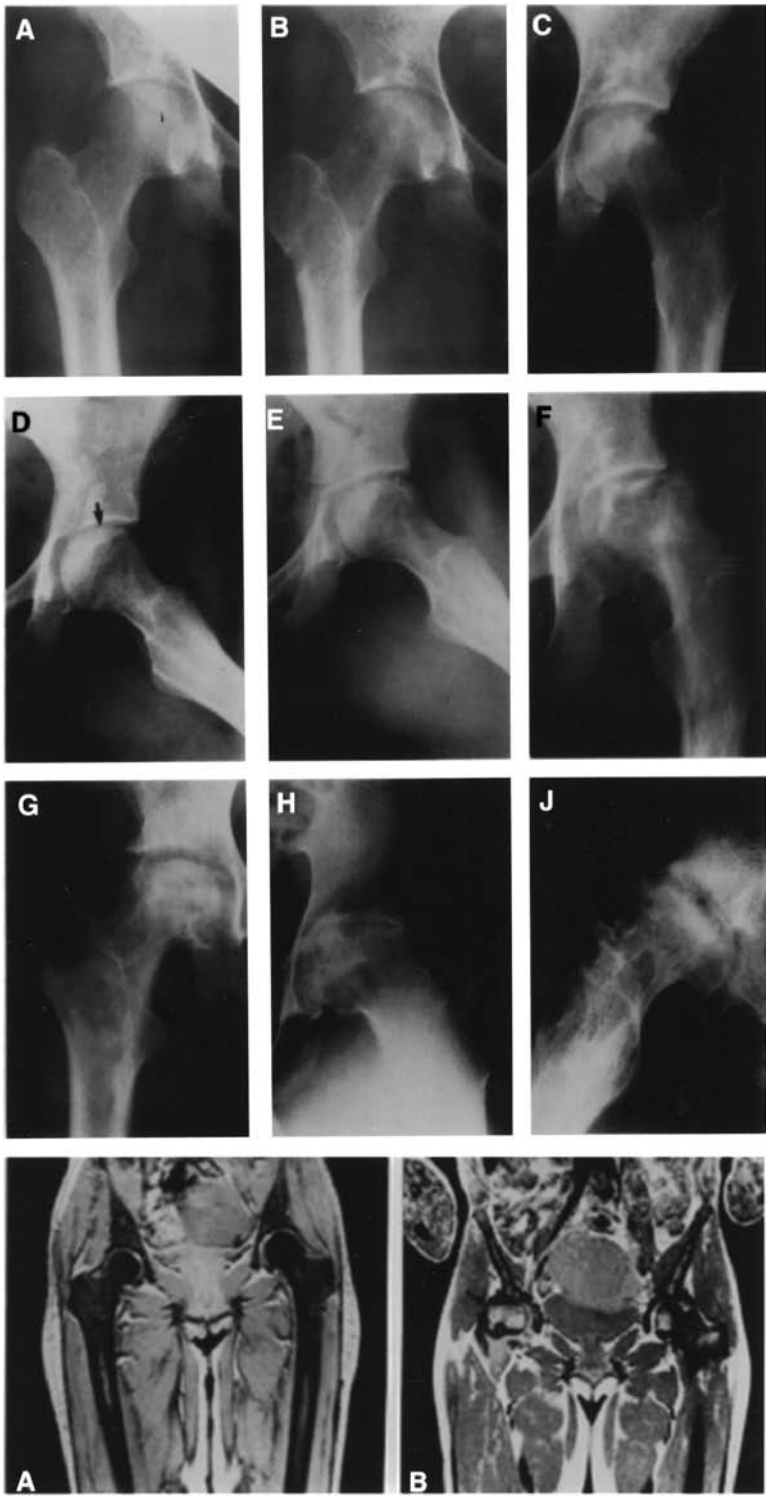

Figure 19.6. Osteonecrosis of the hip in sickle cell disease. **(A)** Subpanels **A** through **C**, the progression of osteonecrosis in a 19-year-old woman with sickle cell anemia is shown. Although the hip was painful, the x-ray was initially normal **(A)** but MRI showed osteonecrosis. Core decompression was done (note track) **(B)**. In **(C)** the joint space is normal but there is sclerosis. In another patient, a crescent sign appears in a painful hip **(D)**. Five weeks later, there is collapse of this segment **(E)**. After an additional 15 months there is extensive joint destruction and total hip replacement was done. (**G**, **H**, and **J**) Show in three different patients with sickle cell disease advanced degenerative changes. **(B)** MRI of the hips in a 30-year-old woman with sickle cell anemia. In subpanel **A**, the femoral heads are normal. After 1 year changes of osteonecrosis are evident **(B)**. (From Embury et al. Sickle Cell Disease: Basic Principles and Clinical Practice, NY, Lippincott-Raven 1994, with permission.)

Pain in osteonecrosis tends to be chronic, and, if possible, narcotic analgesics should be limited. Nevertheless, other analgesics often fail to provide the same measure of comfort as in degenerative joint disease. As destruction progresses, pain becomes severe and joint function is lost, the effected joint needs replacement.

Total hip arthroplasty can be very successful, but using older prostheses, by 4 to 5 years after surgery, approximately one-third have failed and pain can remain a major problem. Cementless components have been tried, and the results of their use are said to be encouraging, but their ultimate value in sickle cell disease is still unknown.[217,218] Postoperative complications of total hip arthroplasty, including infection, fracture, and acute chest syndrome, with persistent pain are very common. Among different series, the need for revision ranged from 30% to 50%, infection occurred in 8%–30%, and failure occurred approximately 40% of cases followed for approximately 5–8 years.[211] It seems prudent to delay this type surgery until symptoms interfere with the activities of daily living.

The inexorable progress of this complication once pain and radiographic abnormalities have appeared has prompted a search for treatment that could stabilize disease progression and relieve its pain. Core decompression is one approach to arresting the progression of osteonecrosis of the hip. Its possible value was discovered serendipitously during measurements of bone marrow pressure and femoral head biopsies when pain decreased after removal of a bone core, and controversy has dogged its application. In this method, a core of bone is removed from the femoral neck, stopping well short of the subchondral plate. This procedure has been studied most intensively in osteonecrosis from causes other than sickle cell anemia and the results, if variable, have been encouraging. An analysis of more than 1,000 hips from 24 different studies, with a 30-month follow-up, showed a clinical and radiographic success rate of 64%.[219] Eighty-five percent of stage I patients had a good result. In comparison, only 23% of patients who did not undergo surgery had a successful outcome. Reports that formed the basis for this synthesis were largely uncontrolled retrospective studies. Treatment of sickle cell osteonecrosis by core decompression decreased pain, restored function, and promoted healing in some patients, but the results of a randomized prospective study were disappointing and did not suggest an advantage for core decompression

compared with physical therapy alone.[220] In this prospective multicenter study, the safety of hip core decompression was evaluated and the results of decompression and physical therapy were compared with those of physical therapy. Forty-six patients with stage I, II, or III osteonecrosis of the femoral head were randomized and 38 completed the study. After a mean of 3 years, the hip survival rate was 82% in the group treated with decompression and physical therapy and 86% in the group treated with physical therapy alone. In a review of 312 total hip arthroplasties in sickle cell disease, the mean age of the patients was 32 years. With a minimum follow-up of 5 years, 10 hips were revised for infection and 21 cups and 17 stems required revision for aseptic loosening at a mean of 14 years. Although the medical complication rate was 27% and orthopedic complications were 13%, the results were generally considered successful, given the severity of the problem.[221]

Rotational osteotomy has been considered when pain is severe and normal activities impossible. Although some good results have been seen in sickle cell anemia, adverse outcomes also occur and there are few or no data to recommend when this procedure is indicated or to judge its effectiveness. Expert orthopedic advice should be sought.

Occasionally shoulder disease becomes severely painful and joint destruction can require total shoulder arthroplasty. There is no published experience with core decompression of the humeral head in osteonecrosis associated with sickle cell anemia, but in uncontrolled studies it has been used with good results in steroid- or alcohol-induced disease.

Other Disorders of Bone and Joints

Joint symptoms in addition to hand–foot syndrome and osteonecrosis are commonly encountered but are usually minor compared with other complications of sickle cell anemia. Joint effusions can be monoarticular or polyarticular, noninflammatory or inflammatory and contain sickled cells. Noninflammatory effusions of the knee can be managed successfully by rest and nonsteroidal antiinflammatory drugs. Acute hematogenous osteomyelitis causes acute pain and swelling and can involve periarticular bone, extend into the joint space, and cause effusion. MRI is a more sensitive diagnostic method than technetium or gallium scanning. Because of increased production of uric acid and impaired renal function, approximately one quarter of patients have elevated uric acid levels and some will have attacks of acute gouty arthritis. Lupus erythematosus is very common in African American women and the coincidence of lupus and its articular manifestations with sickle cell anemia is not rare. Backaches may often be ascribed to osteoporosis from expanded hematopoiesis, sometime with vertebral collapse, and can be treated with physical therapy and mild analgesics. Myofascial inflammation has also been found and is associated with localized edema, severe pain, inflammatory tissue changes, and myonecrosis.[222,223]

Orbital complications are uncommon in sickle cell disease. In one patient with fever, headache, orbital swelling, and optic nerve dysfunction, CT displayed bilateral superior subperiosteal cystic masses that during surgical exploration were found to be bilateral liquefied hematomas.[115] A review of the literature showed 16 young patients with sickle cell disease with rapidly developing findings ranging from frontal headache, fever, and eyelid edema to bilateral complete orbital compression syndrome. Sixty percent had orbital hemorrhage on CT and 80% of 12 patients tested were had orbital bone marrow infarction. Recovery was complete in 94% of cases, 74% of whom were treated conservatively and 11% had a recurrence. These unusual events are likely to arise from vasoocclusive disease in the marrow space surrounding the orbits.

Overgrowth of the maxilla and mandible can lead to facial deformity with separation and anterior angulation of the incisors called sickle gnathopathy. Rare in developed countries, it has been more characteristic of the disease in Africa and the deformities can be of a severity to necessitate surgical correction. Diploic spaces of the skull are also widened giving, at times, a “hair-on-end” radiographic picture, but these changes are not as prominent as described in patients with poorly treated β thalassemia.

Bone Marrow Necrosis

Bone marrow infarction may be associated with painful episodes. Humerus, tibia, and femur were the most common sites of bone marrow infarction when symptomatic sickle cell disease patients were studied by bone marrow scintigraphy.[224] Thirty-four percent of infarcts eventually healed.

An unusual but serious disease complication is diffuse bone marrow necrosis without signs of acute chest syndrome. Diffuse bone marrow necrosis is suspected clinically by an acute, and unusually severe painful episode; patients have fever, leukocytosis, worsening anemia and a rapidly rising LDH.[225] Bone marrow necrosis has been associated with infection with the B19 parvovirus. In many respects, diffuse marrow necrosis resembles the acute chest syndrome caused by embolization of necrotic bone marrow but chest involvement and the development of multiorgan failure are not present. Bone marrow MRI and scintigraphy can suggest the presence of regional or diffuse marrow necrosis but are not needed for the diagnosis of severe, diffuse marrow necrosis.[226] Patients have been treated with transfusion and recovery seems to be the rule.

Endocrinopathies

Sex Hormones

In 10 sickle cell anemia patients with a mean age of 17.5 years who had delayed menarche, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and prolactin levels were reduced compared with normal and

HbAS controls.[227] It was concluded that these patients with delayed menarche had a hypothalamopituitary axis dysfunction.

Thirty-two men with sickle cell anemia, mean age 26.5 years, had reduced testosterone and dihydrotestosterone levels and increased LH and FSH levels consistent with primary gonadal failure. Zinc levels were decreased in hair and erythrocytes, and their erythrocyte zinc content correlated with serum testosterone. These patients had abnormal secondary sexual characteristics and eunuchoid skeletal proportions.[228] Male and female sickle cell disease patients, aged 4–50 years, had gonadal hypofunction with low LH, FSH, cortisol, and testosterone levels compared with age- and sex-matched normal controls.

Semen analysis in 25 patients with sickle cell anemia showed significantly reduced ejaculate volume, sperm motility, and sperm density compared with controls. A significant increase was also observed in the percentage of spermatids and in abnormal spermatozoa with amorphous and tapered heads in the patients' semen. These abnormalities could result from testicular dysfunction and abnormalities in the accessory sex organs, such as the seminal vesicles and prostate. To assess the role of the gonads and anterior pituitary gland in the production of poor-quality semen of males with sickle cell anemia, FSH, LH, prolactin, and serum testosterone were assayed radioimmunologically in 33 men with sickle cell disease and in 29 age-matched normal controls. Individuals with sickle cell disease had significantly lower mean serum testosterone, higher mean FSH, and higher prolactin levels than controls. Higher gonadotrophins associated with lower testosterone suggested an intact hypothalamic–pituitary axis and a primary testicular defect.[229] Testicular failure might also result from repeated infarction.[230]

Hypogonadism in sickle cell anemia could also have a hypothalamic origin.[231] In two 19-year-old men with sickle cell anemia and hypogonadism, hypothalamic dysfunction responded to oral clomiphene therapy. Partial hypothalamic hypogonadism was shown by low levels of testosterone, low to low-normal levels of LH and FSH, and a nearly normal rise in gonadotropin levels in response to exogenous gonadotropin-releasing hormone. Treatment with oral clomiphene raised LH, FSH, and testosterone levels to normal, inducing puberty in both patients.

Parathyroid and Bone Mineral Metabolism

In a cross-sectional study of 32 adults (mean age 34 years) with sickle cell disease, nearly 74% had low bone mineral density at one or more anatomical sites.[232] In 52 patients with HbS–β thalassemia 32% had osteopenia/osteoporosis and 57% had osteosclerosis. Bone resorption was diminished in patients with osteosclerosis and increased in those with osteopenia/osteoporosis. The sRANKL/osteoprotegerin ratio was elevated in the osteosclerotic group. Osteoporosis patients had mild renal impairment and their bone mineral density correlated with osteoprotegerin and bone resorption markers. Osteosclerosis patients had multiple infarctions in the studied bones that led to reduced osteoclast activity and increased bone mineral density.[233]

In children with frequent hospitalizations, growth delay, or need for chronic red cell transfusions, bone density was assessed at the lumbar spine and proximal femur. Calcium intake was inadequate in 60%, and serum (25(OH)D (25-hydroxyvitamin D) [25 OHD] level was less than 50 nmol in 74%. Median Z-scores for lumbar spine (-2.3) and proximal femur (-1.7) were markedly reduced, and 64% of patients had low bone density.[234] In another study of children, 65% of subjects had low vitamin D levels and all were vitamin D deficient in the spring.[68] In contrast, in the tropics, vitamin D levels were normal.[235] Bone mineral density is reduced 6%–20% in most patients with sickle cell anemia.[236] Generalized osteoporosis is commonly present, especially in the spine where vertebrae display a typical "fish mouth" appearance.

Limited studies of parathyroid function in sickle cell disease have been reported. Concentrations of serum calcium, parathyroid hormone (PTH), 25 OHD, and 1,25 dihydroxyvitamin D (1,25(OH)2D) were determined in 99 Saudi sickle cell disease patients and in 104 healthy controls. Serum calcium and 25 OHD were significantly lower in the patients and 14% and 12% had serum calcium and 25 OHD concentrations, respectively, below normal. Thirty-one percent had PTH above normal. These results suggested that sickle cell disease patients have a tendency toward hypocalcemia associated with high PTH levels, implying impaired intestinal absorption of calcium and vitamin D.[237] In 18 children with a median age of 8 years with sickle cell anemia living in the tropical island of Curacao, serum calcium concentration was slightly lower than in controls but no individual was hypocalcemic. In contrast to the studies in Saudis, there were no differences in serum concentrations of phosphate, total protein, albumin, PTH, 25 OHD, and 1,25(OH)2D in patients and controls.

In 14 adults with sickle cell disease 25 OHD and bone mineral density at the femoral neck, lumbar spine, and distal third of the ulna plus radius, along with markers of bone resorption and bone formation was measured before and after 12 months of vitamin D_2 and calcium carbonate treatment. Pretreatment, all patients were vitamin D–deficient, had low bone mineral density at the lumbar spine, femoral neck and the distal radius and ulna, and had elevated collagen type I (CTx) and osteocalcin levels. After treatment, all patients corrected their 25 OHD level with a significant increase in bone mineral density at the lumbar spine and the femoral neck. CTx, osteocalcin and PTH(i) levels were unchanged. These results suggest that treatment of adult sickle cell disease with vitamin D and calcium can restore 25 OHD levels to normal and improve bone mineral density, but markers of bone resorption remained unchanged.[238] These results suggest that early detection and treatment of sickle cell bone disease might prevent its progression and continued bone resorption.

Miscellaneous

Basal and stimulated cortisol levels and the increment of cortisol at 30, 50, and 120 minutes after adrenocorticotropic hormone infusion were similar in patients with sickle cell anemia and controls, suggesting normal adrenal function.[239]

Studies of thyroid function in sickle cell disease have been normal and have also shown mild primary thyroid failure, occasionally associated with iron overload.[240–242]

Some clinicians believe that diabetes is underrepresented among patients with sickle cell disease but cases of this association have been reported. Advanced glycation end-products (AGEs) have been implicated in the oxidant-induced vascular pathology of diabetes and other diseases and were measured in normoglycemic patients with sickle cell anemia and controls.[243] Plasma AGE levels and the rate of erythrocyte AGE accumulation were significantly higher in patients compared with controls. Oxidized glutathione (GSSG) was lower and the GSH/GSSG ratio was higher when a vasoocclusive episode was present, suggesting that this ratio might be an objective indicator or a risk factor for an acute event.

Patients with sickle cell disease who are iron overloaded due to transfusion are less likely to develop endocrinopathies than chronically transfused patients with thalassemia. Fifty-six percent of thalassemia patients had more than one endocrinopathy compared with only 13% of sickle cell disease patients. An endocrinopathy was approximately 10 times more likely in thalassemia and this was related to the duration of chronic transfusion.[244]

Pulmonary Hypertension and Pulmonary Function (also see Chapter 11)

Epidemiology and Diagnosis

Pulmonary hypertension in sickle cell disease has been recognized since at least 1982,[245] and recent studies have suggested that it is present in approximately one-third of adults with sickle cell anemia and lesser numbers of patients with HbSC disease and HbS–β^+ thalassemia.[246] As an increasing number of studies are reported, it is becoming clear that this problem begins in childhood.[247] Although symptoms other than dyspnea on exertion might be lacking, pulmonary hypertension, defined as the presence of a tricuspid regurgitant jet (TRJ) velocity of 2.5 m/second or higher on echocardiographic measurement is associated with a 20%–50% risk of death over a 2-year follow-up period, regardless of whether a patient has sickle cell anemia or HbSC disease.[19,246,248–254] Autopsy studies suggest that 75% of patients have some evidence of pulmonary hypertension, although the typical plexiform arterial lesions are not often seen.[255] Pulmonary hypertension is rarely a result of pulmonary artery obstruction.[256] The high mortality rate may reflect the severity of the underlying sickle vasculopathy, and death might not always be a direct result of pulmonary hypertension.

Pulmonary hypertension might be less common in children and adolescents.[257,258] When 32 children with sickle cell anemia were compared with age-matched controls, their right ventricular free-wall mass index continued to rise gradually throughout childhood and a TRJ velocity of more than 2.5 m/second was found in 16% of patients older than 9 years.[259] In 224 children with sickle cell disease, 44 had echocardiographic measurement of TRJ velocity and 26.2% were found to have pulmonary hypertension. This was associated with anemia, reticulocytosis, and cerebral vasculopathy.[260] In 38 of 43 patients with varied genotypes of sickle cell disease, in whom the TRJ velocity was measurable and whose mean age was 14 years, the TRJ velocity was 2.5 m/second or greater in 34% and was associated with markers of hemolysis.[261] In another study by this same group, TRJ velocity was correlated with LDH, hemoglobin concentration, reticulocyte count, and AST.[262] A study of 228 children with a mean age of 12 years revealed that the TRJ velocity was significantly higher than in age-matched controls and was independently associated with systolic blood pressure and LDH concentration, but not with vasoocclusive events.[263]

In sickle cell pulmonary hypertension, pulmonary artery pressure and pulmonary vascular resistance is only moderately elevated, whereas the cardiac output and pulmonary capillary wedge pressures are high. Echocardiography is an excellent and simple screening test for pulmonary hypertension and some studies have shown an excellent correlation between the TRJ velocity and pulmonary arterial systolic pressure measured directly during right heart catheterization. During echocardiography, it is important to search diligently for and measure the TRJ velocity as this allows calculation of pulmonary artery systolic pressure. The definitive diagnosis of pulmonary hypertension can only be made by right heart catheterization and this should be done before beginning specific treatment.

As the symptoms of idiopathic pulmonary hypertension can be lacking or overlap with symptoms of anemia and findings on physical examination are few or present only with advanced disease, the diagnosis of pulmonary hypertension can be difficult and relies on screening (Chapter 11).

In contrast to pulmonary arterial hypertension in other diseases, pulmonary hypertension in sickle cell disease is mild to moderate, with pulmonary artery systolic pressures in the range of 30–40 mm Hg, and often increased pulmonary capillary wedge pressure, suggesting that in some patients diastolic dysfunction contributes to pulmonary hypertension. It has been recommended that an exercise echocardiogram with assessment of pulmonary pressures be used to evaluate patients with significant exertional dyspnea and a normal resting TRJ velocity. Patients with sickle cell disease, in contrast to most individuals with pulmonary hypertension, have moderate to severe levels of anemia and

this might make any degree of pulmonary hypertension poorly tolerated. This might account for the morbidity and mortality of otherwise 'mild' pulmonary hypertension. The 6-minute walk distance correlates with functional status, peak oxygen consumption, and with survival in patients with pulmonary arterial hypertension.[264]

When 26 patients were studied by echocardiography before and during a vasoocclusive episode, TRJ velocity increased during the event, and this was associated with decreases in hemoglobin concentration and increases in LDH and plasma hemoglobin levels. In 21 additional subjects with pulmonary hypertension, mean pulmonary artery pressures and pulmonary vascular resistance increased during exercise performed during cardiac catheterization. These results suggested that acute elevations in pulmonary pressures during painful episodes or exercise might contribute to morbidity and mortality and that screening studies should be conducted at a time remote from an acute sickle cell vasoocclusive event.[29] The sudden, unexplained death that sometimes accompanies the acute painful episode might be explained by this rise in pulmonary artery pressure in an anemic patient with many comorbidities. TRJ velocity also can increase during acute chest syndrome, and a level of more than 3 m/second was associated with mortality.[265]

N-terminal pro-brain natriuretic peptide (NT-proBNP), released from ventricles under stress, is a biomarker of idiopathic pulmonary arterial hypertension. NT-proBNP levels were measured in 230 sickle cell disease patients screened for pulmonary hypertension and in an independent sample of 121 patients, and a threshold level predictive of high pulmonary artery pressure and mortality was identified. NT-proBNP levels were higher in patients with sickle cell pulmonary hypertension and correlated directly with TRJ velocity. A level of 160 pg/mL or greater had a 78% positive predictive value for the diagnosis of pulmonary hypertension and was an independent predictor of mortality. In the independent sample, 30% of patients had an NT-proBNP level of 160 pg/mL or greater that was associated with mortality. These data suggest that in sickle cell anemia, a NT-proBNP level of 160 pg/mL or higher was a predictor of mortality that was associated with hemolytic anemia and pulmonary hypertension.[266]

Pathogenesis and Clinical Aspects

The pathogenesis of pulmonary hypertension is likely to be multifactorial and related in part to reduced NO bioavailability (Chapters 10 and 11). Also, endothelial cell adhesion molecules mediate binding of inflammatory cells to vascular endothelium and their levels are modulated by NO and increase with endothelial dysfunction and vascular injury. In sickle cell disease, levels of adhesion molecules are related to measures of NO bioavailability. In 160 sickle cell disease patients, increased soluble adhesion molecule expression correlated with severity of pulmonary hypertension, and soluble VCAM-1, ICAM-1, and E-selectin were associated with the risk of mortality.[267] Individuals with sickle cell pulmonary hypertension had higher levels of soluble VCAM activation, thrombin–antithrombin complexes, prothrombin fragment F1+2, D-dimer, and interleukins 6, 8, and 10 compared with patients without hypertension.[268]

Patients with pulmonary hypertension were more likely to have had priapism, iron overload, reduced oxygen saturation, increased creatinine, and a reduced arginine:ornithine ratio compared with controls.[19,254] The history of acute chest syndrome, osteonecrosis, and emergency department visits were not different in cases and controls, whereas leg ulcers, history of stroke, systolic hypertension, and HbF showed disparate associations.[19,250,269] All these studies compared less than 200 cases and controls, and this might account for the difference in the distribution of clinical events and laboratory measurements.

Erythrocyte glutathione depletion is linked to hemolysis and oxidative stress. Glutamine preserves intracellular NADPH levels, which is required for glutathione recycling. Glutathione and glutamine were significantly lower in plasma and erythrocytes of sickle cell disease patients than in controls and were independently associated with pulmonary hypertension and hemolysis.[270]

Pulmonary hypertension[19] is likely to be modulated by the effects of genes that control NO and oxidant radical metabolism, cell–cell interaction, vasculogenesis, and vasoreactivity. For example, mutations in bone morphogenetic protein receptor–2 (*BMPR2*) and other genes have been associated with both familial and sporadic pulmonary hypertension.[271–273] The genetic basis of pulmonary hypertension in sickle cell disease is poorly understood but polymorphisms in genes of the TGFβ/BMP pathway might be involved (Chapter 27).

Pulmonary Function

Dyspnea is a frequent complaint in patients with sickle cell disease. Studies of lung function to date in this population have often involved less than 50 patients and yielded a spectrum of abnormalities including restrictive lung disease, abnormal diffusion capacity for carbon monoxide (D_LCO), obstructive disease, and hypoxemia.[264,274–276]

Using maximal respiratory flow-volume curves, body plethysmography and the response to bronchodilators, a normal pattern of pulmonary function was detected in 57%, obstructive disease in 35%, and restrictive lung disease in 8% of pediatric age group patients with sickle cell anemia. Almost 80% of patients with obstructive disease and 70% with restrictive disease responded to bronchodilators. Lung function was not associated with painful episodes, acute chest syndrome, or asthma.[277]

Spirometry, lung volumes and D_LCO were studied in 310 adults with sickle cell anemia to determine the pattern of pulmonary dysfunction and their association with

other systemic complications of sickle cell disease.[278] Normal pulmonary function tests were present in only 10% of patients. Adult sickle cell anemia was characterized by decreased total lung capacities and D_LCO, and the most common abnormalities were restrictive physiology in 36%, low lung volume in 34% and an isolated low D_LCO in 13% of patients. Decreased D_LCO was associated with thrombocytosis, increased ALT, and renal dysfunction. Based on these studies, pulmonary function was abnormal in 90% of adults with sickle cell anemia. In contrast, preliminary studies in children suggest that D_LCO is not reduced and that obstructive and restrictive disease is associated with TRJ velocity.[279]

Asthma

Asthma and bronchial hyperactivity were more than twice as common in patients with sickle cell disease than in controls.[280] In 74 children evaluated for a painful episode, 36 were diagnosed with asthma. Among children with pain and asthma, the odds ratio of having antecedent or concurrent respiratory symptoms was 4.9 when compared with children with pain and without asthma, suggesting that asthma is a risk factor for painful episodes within 96 hours of an attack.[281] Asthma was also associated with a near doubling of the incidence of acute chest syndrome,[280–283] a twofold increase in mortality[284] and has also been associated with stroke in children with sickle cell disease.[285] Segregation analysis performed in 104 families ascertained through sickle cell anemia probands with asthma found that 19.7% of the parents and 31.8% of siblings of affected probands reported a history of asthma, suggesting that asthma is a comorbid condition.[286] Careful management of asthma might reduce the rates of pain and acute chest syndrome, but no controlled trials of the efficacy of bronchodilators during acute chest syndrome have been reported.

Treatment recommendations. Although the clinical significance of pulmonary hypertension in sickle cell disease is being defined and refined, exactly how this problem should be managed remains unclear (Chapter 11). A standard of treatment based on controlled clinical trials is not available. It is also not clear when and if treatment should be started or how often patients should be screened by echocardiography. Some believe that adults should be screened yearly, whereas in younger individuals screening intervals can be longer. Presently, it appears that few asymptomatic patients are being treated. If treatment appears needed because of symptoms, first, the use of transfusions and hydroxyurea should be optimized even though the HbF levels achieved with hydroxyurea treatment do not appear to protect against the development of this complication (Fig. 19.7).[19] Other complications of sickle cell disease such as iron overload, HIV infection, hypoxemia, especially nocturnal hypoxia, relative systemic hypertension and thromboembolic disease, should be effectively managed before turning to therapies directed more specifically to pulmonary hypertension.[264] Based on the value of anticoagulation in idiopathic pulmonary arterial hypertension, anticoagulation with warfarin might be considered if a specific contraindication does not exist.

Prostanoids such as epoprostenol, treprostinil, iloprost, and beraprost and endothelin-1 (ET-1) antagonists such as bosentan and sitaxsentan and possibly phosphodiasterase-5 (PDE5) inhibitors such as sildenafil are used in other types of pulmonary arterial hypertension, but studies in sickle cell disease are just starting.

The main toxicity of ET-1 receptor antagonists is hepatocellular injury, which could limit their use in sickle cell disease with its high incidence of liver disease of various types. The fall in hemoglobin concentration associated with these agents might lead to symptomatic anemia.

Because of the relationship of reduced NO bioavailability to the development of pulmonary hypertension, the use of PDE5 inhibitors has been explored. The safety and efficacy of sildenafil in 12 patients with sickle cell disease and pulmonary hypertension, NYHA/WHO classes I–III, were studied. Sildenafil, given for 6 ± 1 months, decreased the estimated pulmonary artery systolic pressure and increased the 6-minute walk distance. Three men were studied and none had priapism; however, two received chronic exchange transfusions and one had erectile dysfunction.[287]

Oral arginine, the substrate for NOS, was associated with a 15% reduction in pulmonary artery systolic pressure when given for 5 days to 10 patients.[31]

In summary, adults with sickle cell disease should have yearly screening for pulmonary hypertension by echocardiography. Symptomatic individuals should have elevated TRJ velocity values confirmed by right heart catheterization. If symptoms are judged to be a result of pulmonary hypertension, therapy for sickle cell disease and its complications should be optimized and reevaluated (Fig. 19.7). Presently, the choice of treatment specifically for the pulmonary hypertension should be made with consultation with a pulmonologist with experience managing this condition, as evidence-based approaches to this treatment in sickle cell disease are not yet available.

Leg Ulcers

Epidemiology

On entry into the CSSCD, approximately 5% of patients with sickle cell anemia older than 10 years had leg ulcers. Less than 1% of individuals with HbS–β^0 thalassemia had an ulcer and no ulcers were seen in HbSC disease or HbS–β^+ thalassemia, although they have been reported in these genotypes. When incidence rates were examined according to the genotype of sickle cell disease, individuals aged 20 years and older with sickle cell anemia had a rate of nearly 20 per 100 patient-years, whereas in sickle cell anemia–α

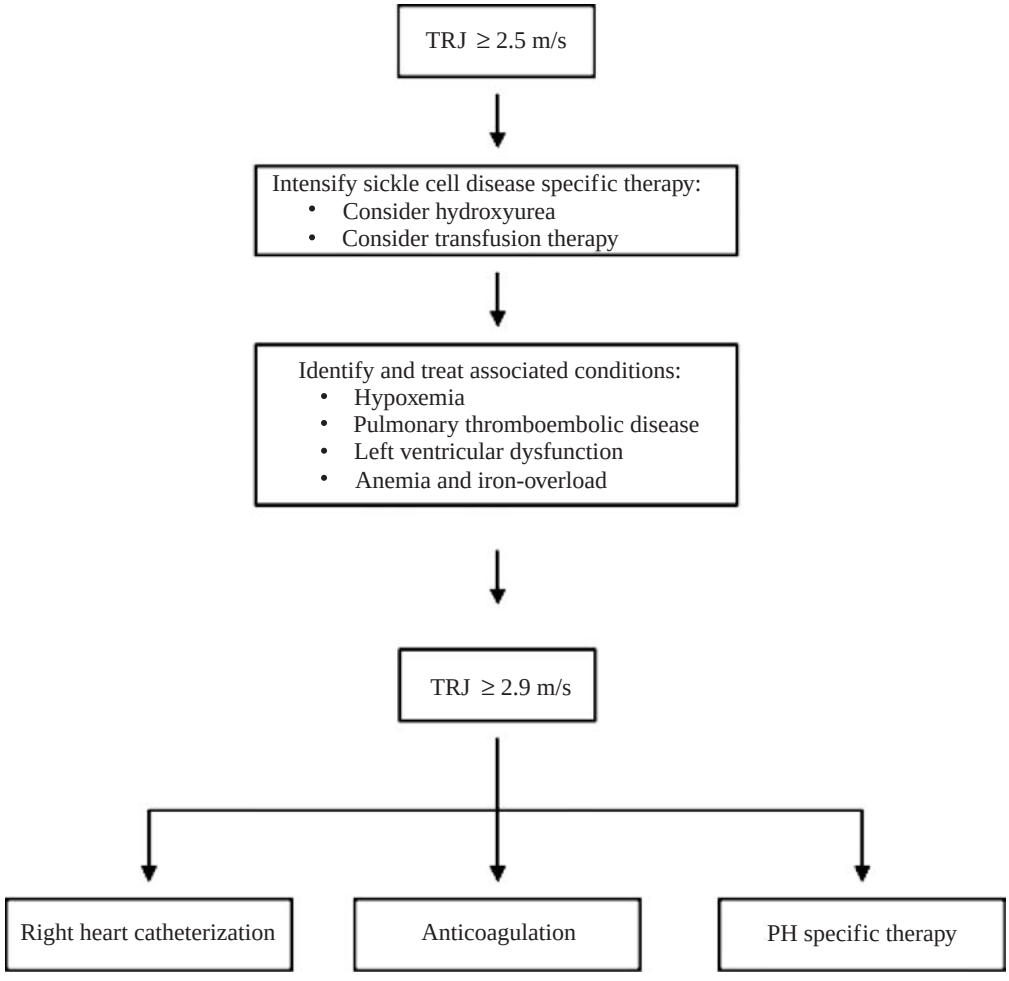

Figure 19.7. Approach to management of pulmonary hypertension.[264]

thalassemia the rate was approximately 10 per 100 patient-years. In total, approximately a quarter of patients had a history of leg ulcer or developed a leg ulcer during an observation period, which was variable but no more than 8 years. Leg ulcers were uncommon in children – none of 1,700 children younger than 10 years had an ulcer – and begin to make their appearance during the early teen years when activities that are most apt to cause trauma to the lower legs become commonplace.[288] Beyond age 20 years, the incidence of ulcers increased sharply. Males were more likely to have ulcers than females whether or not they also had α thalassemia. In Los Angeles, 14% of patients had leg ulcers with a median age at diagnosis of 30 years.[208] In Jamaica, more than 40% of patients and in Africa, between 1.5% and 13.5% of sickle cell disease patients were reported to have leg ulcers.[289]

Leg ulcers are a complication of hydroxyurea treatment in myeloproliferative disorders and new leg ulcers have appeared after institution of hydroxyurea in sickle cell anemia. In the controlled clinical trial of hydroxyurea in sickle cell anemia, the patients randomized to treatment did not have an increase in leg ulcers, but the number of patients was relatively small and the observation period, short.[32,290–293]

Pathophysiology

The cause of leg ulcers in sickle cell disease and in other types of chronic hemolytic anemia is unknown.[10,294,295] Chronic venous ulcers have been associated with thrombophilia, perhaps because of the relationship between thrombophilia and venous thrombosis.[296] Whether or not venous pressure abnormalities contribute to the development of sickle cell leg ulcers is inconclusive.[289,297–299]

Hemolysis, with its associated reduction in NO bioavailability is likely to be a major contributor to the development of leg ulcers.[18] Among the patients enrolled in the CSSCD, 387 patients with sickle cell anemia had a confirmed history of leg ulcers or had leg ulcers at the time of examination,[21] and they were compared with 928 patients without a leg ulcer. Leg ulcer patients had more severe hemolytic anemia than did controls, as shown by their higher reticulocyte counts, LDH, bilirubin, and AST. Cases also had higher leukocyte counts than controls. Leg ulcer

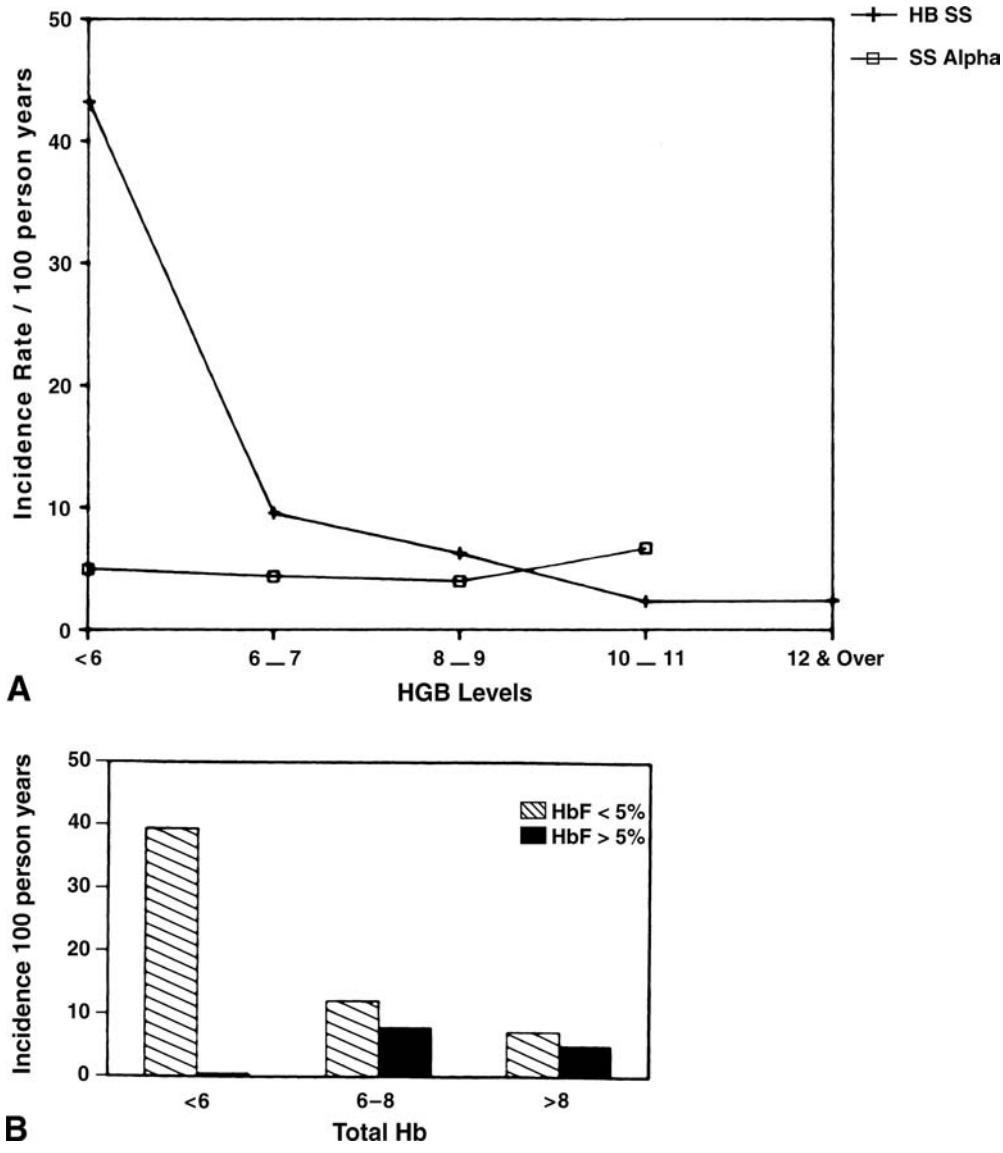

Figure 19.8. Incidence of leg ulcers per 100 patient-years in patients with sickle cell anemia without α thalassemia according to total hemoglobin concentration and HbF level.[288]

patients had lower total hemoglobin and HbF levels and ulcers were more common in males. Individuals with sickle cell anemia–homozygous α thalassemia-2 had an incidence of ulcers less than half that of individuals with sickle cell anemia–heterozygous α thalassemia-2.[288]

Among other elements likely to contribute to the development of leg ulcers in sickle cell anemia are tropical climate, circulatory dynamics, the "exposed" environment of the leg and erythrocyte and vascular injury triggered by the polymerization of HbS and local infection. Both anaerobes and aerobes can be cultured from the base of ulcers more than half of the time.[300,301] It is likely that the ulcer flora varies from clinic to clinic and by region to region. Their role in the development or enlargement of ulcers is unknown. The development of leg ulcers might also be modulated by polymorphic variants of certain genes (Chapter 27).[21]

The higher incidence of leg ulcers in sickle cell anemia compared with thalassemia and other types of hemolytic anemia might be a result of the special characteristics of the sickle erythrocyte (Fig. 19.8).

Clinical Features

Most small and superficial ulcers usually appear on the lower leg and about the medial malleolus[302] and heal spontaneously with rest and careful local hygiene. At times leg ulcers are deep, huge and circumferential, exceedingly painful, disabling, and defy all simple and many complex therapeutic measures.

The first appearance of a leg ulcer usually signifies the high likelihood of their recurrence over a period of many years. Sometimes an ulcer will appear, disappear with treatment or spontaneously, and never recur. More often, they

All patients should be treated with combinations of local treatments. Systemic treatment has not been proven effective. Adapted from ref. 295.

recur after healing but sometimes only after many years. Leg ulcers can occur on the dorsum of the foot and the anterior or posterior aspects of the leg and be bilateral or unilateral. It has been said that skin ulceration can occur on the arms and other locations but if they have the same cause as the typical sickle cell leg ulcer, they must be quite rare. Ulcers often are first found following trauma to the leg that can seem trivial or appear to be the sequelae of an insect bite.

Treatment recommendations. As expected, there are no trials comparing therapies and only a few controlled trials of any type of ulcer treatment. Perhaps nowhere in the annals of treatment of sickle cell anemia have more untested remedies been applied than in the therapy of leg ulceration (Table 19.4). In the CSSCD, recurrence of ulcers was unaffected by treatment that included transfusions, the Unna gel dressing, zinc, skin grafts, and topical medications of different types, including antibiotics. There are reports touting the use of erythropoietin, antithrombin III, propionyl-L-carnitine, perilesional injection of colony-stimulating factors such as GM-CSF, arginine butyrate, pentoxifylline, DuoDERM, Solcoseryl, isoxsuprine, zinc sulfate, ozone, oxygen, topical opioids, honey, various gels, human skin equivalent, and hyperbaric oxygen.[10] All patients, especially those who have had leg ulcers, should be urged to protect their legs with support hose, avoid activities that cause swelling, such as prolonged standing, and use local lubricants that might help prevent excessive skin dryness and cracking. Control of local inflammation and infection ensuring a clean granulating surface for reepithelialization remains the mainstay of treatment. Wet to dry dressings applied several times a day provide debridement. Occasionally surgical debridement is needed to cleanse the ulcer base. Although cultures of the ulcer base are most often positive, topical antibiotics do not uniformly help healing, and systemic and antimicrobials are usually not indicated. When erythema of the ulcer borders and a purulent exudate are present that do not rapidly resolve after débridement, topical neomycin-bacitracin-polymyxin ointment and systemic antibiotics, chosen on the basis of culture, can be considered.[303] A preliminary report suggested that some chronic ulcers resistant to treatment and accompanied by antibodies to staphylolysin and antinuclease antibodies healed after treatment with flucloxacillin, but this has not been followed by any confirmatory data. Dressing the ulcer with an Unna boot protects the involved area and is a reasonable method of conservative management. Zinc sulfate, 220 mg orally three times daily has also been recommended.

Even small ulcers can be excruciatingly painful and require large amounts of narcotic analgesics for relief. Some patients get good analgesia from narcotic-containing skin patches. When healing occurs, the pain usually disappears.

When healing fails after a trial of conservative treatment that should last 6–8 weeks, difficult choices for more radical treatment must be faced. Prolonged bed rest might be helpful but is usually impractical. Controlled studies of transfusion have not been reported, but reducing HbS level to less than 30% by periodic transfusion can be considered. Surgery is a last resort because the recurrence rate and chance of graft failure are high. Different procedures have been used including free flaps, myocutaneous flaps, and simple skin grafts. The type of grafting used depends on the size of the ulcer and surgeon's experience.

Priapism

Priapus, the mythological god of procreation who is associated with debauchery, is personified by an enlarged tumescent phallus. Priapism is a prolonged, undesirable, painful erection, often occurring without sexual stimulation. Rather than provoking sexual profligacy, priapism can terminate in impotence. Regardless of the initial stimulus for priapism, the normal process of detumescence fails, and this is almost always a result of impaired venous outflow.

Pathophysiology

Vascular communication between the paired corpora cavernosa and the single corpus spongiosum does not exist. Draining the corporal sinusoids are emissary veins that enter progressively larger vessels forming the internal pudendal vein. Sinusoids of the glans drain directly into deep dorsal veins, allowing, when medically indicated, therapeutic shunts to be created that permit blood to flow from the corpora cavernosa to the corpus spongiosum (Fig. 19.9).

Normal erection is initiated by psychogenic, tactile, and neural stimuli, mediated partly by reduced α-adrenergic activity. Relaxed arterial vessels enhance blood delivery to the corporal bodies. Venous outflow is restricted as draining veins are compressed against the surrounding fascia

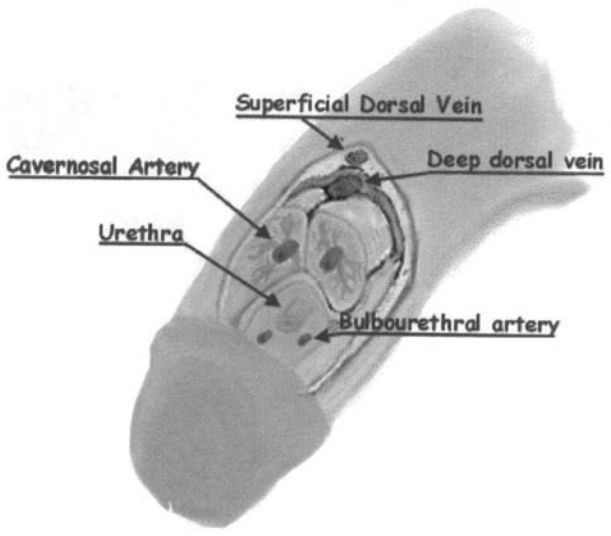

Figure 19.9. Anatomy of the penis. Fed by anastomosing branches of the internal pudendal artery, the erectile apparatus consists of two longitudinal cylinders of sinusoidal tissue: the paired corpora cavernosa with their associated arteries. Ventral to the corpora cavernosa is the corpus spongiosum, pierced by the urethra and terminating in the glans penis. A bulbourethral artery feeds the corpus spongiosum. The corporal bodies – except the glans – are encased in fibrous fascial tunics, the tunica albuginea. There is no vascular communication between the corpora cavernosa and the corpus spongiosum. Draining the corporal sinusoids are emissary veins that enter progressively larger vessels to form the internal pudendal vein. Sinusoids of the glans drain directly into the deep dorsal veins.

by distended sinusoids. As the circumference of the penis is limited by the fascial wrapping of the corpora, when sinusoids become engorged, elongation is paramount. Detumescence reverses this process as α-adrenergic activity increases, feeding arterioles constrict and venous return is reestablished.

Typically, priapism in sickle cell anemia is said to be bicorporeal – only the corpora cavernosa are affected – and is "low flow" – venous outflow is obstructed rather than arterial flow increased. In children, priapism is often associated with normal vascular flow, perhaps accounting for their better prognosis. Tricorporeal priapism has been described in sickle cell anemia and rarely a "high-flow" state, in the absence of penile vascular injury, is present.[303,304] With bicorporeal priapism, the glans remains soft and urination is normal. A tense glans and impaired urination signals involvement of the spongiosa that usually implies infarctive damage to the corpora cavernosa.

An alternative construct of priapism in sickle cell anemia holds that prepubertal patients have bicorporal priapism with high blood flow. Priapic episodes in this population usually last less than 48 hours, tend not to recur, and potency is preserved. In contrast, priapism in adults is usually tricorporal, low flow, recurrent, and long-lasting, and impotence results in over half of these cases, regardless of treatment.[304] These patients have been said to have a higher incidence of stroke, lung disease, renal failure, leg ulcers, and premature death than individuals without priapism.

Priapism is a hemolysis-related complication of sickle cell disease (Chapter 11).[18,20] Penile NO, originating from both neurons and endothelium, modulates penile vascular and smooth muscle relaxation.[305] Low-flow priapism may be the result of venous outflow occlusion because of reduced NO availability.[306,307] Priapic activity and pronounced erectile responses to stimulation are seen in transgenic mice in which both neuronal *(nos1)* and endothelial *(nos3)* NO synthase genes are knocked out and in sickle transgenic mice expressing HbS and lacking any murine hemoglobin.[308] This was thought to be a consequence of dysregulated activity of downstream signaling in the phosphodiesterase type 5 *(pde5a)* pathway. Depleted NO may cause *pde5a* down-regulation, less enzyme available for hydrolysis of cGMP, a reduction in its effector protein kinase G, and supersensitization to local cGMP from other sources. NO deficiency secondary to intravascular hemolysis might down-regulate *PDE5A* and its downstream effectors so that non–NO-mediated uninhibited increases in cGMP result in uncontrolled erection. Sildenafil and similar PDE5A inhibitors might paradoxically alleviate or prevent priapism in these states and pilot studies suggest that sildenafil might be useful in sickle cell priapism.[30] How sickle erythrocytes, neutrophils, and platelets contribute to this pathophysiology is unknown.

In preliminary studies, erythrocytes from patients with priapism had increased adhesion to thrombospondin compared with controls.[309]

The likelihood of developing priapism might be influenced by the presence of polymorphisms in genes associated with NO metabolism and cell adhesion (see Chapter 27).

Epidemiology and Clinical Features

Where sickle cell anemia is common, it is a leading cause of priapism. Less is known about the incidence of priapism in other genotypes of sickle cell disease. Most cases of priapism in sickle cell disease are seen in individuals with sickle cell anemia; in sickle cell anemia–α thalassemia the incidence of priapism decreases; and in HbSC disease the incidence is even lower.[20,304] This is likely to be a result of the less hemolysis in these genotypes and perhaps the greater likelihood of maintaining splenic function.

The incidence of priapism is highly dependent on the assiduousness of questioning. Many different age groups have been studied, most retrospectively: observation periods vary greatly, definitions may be vague, and self-reporting can be poor. In one study of children and adolescents, the actuarial probability of experiencing priapism by age 20 years was 89% ± 9%.[310] The mean age at the initial episode was 12 years, the mean number of episodes per patient was 15.7, and the mean duration of an episode was 125 minutes. Episodes typically occurred around 4:00 AM, and 75% of the patients surveyed had at least one episode starting during sleep or upon awakening from sleep. Other studies of different populations suggested a lower

incidence.[312–316] In another study the mean age of onset was 19 years but priapism was reported in children as young as 5 years.[317]

Recurrent attacks of priapism can last for several hours with tolerable discomfort, and they can be self-limited. These episodes have been termed stuttering priapism and they usually have a nocturnal onset. Erectile function is mostly preserved between these attacks, which can recur over a period of years and number in the dozens. Major episodes of priapism often, but not always, follow a history of stuttering attacks, last for days, and can be excruciatingly painful. They often destroy sexual function by causing irreversible corporal damage. Prolonged or recurrent episodes of priapism cause edema of the vascular septa of the corpora cavernosa leading to fibrosis, destruction of the normal distensible sinusoidal anatomy, and culminate in impotence.[313] In children, impotence seems to be a less common result of priapism, the incidence of which varies directly with age.[318,319] One attack of priapism presages multiple episodes. This may be an indication that sufficient vascular damage is present to alter normal erectile function. It seems reasonable to suspect that subclinical vascular damage precedes overt priapism and to some extent determines the end result of priapic episodes.

A rare complication of priapism is megalophallus. In a well-studied case, in which penile enlargement followed a prolonged severe priapic event, the proximal two-thirds of the penis had a circumference of nearly 20 cm. Using Doppler measurements, penile blood flow was high and MRI showed deoxyHbS in the corpora cavernosa. At least in this instance, corporal fibrosis did not seem to be present and erectile function was preserved. It was hypothesized that sudden loss of elasticity of the tunica albuginea allowed painless penile expansion.[320]

Diagnosis

History and physical examination establish this diagnosis. Six patients, five with a history of priapism, were studied by nocturnal tumescence testing with polysomnography and penile MRI. Nocturnal erections and detumescence times were prolonged and corporal anatomy varied from normal to intracorporeal fibrosis.[321] These studies correlated well with clinical examinations and history, suggesting to the authors that their routine use was not warranted.

Penile scans using technetium-99m can distinguish between low and high blood flow states and which corporal bodies are affected. They may not be helpful in predicting the clinical course of the event. Intracorporeal pressure and blood gases can be monitored. Doppler flow studies and MRI can also provide information on blood flow and which of the corporal bodies are involved. There is little information on how any of these tests can be used to direct therapy or establish a prognosis.

Treatment recommendations. The Cochrane Database Reviews concluded that there is no evidence for the benefits or risks of the different treatments for both stuttering and fulminant sickle cell priapism.[322] Clinicians must decide when "conservative" treatment with analgesics, hydration, and perhaps transfusions should be stopped and operative intervention initiated. Small retrospective case studies comprise the only information available to assist in this decision.[318] Retrospectively, when the adverse outcome of impotence has occurred after a severe bout of priapism, it is easy to assume that earlier operative intervention would have preserved erectile function. It is possible that the natural history of priapism is unaffected by any presently used treatment, conservative or surgical, and that the ultimate loss of potency is governed by the interplay of intracorporeal and systemic factors.

Most "authorities" believe that 24–48 hours is the maximum time that should elapse before treatment of priapism should be converted from "conservative" to operative intervention. There are several difficulties with this pronouncement. No scale is available to gauge the severity of the priapic episode or account for the preceding history of priapism. Conceivably, extreme turgidity with excruciating pain should be managed differently from lesser degrees of penile engorgement. Most episodes of priapism are preceded by a history of other episodes; these can be similar, more severe, or less severe, and have resolved with erectile function preserved. How should this history be incorporated into the treatment plan? It would be invaluable to know how hydration, sedation, and simple or exchange transfusions, compare with aspiration and irrigation and with surgical shunts. One small study found automated exchange transfusions to be ineffective.[323] Whether or not transfusions are helpful, especially if a major episode has occurred, is not known, and a recent review found no benefit of this treatment.[324] If surgery is superior, what type of operation is best? Although priapism is a common complication, the experience of any single urologist or hematologist is limited and their favorite treatment is likely to be biased by their own limited observations. Because of this uncertainty, the many published schema for managing priapism, including our own, cannot be taken as a "standard of care" dictating rigid adherence, but are general guidelines only.

Pain should be relieved with narcotic analgesics and adequate fluids provided. If the episode differs from prior episodes of stuttering priapism according to the patient history and physician experience, aspiration and irrigation should be done within a 12-hour window from the onset of erection. In a prospective study in children, aspiration of blood from the corpora cavernosa and irrigation with a dilute epinephrine solution while the patient received local anesthetic was used to relieve priapism if hydration and analgesics failed to produce detumescence or if priapism had lasted more than 4 hours. Fifteen patients with sickle cell anemia were treated 39 times and detumescence occurred 95% of the time without serious side effects. All patients whose priapism resolved had self-reported normal erectile function at a median of 40 months after the

last procedure.[325] Self-limited attacks of stuttering priapism often resolve after masturbation, cold showers, or exercise.

Invasive treatment for priapism in sickle cell anemia is designed to evacuate stagnant blood within the corpora cavernosa and to prevent immediate recurrence of corporal expansion. The simplest surgical procedure is aspiration of the corporal bodies with irrigation; however, when a major episode of priapism has been present for 24–48 hours aspiration of blood is usually difficult. Creation of shunts between the glans penis and the distal corpora cavernosa with a Tru-cut biopsy needle is an alternate approach favored by most urologists if corporal irrigation fails. This procedure, popularized by Winter and bearing his name, allows blood from the distended corpora cavernosa to drain into the uninvolved corpus spongiosa. If there is tricorporal involvement, this shunt is unlikely to be effective. An operative intervention to create larger shunts between the corpora cavernosa and corpus spongiosum can be considered if detumescence is not achieved with the Winter shunt.

α-Adrenergic activity maintains the vessels feeding the corporal bodies in a constricted state when the penis is flaccid. This suggested that oral and intracavernous administration of α-adrenergic agonists, with or without drainage, may help reverse priapism.[326–328] Etilefrine, an α-adrenergic agonist, and other α-adrenergic agents were used in patients with sickle cell anemia and stuttering or acute priapism.[329,330] When Etilefrine was used orally in stuttering episodes, recurrence was claimed to be prevented, and acute, more severe episodes were reversed after intracavernous injection. These observations do not warrant a general recommendation for using these agents because there are some dangers associated with α-adrenergic agonists, and the reports available do not substitute for well-controlled trials. Vasodilators and even β-adrenergic agents have also been used but there are no good studies of their efficacy.

In perhaps the sole double-blind, placebo-controlled trial of treatment for priapism, stilbestrol was found to reduce attacks of stuttering priapism.[312] Eleven patients with a history of two attacks of priapism weekly were enrolled and after a 2-week baseline were randomized to receive either 5 mg of stilbestrol daily or a placebo. Two individuals stopped having attacks during the baseline period. Five placebo-treated patients continued their attacks and when they switched to active drug ceased having priapism. Four patients randomized to receive active drug stopped their attacks in 1–3 days. A maintenance dose of 2.5–5 mg every few days or weekly was usually effective. Stilbestrol can cause gynecomastia, prevent desired erections, and have other undesirable consequences. This was a short-term study of a small and very select group of patients. The general usefulness of this treatment and its ability to stop major episodes of priapism is unknown.

Low doses of the androgen antagonist, bicalutamide, have been successful in preventing recurrent priapism but very few cases have been reported, and this form of treatment might also have troubling consequences.[331]

In five patients with stuttering priapism who were started on hydroxyurea, four had a reduction in the number and severity of episodes and in two patients the episodes stopped.[332] Two patients had HbF levels of approximately 20%. The absence of an association of HbF levels with priapism raise some skepticism about this approach, although the NO donor properties of hydroxyurea might, in conjunction with an exuberant HbF increase, be useful.

Seven patients with priapism were given sildenafil and tadalafil and followed for 2 years. A retrospective analysis suggested that treatment was successful in alleviating or resolving priapism recurrences in six of the seven patients, and erectile function was unchanged in six patients and improved in one patient at last follow-up. All the patients tolerated the treatment well. The investigators concluded that a rigorously implemented controlled clinical trial was necessary to confirm the utility of this treatment.[30,333] It seems unlikely that when the anatomy of the erectile apparatus is permanently damaged, treatment with sildenafil will be effective for regaining lost erectile function.

When impotence results from priapism, implantable penile prostheses have been used with success, although they might be difficult to insert in fibrotic corporal bodies and might be associated with more complications than when used in cases of idiopathic priapism.[334]

Digestive Diseases

Biliary tract disease and parenchymal liver disease are the most prevalent and serious complications of sickle cell anemia that affect the digestive system. Abdominal pain is a frequent complaint of patients with sickle cell disease. Whether pain results from cholelithiasis or cholecystitis, has its roots in intraabdominal vasoocclusive disease, or is related to intraabdominal pathology unrelated to sickle cell anemia, it is often a difficult to resolve. Some causes of abdominal pain in sickle cell anemia are shown in Table 19.5. In one series, over half of the episodes of abdominal pain were thought to be due to vasoocclusive episodes, approximately a quarter were due to gall bladder disease or appendicitis, 13% had a renal origin, and some were due to pneumonia and gynecological disease.[188]

There is little reliable information on other abnormalities of the digestive system. Documented episodes of bowel ischemia are rare. Pancreatitis has been reported but appears to be uncommon. Controversy surrounds the incidence of peptic ulcer disease in sickle cell anemia, and whether or not these individuals have reduced acid secretion.[313]

Sickle Cell Liver Disease

Hepatomegaly is found in 80%–100% of patients. Liver disease is often a mélange of diverse pathologies that might

be contributed to by intra- and extrahepatic cholestasis, viral hepatitis, cirrhosis, hypoxia and infarction, erythrocyte sequestration, iron overload, and drug reactions. Often it is difficult to differentiate among these causes in an individual and more than one cause of liver disease is often present. In common with liver disease in the general population, treatment options are limited.

Abnormal "liver" tests are often present but might not always reflect hepatocellular disease or even be related to the hemoglobinopathy.[335] Unconjugated hyperbilirubinemia is an expression of hemolytic anemia. Bilirubin levels vary considerably and this is likely a reflection of liver disease, hemolysis, and genetic differences in bilirubin metabolism. Increased levels of alkaline phosphatase, especially in children and adolescents, could be from growing or injured bones. Protein C and protein S levels are lower in sickle cell anemia when compared with controls, an observation that was accounted for by hepatic dysfunction rather than consumptive coagulopathy.[336]

Hepatic drug metabolism is variously affected with some drugs, such as morphine, having increased clearance, others, such as lidocaine, having decreased clearance, and still others, such as meperidine, being unaffected. These differences could exist because of genetic differences and the different routes of drug metabolism, for example glucuronidation or deethylation.[337] Insufficient information is available on which to base changes in drug dosing.

An occasional otherwise well patient will have an isolated elevation of unconjugated bilirubin beyond the usual values seen in sickle cell anemia,[13] with normal liver tests and no indication of hepatic disease. Perhaps some of these individuals have Gilbert syndrome, now known to be associated with polymorphisms of the UDP-glucuronyltransferase (*UDPGT1*) gene promoter (see Chapter 27).

Results of liver biopsy are highly dependent on the clinical events that prompted biopsy. Hemosiderosis is often present, a result of chronic transfusions and parenchymal liver disease. Chronic hepatitis and cirrhosis might suggest transfusion-transmitted diseases.[338] When biopsy was performed during cholecystectomy, sinusoidal dilation and perisinusoidal fibrosis were the pervasive lesions.[339] Kupffer cells often contain phagocytized erythrocytes.

As expected in patients who have often received multiple blood transfusions, viral hepatitis is common. Bilirubin levels may be much higher than found in viral hepatitis uncomplicated by the hemolysis and other liver-related complications of disease.[340] Viral hepatitis B was often present in transfused patients before it was possible to screen blood for its presence.

In 141 patients with sickle cell disease, hepatitis B core antibodies were positive in 14% and hepatitis C viral antibody titers were positive in 16.5%. Hepatitis C positivity was related to transfusion.[341] These observations are unlikely to be representative of the world's population as transmission of hepatitis C by transfusions is dependent on the incidence of this disease in the population of blood donors. Worldwide, hepatitis C viral antibodies are present in 2%–20% of transfused patients. When serum ALT levels were persistently elevated, 90% of these patients were hepatitis C viral antibody positive. Hepatitis E infection has been noted, and as new blood borne viral hepatitides appear, undoubtedly they will be found among transfused patients. Autoimmune hepatitis diagnosed by biopsy and responsive to immunosuppressive therapy has been described.

Sickle hepatopathy, hepatic crisis, and the right upper quadrant syndrome of sickle cell disease have been variously defined. Syndromes of "benign" intrahepatic cholestasis and acute hepatic sequestration – akin to the splenic sequestration syndrome – have been described. Nevertheless, it is difficult from descriptions in the literature to differentiate among these entities, probably because their causes include viral hepatitis and vasoocclusive disease compounded by hemolysis and cholestasis. A syndrome of increasing hepatomegaly, extreme hyperbilirubinemia with levels approaching 100 mg/dL, has been recognized. In this syndrome there are only modest increases in transaminase levels, high alkaline phosphatase and γ-glutamyltransferase levels, right upper quadrant pain, increasing anemia, fever, coagulation abnormalities, and differing degrees of hepatic failure.

When sickle hepatopathy was defined by a total serum bilirubin concentration of more than 13 mg/dL in the absence of acute hemolysis, viral hepatitis, extrahepatic obstruction, or hepatic sequestration, 44 patients were categorized based on whether hepatic dysfunction at presentation was mild or severe. Mild patients were younger with lower maximum bilirubin levels than severe patients (36.2 mg/dL vs. 76.8 mg/dL) and had a 4% mortality compared with a 64% mortality. Two of nine patients who received exchange transfusion died compared with 12 of 13 who did not receive exchange transfusion.[342]

About 11% of deaths in one analysis were attributable to cirrhosis.[251] Liver disease can also be present in HbSC disease and HbS–β^+ thalassemia.

Treatment recommendations. There are no data on the value of interferon for chronic active hepatitis C in sickle cell anemia. Its use should be based on the experience in other diseases. Individuals with the severe right upper quadrant syndrome can reasonably be offered exchange transfusions, although there is not proof of their efficacy. Unless it is unequivocally clear that extrahepatic obstruction is present, surgery should be avoided. The management of iron overload is discussed in Chapter 29.

Gallstones

Hyperbilirubinemia is associated with a high prevalence of gallstones. In Jamaica, 31% of sickle cell anemia and 11% of HbSC disease patients aged 17–24 years who participated in the cohort study had gallstones, but specific symptoms necessitating cholecystectomy occurred in only 2% of sickle cell anemia cases.[343] Gallstones were found in approximately 16% of Kuwaiti children with sickle cell anemia, aged 10.8 ± 5.5 years.[344] Individuals with stones had a lower hemoglobin level and were less likely to have α thalassemia. Although α thalassemia might reduce the development of cholelithiasis by reducing hemolysis, the genotype of the *UGT1A* gene seems of greater importance (Chapter 27).[345]

Patients with sickle cell anemia had a lower frequency of the common *UGT1A* promoter polymorphism $(TA)_6$ and a higher frequency of the $(TA)_7$ allele.[346] Children with the $(TA)_6$ allele had a lower serum bilirubin (2.4 ± 0.8 mg/dL) and had less than half the rate of cholecystectomy than those with the $(TA)_7$ allele who had higher bilirubin levels (5.8 ± 3.1 mg/dL). This polymorphisms is also related to the age of onset of cholelithiasis.[347] In children taking hydroxyurea the hydroxyurea-related decreases in serum bilirubin levels were dependent on the *UGT1A* genotype with individuals with the wild-type promoter genotype having lower levels.[348]

Pigmented gallstones in sickle cell disease can be either radiopaque or radiolucent. Ultrasonography is the preferred means of their detection. Open cholecystectomy accounted for 20% of all operations in 717 patients with sickle cell anemia with only one death.[191] In a study of the effects of preoperative transfusion in sickle cell anemia, 211 open cholecystectomies and 153 laparoscopic cholecystectomies were performed.[349] Nineteen percent of these patients had intraoperative, 11% transfusion related, and 10% postoperative complications, for a total complication rate of 39%. Untransfused patients had the highest rate of postoperative acute chest syndrome and painful episodes. When common duct stones were suspected on the basis of a dilated duct, high alkaline phosphatase levels, and bilirubin that exceeded baseline by 5 mg/dL, endoscopic retrograde cholangiopancreatography, sphincterotomy, and stone extraction followed by laparoscopic cholecystectomy was an effective approach.[350]

Treatment recommendations. Unequivocal episodes of acute cholecystitis are not common and typical obstructive jaundice is equally infrequent. When stones are asymptomatic or symptoms and laboratory findings are equivocal, it is probably best not to do elective cholecystectomy. Laparoscopic cholecystectomy patients were hospitalized for a shorter time period but had a similar rate of complications as those who underwent open cholecystectomy.

Neurocognitive Dysfunction in Adults

Although neurocognitive abnormalities are well known to be present in children with cerebrovascular disease, few studies have been done in adults. To study this problem, adults with sickle cell anemia or HbS–β^0 thalassemia who were neurologically normal and did not have a history of stroke or an abnormal MRI examination were given a standard group of neuropsychological tests and underwent MRI.[351]

Forty percent of young adult patients had abnormal scans. Abnormalities included frontal and parietal atrophy, lacunae and white matter lesions, and reduced intracranial and hippocampal volumes. Mean IQ scores were below average with more than twice as many patients scoring less than 85 on the Wechsler Adult Intelligence and Memory Scales compared with 16% of controls. Approximately 40% of patients had IQ scores 1 standard deviation or more below the normative population mean. Memory, reading, and math performance were also decreased. Hemoglobin concentration was positively associated with IQ, and IQ tended to be associated with hippocampal volume.

Although preliminary, these findings suggest that even neurologically normal adults can be neurocognitively impaired. They could explain some of the unusual behaviors seen in some adults and attributed to “poor adjustment” and other nonorganic psychological problems. A pilot trial is being conducted to see if transfusion can improve neurocognitive function. Perhaps more important is the realization that central nervous system disease, like disease of other organs, can be “silent” but progressive and

Hb, hemoglobin level in g/dL; MCV, mean corpuscular volume (fL); Retic, reticulocyte count (percent); WBC, leukocyte count (10^6/L); PLT, platelet count (10^9/L); HbF, fetal hemoglobin (percent); HAPLO, β-globin gene cluster haplotype [BEN-Benin; CAR Central African Republic; Atyp-atypical]; α genes, α-globin genotype; Cr, creatinine (mg/dL); ALT, alanine aminotransferase (units); Pain, average numbers of pain crises yearly, CHF, congestive heart failure (Y, yes; N, no); Leg ulcer, presence or history of leg ulcers; ON, osteonecrosis, CVA, history of cerebrovascular accidents; Retina, sickle retinopathy; TX, regular transfusions.[353]

that early treatment with drugs such as hydroxyurea might prevent or retard its development.

OLDER ADULTS

Sickle cell anemia, first considered a disease of childhood, is now found in the elderly. Most clinics have seen individuals in their sixth and seventh decades and some individuals have survived into the ninth decade. Increasing numbers of older adults with sickle cell anemia are probably a result of higher standards of supportive care. In follow-up of the Jamaican sickle cell study patients, it was noted that of the 102 patients who had survived their 60th birthday, 40 were known to be alive and were aged 60.2–85.6 years and females predominated.[352]

Older adults with sickle cell anemia have their own array of complications.[353,354] Laboratory and clinical features of a small group of septuagenarians with sickle cell anemia are shown in Table 19.6. In such a small number of cases, generalizations are difficult, but several features of these patients deserve comment. Although their lifespan was near normal, they were not unaffected; most of their serious complications became apparent in later life. Although their HbF levels, the best predictor of morbidity and mortality, were lower than average, Jamaican "survivors" had HbF levels approximately 5% higher than expected. HbF constantly falls with aging in sickle cell anemia and there is very little information on HbF in patients aged 60–80 years.[354] Leukocyte counts, also associated with morbidity and mortality in sickle cell anemia, were lower than average. As both leukocyte counts and HbF fall with age in sickle cell anemia the levels observed may be an effect, not a cause, of longevity. With aging, hemoglobin levels fall and renal function declines.[352] One other septuagenarian with sickle cell anemia had a PCV of 18, HbF of 6.4%, and a leukocyte count of 10.3×10^6/L.[354]

We do not understand why some patients with sickle cell anemia survive their peers by decades. These unusual patients can be examples of the possibility of a long life and should alert physicians that this diagnosis need not be excluded by age alone. Old age in sickle cell anemia does not imply that these are the "golden years." Decades of vascular injury – much of which is subclinical – begins to result in chronic organ damage and failure. The lung, heart, bones, and kidneys are primarily affected.

Eye Disease

Sickle retinopathy is discussed in detail in Chapter 21 and the treatment of hyphema in HbAS is discussed in Chapter 22. Present in approximately one to two thirds of adults with HbSC disease, depending on their ages, proliferative sickle retinopathy is far less common in sickle cell anemia. As hydroxyurea treatment makes sickle cell anemia erythrocytes more like HbSC disease cells, the prevalence of proliferative retinopathy could begin to increase in young sickle cell anemia patients treated with this drug.

In distinction to proliferative retinopathy, central retinal artery occlusion is a rare cause of sudden blindness and is more common in sickle cell anemia than HbSC disease.[355] Approximately half of the reported cases were in association with a vasoocclusive episode and 7 of 17 cases

were bilateral. Most patients had partial recovery of vision, although any relationship of recovery to transfusion, which is usually used for treatment, is unclear.

Some patients with sickle cell anemia have abnormal dark adaptation.[356] This defect is related to tissue zinc deficiency, a consequence of hyperzincuria and improves with zinc replacement. Any clinical consequences of this laboratory observation have not been reported.

Conjunctival vessels in sickle cell anemia are damaged by vasoocclusion and develop corkscrew- and comma-shaped forms, show dropped out segments, and can become obliterated causing avascular regions of the bulbar conjunctiva. These abnormalities have been considered pathognomonic of sickle cell disease, and their presence is inversely correlated with HbF level and directly related to the numbers of ISCs.[357] Conjunctival abnormalities are less often present in HbSC disease and HbS–β^+ thalassemia.

Cardiovascular Complications

Cardiac abnormalities may be present in children with sickle cell anemia. When 23 patients aged 7–17 years underwent exercise myocardial scintigraphy, myocardial perfusion was abnormal in 61%; some patients had irreversible abnormalities and others had cardiac failure, angina, or ventricular tachycardia.[358] Children with a median age of 10.1 years had larger left ventricular and atrial volumes than controls and some had left ventricular hypertrophy and stiffness.[359] Perhaps such changes antedate cardiac disease in adults.

Physical work capacity is reduced by approximately half in adults, and 60%–70% in children with sickle cell anemia, and is related to the severity of the anemia. Cardiac examinations in adults are rarely normal; the heart is usually enlarged and the precordium hyperactive, systolic murmurs are found in most patients, and premature contractions are often present.[360] Cardiomegaly and heart murmurs often raise the question of whether congestive heart failure is present, but contractility is usually normal and overt congestive heart failure is uncommon, especially in children.[361] Preliminary studies of transfused and nontransfused patients with sickle cell disease suggest that left ventricular dysfunction is relatively uncommon compared with transfused patients with β thalassemia. When heart failure is present, it often can be related to secondary causes such as fluid overload.

Hypertension can cause ventricular hypertrophy and heart failure. Cardiac output is increased at rest in individuals with sickle cell anemia and rises further with exercise. Electrocardiograms often have nonspecific abnormalities and can show sign of ventricular hypertrophy. Cardiac index is increased approximately twice normal at rest and increases further during exercise. Cardiac index was not related to hemoglobin level or oxygen content suggesting increased tissue extraction of oxygen. This was postulated to be due to the increased capillary diffusing surface.

Cardiac abnormalities in almost 200 patients aged 13 years and older with sickle cell anemia were studied echocardiographically by investigators of the CSSCD.[361] Compared with normal controls, patients had increased left and right ventricular and left atrial chamber dimensions, increased interventricular septal thickness, and normal contractility. These dimensions, except for those of the right ventricle, were inversely related to the hemoglobin level and indicated cardiac dilation. Cardiac dilation was also dependent on age. Pericardial effusions were present in 10% of patients. When homozygous α thalassemia-2 was present, left ventricular dimensions were more normal but wall thickness was increased.[362] This difference was postulated to be a result of the higher hemoglobin levels caused by α thalassemia. Nevertheless, the response to exercise was not improved.

Diastolic dysfunction was found in 18% of 141 patients with different genotypes of sickle cell disease. A combination of diastolic dysfunction and pulmonary hypertension was present in 11% but diastolic dysfunction explained only 10%–20% of the variability in TRJ velocity. Diastolic dysfunction independently contributes to prospective mortality.[363] Most patients had no evidence of impaired right or left ventricular systolic function.

Chest pain, a common entity in sickle cell anemia, often leads to patients being told they have had a “heart attack.” In fact, obvious myocardial infarction is unusual, but has been reported. Paradoxically, coronary artery occlusion is not common, suggesting that small vessel disease is responsible for the cardiac damage.[364] Gross and microscopic findings consistent with acute (three patients) and healed (four patients) myocardial infarction were found in seven (9.7%) of 72 consecutive hearts from patients with sickle cell disease studied at autopsy. Gross obstructive and atherosclerotic lesions were absent in all seven patients, whereas microthrombi were present in the arterioles of infarcted tissue in two. Chest pain occurred clinically in six of the seven patients and electrocardiographic findings typical of infarction were found in two. One patient died suddenly. These findings suggest that ischemic heart disease can be present in patients with sickle cell disease and should not be categorically excluded in patients with chest pain.[365]

Sudden unexpected and unexplained death is common in adults with sickle cell anemia. In postmortem examinations of the cardiac conduction system and coronary chemoreceptors from the hearts of two black males who died suddenly there were abundant foci of old and recent degeneration in the sinus node, atrioventricular node, and His bundle, and also the coronary chemoreceptor.[366] Many capillaries and small arteries were packed with sickled erythrocytes, among which small groups of aggregated platelets were also present. Focal fibromuscular dysplasia caused moderate to severe narrowing of many small coronary arteries, including those supplying the conduction system and chemoreceptor. These abnormalities suggest

that electrical instability might be one component of the lethal terminal events in some individuals. Cardiovascular autonomic function tests were performed in 24 patients with sickle cell anemia and 38 healthy white controls. Fifty-eight percent had cardiovascular autonomic dysfunction based on abnormal values for at least two cardiovascular autonomic function tests, whereas 41.7% had preserved autonomic function.[367]

Treatment recommendations. Overt congestive heart failure in sickle cell anemia is not common and when present should be treated with the usual methods. When "rehydrating" patients during treatment of acute vasoocclusive events, care should be taken so that excessive fluids do not lead to iatrogenic congestive failure. Severely anemic patients with symptoms of congestive heart failure or angina pectoris might be helped by cautiously increasing their hemoglobin concentration by transfusion or erythropoietin treatment.

Renal Disease

Renal complications are a common cause of morbidity and mortality in sickle cell disease and the incidence of renal failure increases as overall patient survival increases. Early elements of sickle cell renal disease include increased renal plasma flow, glomerular hyperfiltration, increased proximal tubular function and hematuria. Subsequently, reduced concentrating ability, focal segmental glomerulosclerosis with proteinuria, papillary necrosis, impaired urine acidification and potassium secretion and reduced glomerular filtration can develop.[368–375]

Epidemiology

In the United States, between 1992 and 1996, there were 345 reported new cases of end-stage renal disease in sickle cell anemia (U.S. Renal Data System 1997 Annual Report, NIDDK, NIH). In one study, patients with a Bantu β-globin gene cluster haplotype were most likely to develop renal failure.[376,377] This study was a prospective, 25-year longitudinal demographic and clinical cohort study of 725 patients with sickle cell anemia and 209 patients with HbSC disease. Approximately 4% of sickle cell anemia and 2.4% of HbSC disease patients developed renal failure, with median ages of onset of 23 and 50 years, respectively. Sixty percent of patients older than 40 years had proteinuria and 30% had renal insufficiency. Nephrotic syndrome was found in 40% of patients with creatinine levels above 1 mg/dL for children and 1.5 mg/dL for adults. In the Jamaican cohort study, subjects with sickle cell disease, aged 18–23 years had lower blood pressure and normal or increase glomerular filtration rate and renal plasma flow compared with controls. Twenty-six percent of patients had microalbuminuria, and this correlated positively with glomerular filtration rate and blood pressure.[375] Approximately 20% of children aged 3–20 years had microalbuminuria.[378]

Survival time for patients with sickle cell anemia after the diagnosis of sickle renal failure was 4 years even when on dialysis, and the median age at the time of death was 27 years. Case-control analysis showed that ineffective erythropoiesis with increasingly severe anemia, hypertension, proteinuria, the nephrotic syndrome, and microscopic hematuria were significant preazotemic predictors of chronic renal failure. Perhaps the lower levels of HbF associated with the Bantu haplotype was responsible for more rapid organ failure.

α Thalassemia might prevent or retard sickle glomerulopathy. In 76 adults with sickle cell anemia, albumin excretion of more than 300 mg/g creatinine was found in 13% of patients with heterozygous or homozygous α thalassemia-2 compared with 40% of patients with a normal α-globin gene haplotype.[379] Renal failure is a risk factor for early death with survival reduced by nearly half compared with patients having normal renal function.[207,250,377]

Pathophysiology

Two major abnormalities characterize the renal lesions associated with sickle cell disease. The first, and least important, is medullary disease that is found in most individuals with sickle cell anemia and even in carriers of HbAS (Chapter 22). Acidosis, hypoxia, and hyperosmolarity, conditions that favor HbS polymerization, typify the conditions in the renal medulla. Even HbAS cells deform in this environment, leading to hyposthenuria and occasionally hematuria. In sickle cell anemia, the vasa recta may be severely damaged or lost entirely. Isosthenuria, distal renal tubular acidosis, and impaired potassium excretion are signs of medullary dysfunction. Clinically, the loss of concentrating ability is not important unless access to fluid is restricted. Systemic acidosis is not a clinical problem despite the acidification defect. Hyperkalemia can accompany renal failure and the use of angiotensin-converting enzyme (ACE) inhibitors and might be worsened by type IV renal tubular acidosis. Hematuria and papillary necrosis are also seen. The former is almost always benign as it is in HbAS. Proximal renal tubular function is supranormal and creatinine secretion and phosphate reabsorption are increased. This is of no clinical significance but can lead to overestimation of glomerular filtration rate.

The major renal abnormality of sickle cell disease is a glomerulopathy, characterized by glomerular hypertrophy, hypercellularity, mesangial proliferation, and segmental glomerulosclerosis.[380,381] Why glomerular hypertrophy occurs is unclear, but might be related to increased renal plasma flow, hypoxia, increased prostaglandin production, and dilation of afferent glomerular arterioles. Arteriolar dilation could produce glomerular hypertension, which is ultimately responsible for loss of filtration. Glomerular permeability is increased before renal insufficiency develops and decreases with chronic renal failure.[382] When macroalbuminuria occurs, glomerulopathy is present, and the

Nephrotic syndrome with focal glomerular sclerosis
Chronic renal failure; decreased filtration fraction

glomerular filtration ability is reduced to approximately 40%, even in patients with a preserved glomerular filtration rate.[369] Glomerular hypertrophy and hyperfiltration lead to increased secretion of creatinine and explain the very low creatinine levels of children and adolescents with sickle cell anemia and their increased creatinine clearance. A "normal" creatinine level in teenagers and young adults with sickle cell anemia is "abnormal" and is evidence for sickle nephropathy.[375]

Acute reversible deterioration of renal function due to tubular necrosis, occasionally severe and requiring dialysis, sometimes develops in hospitalized patients. It is often associated with volume contraction, anemia, and infection, but most patients recover with time. Renal cortical necrosis can also occur and here, recovery is less likely. Renal abnormalities in sickle cell anemia are shown in Table 19.7.

Diagnosis

Albuminuria is a sensitive marker of glomerular damage in sickle cell disease and precedes the development of overt renal insufficiency. In 300 patients with sickle cell disease, including 184 with sickle cell anemia, albumin excretion rates and renal function were measured. Micro- and macroalbuminuria occurred in 68% and macroalbuminuria in 26% of adults with sickle cell anemia, whereas in other disease genotypes, micro- and macroalbuminuria occurred in 32% and macroalbuminuria in 10%. In one study, development of albuminuria was age dependent and correlated with serum creatinine, but not with blood pressure.[383] In a cross-sectional study, albuminuria was associated with blood pressure.[375]

Yearly screening, by measuring the albumin/creatinine ratio in a random urine specimen, might help identify patients for treatment with ACE inhibitors or ACE receptor antagonists should controlled clinical trials shown that they can retard the progression of disease. Other proposed markers for renal failure and injury are urinary kallikrein,[384] cystatin-C and N-acetyl-beta-D-glucosaminidase,[232] the ^{51}Cr EDTA measurement of glomerular filtration rate,[385] and endothelin-1.[386]

Transgenic sickle mice also have glomerular hyperfiltration and hyposthenuria, excrete increased amounts of stable NO metabolites, and have raised levels of glomerular iNOS.[387]

Treatment recommendations. Nonsteroidal antiinflammatory drugs that inhibit the production of prostaglandins can reduce glomerular filtration rate in sickle cell anemia and might best be avoided in older individuals with signs of incipient renal failure. Dialysis and renal transplantation are used in end-stage sickle cell nephropathy with outcomes less favorable than in other types of renal failure.[388] If drugs such as hydroxyurea that increase HbF concentration can be used successfully in young children, presumably the glomerulopathy of sickle cell disease can be forestalled or prevented. Medullary disease precedes glomerular damage so that drug therapy will need to be started earlier in life to prevent this type of damage; however, these lesions are not as critical as glomerulopathy.

Concordant with the rise in creatinine, PCV begins to fall and, not infrequently, symptoms of severe anemia and congestive heart failure appear and dominate the clinical picture. In sickle cell anemia, erythropoietin levels are lower than predicted and the judicious use of erythropoietin can return hemoglobin to the prerenal failure baseline.[389] If this approach is chosen, care should be taken not to increase the PCV beyond the level present prior to the onset of renal disease because this might have the potential of promoting vasoocclusive episodes. Larger than customary doses of erythropoietin might be needed.

Hemodialysis can be an effective in end-stage renal failure in sickle cell disease. Renal transplantation has also been advocated. In the most comprehensive examination of the results of renal transplantation in sickle cell disease, the incidence of acute rejection, mean serum creatinine after surgery, and 1-year graft survival in 82 patients with end-stage sickle cell nephropathy who underwent renal transplantation after an average dialysis period of 41 months was similar to age-matched African American controls. The 3-year cadaveric graft survival of 61% was poorer than that of controls (86%). Patient survival at 1 and 3 years posttransplantation was also worse in the sickle cell disease. Compared with patients treated with dialysis and wait-listed for transplantation, there was a trend toward improved survival.[390] This report, in which the results differ from earlier smaller studies which concluded that renal transplantation in sickle cell anemia had poor

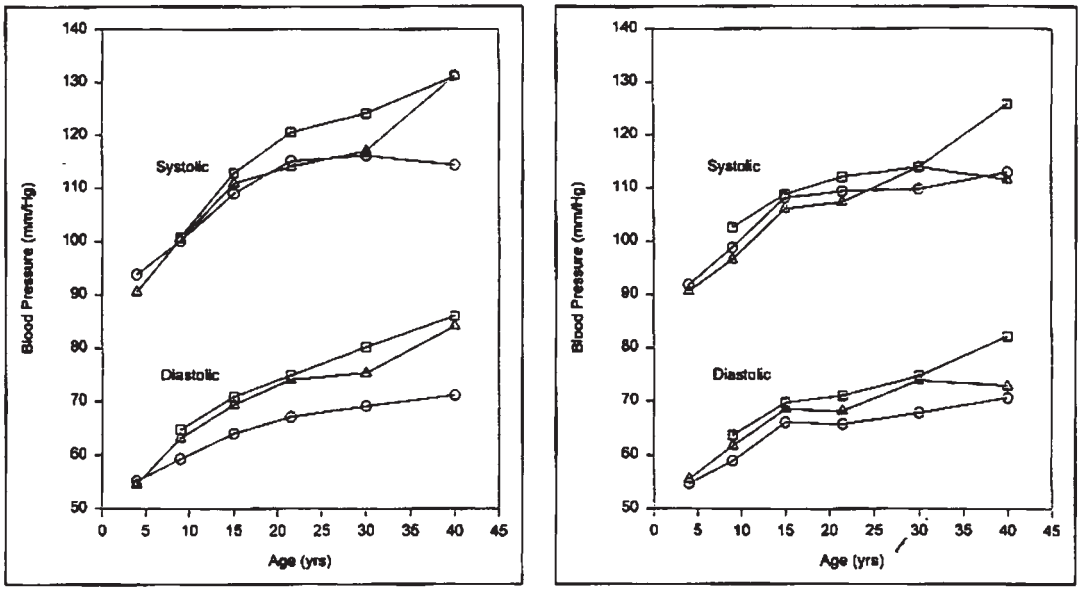

Figure 19.10. Systolic and diastolic blood pressure in male (left panel) and female (right panel) patients with sickle cell anemia (○) and HbSC disease (⁻) and in African American participants in the NHANES II study (□). In most age categories, both men and women with sickle cell anemia had lower systolic and diastolic blood pressure than NHANES II controls and individuals with HbSC disease.[87]

results, suggests that the outcome of renal transplantation in sickle cell anemia can be at least as good as dialysis and should be seriously considered for individuals with end-stage renal failure.

ACE inhibitors and receptor antagonists that can decrease glomerular pressure by dilating the efferent arterioles can reduce the proteinuria of sickle cell anemia and are being studied as treatment for sickle nephropathy.[378,380,391,392] In a randomized double-blind study of 22 patients, after 6 months treatment, 25 mg/day of captopril caused a 37% reduction in microalbuminuria compared with a 17% increase in placebo-treated patients. A small but significant reduction in diastolic blood pressure was seen in captopril-treated patients. At present, no controlled clinical trial has examined the efficacy of these drugs in sickle nephropathy.

In a pilot trial, effects of angiotensin blockade with losartan were studied in 15 patients with biopsy-proven sickle cell glomerulopathy and macroalbuminuria. Losartan, at a dose of 50–100 mg given for 4–8 weeks, reduced proteinuria in all individuals by an average 40% and did not reduce glomerular filtration rate or blood pressure; hyperkalemia, requiring diuretics or weekly oral kayexalate, occurred in three patients.[393]

Blood Pressure and Hypertension

Patients with anemia have lower than expected blood pressure and individuals with sickle cell anemia are no exception. This could be due to renal sodium wasting; however, its cause is not known for certain.[87] Compared with individuals with β thalassemia who had similar hemoglobin concentrations, the blood pressure of patients with sickle cell anemia was higher than expected, suggesting the possibility that they had "relative" hypertension.[304] In this study of 89 patients, there was an association between higher blood pressures and stroke. Figure 19.10 shows blood pressure as a function of age in more than 2,500 African Americans with sickle cell anemia and 800 with HbSC disease.[87] Compared with controls, individuals with sickle cell anemia had significantly lower systolic and diastolic blood pressures. Survival decreased and the risk of stroke increased as blood pressure rose (Fig. 19.11), even though the blood pressure at which these risks increased was below the level defining early hypertension in the normal population. This suggests that "relative" hypertension was pathogenetically important. "Relative" hypertension in sickle cell anemia might reflect impaired NO bioactivity due to intravascular hemolysis. Higher systemic blood pressure is associated with sickle cell pulmonary hypertension and renal dysfunction.[19,268] Systolic blood pressure was also a component of a network model predicting survival.[44]

Treatment recommendations. Although blood pressure is a major contributor to mortality, there are no trials in patients with sickle cell anemia that can guide the decision of when to begin antihypertensive treatment, what agents are most effective, what the blood pressure goals of treatment should be, and if blood pressure reduction can reduce the incidence of stroke or prolong life. A reasonable approach, based on experience in the general hypertensive population in which the risk of stroke begins well below

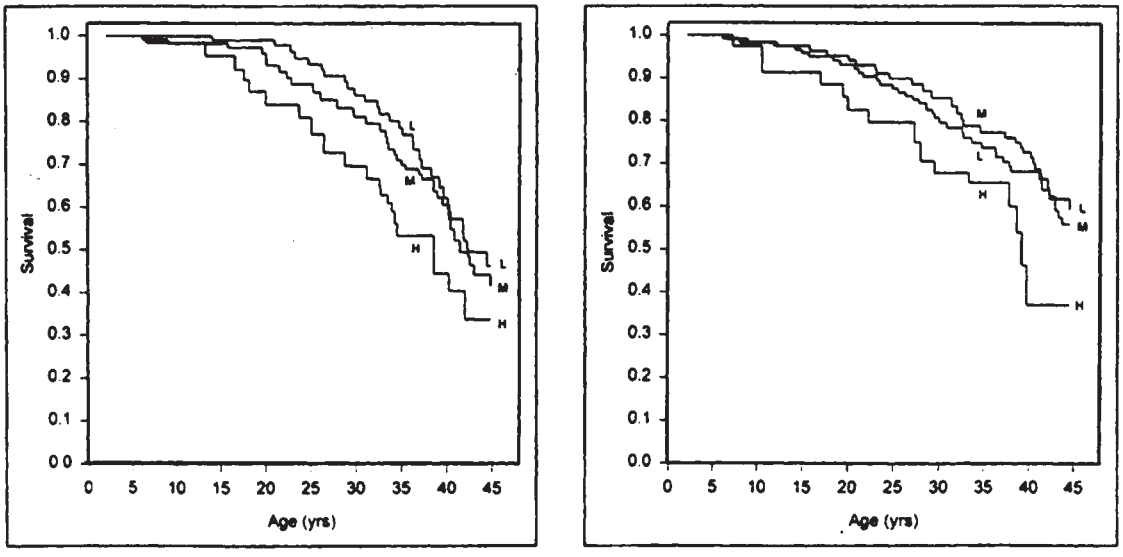

Figure 19.11. Survival of male (left panel) and female (right panel) patients with sickle cell anemia classified according to their diastolic blood pressures. High diastolic press (H) is the 90th percentile or above, medium diastolic blood pressure (M) in the 50th through 89th percentile, and low (L) diastolic pressure, below the 50th percentile. Mortality is increased for men ($p = 0.007$) and women whose diastolic blood pressure is above the 90th percentile but only the result in males is significant. Blood pressure in the 90th percentile of these sickle cell anemia patients overlaps with "normal" blood pressure.[87]

the "normal" blood pressure, is to make a careful evaluation of the patient and consider beginning antihypertensive treatment when systolic blood pressure is greater than 120/80 mm Hg or when there is evidence of target organ damage that includes heart disease, nephropathy, and peripheral vascular disease. Theoretically, diuretics, by causing hemoconcentration, might predispose to vasoocclusion. In practice, it is not clear if this occurs, and their use is not contraindicated. β-Adrenergic receptor blocking agents can also be used. Renin-dependent hypertension can result from focal area of renal ischemia. Severe blood pressure increases in sickle cell anemia should be evaluated thoroughly to exclude this and other forms of secondary hypertension.

Mortality

In the United States, median ages of death for males and females are were 42 and 48 years, respectively, when reported in 1994. These data do not reflect many children who now survive because of prophylactic penicillin and other treatment innovations.[371] In Jamaica, where over 3,000 patients with sickle cell anemia were followed, Kaplan–Meier survival curves estimated a life expectancy of 58 years for men and 66 years for women, a reduction of 14 and 10 years, respectively, compared with all Jamaicans.[394]

In a study of 232 deaths in more than 1,000 patients, the leading primary causes of death were chronic lung disease (including pulmonary hypertension) in 20%, renal disease in 14%, cerebrovascular disease in 10%, sepsis in 8%, and acute chest syndrome in 5%.[207] Left ventricular diastolic dysfunction and pulmonary hypertension are independent risk factors for mortality. Diastolic dysfunction alone is associated with a risk ratio of 3.5, whereas combined with increased TRJ velocity the risk ratio increases to 12%.[363]

In the CSCCD, acute chest syndrome was the leading specific cause of death in the patients aged 20 years or older.[371] There were 32 deaths in 1,741 acute chest syndrome events in 949 patients for an overall death rate of 1.8%.[395] Fourteen of the deaths were in patients younger than 20 years for a death rate of 1.1%, whereas the death rate in adults was 4.3%. Patients with sickle cell anemia and HbSC disease had similar rates of death from acute chest syndrome (1.9% and 1.6%). Pulmonary embolism, with or without fat embolism, pneumococcal sepsis, extremity pain episode, and respiratory failure within 48 hours of admission were all common in those who died. Preliminary studies suggest that prolongation of the QTc interval is common in sickle cell disease, associated with death, and that QTc prolongation is related to elevated serum ferritin levels.[396]

For comparison, in a study of 306 autopsies of sickle cell disease patients, the most common cause of death was infection (33%–48%) associated with respiratory tract syndromes in 72.6% and gastroenteritis in 13.7%. Other causes of death included stroke (9.8%), therapy-related complications (7.0%), splenic sequestration (6.6%), pulmonary thromboembolism (4.9%), renal failure (4.1%), pulmonary hypertension (2.9%), hepatic failure (0.8%), hemolysis/red cell aplasia (0.4%), and left ventricular failure (0.4%). Consistent with clinical observations, approximately 40% of deaths were sudden and unexpected and usually associated with acute events.[120] The discrepancy among these results

is likely to result from the respective difficulties of assigning causes of death by autopsy and by clinical impressions and the very selective nature of the autopsy-based sample.

Bayesian network modeling, discussed previously, identified laboratory markers of the severity of hemolytic anemia and its associated clinical events as contributing risk factors for mortality.[44]

GENERAL MEASURES OF TREATMENT

Most general measures to preserve good health have been discussed earlier. Sickle cell disease is a chronic disorder, and attention should be paid to good nutrition, immunizations, and avoidance of extremes of temperature and activity. Work should be encouraged, but for most individuals it is best to avoid overly strenuous occupations.

Oxygen

Oxygen is considered by many to be a mainstay of treatment; however, there have been few studies of the value of oxygen in normoxic patients with sickle cell anemia. Inhaled oxygen did reduce the numbers of reversible sickled cells but not ISCs, when given to children with acute painful episodes and had no effects on the intensity and duration of pain.[397] When hypoxia or oxygen desaturation accompanies surgery, acute chest syndrome, or occurs nocturnally,[398] oxygen treatment can reverse the abnormality. There is no evidence that high concentrations of inhaled oxygen can curtail or prevent deoxyHbS polymerization. Moreover, inhaled oxygen can have adverse effects in sickle cell anemia as discussed previously. Although hyperbaric oxygen has been used for treatment of pain, ocular disease, and leg ulceration, controlled studies of its effectiveness have not been conducted.

CONCLUSIONS

Until cures of disease by stem cell transplantation or gene therapy become feasible and widely applicable, drug treatment will remain of paramount importance. Using a single agent to prevent or reverse disease pathophysiology seems an unlikely prospect. This suggests that combinations of agents that increase HbF and decrease hemolysis might be more effective than any single agent. Trials of combined treatments might include one or more HbF-inducing agents. To this could be added agents that target facets of pathophysiology other than HbS polymerization. One can imagine clinical trials that combine agents that increase NO bioavailability, reduce intercellular interactions, reduce hemolytic anemia, and are antiinflammatory, used along with one or more HbF-inducing drug. The pathophysiology of disease argues that treatment should be started as early as safely possible to avoid chronic irreversible organ damage.[34]

Current treatments for the complications of sickle cell anemia are rarely guided by the results of controlled clinical trials. Better understanding of the use of mainstay treatments, such as transfusion and opioids, coupled with the advent of new treatments have likely improved and prolonged life. Discussed elsewhere in this volume are blood transfusion (Chapter 29), hydroxyurea (Chapter 30), stem cell transplantation (Chapter 32), and various experimental therapies (Chapter 31), including gene therapy (Chapter 33).

Sickle Cell Pain: Biology, Etiology, and Treatment

Samir K. Ballas and James R. Eckman

INTRODUCTION

Definition of Acute Pain Episodes

Pain is an unpleasant sensory and emotional experience. Acute pain episodes in sickle cell disease are mildly to excruciatingly unpleasant sensory and emotional experiences that occur episodically and unpredictably in one or many parts of the body, lasting from hours to weeks for which there is no other pathological explanation. Episodes of acute pain are the most common and distressing manifestations of sickle cell disease for the affected individual and their families. Their onset is early in life and unpredictable recurrences cause life-long suffering; they are disruptive to social and psychological functioning; they result in frequent utilization of healthcare resources, and they are a predictor of reduced survival.[1–4]

Pain can occur anywhere, be localized to one or a few areas, be migratory, or be generalized. Back, chest, extremities, and joints are most often involved. Swelling and tenderness over affected areas and low-grade fever are common.[5–7] The pain episode occurs in phases[8–10] with an average length of approximately 10 days in adults.[11]

The pathophysiology of painful episodes is poorly understood despite years of investigation. Observations during acute painful events suggest they result from diffuse ischemia of bones and muscles caused by disruption of blood flow in small and large blood vessels.[12–14] The pathogenesis of the disruption of blood flow is complex and not well understood and is likely to be related to sickle cell–related vasoocclusion and vasculopathy, whose proximate cause is polymerization of deoxygenated sickle hemoglobin (HbS).[15–17] Factors that contribute to vasoocclusion include blood viscosity, entrapment of irreversibly sickled cells (ISCs), adhesion of sickle erythrocytes to vascular endothelium and other cells, changes in vascular tone from nitric oxide (NO) consumption, activation of coagulation, inflammation, and vascular remodeling.[17–22] The onset of sickle pain episodes simultaneously in many different parts of the body suggests that circulating factors such as inflammatory cytokines, free hemoglobin, and activated coagulation proteins could be of cardinal importance.

Pain is reported as intense and unremitting. One patient characterized his pain as, “like all of the bones in my body breaking at once.” Another reported, “the pain of childbirth was nowhere near as severe.” The life-long occurrence, intensity, unpredictable nature, and its duration make sickle pain unique, which causes psychological and social problems for patients.

As patients age, and if their acute pain is not appropriately treated, they can develop chronic pain syndromes that make coping more difficult. Repeated bone infarctions, spinal changes, and avascular necrosis of the hips and shoulders can cause severe unremitting pain that becomes a challenge for the patient and healthcare provider. Inadequate treatment and also overtreatment can lead to severe disability and chronic suffering.[23]

ACUTE PAIN EPISODES

Pathophysiology of Pain

Vasoocclusion, which can involve the micro- and macrovasculature, is a key pathophysiological event that explains many of the clinical manifestations of sickle cell disease and is the presumed prerequisite for the development of acute pain.[18,19,24–30] Tissue damage due to vasooccclusion initiates a series of complex biochemical, neurological, and electrochemical events, collectively referred to as nociception, that culminate in the perception of acute pain. Acute pain can become chronic.[31,32] Vasoocclusion is also responsible for creating a state of chronic vascular inflammation.[33,34] Psychological, social, cultural, and spiritual factors often interact with vasoocclusion to produce the unique nature of sickle cell pain.

Cellular and Molecular Mechanisms of Pain

Nociception involves four major pathophysiological processes that seem to occur in tandem to explain the pain experience (Table 20.1, Fig. 20.1). They are transduction, transmission, modulation, and perception (Fig. 20.2).[31,32,35–38]

Transduction

Transduction is the process through which noxious inflammatory mediators (collectively referred to as inflammatory soup) activate nociceptors (naked nerve endings) by converting chemical, mechanical, or thermal energy to an electrochemical impulse in the primary afferent nerve fibers. The “soup” contains prostaglandins, histamine, bradykinin, H^+, K^+, cytokines, serotonin, substance P, calcitonin gene–related peptide (CGRP), leukotrienes, and

Table 20.1. Pathophysiology of sickle cell pain

- Vasoocclusion

      - Transduction
        - Transmission
          - Modulation
            - Perception

These pathophysiological events seem to occur in tandem.

more (Fig. 20.3).[39] These inflammatory mediators sensitize or activate nociceptors in the primary afferent nerve fibers. The relative abundance of these mediators might explain some clinical findings. Interleukin-1 is an endogenous pyrogen and also activates the cyclooxygenase gene, which leads to synthesis of prostaglandins E_2 and I_2. Bradykinin, potassium, and hydrogen ions, and serotonin activate nociceptive afferent nerve fibers and evoke a pain response.[40,41] Prostaglandins, leukotrienes, nerve growth factor, and bradykinin also sensitize peripheral nerve endings and facilitate the transmission of painful stimuli that reach the cerebral cortex via the spinal cord and the thalamus. Moreover, activated nociceptors release stored substance P in peripheral nerves and in the spinal cord, which facilitates the transmission of painful stimuli. Bradykinin and substance P also cause vasodilation with extravasation of fluids that can lead to local swelling and tenderness.[41] Prostaglandins increase the effective renal blood flow and effective renal plasma flow in children and young adults (Chapter 19).[42]

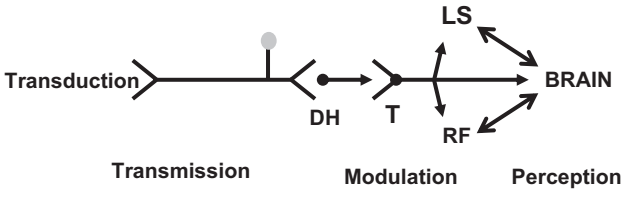

Figure 20.1. Molecular mechanisms of pain. DH, dorsal horn; T, thalamus; LS, limbic system; RF, reticular formation.

The conversion of chemical, mechanical, or thermal energy into electrochemical impulses occurs by depolarization of the neuronal membrane (Fig. 20.4). Depolarization occurs by simple diffusion of Na^+ and K^+ into and out of the axon fiber, thus decreasing the normal action potential or the threshold for electrical excitability to propagate the painful stimulus.[43] Many drugs such as anesthetics, anticonvulsants, opioids, and benzodiazepines exert their effect by causing hyperpolarization of the cell membrane. Hyperpolarization can be achieved by decreasing

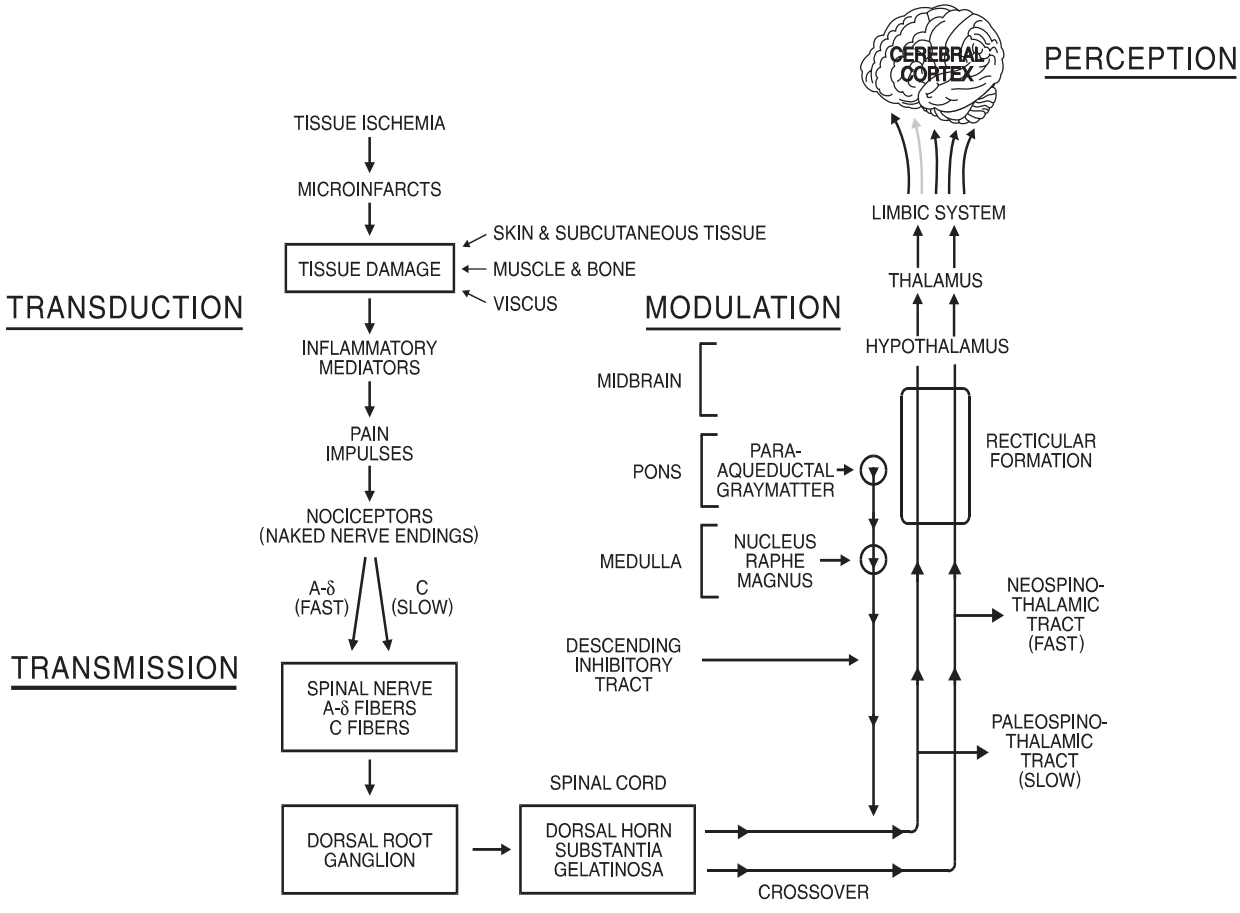

Figure 20.2. Anatomical pathways of pain in sickle cell disease. (Modified from ref. 39 with permission.) (See color plate 20.2.)

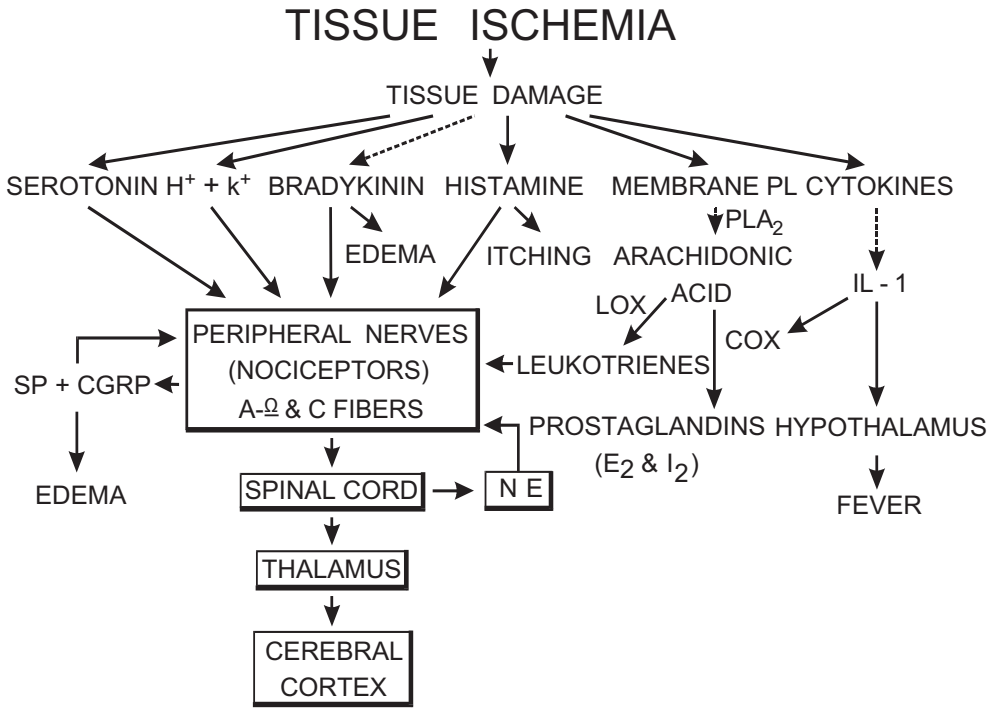

Figure 20.3. Pain pathways. Tissue damage results in the release of numerous inflammatory mediators that initiate the production of noxious stimuli. These activate peripheral nerves that in turn transmit painful stimuli to the central nervous system. (Modified from ref. 40 with permission.)

the entry of Na^+ into the cell (anesthetics and anticonvulsants), enhancing the exit of K^+ from cells (opioids), enhancing the entry of Cl^- into cells (benzodiazepines), or by other mechanisms.[40] Sudden discontinuation of medications that cause hyperpolarization might result in rebound depolarization, increased pain intensity, seizures, or status epilepticus.

Transmission

Transmission is a process by which electrical impulses carrying coded information about noxious stimuli are relayed to and through the central nervous system to brain regions where pain sensation is perceived. The neural pathways established in transmission include primary afferent nociceptor nerves, the dorsal root ganglion, dorsal horn cells of the spinal cord, spinothalamic tracts, the thalamus, and the thalamocortical projections to the somatosensory cortex. These sites also have connections with other areas of the nervous system including but not limited to the sympathetic system, microglia, the limbic system, the hypothalamus, and reticular formation (Figs. 20.1 and 20.2).[44]

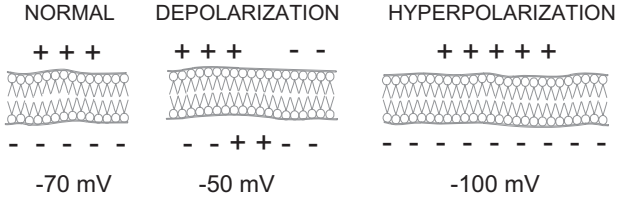

Figure 20.4. Action potential across axonal membrane during depolarization and hyperpolarization compared with normal.

Primary afferent nociceptors (PANS) are involved in both transduction and transmission. Several somatic PANS are located in skin, subcutaneous tissue, muscles, and joints. These subtypes are defined by their microscopic appearance, conduction, velocity, and pattern of response to chemical, thermal, and mechanical stimuli. Visceral PANS are found in the gastrointestinal tract, cardiopulmonary system, and genitourinary tract; they are activated by irritation, torsion, traction, and distention, particularly in conjunction with inflammation. Impulses generated by visceral nociceptors are conducted via splanchnic nerve fibers.

Impulses generated by activation of nociceptors are conducted by specific fibers within peripheral nerves. Table 20.2 summarizes the characteristics of these nerve fibers, which are classified into types A, B, and C according to size and conduction velocity of noxious stimuli.[31,43] The Aδ and C fibers are most important in transmitting the painful stimuli of acute sickle cell pain. Aδ fibers are thin myelinated fibers, approximately 50% of which respond to noxious mechanical, thermal, or chemical stimuli. They elicit sharp, localized pain. In contrast, C fibers, conducting at less than 2 m/s, are unmyelinated, respond to mechanical, thermal, and chemical stimuli, and elicit dull, diffuse pain sensations.

Central pain mechanisms involve the dorsal horn of the spinal cord, ascending spinothalamic tracts, and the cerebral cortex. The dorsal horn region of the spinal cord receives pain stimuli from the Aδ and C fibers of the spinal

Table 20.2. Characteristics of primary afferent nociceptors

Type	Stimulus	Conduction velocity (m/s)	Diameter (μm)	Sensation
Aβ	Mechanical, motor, pressure, proprioception	30–70	5–15	Sharp pain, allodynia
Aδ	Mechanical, thermal, nociception	5–30	1.4	Sharp, localized pain
C	Mechanical, thermal, chemical	0.2–1.5	0.5–1.5	Dull, diffuse pain

From ref. 44 with permission.

and cranial nerves via the dorsal root ganglion (Fig. 20.2). Afferent fibers that enter the spinal cord laterally in the dorsal root bifurcate, ascend, and descend in the Lissauer tract, and synapse in the dorsal horn with a complex structure consisting of six laminae, with lamina I the most dorsal. Each lamina corresponds to some of the horn's anatomical and functional characteristics. Cells in laminae I, II, and V respond preferentially to noxious stimuli. Laminae II and III constitute the substantia gelatinosa, where nociceptive and nonnociceptive input into the spinal cord are integrated.[45,46]

Primary afferent nociceptors form synaptic connections with neurons in laminae I, II, and V in the dorsal horn. Some of these dorsal horn neurons cross over to form the contralateral spinothalamic tract that sends connections to the brainstem, hypothalamus, and thalamus. Some thalamic relay neurons connect to limbic forebrain structures associated with the emotional aspect of pain (Fig. 20.2). In addition to the spinothalamic tract, other afferent systems such as the spinoreticular and spinomesencephalic tracts provide ascending pathways for noxious stimuli.

Important events occur along the route of transmission of the painful stimulus from the afferent nerve fibers to the somatosensory cortex. These events affect the final outcome of the pain experience due to tissue damage. Some of these events are[44]

- At the level of the dorsal horn, painful stimuli may be enhanced or suppressed by several receptors. Most important among these is the N-methyl-D-aspartate (NMDA) receptors that facilitate the transmission of painful stimuli once activated.
- Excitatory amino acids are the major neurotransmitters and their receptors are located in the presynaptic terminals of primary afferents, on dorsal root ganglion cells, and at postsynaptic sites in the dorsal horn. Table 20.3 lists the major endogenous neurotransmitters and their effect on pain transmission. The most important and best-studied excitatory amino acid is glutamate, which facilitates the transmission of the painful stimulus.

Table 20.3. Major endogenous neurotransmitters and their effect on pain transmission

Neurotransmitter	Effect of pain transmission
Substance P	Excitation
L-Glutamate	Excitation
Somatostatin	Excitation
Norepinephrine	Inhibition (central) Excitation (peripheral?)
Serotonin	Inhibition (central)
Opioid peptides	
Enkephalin	Inhibition
β-Endorphin	Inhibition
Dynorphin	Inhibition

From ref. 44 with permission.

- The primary afferents are unique neurons in that their cell bodies are located in the dorsal root ganglion. The majority of primary root afferent axons project from the dorsal root ganglion to the spinal cord mostly through the dorsal root. Substance P and CGRP, which are synthesized in the dorsal root ganglion, are thus transmitted either to the spinal cord or antidromically to the periphery at the site of injury. This antidromic transmission mediates neuroinflammation characterized by pain, redness, and swelling due to the presence of substance P and CGRP. A patient with sickle cell disease who develops sudden onset of pain and swelling of a joint most likely has nociceptive inflammation due to tissue damage and edema due mostly to bradykinin. Sudden onset of pain, followed by swelling 1 or 2 days later, represents neuroinflammation where the swelling and redness is most likely due to the antidromic accumulation of substance P and CGRP. Careful history can differentiate the two types that could affect management (Table 20.4). Definite differentiation, however, requires the measurement of the mediators in tissue fluids at the affected sites.
- Activated by the primary nerve afferents, the dorsal root ganglion forms fibers that in turn activate adjacent mechanoreceptor neurons located in the intermediolateral column of the spinal cord. These activated neurons stimulate their respective sympathetic ganglia to release norepinephrine that is transmitted antidromically to the periphery via postganglionic fibers. Norepinephrine, in the setting of tissue injury, causes more spastic tissue

Table 20.4. Types of inflammation associated with acute pain

- Nociceptive inflammation
  - Release of peripheral proinflammatory metabolites
  - Acute onset of pain and swelling
- Neuroinflammation
  - Antidromic release of cytokines, substance P, and calcitonin gene–related peptide (CGRP)
  - Delayed onset of swelling and redness
  - Neuropathic pain

ischemia thus creating a vicious circle of pain (Fig. 20.3). This is the coupling of the somatosensory system (tissue damage) and the sympathetic system (neuroinflammatory response) that makes sickle cell pain unique.

- Repetitive transmission of the painful stimuli activates the dorsal root ganglion that in turn activates the astrocytes and the microglia in the spinal cord. Once activated, microglia and astrocytes upregulate the immune system to secrete proinflammatory cytokines such as tumor necrosis factor–α, interleukin-6, NO, excitatory amino acids, prostaglandins, and adenosine triphosphate that influence the induction and maintenance of pain, especially its neuropathic component. It is this novel immune-mediated pathway that seems responsible for opioid-induced hyperalgesia (see later).
- The hippocampus is the most important organelle of the limbic system.[47] As the site of memory, the memory of a previous pain experience might affect the characteristics of subsequent painful events. A relationship between memory and pain is suggested by the observation that patients with chronic pain who developed sudden onset of amnesia had pain relief without medication.[48]

Modulation

Modulation is the process by which transmission of nociceptive stimuli are modified. The mechanisms involved can enhance or inhibit their transmission (Table 20.3).[44] Pain modulation occurs at the level of the dorsal horn of the spinal cord. Proposed neural mechanisms include segmental sensory inputs and the descending inhibitory tract.

The supraspinal descending neural systems have considerable modulating influence on dorsal horn pain transmission neurons.[49,50] One such pathway begins in the periaqueductal gray matter (Fig. 20.2) of the midbrain and descends to the nucleus raphe magnus. From here, long fibers descend via the dorsolateral funiculus to terminate in laminae I, II, and V of the dorsal horn, where they modulate afferent nociceptive impulses.[39] Both electrical stimulation and opiate microinjection of the periaqueductal gray matter result in analgesia; both these forms of analgesia are abolished by naloxone. Neurotransmitters of the inhibitory descending pathway include norepinephrine and serotonin.

Perception

Perception is the final outcome of the interactions of transduction, transmission, and modulation with the unique environment, genetic makeup, and the psychosocial status of the individual to perceive mild, moderate, or severe pain.

EPIDEMIOLOGY OF PAIN IN SICKLE CELL DISEASE

Acute Pain Episodes

Acute pain punctuates the clinical course of most patients with sickle cell disease. These episodes include, among others, acute painful episodes, dactylitis, acute splenic sequestration, splenic infarcts or subcapsular hemorrhage, avascular necrosis of joints, bone infarcts, acute chest syndrome, priapism, hepatic crises, and leg ulcers (Chapter 19).[24,25,44] The acute sickle cell painful episode, however, is the hallmark of sickle cell disease, the number one cause of treatment in the Emergency Department (ED) and of hospitalization.[51]

The frequency of acute pain episodes varies within and among individuals from rare occurrences during a lifetime to many times a month.[7] Approximately 30% of patients have rare or no pain episodes, 50% have occasional episodes, and 20% have weekly or monthly episodes requiring medical attention.[52] The frequency of pain episodes increases late in the second decade of life and decreases in frequency after the fourth decade, for reasons that are not understood.[1,7] More than three episodes a year is associated with a reduced life expectancy.[1] A small number of patients account for the majority of patients requiring healthcare for acute pain episodes.[1] Among the predisposing factors, there are at least three elements that seem to predict the frequency and severity of the acute sickle cell painful episode. They include genetic, cellular, and environmental factors.

Genetic factors include fetal hemoglobin (HbF) level, the coinheritance of α or β thalassemia, the coinheritance of other hemoglobin variants such as HbC, the nature of the β-like globin gene cluster haplotype, and sex. Unknown genetic factors are also likely to be important. As a rule, the higher the level of HbF, the milder is the disease and the less frequent are the painful episodes.[30,53,54] The coinheritance of β^+ thalassemia, HbC, and hyperhemolysis decreases the frequency of episodes. The Senegalese β-gene haplotype seems to be associated with fewer episodes than the Benin or the CAR haplotypes, most likely because of the higher HbF level in these patients (Chapter 27).[55] Females are admitted less frequently to the hospital than males, but they have longer hospital stays.[51,56]

Cellular factors associated with decreased erythrocyte deformability and increased numbers of dense cells in the steady state have a salutary effect, most likely because these are associated with more severe anemia and, hence, relatively decreased whole blood viscosity.[57,58] Conversely, patients with sickle cell anemia and relatively high hemoglobin levels are more likely to experience more frequent episodes than those patients with lower hemoglobin levels.[59,59a]

Nocturnal hypoxia, sleep apnea, and nutritional factors such as vitamin A deficiency are environmental factors amenable to preventative therapy.[60,61]

Patients often relate onset of pain to emotional stress, changes in weather, exposure to cold, dehydration, infection, fatigue, and overexertion. Major reported factors that seem to precipitate vasoocclusive events include dehydration; physical, traumatic, physiological, psychosocial, or emotional stress; infection; acidosis; sleep apnea; climate; and pregnancy.[23,44] Nevertheless, most painful episodes

are not preceded by an obvious precipitating factor. Daily mood and stress predict painful events, utilization of healthcare facilities, and work activity in adults.[62]

Anecdotally, many patients report that sudden changes in temperature seem to precipitate acute painful episodes. Several studies have found an increased incidence of pain episodes during cold and rainy weather.[63–65] Others have disputed this association, although these studies were underpowered because of sample size.[66–69] The effect of high wind and low humidity is likely to be related to skin cooling. More recent studies suggest that windy dry weather and increased air pollution might precipitate pain episodes.[70,71,71a] Patients' suggestion that swimming or exposure to cold water is a precipitant was directly supported in one study.[72]

Frequent or Chronic Pain

Studies using pain diaries in children, adolescents, and adults show that much of the pain experience in sickle cell disease does not come to the attention of the health professionals as acute pain episodes because it is managed successfully at home.[3,73–78] A recent study in 232 adults characterized pain over 6 months. Pain was reported on 54.5% of analyzed patient days; pain without healthcare utilization was present on 12.7% of days; pain resulting in healthcare utilization occurred on only 3.5% of analyzed days.[78] Only 14.2% of patients reported pain on less than 5% of days and 29.3% reported pain on more than 95% of days.[78] This suggests that the majority of patients have frequent pain and that previous studies based on ED visits and hospitalizations have greatly underestimated the frequency and severity of pain in adults with sickle cell disease. These findings have importance in defining the epidemiology of pain in sickle cell disease, managing pain, and in designing outcome studies in which impact on pain frequency and severity is important.

Phases of the Acute Painful Episode

The concept that the painful episode evolves in phases was introduced by Ballas and Smith[9] and Akinola et al.[79] who, in prospective longitudinal studies of adults, independently described the presence of two phases of the uncomplicated painful episode. Akinola et al. studied 20 patients over 16 months, and Ballas and Smith studied 117 painful events affecting 36 patients with sickle cell anemia over 6 years. Both studies indicated the presence of two phases. The initial phase was associated with increasing pain, decreased red cell deformability, increases in the number of dense cells, red cell distribution width ([RDW], see Chapter 28), hemoglobin distribution width (HDW), reticulocyte count, leukocyte count, and a decrease in the number of platelets. The second phase was characterized by established pain of maximum severity and gradual reversal of the abnormalities of the first phase. Later, Ballas[80] revised the description of the painful episode and redefined its evolution into four

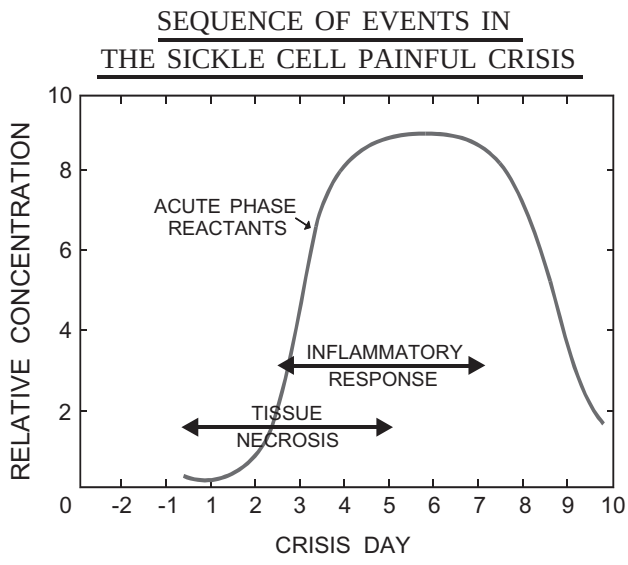

Figure 20.5. In situ sickling initiates a vicious circle of ischemic tissue damage and subsequent inflammatory response.

phases by including observations by several other investigators. The characteristics of these phases are described and illustrated in Figure 20.5 and are termed, prodromal, initial, established, and resolving. Subsequent studies in children found that the painful episodes also evolved in phases, although the phases were named differently.[10,81]

The evolution of the uncomplicated painful episode allows the observer to determine the presence of objective signs. This requires careful baseline observations when the individual is well and serial laboratory studies during the episode. The presence of phases permits the provider to monitor the progress of the event and manage it rationally, thus avoiding the conflicts that often arise between patients and providers about the authenticity of pain. Several parameters change at variable points in the progression of a painful episode.

Outcomes of the Painful Episode

Objective Signs

Severe painful events are usually associated with fever up to 101°F (38.3°C) and sometimes more. Fever develops after the onset of pain and gradually declines as the pain severity decreases.[5,25,57] Up to 21% of the painful episodes that required hospitalization were accompanied by fever of at least 100°F (37.8°C) in the absence of infection whereas another nearly 15% of the events were associated with swelling, tenderness, or vomiting.[57] Passage of dark urine is common and could reflect increased urinary porphyrin excretion.[82] Painful episodes can also be associated with joint effusion.[25,83,84] Aspirates are usually sterile and are thought to result from nociceptive or neuroinflammation, as described previously. Joint effusions can be mild and unilateral or severe and migratory.[85,86] These signs of the

painful episode reflect the accumulation of inflammatory mediators such as bradykinin and substance P that are known to cause local pain, vasodilation, extravasations of fluids, and edema.[87] Other clinical signs include tenderness or pressure over affected sites, usually over bone.[88–90] Acute urinary retention and muscle swelling and tenderness due to myonecrosis can also occur.[89–91]

Erythrocyte Changes

Red blood cell changes during the acute sickle cell painful episode have centered on hemoglobin levels, the percentages of ISCs and dense cells, RDW, HDW, and red cell deformability. Erythrocyte changes are biphasic. Early in the event the number of dense cells, RDW, and HDW increase, whereas red cell deformability and hemoglobin concentration level decrease. Three to 5 days into the episode, there is reversal in these parameters to levels higher than those in the steady state. Serial examination of the peripheral smear also reflects these changes. Early in the episode there is abundance of ISCs that disappear almost completely when the episode resolves.

Hyperhemolysis

The decrease in hemoglobin level with concomitant increase in reticulocyte count seems to be most probably due to transient hyperhemolysis that occurs in some patients during uncomplicated painful episode. This has been confirmed in selected patients by finding decreased red cell survival during the evolution of the painful episode.[92]

Changes in Leukocytes

The white blood cell count increases during painful episodes to levels higher than those of the steady state.[93] This occurs in the absence of overt infection and might be secondary to the inflammatory response to ischemic tissue damage. If an infectious process complicates the painful episode, the leukocyte count will increase further and be associated with an increase in the percentage of band cells. One study reported no significant change in leukocyte count from steady state to painful episode, but a decrease from days 1–3 to 6–9 of hospitalization.[94] Others found that the white blood cell count was elevated on day 1 of the episode, reached a peak on days 3–5, and then decreased toward steady state values after the day 6.[79]

Changes in Platelets

Patients with sickle cell anemia usually have increased platelet counts in the steady state, with a mean value of $320 \times 10^3/\mu L$.[95–97] Some studies reported that platelet counts did not change during painful episodes irrespective of the presence or absence of infection.[94,95,98] The lifespan of autologous platelets in adult patients is one-third of normal. Platelet counts decrease during an acute pain episode,

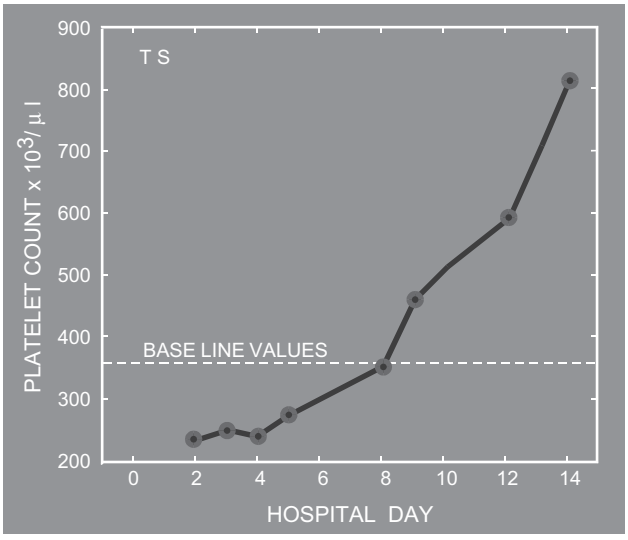

Figure 20.6. Typical changes in the platelet count during an acute sickle cell painful episode.

rebound to levels above those of the steady state during the second week following the onset of pain, and platelet aggregation, normal during the acute episode, increases during the period of rebound thrombocytosis (Fig. 20.6).[96,99–101]

Blunted Pain Relief

In some patients, a blunted response to analgesic therapy with failure to achieve adequate pain relief occurs after the fourth–sixth hospital day.[51,102,103] Although these patients had significant decrease in intensity of pain from the first day of hospitalization to the fourth–sixth day, they continued to have severe pain with an intensity score of more than 6/10 at discharge (Fig. 20.7). These patients were the most likely to be readmitted within a few days to 1 week after discharge. The reasons for this blunting in pain relief are unknown. Possible causes include inadequate pain management, increase in the level of acute phase reactants that bind to opioids and make them unavailable for pain relief, the development of tolerance to opioids, hyperalgesia, or changes at the opioid receptor sites.

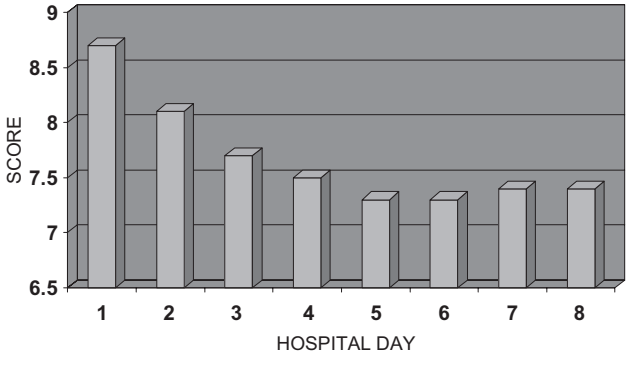

Figure 20.7. Pain intensity scores during hospitalization for acute painful episodes in 1998–2002. (Adopted from ref. 51 with permission.)

Hypercoagulability

As the acute episode resolves, markers of hypercoagulability can be seen. These include, increased serum fibrinogen, increased orosomucoid, thrombocytosis, increased sedimentation rate, and increased plasma viscosity.[80] Together these suggest a hypercoagulable state that could promote further vasoocclusion.[104]

Relapsing Pain Episodes and Hospital Readmission

Approximately 16% of patients with sickle cell disease are readmitted to the hospital with a painful episode within 1 week and approximately 50% within 1 month of discharge.[9,51] Other studies reported an average time between admissions of 10.7 days, with 50% readmissions within 8 days, and 77% within 21 days after discharge.[105]

Possible reasons for rapid hospital readmission include premature discharge, opioid withdrawal, a new acute painful episode, and maladaptive behavior. Withdrawal syndrome can precipitate a new acute painful episode and might be iatrogenic in nature. Providers who are unfamiliar with the patients or the disease often feel uncomfortable writing prescriptions for outpatient opioids. Consequently, patients might go home with no prescription or with one for insufficient medication. The dose taken at home would then be much smaller than the dose taken in the hospital. This sudden decrease in opioid dose precipitates withdrawal syndrome in some patients. Another reason for readmission is the occurrence of a genuinely new acute painful episode that could be due to the hypercoagulable state generated by a previous resolving episode or a change in the distribution of circulating sickle erythrocytes. Patient outcomes after hospital discharge can be improved if their postdischarge care is with physicians who treated them in the hospital rather than with other physicians.[106] Adverse events occurred in approximately 20% of patients in the peridischarge period with adverse drug events and medical errors occurring most frequently during the first 2 weeks of discharge.[107] Although not specific to patients with sickle cell disease, the postdischarge period is one of vulnerability that could conceivably contribute to early readmission.

Maladaptive behavior could potentially be a cause of readmission. This seems to be the exception rather than the rule and seems to apply to approximately 3% of readmitted patients.[51] Morbidity and mortality rates seem to be higher in patients with frequent painful episodes that require hospital admission and readmission.

These data suggest that special attention must be paid to the resolving phase of the painful episode. Providers using aggressive pain therapy during hospitalization should exclude the possibility of tolerance, consider opioid rotation, and design discharge instructions that avoid causing withdrawal. The establishment of a clinic to evaluate patients within a few days after discharge to ensure compliance with discharge instructions is recommended.

PHARMACOLOGICAL MANAGEMENT OF SICKLE CELL PAIN

Complementary and Alternative Medications

Rational and effective management of sickle cell pain relies on thorough assessment and individualization of therapy coupled with the use of nonpharmacological and pharmacological approaches.

Pharmacological management of sickle cell pain entails the use of three major classes of compounds: nonopioids, opioids, and adjuvants (Tables 20.5–20.7). Some patients use complementary and alternative supplements on their own, based on hearsay, advertisements, or the media. Such medications are available over the counter or at health food outlets and include antioxidants, vitamins, herbal products, magnesium, garlic extract, glucosamine, and others. Patients should be advised to use these products only after discussion and approval by their care providers to avoid possible deleterious interactions with approved opioids and nonopioids.

Niprisan, a phytomedicine, in a phase 2B study of 82 patients with sickle cell disease, was effective in reducing episodes of painful episodes associated with severe pain over a 6-month period, without serious side effects.[108] It did not affect the risk of severe complications or the level of anemia. A phase 3 multicenter trial of this agent has not been reported. In a study of 19 hospitalized children with sickle cell disease given intravenous magnesium sulfate, the duration of hospital stay was reduced compared with historical controls.[109] It was not clear if the response to magnesium sulfate was dose dependent, and a randomized, controlled study is needed to confirm these promising findings.

Clinical Pharmacology of Analgesics: General Features

A major difference between opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) is that the latter have a ceiling effect. This is a dose above which there is no additive analgesic effect. NSAIDs are associated with serious systemic side effects such as gastritis, nephropathy, and hemostatic defects.

Opioid analgesics have fewer systemic side effects than NSAIDs, but their use in sickle cell disease is associated with many misconceptions and phobias. They are the most-often used class of drug for severe sickle cell pain. Opioid agonists can be given orally, subcutaneously, intramuscularly, intravenously, transdermally, and transmucosally, and the methods of parenteral administration include continuous intravenous drip, patient-controlled analgesia (PCA) pump, or intermittent injections. Other routes of administration such as nebulization, iontophoresis, topical, epidural, or implantable intrathecal drug delivery systems are rarely, if ever, used in sickle cell disease. Meperidine, morphine, hydromorphone, and fentanyl are the major opioid analgesics used in the treatment of severe pain in the ED and the hospital. Oxycodone with codeine is most

Table 20.5. Dosing equivalents and starting doses for nonopioid analgesics*

Drug	Usual dose for adults and children >50 kg	Usual dose for children and adults <50 kg body weight	Comments
Acetaminophen	650–1000 mg q 4 h	10–15 mg/kg q 4 h 15–20 mg/kg q 4 h rectal	Liquid available, not antiinflammatory, use with caution in liver disease
NSAIDs			Use with caution with renal or heart failure
Aspirin	650–1000 mg q 4 h	10–15 mg/kg q 4 h 15–20 mg/kg q 4 h rectal	Not safe in febrile children, inhibits platelet function
Ibuprofen	400–600 mg q 6–8 h	10 mg/kg q 6–8 h	
Naproxen	500 mg initial then 250 mg q 6–8 h	10–20 mg/kg/d in divided doses q 8–12 h	Available as a liquid
Naproxen sodium	550 mg initial then 275 mg q 6–8 h	10–20 mg/kg/d in divided doses q 8–12 h	
Choline magnesium trisalicylate	1000–1500 mg q 12 h		Minimal platelet inhibition, liquid available
Diclofenac potassium	50 mg q 8 h		Maximum 200 mg first day then 150 mg/d
Diflunisal	1000 mg initial then 500 mg q 12 h		
Etodolac	200–400 mg q 6–8 h		
Flurbiprofen	50–100 mg q 8–12 h		Maximum 300 mg/d
Fenoprofen	200 mg q 4–6 h		
Ketoprofen	25–50 mg q 6–8 h		Maximum 75 mg/d
Ketorolac tromethamine	10 mg PO q 6–8 h		Not to exceed 5 d
Magnesium salsalate	650 mg q 4 h		
Meclofenamate sodium	50 mg q 4–6 h		Maximum 400 mg/d
Mefenamic acid	250 mg q 6 h		Maximum 7 d
Piroxicam	20 mg q 24 h		
Salsalate	500 mg q 6 h		
Sulindac	200 mg q 12 h		
Ketorolac tromethamine parenteral	30–60 mg initial then 15–30 mg q 6–8 h	0.5 mg/kg IM/IV q 6 h up to 72 h; 1.0 mg/kg IM/IV q 6 h 24–48 h	Maximum daily 120 mg Not to exceed 5 d

often used to treat painful episodes of mild or moderate severity at home.[110] Opioids such as extended-release (ER) oxycodone and ER morphine, or long-acting opioids such as methadone and levorphanol are useful in the management of chronic pain at home in combination with short-acting opioids for breakthrough pain.

The concurrent administration of adjuvant medications with the primary opioid analgesics can enhance their analgesic potential and obviate or ameliorate opioid side effects. Anticonvulsants can be useful especially if the pain has a neuropathic component. Adjuvant drugs commonly used in the management of sickle cell pain are listed in Table 20.7. These agents have their own set of side effects and hence, their use should be carefully monitored. Some of the side effects overlap with those of sickle cell disease. For example, some antidepressants like trazodone are associated with priapism and might best be avoided.

The choice of an opioid, its dose, and route of administration should be individualized based on history and experience. No single opioid constitutes a panacea for all patients. Any opioid might be the treatment of choice in a patient. A general trend is to avoid the use of meperidine, to administer opioids orally for mild pain and intravenously or subcutaneously for severe pain, and avoid the intramuscular route if possible.

The use of meperidine is controversial.[111–113] Meperidine is associated with seizures in 1%–12% of patients with sickle cell disease.[114] A retrospective study of hospitalized children reported a very low rate of seizures in sickle cell disease patients receiving meperidine, which was comparable with that observed in patients receiving morphine.[115] In a subset of adult patients with sickle cell disease, meperidine is the only opioid that gives relief without serious side effects.

Table 20.6. Dosing equivalents and starting doses for opioid analgesics in opioid naïve patients*

		Approximate equianalgesic dose		Appropriate starting dose adults >50 kg body weight		Appropriate starting dose children & adults <50 kg body weight†		
Opioid agonist	Active agent	Oral	Parenteral	Oral	Parenteral	Oral	Parenteral	Comments

The use of implantable intravenous access devices in patients with sickle cell disease seems to be associated with a higher rate of infection than in other diseases.[116] Decisions to rotate opioids should follow equianalgesic dosing equivalents, taking into consideration the comparative absorption, availability, and half-life of the opioid. Thus, the dose of oral methadone to replace the dose of ER morphine will be one-sixth the dose of morphine because methadone absorption is twice that of morphine and its half-life is three times longer than that of morphine. Moreover, the dose of methadone will take five half-lives to stabilize orally. Many recommend starting the new opioid analgesic at half the equivalent dose and then titrating to control the pain.[117] If the comparative absorption and half-lives are not known, it is advisable to do gradual conversion from one opioid to another.

Basic Pharmacology of Opioids: Pharmacokinetic and Pharmacodynamics

To manage sickle pain effectively with opioid analgesics, it is essential to know their pharmacokinetics and pharmacodynamics, including their side effects and complications. Pharmacokinetics refers to "what the body does to the drug," including absorption, distribution, binding to tissues, metabolism, and excretion. Pharmacodynamics, on the other hand, refers to "what the drug does to the body" in terms of the mechanism by which the drug produces therapeutic effects.[37,38,44,118,119] An important step in the pharmacokinetics of opioids is their conversion into metabolites that could be active or inactive (Table 20.6).[37,38,44,118,119]

Prodrugs are not active by themselves but have active metabolites. Codeine is a prodrug without an analgesic effect by itself, but its metabolite, morphine, is the active analgesic. The conversion into an active metabolite depends on the presence of the required enzyme and its polymorphic variants. Approximately 5%–10% of the general population lack the enzyme *CYP2D6* and hence, will not achieve pain relief by using codeine alone. Moreover, the enzyme is polymorphic, and some variants are more efficient in the conversion into active metabolite than others. The same principles apply to the conversion of hydrocodone into hydromorphone and oxycodone into oxymorphone. Morphine is unique in that it is an active drug itself, and its metabolites, morphine-6-gluconide (M6G) and morphine-3-glucuronide (M3G) are also active (Table 20.6).

Opioid agonists produce their effect by binding to μ receptors.[37,38,118–123] The L isomers of opioids exert analgesic activity. The binding affinity, or strength with which a drug binds to its receptors, varies considerably among opioids, with fentanyl, for example, having a higher binding affinity than morphine. The binding affinity of opioids seems to correlate well with their analgesic potency. Bound opioids activate their receptors and initiate a series of biochemical events, including activation of G-proteins, inhibition of adenylate cyclase activity, and extrusion of K^+ that results in hyperpolarization of cell membranes, resulting in delay or prevention of the transmission of painful stimuli. Moreover, receptors are also polymorphic and some variants are more efficient in mediating the analgesic effect of opioids than others. Thus, the response to opioids depends not only on the type of opioid used, but also on the number and activity of the opioid receptors. An opioid that has poor affinity and that binds to one or two receptors, for example, is unlikely to produce effective analgesia in certain patients even if the dose is high. On the other hand, an opioid with moderate- or high-binding affinity that binds to several efficient receptors would provide effective analgesia even if used in small doses. This provides a possible explanation for the immense variability in patients' response to opioids.

Characteristics of Selected Opioids

Morphine

Morphine[37,38,44,118] is a strong μ-opioid agonist. It is a naturally occurring alkaloid derived from the opium poppy; it is hydrophilic and thus is rapidly distributed to tissues and organs. It can be administered by any route and is available in immediate-, controlled-, and sustained-release formulations. Morphine is metabolized by conjugation with glucuronic acid by the enzyme uridine diphosphate–glucuronosyl transferase 2B7(*UGT2B7*) into M6G and M3G.[124] The former is four times more potent and has a longer half-life than its parent drug, explaining why sometimes repeated administration of morphine results in severe sedation. Moreover, functional allelic variants of *UGT2B7* might alter the conversion of morphine to M6G and M3G. The G allele of this enzyme (*UTG2B7* promoter variant -840G-A) is associated with reduced glucuronidation of morphine.[125] Both morphine and M6G are associated with toxicity in patients with renal failure. Morphine is highly histaminergic and is often associated with pruritus that can be severe. Other reported adverse effects of morphine in sickle cell disease include increased risk of acute chest syndrome,[126,127] acceleration of renal injury,[128] and retinopathy in transgenic sickle mice. Morphine accelerates sarcoma-induced bone pain, bone loss, and spontaneous fracture in a murine model of bone cancer.[129] Morphine, hydromorphone, and fentanyl seem to heal ischemic wounds in rats.[130]

Codeine

Codeine,[37,38,44,118] like morphine, is a naturally occurring alkaloid. It is a weak μ agonist. In the liver, approximately 10% of the dose is converted to morphine via *CYP2D6* that

Table 20.8. Commonly prescribed drugs with potential for QT interval prolongation

• Amitriptyline	• Sertraline
• Imipramine	• Tamoxifen
• Doxepin	• Salmeterol
• Risperidone	

is part of the cytochrome P-450 system. In addition to its absence in 10% of the population, *CYP2D6* can be duplicated in some patients. In these individuals, approximately 20% of the dose of codeine is converted to morphine with better pain relief. Codeine is available in the market as schedule II (codeine), schedule III (codeine with nonopioids like acetaminophen) and schedule V (codeine in antitussive formulations).

Methadone

Methadone,[37,38,44,118] the least expensive opioid, is a potent synthetic opioid agonist. Its formulation is a racemic mixture of L and D isomers both of which are NMDA antagonists. Only the L-isomer is a μ agonist. Methadone also mildly inhibits the reuptake of serotonin and norepinephrine and suppresses heroin and other opioid craving for 24 hours. It has a half-life of at least 36 hours, but short duration of analgesia of 4–6 hours. This difference might predispose to drug accumulation following the initiation of therapy or dose escalation.

Methadone is associated with cardiotoxicity due to prolongation of the QTc interval with arrhythmia that can be fatal. It is associated with death more than any other opioid. Other medications, such as antibiotics and antidepressants (Table 20.8), contribute to its cardiotoxic effect, and their use with methadone should be avoided or monitored carefully. Nevertheless, methadone is an excellent analgesic that is useful in treating chronic pain, provided the prescriber knows its pharmacology and has experience in its use. Careful monitoring of patients coupled with initiation of a low dose followed by gradual stepwise dose escalation or reduction decreases the risk of toxicity from its accumulation. Monitoring should include performing periodic electrocardiograms. Oral and parenteral preparations of methadone are available; subcutaneous injections cause local skin toxicity and are not recommended.

Oxycodone

Oxycodone[37,38,44,118] is a semisynthetic μ opioid derivative of morphine and has a similar profile. It is available for oral but not parenteral administration. It is metabolized in the liver into noroxycodone and oxymorphone. Like codeine, oxycodone is usually admixed with nonopioid analgesics in commercial preparation for the management of mild to moderate pain. Dose escalation is limited in the combination form because of a potential toxicity from the acetaminophen or aspirin component. It is also available as a short-acting single entity and doses can be increased to achieve pain relief. A controlled-release formulation (OxyContin) is also available but has strong abuse potential.

Hydromorphone

This semisynthetic μ agonist morphine congener is five–seven times more potent than morphine.[37,38,44,118] It is more soluble and is available in a concentrated dosage form of 10 mg/mL and has been widely used by subcutaneous infusion in PCA pumps. The bioavailability of hydromorphone by continuous subcutaneous infusion is approximately 80% of the intravenous route. An ER form of hydromorphone (Palladone) was initially approved by the Food and Drug Administration and later withdrawn from the market because of fatality associated with the use of alcohol that dissolves the formulation and releases the hydromorphone as a short-acting formulation. Nevertheless the ER formulation is available outside the United States. Hydromorphone is not contraindicated in renal failure.

Oxymorphone

Oxymorphone[37,38,44,118] is a lipophilic semisynthetic μ agonist congener of morphine. When administered parenterally it is approximately 10 times more potent than morphine. It is available in rectal formulation, which is approximately one-tenth as potent as intramuscular administration. It has a half-life of 1.2–2 hours and is less likely to produce histamine release than morphine. Its major disadvantage is its high cost. Recent oral preparations of oxymorphone include immediate-release (Opana) and extended-release (Opana ER) formulations.

Meperidine

This semisynthetic μ agonist opioid is a member of the phenylpiperidine series of μ opioid agonists.[37,38,44,111–113,118] More lipophilic than morphine, it produces euphoria, and has fast onset of action after parenteral administration. Problems with meperidine center around one of its major metabolites normeperidine. Approximately 90% of a dose of meperidine undergoes N-demethylation in the liver to produce normeperidine, which has a half-life four–five times that of meperidine (18 vs. 3.5 hours) and is twice as potent a convulsant and half as potent an analgesic as its parent compound. Accumulation of normeperidine after repetitive dosing of meperidine can result in central nervous system excitability characterized by subtle mood changes, anxiety, tremor, multifocal myoclonus, and seizures. The effects of meperidine and normeperidine on seizure induction are more pronounced in the presence of renal failure. Oral

meperidine has only 15%–25% of the analgesic effectiveness but produces just as much normeperidine. Oral meperidine should not be used for control of sickle pain, and prolonged high-dose therapy should be avoided if possible. Naloxone does not reverse meperidine-induced seizures and to the contrary might precipitate seizures by blocking the depressant action of meperidine and facilitating the manifestation of the convulsant activity of normeperidine. Unlike other opioids, meperidine is anticholinergic and hence, is associated with tachycardia and does not cause constriction of the pupils.

Fentanyl

This synthetic μ agonist congener of meperidine is a member of the phenylpiperidine series (Table 20.6).[37,38,44,118] Fentanyl is extremely lipophilic and is approximately 100 times more potent than morphine as an analgesic. It is available in parenteral (Sublimaze), transdermal (Duragesic), oral transmucosal (Actiq), and buccal (Fentora) formulations.

Characteristics of Selected Nonopioid Analgesics

Tramadol (Ultram)

Tramadol[37,38,44,118] is a synthetic centrally acting analgesic, not chemically related to opiates, which acts as a weak agonist at opioid receptors with preferential affinity for the μ receptor. Moreover, it inhibits neuronal uptake of both serotonin and norepinephrine and stimulates the release of serotonin. Thus, functionally, it has properties of an opioid and an antidepressant. It seems to be as effective as acetaminophen with 30 mg codeine with the added advantage of tricyclic antidepressant-like effect. Tramadol can be used by the oral or parenteral route and it is available in slow-release form. Only the oral form is approved for marketing in the United States. Major adverse effects include seizures, abuse potential, respiratory depression, and serotonin syndrome.

Ketorolac Tromethamine (Toradol)

Ketorolac tromethamine[37,38,44,118,131] is a member of the pyrrole acetic acid group of NSAIDs. It was introduced into the United States as a short-acting parenteral analgesic and is also available in an oral formulation. Ketorolac possesses many desirable features as an adjunctive or alternative medication to opioids. After intramuscular injection, analgesia is perceptible at approximately 10 minutes, similar to opioids and the duration of analgesia is approximately 6 hours. Similar to other NSAIDs, ketorolac is highly bound to plasma proteins and is metabolized to inactive products, which are excreted in the urine. Clearance is significantly reduced in patients aged 65 years or older and in patients with renal disease.

Ketorolac has analgesic potency similar to opioids. It should be given every 6 hours to maintain a steady-state plasma level. A loading dose of 30 or 60 mg intramuscularly or intravenously should be followed by 30 mg intramuscularly or intravenously every 6 hours for 3–5 days. In patients weighing less than 60 kg or aged 65 years or older or with reduced renal function, a loading dose of 30 mg intramuscularly should be followed by 15 mg intramuscularly every 6 hours. No dosage adjustment is indicated in patients with chronic cirrhosis. The coadministration of ketorolac with opioids exerts an additional analgesic effect and decreases the amount of opioids consumed for the treatment of acute sickle cell painful episodes.[132] Unlike opioids, ketorolac does not produce respiratory depression, reduction of gastrointestinal motility, psychomotor effects, or addiction. As with other NSAIDs, heart failure, gastrointestinal, hematological, and nephrotoxic side effects are possible.

Opioid Antagonists

Traditionally, the use of opioid antagonists has been primarily limited to counteract the depressive effects of opioid agonists. Recently, however, there have been reports showing that small doses of antagonists in combination with agonists appear to enhance the analgesic effect and prevent or delay tolerance to opioid agonists.[133] Moreover, new formulations in development include the use of naltrexone in combination with oxycodone or morphine to deter abuse; this is reminiscent of the use of disulfiram (Antabuse) with alcohol.

Adverse Effects and Complications of Opioids

Adverse effects of opioid analgesics include pruritus, hives, nausea, vomiting, constipation, and respiratory depression. All opioids can induce seizures – meperidine is the most frequent inducer – if used in high doses over a long period of time. The mechanism of seizure induction by other opioids is different from that by meperidine and seems to be related to their excitatory effects. The incidence of seizure due to morphine has been reported to be 1.2%.[134] Metabolites of morphine can accumulate to toxic levels in the presence of renal failure.

The serious complications of opioids that are often misunderstood and confused with each other are collectively referred to as aberrant behavior and include addiction, physical dependence, withdrawal, tolerance, and pseudoaddiction. Their definitions according to the American Academy of Pain Medicine, American Pain Society, and American Academy of Addiction Medicine consensus document are[135]

- Tolerance, a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug's effects over time.
- Physical dependence, a state of adaptation manifested by a drug class–specific withdrawal syndrome that can

be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. Signs and symptoms include tremor, shakiness, anxiety, depression, lacrimation, rhinorrhea, fatigue, irritability, and diarrhea.

- Addiction, a primary, chronic, neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.
- Pseudoaddiction, the seeking of additional medication, secondary to undertreatment of pain. When the pain is treated properly, all inappropriate behavior ceases.
- Aberrant drug-taking behaviors less predictive of addiction include aggressive demand for more drug, drug hoarding (e.g., obtaining drug from more than one source), unsanctioned dose escalation, unapproved use of drug.
- Aberrant drug-taking behaviors more predictive of addiction, like selling prescription drugs, forging prescriptions, stealing drugs, frequent prescription "loss," injecting oral/topical formulations, concurrent abuse of illicit drugs.

Complications of opioids are best understood by knowing their mechanisms. Theses include the histaminergic, excitatory (hyperalgesia), dopaminergic, and proserotonergic effects.

Histaminergic Effects

Histamine is a neurotransmitter in the brain and an autocoid stored in the granules of mast cells and basophils that accumulate at sites of injury or potential injury. Opioids in general and morphine in particular, release both neuronal and nonneuronal histamine. Released histamine causes vasodilation, bronchoconstriction, smooth muscle activation, pruritus, and hives. It is for this reason that antihistamines are usually given as adjuvants to opioids in treating sickle cell pain. The antihistamines most commonly used include hydroxyzine (Vistaril) and diphenhydramine (Benadryl). The former is a piperazine antihistamine and the latter is an H1 receptor antagonist.

Opioid-induced Hyperalgesia

Paradoxically, the chronic administration of opioid analgesics to treat pain can contribute to or cause pain, a condition referred to as secondary hyperalgesia.[136,137] This has been described most often with morphine administration, but could occur with other opioids such as hydromorphone and methadone. The pathophysiology of this is not well understood. In the case of morphine, it seems to be due to an excitatory pathway initiated by the M3G metabolite. Morphine has a major inhibitory effect that controls pain and a minor excitatory effect that initiates tolerance and hyperalgesia. With chronic use, the excitatory pathway is magnified and its effect becomes dominant. Moreover persistent nociceptive input into the central nervous system induces sensitization of the dorsal horn and other neuronal sites.[136,137] This central sensitization, in turn, produces pain hypersensitivity by shifting the response curves to the left, relative to the normal nonsensitized situation (Fig. 20.8).[138,139] Consequently, ambient stimuli that normally do not cause pain induce severe pain in the centrally sensitized patient. This sensitivity to ambient stimuli is referred to as allodynia. Chronic pain can alter brain function. Using functional magnetic resonance imaging during simple visual attention tasks in back pain patients and controls, chronic pain had a widespread impact on overall brain function that might underlie its cognitive and behavioral impairment.[140]

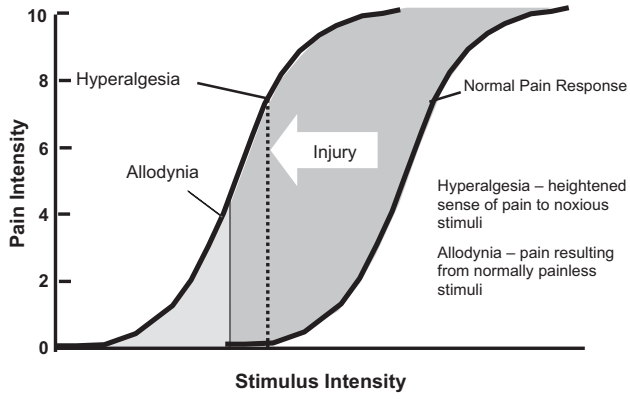

Figure 20.8. Pain hypersensitivity induced by injury. In the normal pain response, pain intensity increases as the stimulus intensity increases. Sensitization following injury causes the curve to shift to the left, resulting in hyperalgesia, in which noxious stimuli cause greater and more prolonged pain, as well as allodynia, in which pain results from normally painless stimuli. Sensitization is the manifestation of neuronal plasticity. (From ref. 139 with permission.) (See color plate 20.8.)

The molecular/cellular mechanism of hyperalgesia is poorly understood. One possible mechanism is secondary to activation of the NMDA receptor normally blocked by Mg^{++}. With persistent nociceptive input from the periphery, postsynaptic sodium channels become saturated. As a result, the Mg^{++} block from the NMDA receptor is removed allowing the entry of Ca^{++} into excitatory neurons. Ca^{++} initiates a cascade of intracellular enzymatic reactions that maintain the excitability of nociceptive neurons. Protein kinase C is activated and deactivates opioid receptors, resulting in receptor desensitization and reduced analgesia.[141–144] Another possible mechanism pertains to the activation of microglia and astrocytes to secrete proinflammatory cytokines that influence the induction and maintenance of pain.[145–147]

The pain caused by drug-induced hyperalgesia usually involves the same sites involved by the pain due to vasoocclusion, but its quality can be different. It is more neuropathic than nociceptive in nature and is usually superficial, not deep, and burning, tingling, and lancinating.

Dopaminergic Effects

All opioids have a dopaminergic effect that affects the reward/pleasure circuitry of the brain.[37,38] This circuitry includes the ventral tegmental area, nucleus accumbens, and the prefrontal cortex. The fundamental reward neurotransmitter in the brain is dopamine. This circuitry subserves natural rewards of all kinds, such as food, sex, listening to music, or watching a favorite movie. Opioids derive their abuse potential from acting on the reward/pleasure circuitry in the brain by increasing the level of dopamine, which in turn enhances the desire to achieve reward/pleasure. Depending on the environment and the genetic potential of individual patients, this dopaminergic effect of opioids can sometimes lead to addiction. Addiction is a disease by itself and should be treated as such. Recent reports suggest that topiramate is effective in the treatment of drug dependence.[148] Strategies to prevent or decrease the abuse potential of prescribed opioids include measures to uncouple the circuitry that links the dual effect of analgesia and reward.

Proserotonergic Effects

The serotonin syndrome is a clinical triad of altered mental states, autonomic dysfunction, and neuromuscular abnormalities.[149] It is not an idiopathic drug reaction but the result of excess use of central and peripheral nervous system serotonergic drugs. Table 20.9 lists some of the drugs associated with the serotonin syndrome. Signs and symptoms range from tremors and diarrhea in mild cases to delirium, neuromuscular rigidity, and hyperthermia in life-threatening cases (Fig. 20.9). The classic example of this syndrome is with the use of meperidine and monoamine oxide inhibitors.[149] Modulation of the painful stimuli includes the release of serotonin in the central nervous system to inhibit pain transmission.

Table 20.9. Drugs associated with the serotonin syndrome

- Antidepressants including selective serotonin reuptake inhibitors (SSRIs)
- Monoamine oxidase inhibitors (MAOIs)
- Anticonvulsants
- Analgesics
- Antiemetic agents
- Cough and cold remedies
- Antimigraine drugs

It is not unusual for hospitalized sickle cell disease patients to receive multiple proserotonergic medications, including an antidepressant, an opioid, an antiemetic, an anticonvulsant, and an antibiotic. The net result of such combinations can increase the level of serotonin. The signs and symptoms of the serotonin syndrome overlap with those of withdrawal, but careful history-taking can help in their differentiation.

MANAGEMENT OF ACUTE SICKLE CELL PAIN

Reviews of sickle pain management can serve as resources in guiding the treatment.[150–152] Evidenced-based reviews of the literature on management of acute pain episodes are scanty.[153]

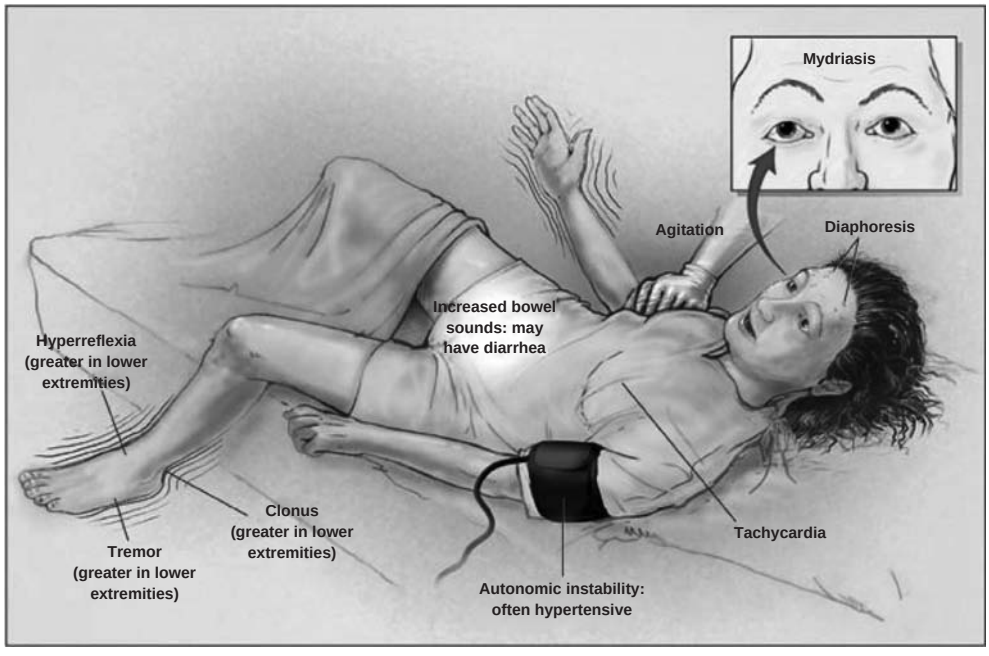

Figure 20.9. Findings in patients with moderately severe serotonin syndrome. Hyperkinetic neuromuscular findings of tremor or clonus and hyperreflexia should lead the clinician to consider the diagnosis of the serotonin syndrome. (From ref. 149 with permission.) (See color plate 20.9.)

Outpatient Pain Episode Treatment

Emerging data that suggest that individuals with sickle cell disease and their families manage the majority of pain successfully in the home.[73,78,154,155] This suggests that significant improvements in pain management and reductions in healthcare utilization could occur if individuals and their families are taught appropriate and effective methods for managing daily pain. To accomplish this, individual home management plans should be developed that include prevention, early nonpharmacological, and appropriate graded pharmacological interventions. Management plans should also incorporate guidelines for immediately seeking medical care.

Many patients have a premonition signaling the imminent onset of a pain episode. They should increase water intake, get more rest, and use behavioral and cognitive interventions to try to avoid the onset of a pain episode. Physical interventions such as taking a warm bath or shower, heating pad or blanket, and resting might prevent progression. Approaches should be individualized and patients and their families should be coached to identify successful techniques.

When these interventions fail, the World Health Organization (WHO) pain ladder approach to cancer pain is an effective approach to home management.[156] This starts with nonopioid analgesics such as acetaminophen, aspirin, and NSAIDs (Table 20.5).[157] These should be given by the clock in an appropriate dosing schedule based on the drug's half-life. Education should include discussion of the maximum doses that are safe and the ceiling effects of NSAIDs. Pain that is not controlled by these medications should be treated by the addition of oral opioid analgesics of appropriate potency.[157] Early in life, and in patients with infrequent pain, less potent oral analgesics such as codeine, hydrocodone, and tramadol (using fixed dosing based on biological half-life) should be added to the initial drugs. If the pain is not relieved, then a strong opioid such as morphine, oxycodone, hydromorphone, or methadone could be considered as a substitute for the less potent opioid. This will require that a limited supply of these analgesics be available to the individual in the home.

If the pain is not typical of the usual pain episode, fever is more that 101°F, signs of infection are present, or if the pain does not improve within 24–48 hours, immediate medical attention should be sought. It is also very important that the individuals and their caretakers understand that the pharmacological approach to the pain be graded based on the type and severity of the pain. For example, headaches and menstrual pain will often respond better to acetaminophen or NSAIDS than to opioid analgesics.

Outpatient Pain Treatment in Medical Facilities

The majority of pain episodes in the United States that require medical intervention are treated in EDs.[158] There are a limited number of day hospitals, clinics, and one 24-hour center that provide extended outpatient care for individuals with sickle pain episodes.[159–162] Guidelines have been published that provide a review of approaches to sickle cell pain management by health professionals.[23,151,163,164] Recent publications document the effectiveness of the systematic approach to outpatient management of sickle pain.[160,165,166]

Successful management of acute sickle pain is facilitated by a knowledgeable healthcare team that has a positive therapeutic relationship with the patient. Treatment should be initiated as rapidly as is possible. Significant delays occur in the initiation of care in the ED so every effort must be made to give these patients high priority for assessment and treatment.[167] Emergency treatment of sickle pain occurs in four stages; 1) assessment; 2) initiation of therapy; 3) evaluation of effectiveness; and 4) adjustment of therapy based on response. After these stages are completed, the patient is evaluated for the effectiveness of response and whether further treatment can be managed at home or in the hospital if more prolonged therapy is needed.

Initial assessment requires a history of the present episode, review of past approaches and responses to treatment, and the therapies that the individual has used prior to arriving at the hospital. It is very important to screen for precipitating complications and pain from other causes or other complications of sickle cell disease.[163] Allergies, adverse reactions to past treatment, and treatment approaches that have worked in the past should be identified. A physical evaluation should focus on exclusion of infection and other acute medical problems such as cholecystitis, acute chest syndrome, pregnancy, and so forth. Laboratory screening should include a complete blood count, reticulocyte count, platelet count, chemistry panel that includes creatinine and liver tests, and a urinalysis.[168]

The approach to initial therapy must be individualized. Acute pain intensity can be measured and recorded using a number of age-appropriate instruments that have been well validated.[151] The Attia behavioral pain scale is available for infants; the Childrens' Hospital Eastern Ontario Pain Scale for children aged 1–3 years; The Ocher, Pokerchip Tool, and Wong-Baker Faces for children; and Word Graphic Rating Scale, Numerical Pain Score-Intensity Scale, and the Visual Analog Scale for older children, adolescents, and adults.[151] Consistent use of one of these scales will allow rapid assessment and recording of pain and assessment of efficacy of treatment by frequent reassessments of the pain score by using the same instrument. The goals for therapy should also be determined based on the patient's desire for pain relief and acceptance of side effects.

The WHO analgesic ladder should also be used in acute pain management in the healthcare setting. All patients who do not have contraindications should be treated with oral or intravenous NSAIDs (Table 20.5). These should be given at analgesic doses on a fixed interval based on their half-life and not escalated because of ceiling effects. Moderate pain that has not been treated with oral opioid

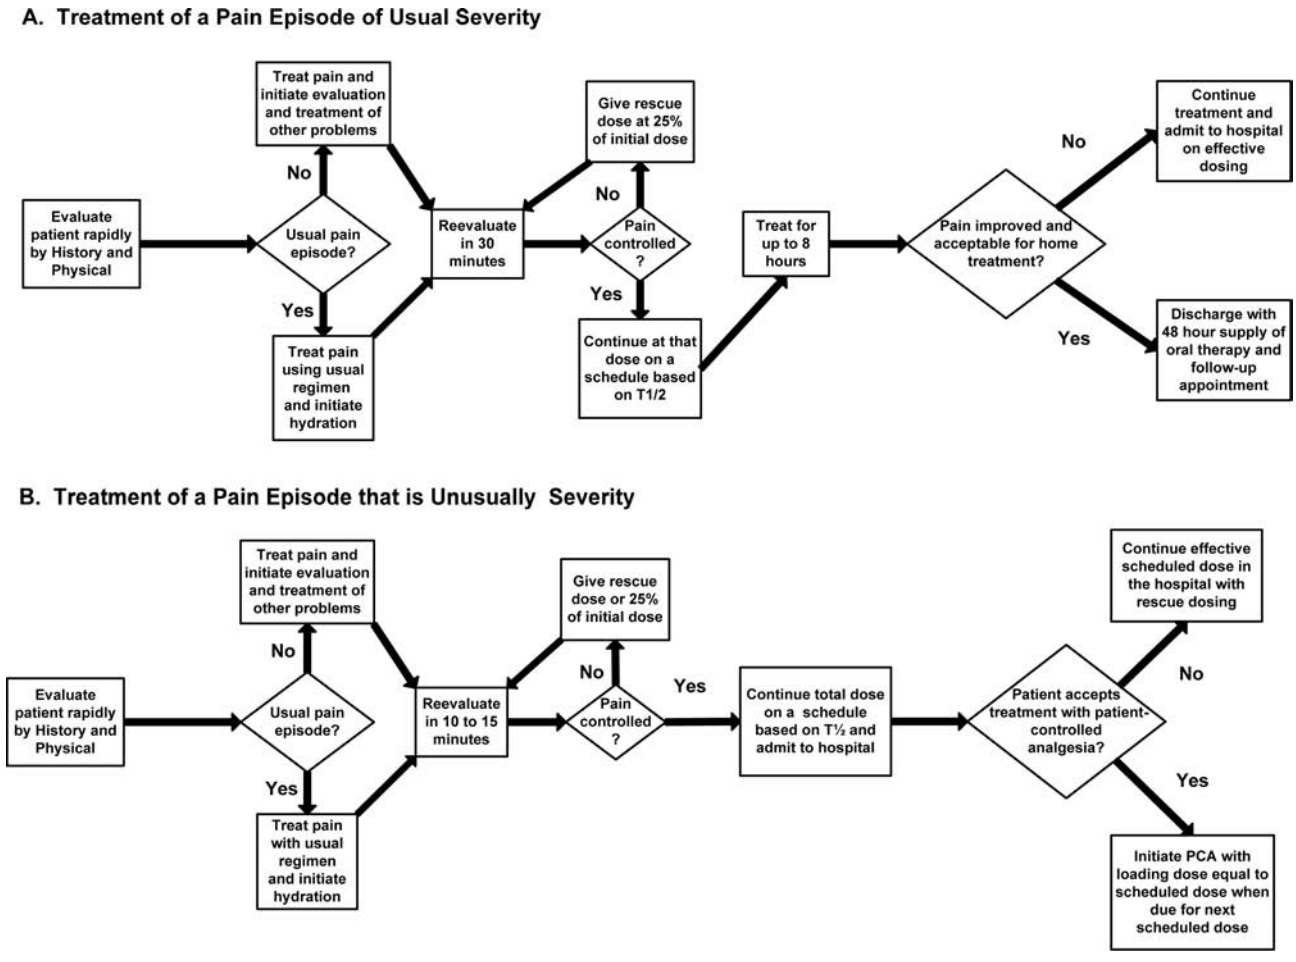

Figure 20.10. Outpatient approach to the treatment of pain in the 24 hours a day 7-day-a-week Georgia Comprehensive Sickle Cell Center at Grady. Patient's initial history-taking includes determining previous pain medication utilization and results of therapy. Patients with pain episodes and other complications such as fever, pneumonia, urinary infection, or significant changes in laboratory parameters are usually admitted without 8 hours of outpatient treatment. **(A)** Management of a patient who is known, to the Center and is presenting with a typical pain of usual intensity. **(B)** Management of a patient who is new to the Center or a known patient who presents with an unusually severe pain episode.

medications prior to presentation might respond to oral therapy.[166] More severe pain should generally be treated with intravenous, intramuscular, or subcutaneous opioid analgesics (Table 20.6). The medication should be administered using a dose based on the patient's previous response to therapy and the response reassessed in 15–30 minutes. If adequate relief is obtained, the medication can be administered using a fixed dosing interval based on the effective half-life of the medication (Fig. 20.10).

If the patient's history of opioid use is unclear or there is inadequate response to the initial dose of opioid, the drug should be administered in small doses every 15–30 minutes until an adequate response is obtained and then this amount can be given on a fixed schedule based on the effective half-life. Duration of treatment before discharge or admission to inpatient care depends on the individual's response to therapy and the ability to provide extended care in the outpatient setting. Extended care observation units allow effect treatment, and individuals may avoid hospital admission.[159–162] The decision to admit the patient to the hospital should be based on the patient's assessment of their ability to manage their pain at home and the presence of complications such as changes in baseline laboratory values, signs of infections, or other medical problems. Discharge medications should provide sufficient analgesic medications to treat the pain for 48–72 hours, and the patient should be instructed to return if pain cannot be adequately managed at home because of intensity or duration. Patients treated in EDs should be referred to their primary care provider for follow-up and provision of outpatient analgesics (Fig. 20.10). More detailed outpatient management protocols are available in monographs, on the Internet, and in books.[44,151,169]

Inpatient Pain Episode Treatment

Individuals requiring inpatient care should be treated with regimens that were effective in the outpatient setting or the treatment should be escalated if pain control was inadequate. Patients should be treated with an around-the-clock fixed-dose schedule with rescue doses of 25%–50% of the fixed dose for breakthrough pain.[23,151] Continuous

intravenous dosing and long-acting oral preparations should be used instead of fixed dosing with short-acting preparations, especially if the patient reports awakening in pain.[170,171] If frequent rescue doses are required, the dose of the continuously administered analgesic can be increased.[151] If patients report that the pain is not adequately relieved by the fixed dose, it should be increased, and if the duration of pain control is inadequate, the interval of administration should be decreased.

Acute chest syndrome often develops several days after admission for an acute painful episode (Chapter 19). It should always be expected if there are increases in leukocyte count, fall in hemoglobin concentration, cough, chest pain, or fever.

Use of PCA

PCA has been used effectively in children and adults with sickle cell pain episodes[170,172–178] even though controlled studies have not validated its effectiveness compared with other treatment approaches.[153] Two studies suggest that PCA alone or PCA plus a low-dose infusion of morphine might be superior to continuous infusion or high-dose continuous infusion with rescue dosing.[175,176] Morphine PCA provides the only published experiences, although some centers use meperidine, hydromorphone, or other opioids for PCA.

Loading doses of morphine up to 0.05–15 mg/kg can be given based on severity of pain and initial response to therapy. Demand doses of 0.018–0.04 mg/kg with a 5–15-minute lockout are the usual range for sickle cell disease patients. Continuous infusion doses, if necessary, can be given at night or around the clock. The usual dose ranges are between 0.01 and 0.04 mg/kg/hour. One-hour or 4-hour limits, if required by the PCA pump, should be calculated so that the patient can get treatment for the entire period. That is, the limits should be based on the sum of the maximum demand dose plus the continuous infusion dose. Standard orders should provide for proximity to nursing station, frequent measurement of vital signs and O_2 saturation, naloxone at the bedside, and a resuscitation bag in proximity. Other narcotics and sedatives should be stopped. Orders should require that PCA should immediately be stopped and the physician notified for over sedation, respiratory rate of less than 12 per minute, or loss of intravenous access. PCA use and pain relief should be reevaluated frequently and at least every 24 hours. Once the pain episode is improving, the infusion should be tapered and the amount of the demand dose reduced. If a basilar infusion of morphine greater than 1 mg/hour is required to prevent adequately pain recurrence, oral sustained-release morphine in a dose equivalent to the infusion can be substituted for the infusion to prevent rebound pain as the infusion is stopped. Oral analgesic medications are started and the PCA discontinued when the patient's pain can be managed with oral analgesia alone.

Adjuvant Drugs

Adjuvant therapies are also very important to maximize pain management and to treat complications of therapy (Table 20.7). Morphine and all related analgesics can cause pruritus that can be controlled with antihistamines. Nausea is also common and best managed with antiemetics. Pain and opioid administration both cause in decrease in intestinal smooth muscle motility and constipation. All patients without diarrhea should be started on stool softeners and laxatives while being treated with opioids. Although it is not appropriate to substitute sedatives for appropriate analgesic drugs, most patients admitted for pain episodes have significant anxiety and might benefit form careful administration of appropriate anxiolytics. Patients also benefit from nonpharmacological interventions such as heat, cognitive and behavioral therapy, and distraction. Patients learn what works best for them over time and healthcare providers must understand that watching television, walking, playing games, doing puzzles, and other interventions are positive approaches to therapy and not indications that the patient is not in pain. The patient's assessment of their status is generally the best guide to when hospital discharge is appropriate.

CHRONIC PAIN IN SICKLE CELL DISEASE

Pain in sickle cell disease has some unique characteristics that must be appreciated for optimal management. Sickle cell pain is a lifelong experience with pain episodes beginning in early life and recurring with unpredictable frequency throughout life, resulting in physical, psychological, social, and economic impact on an individual's life experience. It results in frequent interactions with healthcare providers that can be positive or might result in negative experiences because of health professionals' attitudes and actions toward patients in pain. The negative attitudes and actions of some health professionals toward individuals with sickle cell disease have been documented.[179–184]

Another unique aspect of sickle cell pain is that early in life the pain is episodic with defined periods of pain and painfree intervals. As patients age, chronic pain becomes common. Adults have frequent pain that is not characterized as an acute pain episode and does not prompt seeking healthcare.[78] This change in pain character has important implications for pain management and requires reeducation of the individual with sickle cell disease and the families. Previous goals of being pain free are unrealistic and efforts need to be redirected at minimizing pain, maximizing functioning, optimizing positive pain coping strategies, and minimizing negative coping styles. Nonpharmacological interventions become much more important in the successful management of chronic pain.

The many sources of chronic pain have been discussed.[151] Neuropathic pain can result from frequently recurring acute pain, nerve entrapment syndromes, neuronal

Table 20.10. Nonpharmacological interventions for chronic pain in sickle cell disease

Physical measures	Psychological interventions	Behavioral interventions
Heat	Relaxation imagery	Relaxation therapy
Immobilization	Distraction	Breathing exercises

Acupressure	Patient education	
	Caregiver education	

ischemic damage, consequences of undertreated chronic pain, and complications of therapy.[23,44,151,185] Patients with HbSC disease and HbS–β^+ thalassemia have fewer acute pain episodes when they are younger but might have chronic pain from bone disease as they age. Each of these sources of chronic pain needs a systematic approach to management and specific therapy directed at the underlying cause.

Management of chronic pain is challenging for those affected and their care providers. Assessment includes defining the etiology of the pain, determining the pain intensity and impact on functioning and quality of life, and successful and unsuccessful coping strategies. This requires a detailed history-taking, thorough physical evaluation, assessment of psychological functioning, social functioning and support systems, and vocational activities. A detailed care plan is developed that includes pharmacological, physical, psychological, behavioral, social, and occupational pain management strategies (Table 20.10). A therapeutic agreement is developed with the individual, their caregivers, and families that clearly articulates the goals of treatment, limitations of therapy, the responsibilities of the patient, and those of the healthcare team.[186,187] The care plan is implemented with periodic review and refinement based on response to therapy. Assessing of use of medications, coping strategies, and therapeutic response can be facilitated by daily pain diaries.[3,73,75,76,188,189] Because of the complexity of chronic pain management, a multidisciplinary team that includes physicians, nurses, pharmacologists, psychologists, social workers, physical therapists, and occupation therapists is useful.[52,151,187]

The most common form of chronic pain experienced by individuals with sickle cell disease is bone pain.[190] Bone infarction often occurs during severe acute pain episodes and can last weeks to months. Avascular necrosis of the femur and humerus is also a common cause of pain.[191,192] Marrow expansion in the vertebral bodies leads to osteopenia, protrusion of the intervertebral discs, stepwise depression, and occasional compression fractures, which can contribute to the frequent occurrence of acute and chronic back pain.[190,193–195]

Management of chronic bone pain is challenging. NSAIDs and acetaminophen should be used as initial therapy if they are not contraindicated. Pain from avascular necrosis might respond well to physical therapy and could require changes in employment if prolonged standing and heavy lifting are required.[196] Avascular necrosis can require surgical intervention, which can significantly improve the pain (Chapter 19).[197–199]

Leg ulcers can cause severe chronic pain that requires opioids (Chapter 19).[200–203] Pain associated with dressing changes and debridement procedures may benefit from saturation of the area with topical anesthetics.

Neuropathic pain can be present in sickle cell disease and is underrecognized. Characteristics such as burning, lancinating, shooting, tingling, and associated numbness should suggest the presence of a neuropathic component. Specific neuropathies can cause chronic neuropathic pain.[23,204–206] Neuropathic pain responds poorly to opioid analgesics and is generally managed with topical analgesics, anticonvulsant medications, tricyclic antidepressants, and new approaches.[207–210]

Some patients develop intractable pain, without other signs or symptoms of disease pathology.[203] Acute exacerbations of pain can occur, but patients report pain on the majority of days that is severe enough to require treatment. The cause of intractable chronic pain is unknown. Central sensitization from recurrent and perhaps undertreated pain leads to allodynia and hyperalgesia.[185] Because of the frequency of chronic pain in a number of unrelated diseases, it has been suggested that persistent pain is a disease entity that might require removal of the painful stimulus and addressing the psychological and social contributors to, and the consequences of, the pain.[211] Genetic and acquired differences in pain perception might predispose some individuals to developing chronic pain because of increased baseline pain sensitivity and reduced pain inhibitory processing.[212]

Managing the individual with chronic pain is challenging. The availability of a multidisciplinary team is essential and models exist in primary care settings.[52,187] The goals of therapy are to minimize pain and negative pain–related behavior and to maximize positive behavior and quality of life. A formal care plan that is understood and followed by the patient and all members of the care team to minimize miscommunication and negative interactions is imperative. The goals of the plan and details of implementation should be negotiated with the patient, their caregivers, and family and form the basis of a therapeutic agreement.[186] Nonpharmacological approaches including psychological, behavioral and physical strategies are the primary initial methods of pain management. Pharmacological treatment should be based on the WHO analgesic ladder for cancer pain starting with acetaminophen and long-acting NSAIDs. Weaker short-acting opioid analgesics can be added for breakthrough pain. The regular use of stronger opioid analgesics in noncancer pain is still

controversial, but will often be required in individuals with sickle cell disease and severe, intractable pain. Adjunct medications including antihistamines, antiemetic drugs, stool softeners, laxatives, antidepressants, and anticonvulsive medications can be added to control side effects of opioid analgesics and for specific pain syndromes and complications such as depression.

Chronic Opioids

The use of chronic opioid analgesics in sickle cell disease is problematic. Because patients median lifespan is probably in the fifth or sixth decade, pain management strategies must be continued for many years. Regular use of opioid analgesics induces physiological tolerance that reduces their efficacy and therapeutic index. Treatment of acute pain episodes can become increasing difficult if a patient has high levels of tolerance. Interruption of regular opioid use can lead to abstinence syndromes characterized by pain, often in the sites of sickle cell pain, tachycardia and increased blood pressure, piloerection, anxiety, dysphoria, irritability, insomnia, rhinorrhea, lacrimation, myalgia, nausea, vomiting, diarrhea, and other neuroendocrine responses.[213] Many patients interpret these as acute pain episodes and seek further treatment leading to continuously increasing utilization of opioid analgesics and increasing difficulty managing pain.

Chronic use of opioid analgesics in individuals with intractable nonmalignant pain was studied in 38 patients without a history of drug abuse and showed that maintenance therapy can be effective, humane, and safe.[214] Other studies have questioned the benefits of such therapy, citing its lack of efficacy in improving pain and increasing function with acceptable side effects and risks. Only a small subset of patients with chronic pain might benefit from such therapy. These include patients with ongoing nociception and moderate to severe refractory pain or neuropathic pain. The more common chronic pain patient with pain and disability out of proportion to the physical stimulus is unlikely to benefit, and that benefit should be judged on reduction in pain with stable doses of opioid analgesics, improved quality of life, and improvement in social and psychological function.[215] An excellent review outlines a realistic approach to treatment of chronic pain with opioid analgesics. This stresses development of a formal treatment plan with goals and objectives specified, use of moderate doses of medications, frequent assessment documenting improvement in pain and functioning, and avoidance of high-dose treatment over prolonged periods.[216] Accumulating evidence suggests that a conscious, structured approach in a selected subset of patients suffering chronic pain with objective evaluation of outcome in terms of pain control, quality of life, and functioning is the best treatment approach. [216–219] Little evidence is available to guide selection of sickle cell disease patients for chronic opioid treatment.

Once the decision is made to initiate chronic opiate therapy, it is generally recommended that such therapy be based on a well documented evaluation and treatment plan and that it be closely monitored.[220] Reviews have documented the limitations of monitoring of chronic opioid therapy.[221] A model policy for using controlled substances for the treatment of pain outlines recommended guidelines for the physician.[222] Many have suggested that an opioid contract for the management of chronic pain be developed and used in all individuals receiving chronic opioid treatment.[223] The elements of these agreements and model consent forms and sample agreements have been published.[223–225] These agreements stress opioids are part of a comprehensive pain treatment program, indicate the methods by which adherence and improvement will be evaluated, document the healthcare providers' responsibility to improve the patient's pain, indicate the purpose is to improve communication and reduce misunderstanding, state behaviors that will result in modification of the agreement and their specific consequences, and have a positive and cooperative tone.[223,226] Little evidence is available to determine the utility of these agreements to improve adherence to therapy and improve outcome. Some have raised concerns about their utility and purposes; however, they are recommended and widely used in chronic pain clinics.[226,227]

SPECIFIC MANAGEMENT ISSUES

Many important issues develop during the treatment of pain in all patients. They include pseudoaddiction, opioid-induced hyperalgesia, addiction, and managing the "difficult" patient. Although not unique to sickle cell disease, they might be more prevalent because of the lifelong nature of pain in this disorder.

Pseudoaddiction

Pseudoaddiction occurs in two forms. The first is the induction of pain medication–seeking behavior by undertreatment. This is easily treated by increasing the amount or frequency of the analgesic therapy, and the behavior disappears when the pain is adequately controlled. The second form is the occurrence of repeated episodes of abstinence syndrome when opioid analgesics have been discontinued abruptly after prolonged therapy induces physical dependency. This is common in sickle cell disease after prolonged therapy for an unusually severe pain episode or other major complication that results in the need for prolonged, high-dose opioid treatment. When the medication is stopped or the dose significantly decreased, the patient will experience the onset of pain approximately 48–72 hours later requiring repeated ED visits or hospitalizations. This pattern persists until the problem is recognized and treated by administration of long-acting opioid analgesics and slowly tapering the total daily dose with reductions every

2 or 3 days. Prevention requires recognizing this potential in individuals requiring prolonged inpatient treatment and discharging them on a tapering schedule when high-dose opioid therapy is required for more than 5–7 days.[151]

Opioid-induced Hyperalgesia

Opioid-induced hyperalgesia is likely much more frequent than previously thought and occurs in sickle cell disease patients receiving high-dose opioid analgesics for prolonged periods.[228] This syndrome was first recognized in individuals receiving methadone maintenance[229] but is now recognized to occur in many pain settings. Animal models exist documenting the physiological basis for the syndrome.[230–234]

Improvement in pain, quality of life, and psychosocial functioning can be achieved by recognizing the syndrome, stabilizing opioid dose with long-acting preparations, and decreasing the doses of opioid slowly over time. Diagnosis is based on lack of lasting benefit from increases in doses, rapidly developing tolerance, changes in pain pattern with increasing pain as doses are escalated, hyperalgesia, and allodynia.[228] Treatment includes decreasing doses, use of NMDA antagonists such as ketamine and dextromethorphan, α 2-agonists such as clonidine, cyclooxygenase inhibitors, and rotation of opioids.[117] Prevention includes avoidance of prolonged treatment with high-dose opioid analgesics.[233]

Addiction

The American Pain Society defines addiction as, "a pattern of compulsive drug-use behaviors characterized by continued craving for an opioid and a need to use the opioid for effects other than pain relief."[151] The *Diagnostic and Statistical Manual of Mental Disorders-IV* stresses tolerance, withdrawal, longer use than intended, repeated desire or unsuccessful attempts to cut down, spending a great deal of time obtaining substances, negative impact on social, occupational, or recreational activities, and continued use despite knowledge of psychological and physical harm.[235] Addiction is a problem distinct from sickle cell pain and is not a consequence of pain treatment. Recent research suggests that addiction results from genetic, environmental, and social vulnerabilities that when coupled with drug effects lead to changes in brain circuitry causing the addictive phenomenon.[236] Addiction does not appear to be more common in sickle cell disease than other chronic pain states.[151] Recognition of individuals who have this problem is important because the addiction needs specific and likely lifelong treatment.[237]

The "Difficult" Patient

The "difficult" patient is not unique to sickle cell disease. Studies show that 15% of patient interactions are viewed as difficult by physicians in primary care.[238] These are better characterized as difficult patient–provider interactions that arise because of patient characteristics, physician characteristics, and situational issues.[238–241] Some characteristics of sickle cell disease patients directly related to their disease can make them more likely to be perceived as difficult. These include many bothersome physical symptoms and their severity, worry about the seriousness of their illness, and mood and anxiety disorders.[238] Physician characteristics that were more commonly associated with frustration with patients include: age younger than 40 years, work hours more than 55 hour/week, subspecialty practice, and more symptoms of depression, stress, and anxiety. These characteristics may or may not be more common in the physicians caring for sickle cell disease patients.[241] The results of these interactions for the patient include poorer functional status, more unmet expectations, less satisfaction with care, and higher use of health services.[238] This sounds like the description of the "frequent flier" who is the sickle cell patient most likely to be viewed as problematic by the healthcare community.

A recent authoritative review of pain management in sickle cell disease included an excellent discussion of specific methods of approaching the sickle cell patient who is viewed as difficult. Useful approaches have defined a successful physician–patient encounter including collaboration in problem solving, direct proactive communication, appropriate use of power, showing empathy, avoiding being drawn into conflict, and being aware of one's stress, fatigue, and beliefs with limit setting.[238–240,242–245]

SUMMARY

Pain is one of the most frequent and distressing clinical problems facing individuals with sickle cell disease. Its treatment presents major challenges to healthcare providers. Pain episodes are unpredictable and severe. As the individual with sickle cell disease gets older, chronic pain becomes more common and presents new management challenges. Recent studies in adults show that acute and chronic pain is more prevalent than once appreciated because most pain is managed successfully at home and without interaction with the healthcare system.

Despite significant advances in the understanding of mechanisms of pain, new insights into complications of pain, and new information on management, the treatment of acute and chronic pain in sickle cell disease is unsatisfactory. Many healthcare providers have inadequate training in pain management. High levels of frustration for patients, their families, and their healthcare providers are common because the pain is recurrent and difficult to manage adequately. Much of the patient's frustration relates to the healthcare providers failure to believe the severity or even the presence of pain. Although there are consistent laboratory changes during a pain episode, these are only apparent after careful retrospective analysis and comparisons

with baseline values and those obtained well after the pain episode has resolved. No reliable way of determining the presence or severity of the pain is available except for the patient's report and studies document that the pain is underappreciated by healthcare providers.[183] Barriers to treatment of pain in general[246] and sickle cell disease specifically have been enumerated.[179,182,247,248] These might be becoming more of a problem for both patients and providers because of the significant push to minimize utilization of inpatient services and limit outpatient visits.

A major advance in prevention of sickle pain episodes is the introduction of hydroxyurea therapy. Treatment with hydroxyurea significantly reduces the incidence of pain episodes in adults and children with sickle cell anemia and HbS–β^0 thalassemia (Chapter 30).[249] Unfortunately, there is presently no treatment that directly focuses on the immediate cause of the acute painful episode.

Chronic pain is emerging as a major problem for the older patients with sickle cell disease. Approaches to management of chronic pain are unsatisfactory. Better understanding of the effects and side effects of opioid analgesics requires reevaluation of their use in all patients with chronic nonmalignant pain.[216] NSAIDs, physical, psychological, and behavioral approaches need to be the basis for therapy in chronic pain, and multidisciplinary healthcare teams are required.

Finally, recent reviews document a lack of clinical research in sickle pain management, thus sufficient data are lacking to recommend evidence-based approaches to either acute or chronic pain.[153,250–252] New research is needed to refine pharmacological and nonpharmacological approaches to acute and chronic pain in sickle cell disease and to translate the elegant understanding of the disease pathophysiology into effective strategies to abort and prevent acute pain and nervous system adaptation that leads to chronic pain syndromes.

Hemoglobin SC Disease and Hemoglobin C Disorders

Martin H. Steinberg and Ronald L. Nagel

INTRODUCTION

HbC (*HBB* glu6lys), along with HbS (*HBB* glu6val) and HbE (*HBB* glu26lys), is one of the three most common hemoglobin variants in humankind. Its positive charge that allows it to bind the erythrocyte membrane, and perhaps other unique features of this variant, lead to loss of cell K^+ and water, thereby increasing erythrocyte density. HbC disease, defined as homozygosity for the HbC gene, causes mild hemolytic anemia; simple heterozygosity for HbC (HbC trait, HbAC) is innocuous. In HbSC disease, in which the erythrocyte concentration of HbS and HbC is nearly equal, the dehydrated, dense erythrocyte accentuates the deleterious properties of HbS by producing a milieu favoring HbS polymerization. HbSC disease causes vasoocclusive disease and hemolytic anemia, albeit on average both less severe than found in sickle cell anemia (homozygosity for HbS). Like sickle cell anemia, the hematological and clinical features of HbSC disease are heterogeneous, but all of the complications that make sickle cell anemia notorious can be present; some even appear more often in HbSC disease.

HbC and HbC Disease

Origins, Selection, and Distribution of HbC

HbC, the second hemoglobin variant discovered, was described in 1950, and the first homozygous case was reported in 1953. The β^C-globin gene contains a GAG→AAG transition and codes for lysine instead of glutamic acid. Shortly after its description in African Americans, HbC was found to be common in Africa.

Origins. The HbC mutation originated on a β^A-globin gene in West Africa and by means similar to the dispersion of the HbS gene (Chapter 27) spread throughout the world. The β^C-globin gene migrated northward through ancient trans-Saharan trade routes. Predicated on the identity of their haplotypes, HbC in sub-Saharan Africa and North Africa, appears to have had the same origin as in Burkina Faso. Strong gene flow, influenced by the selective pressure of *Plasmodium falciparum* malaria, has distributed HbC throughout central West Africa and toward North Africa, particularly Morocco.

Absence of a Hpa I restriction site 3′ to the HbC gene made it doubtful that HbC arose from mutations in a HbS gene.[1] HbC, which is found in Africa in a restricted distribution, reaches its highest frequency in central West Africa and its gene frequency decreases concentrically outward from there.[2,3] Interestingly, HbC is found in Africa almost exclusively in areas where HbS exists. Although the possibility of a second origin of the HbC gene in Africa has been raised by the presence of a 3′ β-globin gene Hpa I site in several patients, this site is in the middle of an extensive L1 repeat where a high probability of rearrangement exists.

Recombination is expected to reduce the effect of selection on the extent of linkage disequilibrium. It was estimated that the HbC mutation originated less than 5,000 years ago, but despite strong selection and this recent origin, crossing-over or gene conversion present in the "hotspot" 5′ to the β-globin gene locus in more than a third of the HbC chromosomes sampled led to rapid decay in linkage disequilibrium upstream of the HbC allele mitigating the effects of positive selection.

Two instances of independent origin of the β^C have been found in Thailand and in Oman.[4] In both, a strong case for independent origin is made by the presence of the mutation in a different chromosomal framework.

Haplotypes of the HbC Gene. Haplotypes of β^C-globin gene–bearing chromosomes are shown in Figure 21.1A. Three major haplotypes of the β^C-globin gene, termed CI, CII, and CIII are found. Several minor unusual haplotypes have also been described (Fig. 21.1B). Of 90 β^C-globin gene chromosomes, 70% were CI, 20% CII, and 10% had other haplotypes that were either CIII or compatible with recombination events. Heterogeneity of haplotypes associated with the β^C gene is likely to result from crossovers in the 5′ portion of the β-globin gene cluster, an event that is common and results in atypical haplotypes of the β^S gene. In Africa, most β^C chromosomes from Burkina Faso and Benin had the C I haplotype.

HbC and Malaria

HbC provides some protection from malaria.[5] In a case-control study in Burkina Faso, HbC was associated with a 29% reduction in risk of clinical malaria in carriers and a 93% reduction in HbC disease.[6] It was also associated with reduced parasitemia and protection from malarial attacks.[7] Among children with severe malaria, asymptomatic parasitemia and no malaria studied in Ghana, HbC trait did not prevent infection with *P. falciparum* but reduced the odds of developing severe malaria and anemia, albeit to a lesser extent than sickle cell trait (HbAS). The multiplication rate

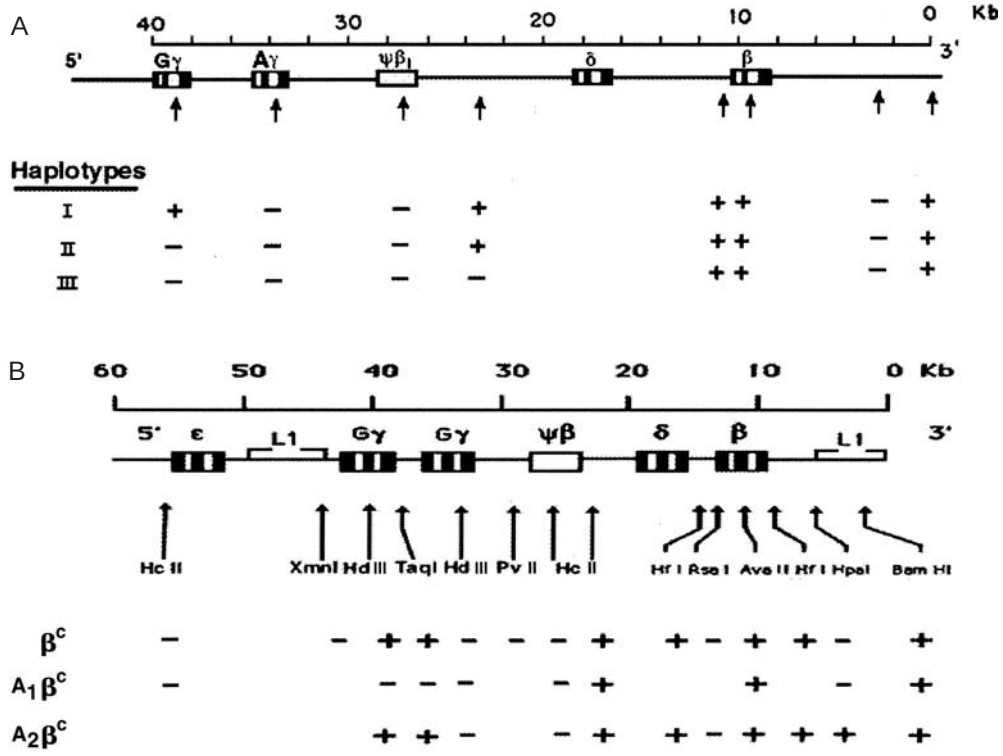

Figure 21.1. β-Globin gene cluster haplotypes associated with the β^C-globin gene. Above each section are depicted the β-like globin genes with approximate size markers in kilobases. **(A)** Haplotypes of β^C-globin gene–bearing chromosomes were determined using eight restriction fragment length polymorphisms (RFLPs). Shown are the "typical" haplotypes CI, CII, and CIII. Arrows indicate, from left to right, the polymorphic restriction sites, *Hind* III (2 sites), *Hinc* II (2 sites), *Hinf* I, *Ava* II, *Hpa* I, and *Bam* HI. **(A)** (+) indicates cleavage and a (−), lack of cleavage by the designated enzyme. **(B)** Two atypical haplotypes associated with the β^C-globin gene (A_1 β^C and A_2 β^C). These haplotypes were determined using additional RFLPs as shown.[107,108]

of *P. falciparum* in HbC disease erythrocytes is lower than in normal cells with a high proportion of ring forms and with trophozoites disintegrating. Also, knobs present on the surface of infected cells are fewer and morphologically aberrant when compared with those on normal cells.[8] These data support natural selection acting on the HbC gene because of the relative resistance it confers against severe malaria but not resistance to acquiring an infection.[9,10]

PATHOPHYSIOLOGY OF HbC DISORDERS

Biochemical Features of HbC

HbC was first detected because of its slow migration compared with HbA and HbS during cellulose acetate electrophoresis at pH 8.6, a difference caused by the net increase of two units of positive charge per molecule. Newer techniques of hemoglobin separation now allow high-performance liquid chromatography (HPLC) separation of variants with similar positive charges such as HbE and HbO-Arab (*HBB* glu121lys) and also the normal HbA_2, from HbC (Chapters 7, 23, and 28).

Carboxy HbC has decreased solubility in phosphate buffers, whereas deoxy HbC has nearly the same solubility as deoxy HbA. In concentrated phosphate buffers, deoxy HbC had even higher solubility than HbA. Oxygen affinity of HbC "stripped" of 2,3-BPG was normal.

HbC Crystallization. When concentrated solutions of purified hemoglobins are incubated in high-molarity

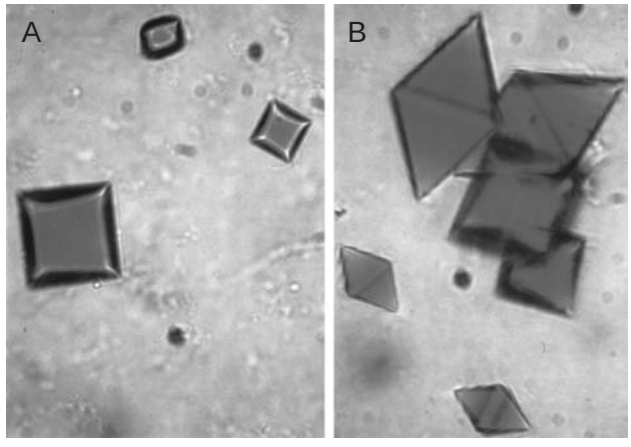

Figure 21.2. Crystal forms observed in hemolysates of patients with HbC. **(A)** Cubic crystals, generated in hemolysates of compound heterozygotes for HbC and Hb Korle-Bu. **(B)** Tetragonal crystals observed intracellularly and in hemolysates of patients homozygous for HbC, with HbSC disease and compound heterozygotes for HbC and HbA and other mutants. (See color plate 21.2.)

phosphate buffer, hemoglobin crystals usually form (Fig. 21.2). In these crystals, hemoglobin can be liganded either as cyanmet, oxy, or CO hemoglobin. HbC crystals form within 25 minutes in a 100% HbC solution and HbF appears to inhibit crystallization.[11] In HbC disease erythrocytes, cells with crystals isolated from density gradients had very low HbF concentrations.[12] In the dense cell fraction, F cells did not contain HbC crystals.

HbA_2 inhibited HbC crystallization to a greater extent than HbF. The critical residue involved is at position 87 in the δ- and γ-globin chains where a gln replaces thr. This is the same residue that might account for the inhibition of HbS polymerization by HbF and HbA_2.[11] An examination of the interactions of HbC with Hb Lepore-Boston, which inhibits HbC crystallization to a lesser extent than HbF and HbA_2, suggests that a reduction in inhibition could arise from the slight difference in hemoglobin conformation due to the shift of oxygen equilibrium observed in Hb Lepore.[11,13] Other amino acids located between positions 88 and 146 could add to the inhibitory effect of both the γ -and the δ-globin chains on HbC crystallization.

Other mutant hemoglobins that are present with HbC can affect its in vitro crystallization. Compound heterozygotes having HbC-HbN-Baltimore (*HBB* lys95glu) and HbC-Hb Riyadh (*HBB* lys120asn) suggest that β120 and β95 are additional contact sites in the crystal. Hb Riyadh inhibited the in vitro crystallization of HbC explaining the lack of overt pathology, with the exception of microcytosis, in a compound heterozygous infant. In contrast, HbN-Baltimore accelerated the crystallization of HbC and contributed to abnormal red cell morphology, suggesting that the crystal is sustained by hydrophobic interactions.[14]

Hb Korle-Bu (*HBB* asp73asn) accelerates HbC crystallization.[15] Compound heterozygotes for Hb Korle-Bu and HbC have mild microcytic hemolytic anemia and in vitro acceleration of crystal formation, where precrystal hemoglobin structures convert rapidly into cubic-like crystals as opposed to the typical tetragonal crystal structure. In vitro crystallization studies led to the conclusion that β87 and β73 are contact sites of the oxyhemoglobin crystal.[13]

Hemoglobin $\alpha_2{}^{\text{G-Philadelphia}}\beta_2{}^{C}$ has an increased rate of crystal nucleation compared with HbC, implying that position α68, the mutation site of HbG-Philadelphia, is a contact site in the crystal of HbC.[16]

Mixtures of HbA and HbC crystallize with a different morphology than the classic HbC crystal habit, raising the question of the hemoglobin composition of crystals generated in mixtures of HbC with HbF or HbA_2. As the HbA concentration of the mixture increases, more tetragonal crystals are formed as opposed to typical orthorhombic crystals. HbA alone does not form crystals under these conditions, making it likely that hybrid tetramers ($\alpha_2\beta^C\beta^A$) are incorporated into these crystals. It also suggests strongly that these two hemoglobins cocrystallize. HbS also cocrystalizes with HbC.

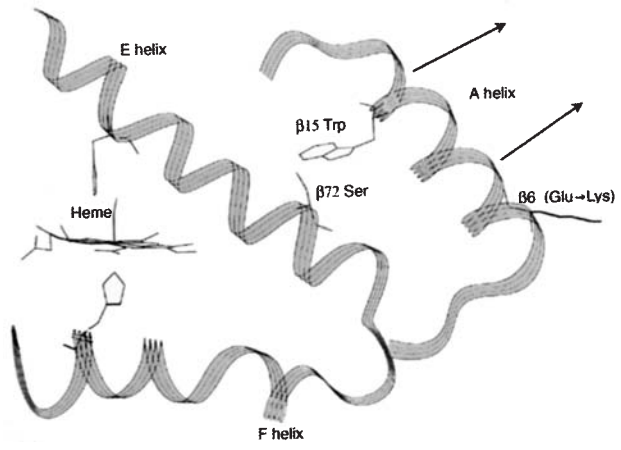

Figure 21.3. View of the F, E, and A helix in the β chains of hemoglobin. Also depicted are the heme, the β15 trp - β72 ser bond and the β6 Lys (the mutation of HbC). The arrows depict the likely movement of the A helix away from the E helix, which is compatible with conformational changes in the central cavity of the tetramer.[13]

A weakening of trpβ15–serβ72 bond most likely leads to a displacement of the A helix away from the E helix.[13] The central cavity (between the two β-globin chains of HbC, is altered compared with HbA[17] (Fig. 21.3).

HbC crystals do not grow by the alignment of the preformed strand but by the attachment of single molecules to suitable sites on the surface. These sites are located along the edges of new layers generated by two-dimensional nucleation. During growth, the steps propagate with random velocities, with the mean being an increasing function of the crystallization driving force.[18] Static and dynamic light scattering characterization of the interactions between the R-state (CO) of HbC, HbA, and HbS molecules in low-ionic-strength solutions showed that the interactions are dominated by the specific binding of solutions' ions to the proteins. Crystals of HbC nucleate and grow by the attachment of native molecules from the solution and concurrent amorphous phases. Spherulites and microfibers are not building blocks for the crystal. HbC crystallization is possible because of the huge entropy gain stemming from the release of up to 10 water molecules per protein intermolecular contact–hydrophobic interaction, suggesting that the higher crystallization propensity of R-state HbC is attributable to increased hydrophobicity.[18] Deoxy HbC formed aggregates and twisted macroribbon forms similar to those seen in the oxy liganded state. In contrast to oxy HbC, deoxy HbC favored the formation of a greater morphological variety of aggregates including polymeric unbranched fibers in radial arrays with dense centers, with infrequent crystal formation in close spatial relation to both the radial arrays and macroribbons. These results suggest that the glu6lys substitution evokes a crystallization process dependent on ligand state conformation. Oxy HbC is thermodynamically driven to a limited number of aggregation pathways with a high propensity to form the tetragonal crystal structure. In contrast, deoxy HbC energetically equally favors multiple pathways

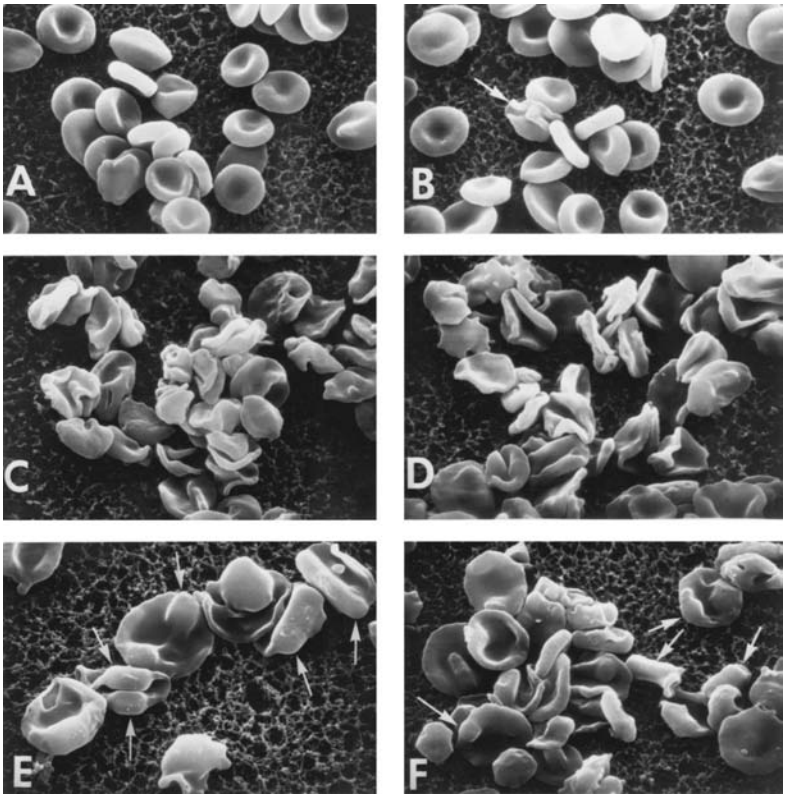

Figure 21.4. Scanning microscopy of HbC disease fractions. **(A** and **B)** Whole blood, in **B** a folded cell. **(C** and **D)** Middle density red cell fraction, notice the abundance of folded cells. **(E** and **F)** The highest density red cell fraction, arrows point to crystal containing red cells.

of aggregation, not all of which might culminate in crystal formation.[19]

Intracellular Crystals in HbC Disease. HbC crystalizes in its oxy configuration and crystals probably exist in vivo. Nevertheless, they are unlikely to play an important role in the pathophysiology of this disorder because deoxygenation will induce melting before or as they enter the microcirculation.

Observations of crystals in vivo were first made under circumstances in which crystal formation could have been induced by cell processing. When blood from splenectomized HbC disease patients was examined by continuous density gradients, a new, very dense band of cells containing crystals 1 μm or more in size were observed. This cell fraction was absent from most HbC disease individuals with intact spleens but present in smaller amounts in some HbC disease patients older than 55 years. Scanning electron microscopy of HbC cells isolated from density gradients and freeze-fracture preparations show intracellular crystals (Figs. 21.4 and 21.5). Circulating crystals can be detected in unperturbed wet preparations from individuals with HbC disease but are rare in unsplenectomized cases.[20]

HbC crystals in the red cells of a splenectomized HbC disease patient were found to be in the oxy state and melted after deoxygenation (Fig. 21.6).[12] When cells from venous and arterial blood were fixed and counted, a small but significant difference in the mean percentage of crystal-containing cells in the arterial circulation versus the venous

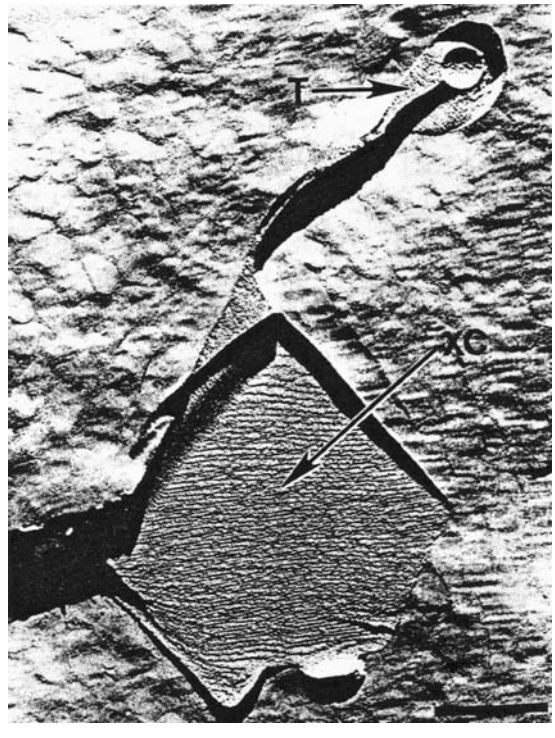

Figure 21.5. Freeze fracture of an HbC disease cell from a splenectomized patient containing a highly ordered crystal (XC) and tail portion (T) that correspond to the membrane of the cell devoid of hemoglobin. This is a negative print (light areas have accumulation of platinum) of a predominantly cross-fractured cell.

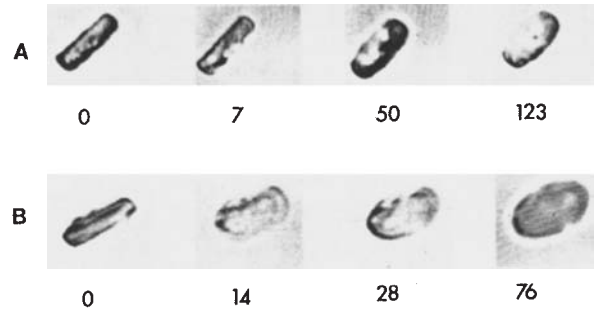

Figure 21.6. Melting of oxy HbC crystal intracellularly by deoxygenation. Time sequence (in seconds) recording of oxy HbC intracellular melting after the addition of isotonic dithionite solution for deoxygenation. Demonstration that the crystal habit of the intracellular crystal is indeed oxy, which is incompatible with the deoxy conformer of HbC.

circulation was present. HbC crystals were not observed either in vitro or in vivo in HbC trait.

PROPERTIES OF THE HbC ERYTHROCYTE

Morphology

HbC disease erythrocytes are noted for their bizarre morphology. In wet preparations, microcytic and hyperchromic cells are present, whereas in dried stained blood films, target cells, microspherocytes, and cells with crystalline inclusions are found. Target cells, a diagnostically useful artifact, are presumably the consequence of the greater surface/volume ratio of HbC disease cells, which is in turn the consequence of their reduced water content.

Ion Transport and Cation Content

Erythrocytes that contain HbC have a characteristic volume-stimulated K^+ leak. Consequently, intracellular cation and water content of HbC disease cells are strikingly reduced, whereas the cation content of HbC trait and HbSC disease cells is less prominently depleted (Chapter 9).[21,22] When the cation and water content of HbC disease cells were increased by making the membrane permeable to cations and returning the cells to an isotonic medium, they returned to their original volume by gaining K^+, a behavior that was not observed in control cells. Volume-stimulated K^+ efflux was neither inhibited by ouabain and butamide nor blocked by inhibitors of Ca^{2+}-activated K^+ permeability. A volume-regulated decrease in cell water in HbC disease cells stands in sharp contrast to the usual description of the human red cell as a passive, slightly imperfect osmometer and probably explained the reduced response of HbC disease cells to changes in the extracellular osmotic pressure. From these observations, it was concluded that HbC disease cells have a potassium transport mechanism that is either absent from, or inactive in, normal cells, and raised the possibility that the presence of the abnormal hemoglobin was responsible for the activity of this transporter. Volume-stimulated K^+ efflux occurred when osmolarity and pH were both reduced, an effect that was chloride–dependent, N-ethylmaleimde stimulated, and similar to previously reported K^+Cl^- transporters.[23–25] Transporters of this sort are present in normal and sickle reticulocytes under oxygenated conditions and decrease in activity with cell aging.[26] Although red cell lifespan is shortened to approximately 40 days in HbC disease, this is more than three times the lifespan of sickle cell anemia erythrocytes, suggesting that factors beyond a high proportion of young cells contribute to the high activity of the K^+Cl^- transporter in HbC disease. Total cellular calcium was elevated in HbC disease cells as it was in sickle cell anemia and was sequestered in endocytic vesicles.

K:Cl cotransport is a powerful volume regulator in young erythrocytes. The delay time for activation of K^+ efflux in sickle cell anemia cells was sixfold shorter than for HbC disease cells and 5.1-fold shorter than for normal cells. HbC cells were first swollen to activate the K:Cl cotransport and then shrunk by reestablishing normal osmolarity. The delay time for K^+ efflux was eightfold longer than sickle cell anemia cells. When K:Cl cotransport was activated by acidification, similar differences in the delay times for activation and deactivation were observed. Moreover, the delay time for activation increased markedly with cell density, but the delay time for deactivation was approximately equal in all density fractions. These studies suggest that K:Cl cotransport is very active in young HbC disease cells but has a longer delay time for deactivation by cell shrinkage than in sickle cell anemia or normal red cells. This suggests that transient activation of K:Cl cotransport in HbC disease reticulocytes, followed by a slow deactivation, can gradually decrease hydration and increase mean corpuscular hemoglobin concentration (MCHC). It implies that K:Cl cotransport regulation by phosphorylation/dephosphorylation might be altered either by a direct effect of HbC and/or by HbC-dependent alteration of enzymes controlling the phosphorylated state. Many of the same abnormalities in K:Cl cotransport can be found in HbC transgenic mice.[27–30]

Oxygen Affinity

P_{50} of HbC disease cells was increased to 29.5 mm Hg (normal, 26.5 mm Hg). The 2,3-BPG content of HbC disease cells was equal to that of normal cells, whereas the difference between the intracellular and extracellular pH was increased for HbC disease cells. Decreased oxygen affinity of HbC disease cells was attributed primarily to reduced intracellular pH, but the “normal” 2,3-BPG content failed to take into account the diminished intracellular water content. When this is considered, the effective 2,3-BPG content is considerably higher than normal and should further decrease oxygen affinity. Decreased oxygen affinity could modulate the anemia of HbC disease by increasing oxygen delivery to tissues.

Osmotic Response and Cell Density

High MCHC and low intracellular water content are characteristics of HbC cells, and the cells in HbC trait and HbC disease are denser than normal. Average MCHC in HbC disease, HbSC disease, HbC trait, and HbA cells were 38, 37, 34, and 33 g/dL, respectively. The youngest and lightest cells differ from the oldest and most dense cells by only 3–4 g/dL. In contrast, cells of sickle cell anemia have a very wide density distribution. HbC disease, HbSC disease, and HbC trait reticulocytes are denser than normal reticulocytes. Either these cells are denser than normal when they first enter the circulation or their density changes within 24 hours while they are still recognizable as reticulocytes. Reduced osmotic fragility in HbC disease is consistent with an increased surface to volume ratio.

Binding of HbC to Red Cell Membrane

HbC, like HbS, interacts more strongly with the erythrocyte membrane than HbA. This interaction has been studied using changes in the fluorescence intensity of the membrane-imbedded fluorescent probe, whose fluorescence is quenched when it is approached by hemoglobin. At pH 6.8, the affinity of HbC for the erythrocyte membrane was approximately five times greater than that of HbA. Deoxy HbA and HbC were less strongly bound than the oxy form. When the NaCl concentration was increased, HbC was approximately 90% dissociated from the membrane.

At higher hemoglobin concentrations, HbC binding was stronger, and higher salt concentrations were required to displace the hemoglobin from the membrane. The cytoplasmic portion of band 3 was implicated as the binding site for both HbA and HbC. HbO-Arab is more strongly bound than HbS and is even more tightly membrane bound than HbC, suggesting that both electrostatic charge and the protein conformation in the vicinity of the charged groups play roles in membrane binding. Membrane binding of abnormal hemoglobins could affect membrane proteins involved in anion or cation movement and play a role in altering red cell density.

Rheological Properties of HbC Disease Erythrocyte

HbC disease cells were less filterable than normal cells. Although the optimum filterability of normal cells occurred at 300 mOsm, HbC disease cells were maximally filterable at 200 mOsm, an observation consistent with increased density. By measuring cellular elongation in response to a fluid shear stress, cellular deformability was examined as a function of buffer osmolarity. HbC disease cells were poorly deformable in isotonic media but deformability improved when osmolarity was reduced to 100–200 mOsm.

HbC disease cells caused a 10%–20% increase in peripheral resistance when studied in a rat mesoappendix model. This minimal change is compatible with the benign clinical course of HbC disease and also suggests that the adverse affects density could be offset by their microcytosis.

HbC Disease, HbC Trait, HbC–β Thalassemia, and HbC–α Thalassemia

HbC trait is found in 2% of African Americans.[31] In parts of West Africa, the prevalence of the HbC gene can reach 0.125.[3,32] Among African Americans, the prevalence of HbC disease is 1 in 6,000. Vasoocclusive episodes are not a feature of HbC trait or HbC disease. Although poorly deformable, HbC cells are rheologically competent. Any oxy HbC crystals formed will tend to melt when cells become lodged in the microcirculation.

Laboratory Features and Diagnosis

Both HbC trait and HbC disease are characterized by target cells and other abnormal erythrocytes. Individuals with HbC trait are not anemic, have normal mean corpuscular volume (MCV) and normal red cell lifespan. MCHCs were approximately 2 g/dL higher than normal cells and 1 g/dL more than HbAS cells.[33] HbC trait erythrocytes contain approximately 40% HbC and 2%–3% HbA_2. In HbC disease, HbC is the predominant hemoglobin with normal amounts of HbA_2 and HbF. Many of the older commonly used methods of hemoglobin separation did not resolve HbC from HbA_2 and positively charged variants like HbE and HbO-Arab.

α Thalassemia can be present in individuals with HbC trait or in homozygotes with HbC disease. Trimodality in the percentage of HbC in carriers of HbC trait first suggested the presence of α thalassemia as a modulator of HbC concentration. HbC plus HbA_2 concentration was 44%, 38%, and 32% in HbC trait carriers presumed to have four, three, and two α-globin genes, respectively. In other cases in which the carrier was presumed to have heterozygous α^+ thalassemia, MCV was reduced and HbC and HbA_2 together were approximately 33%; however, the ascertainment of α thalassemia did not rely on DNA analysis. A case of HbC trait–HbH disease, caused by compound heterozygosity for the $-\alpha^{3.7}$ and SEA deletions (Chapter 13), had splenomegaly, mild anemia, MCV of 59 fl, and 24% HbC.[34] HbC disease–α thalassemia has been described with a phenotype similar to HbC disease, but again, α-globin gene mapping was not done.

In HbC trait–α thalassemia, the concentration of HbC is reduced similarly to HbS levels in HbAS–α thalassemia and this reduction depends on the number of deleted α-globin genes (Chapter 23). mRNA isolated from individuals with simple HbC trait and HbC trait with either homozygous α thalassemia-2 or HbH disease, supported balanced expression of β^C and β^S globin favoring a post translational mechanism for the modulation of HbC concentration.[35] Compared with the wealth of information on the effects of the interaction of α thalassemia and HbAS,

there are few available data on the hematological and clinical aspects HbC trait or HbC disease with α thalassemia. Because both HbC trait and the -$\alpha^{3.7}$ type of α thalassemia are clinically innocuous there is no reason to believe that their concordance should be any different.

HbC crystals, very prominent target cells, and anemia are present in HbC disease. Mild hemolytic anemia is customary: the packed cell volume (PCV) is usually 32%–34% and hemoglobin concentration between 9 and 12 g/dL, with a moderate reticulocytosis of between 5% and 10%. Characteristically, the MCV is between 55 and 65 fL. Using DF ^{32}P(di-isopropylfluoropropyl phosphate)-labeled red cells, a mean red cell lifespan of 38.5 and 35.1 days was found in two individuals with a ^{51}Cr red cell survival of 19 days.

Hemolysis is unlikely to be the sole mechanism generating anemia in HbC disease. A reduced oxygen affinity of HbC cells, could account for a portion of the reduction in PCV as these red cells would more readily unload oxygen in the tissues. In turn, erythropoietin production would be stimulated at a lower hemoglobin level than normal. Anemia might therefor appear to be uncompensated because of the decreased oxygen affinity of HbC disease red cells. Dyserythropoietic features, including nuclear disorganization and altered chromatin staining, have been found in erythroblasts of HbC disease but not sickle cell anemia. These findings suggest that ineffective erythropoiesis could account for some of the anemia in this disorder although why this should be is unclear. In children with HbC disease, hemoglobin levels and reticulocyte counts were similar to those in adults and the MCV was between 60 and 80 fL.[36]

HbC–β^+ thalassemia and β^0 thalassemia have been described, and like HbS-β thalassemia, the phenotype is determined by the β thalassemia mutation. In individuals of African descent, because of the prominence of the "mild" promoter mutations in this population, HbC-β^+ thalassemia has hematological features of β thalassemia trait with microcytosis and either no anemia or very mild anemia. HbC levels are 20%–30% and similar to HbS levels in most black patients with HbS–β^+ thalassemia. Like HbS–β^+ thalassemia in Mediterranean populations, β^+ thalassemia mutations that considerably reduce gene expression produce a more severe phenotype approaching that of HbC–β^0 thalassemia.

HbC–β^0 thalassemia can be difficult to distinguish from HbC disease because HbA is absent and HbA_2 is not always easily measured when HbC is present (Table 21.1). DNA analysis or family studies are required when it is important to make the distinction between HbC disease and HbC–β^0 thalassemia. Further complicating the separation of these disorders is the possibility of α thalassemia coincidental with HbC disease, which is likely to cause a phenotype similar to HbC–β^0 thalassemia. HbC trait has been described with gene deletion hereditary persistence of HbF, Hb Lepore, and with δβ thalassemia. All are mild conditions resembling HbC–β^+ thalassemia because of the presence of HbF and Hb Lepore.

Table 21.1. Hematological findings in HbC disease and HbC–β^0 thalassemia*

Genotype	Hemoglobin (g/dL)/PCV	MCV (fL)	HbF (%)	Reticulocytes (%)	Spleen
HbC Disease	10–15/30–45	60–90	2–4	2–7	↑↑
Hb C–β^0 Thalassemia	8–12/25–35	55–70	3–10	5–20	↑↑↑

* These data are a composite of many cases reported in the literature.

Clinical Features and Treatment of HbC Trait and HbC Disease

HbC trait is not associated with clinical disease. Hematuria and isosthenuria, the best-characterized clinical abnormalities of HbAS, are not associated with HbC trait.

Individuals with HbC disease have hematological and clinical evidence of their hemoglobinopathy but appear to have a normal lifespan and few signs or symptoms besides splenomegaly that are attributable to their disease. They do not have vasoocclusive events typical of sickle cell disease.

Splenomegaly has been reported in most adult patients with HbC disease and is usually asymptomatic. In the past, splenectomy was frequently recommended with the hope of correcting the anemia; current practice avoids splenectomy in all but very selected cases. Splenectomy is usually followed by a slight increase in PCV and by increased numbers of circulating cells containing HbC crystals. Children might have a lower prevalence of splenomegaly.[36] Spontaneous rupture of the spleen has been described in HbC disease. Increased density of the HbC-containing erythrocytes does not impair renal concentrating ability.

Treatment Recommendations

As HbC disease is clinically asymptomatic and hematologically benign, no special treatment is needed. Iron should be avoided because it will not, in the absence of iron lack, repair anemia or microcytosis. Hemolysis is very mild, so a reasonably nutritious diet should provide sufficient folic acid, and supplementation is unnecessary. No information exists about hemolysis related pulmonary hypertension in HbC disease.

Parvovirus B19 can transiently interrupt erythropoiesis but because hemolysis is mild, the sequelae of this infection should not be as serious as when it occurs in sickle cell anemia and might not reach the threshold of clinical detection.

Patients sometimes have aches and pains and it is not clear if these can be linked to HbC disease. There is no evidence that HbC disease is accompanied by a reduction in longevity in the Western World, although this might not be true in the harsh environmental conditions of the African Sahel.

HbSC Disease

In HbSC disease the erythrocytes contain nearly equal concentrations of HbC and HbS and each hemoglobin component exerts its own special pathological effects that synergistically cause the well-delineated features of HbSC disease. HbSC disease is the neglected stepchild of sickle hemoglobinopathies. Its unique pathophysiology suggests that it could be amenable to treatments that might prevent dense cell formation, yet until very recently, therapeutic trials in HbSC disease have not been done and most often, in clinical trials, its treatment has been lumped with treatment for sickle cell anemia. This might have the dual unfortunate effect of confounding the interpretation of trials for sickle cell anemia and retarding the development of novel treatments for HbSC disease.

Cellular Determinants of Pathophysiology and Severity

HbAS and HbSC disease erythrocytes both have far lower concentrations of HbS than cells of sickle cell anemia. Nevertheless, the expectation that because of low HbS concentrations polymerization-induced defects will be attenuated or absent is realized only in HbAS. The reasons why HbAS and HbSC disease differ, which elucidate the pathophysiology of HbSC disease, are discussed in the following sections.

HbC Crystals in HbSC Disease. Crystals are the most striking and distinctive feature in circulating red cells of HbSC disease, especially when patients have a normal complement of α-globin genes (Figs. 21.7 and 21.8). HbS accelerates the crystallization of HbC in vivo and in vitro.[37] HbC crystals are observed in Wright and vital dye–stained smears and in "wet" blood preparations (Fig. 21.7).

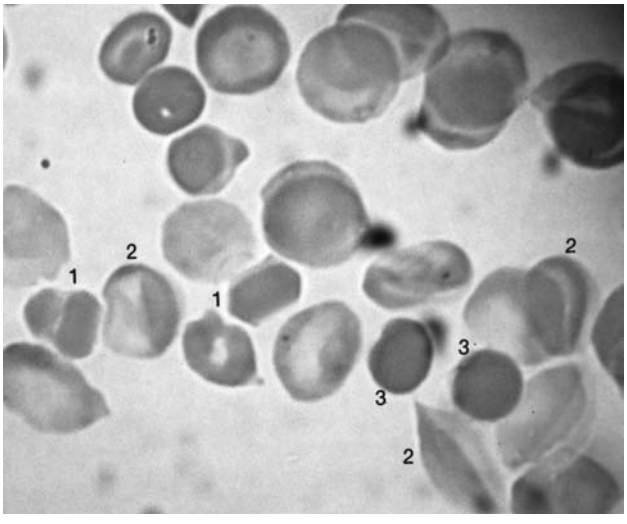

Figure 21.7. Erythrocytes in HbSC disease. These cells are characterized by sharp edges, increased red color (particularly in a reticulocyte stained smear), and often by having all the hemoglobin of the cells recruited into the crystal, leaving a ghost of the red cell without cytosolic dissolved hemoglobin. 1 = crystal containing red cell; 2 = "billiard ball" cells; 3 = folded cells. (Lawrence et al., *Blood* 1991;78: 2104–2112.)

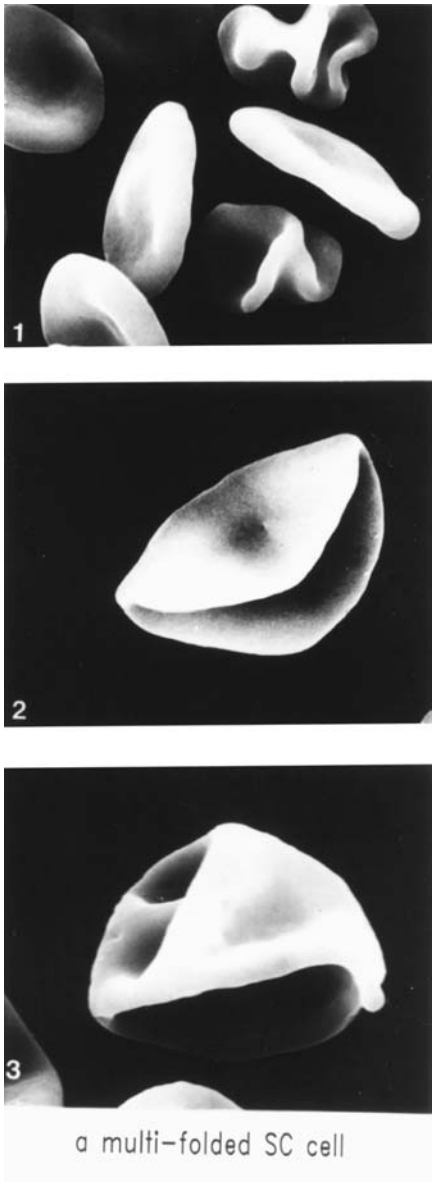

Figure 21.8. Several types of red cells found in the blood of HbSC disease patients illustrated by scanning electron microscopy: Folded red cells (Top panel), "pita bread" red cells (middle panel), and highly folded red cell (lower panel) from whole blood of a HbSC disease patient.

When α thalassemia is present with HbSC disease, typical crystals are absent in some patients. All HbSC disease patients' red cells exhibit heavily stained conglomerations of hemoglobin that appear marginated with rounded edges in distinction to the straight edged crystals. Both crystals and hemoglobin conglomerations are found in the densest fraction of HbSC disease and represent hemoglobin aggregation distinct from HbS polymer. Regardless of the α-globin gene haplotype, the blood of HbSC disease patients has additional abnormally shaped cells that are strikingly apparent upon scanning electron microcopy (Fig. 21.8). These bizarre shapes are the product of an increased surface/volume ratio. Crystals, pitted by a normal spleen might

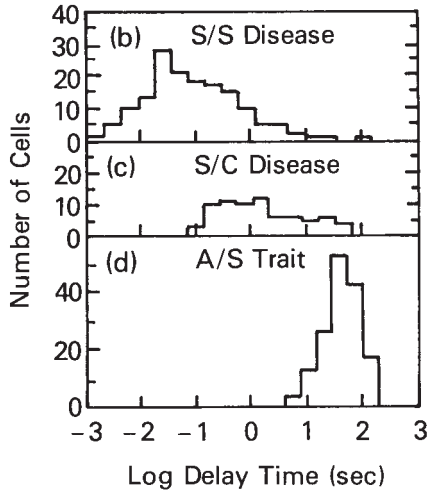

Figure 21.9. This graph depicts individual red cell delay times of polymerization in HbSC disease compared with sickle cell anemias and HbAS. Notice that many HbSC cells behave as sickle trait cells, as far as delay times, but that also some of the cells behave as the slowest sickle cell anemia cells. In effect, delay time of HbSC cells is intermediate between sickle cell anemia and sickle cell trait cells, with overlapping.[109]

remain in the cell in the presence of an enlarged, infarcted and perhaps abnormally functioning spleen.

Ratio of HbS to HbC. The ratio of HbS/HbC is approximately 50:50 compared with the 40:60 ratio of HbS/HbA in HbAS. Charge-related differences in αβ dimer assembly account for the lower proportion of HbS in HbAS and HbC in HbC trait. Although HbC has an additional positive charge compared with HbS, both these abnormal variants can compete similarly for α-globin chains equalizing the HbS/HbC ratio.

Just as HbF is unequally distributed among all cells, there is some evidence that HbC is unequally apportioned among red cells. Using single-cell electrophoresis, the distribution of HbS in HbAS and HbC in HbC trait was found to vary among cells but whether HbS concentration differs among cells in HbSC disease is unknown.

HbSC disease is associated with hemolytic anemia and vasoocclusive complications, whereas HbAS is not, a difference that might be attributed to the higher concentration of HbS in HbSC disease. Although the effects of HbA and HbC on HbS polymerization are equivalent, increasing the HbS from 40% to 50% increased the rate of polymerization nearly 15-fold. The duration of the delay time before sickling occurs could play a role in the pathophysiology of HbSC disease. A long delay might allow a cell to move through hypoxic microvasculature before rigidity and rheological incompetence ensue, whereas a shorter delay time could increase a cell's propensity to induce vasoocclusion (Fig. 21.9).

Cell Density, Cation Content, and Density-related Properties. Cation content of HbSC disease red cells is intermediate between normal and HbC disease cells. Oxygenated HbSC disease cells exhibit a volume-stimulated K^+ efflux similar to that observed in sickle cell anemia and HbC disease. HbSC disease cells also exhibit a diminished change in cell volume in response to variation of the osmolarity of the suspending medium, which is likely to be due to volume, regulated K^+ efflux. Volume-regulated K^+ efflux should impact adversely the pathophysiology of disease because any increase of MCHC will aggravate HbS polymerization.

The intracellular HbS concentration in HbSC disease is raised to a level where polymerization occurs under physiological conditions. This contrasts with HbAS cells in which polymerization occurs only at high osmolarity and low pH, such as in the renal medulla. Reducing the MCHC in HbSC disease to normal levels of 33 g/dL by osmotically swelling resulted in normalization of many of their polymerization-dependent abnormal properties.[38] Among the beneficial effects of cell rehydration were increased hemoglobin oxygen affinity, reduction of viscosity of deoxygenated erythrocyte suspensions, fall in the rate of sickling, and reduction in the deoxygenation-induced K^+ leak. At an osmolality of 240 mOsm, where the density distribution of HbSC disease cells most nearly matched normal cells, the cells were found to be biconcave disks. These observations suggest that restoring the density of HbSC cells toward normal might be an efficacious treatment.

Analogous to sickle cell anemia, when α thalassemia coexists with HbSC disease fewer dense cells are present. During the course of vasoocclusive crisis in HbSC disease, dense cells decrease just as in sickle cell anemia, suggesting their sequestration.[39,40]

HbSC disease cells exhibit pathological properties characteristic of both sickle cell anemia and HbC disease cells, and this feature helps explain the greater than anticipated severity of HbSC disease. A morphological analysis of density-separated HbSC disease cells indicated that they became progressively more aberrant in shape as their density increased. The densest fraction of the gradient contained cells with the most abnormal shapes, which were particularly noticeable for their gross pitting and membrane invaginations. HbSC disease cells destined to become extremely dense are likely also to produce crystals as a byproduct of their progressive MCHC increase as the concentration of hemoglobin within crystals is approximately 68 g/dL. Irreversibly sickled cells are rare in HbSC disease and are found in the densest cell fractions (Fig. 21.10).

α Thalassemia is associated with a decrease in the dense cell fraction. In contrast with sickle cell anemia, the highest percentage of reticulocytes is found within a fraction of dense cells, although the youngest, or stress reticulocytes, are predominant in the least dense fraction. This suggests that in HbSC disease reticulocytes exit the marrow as low-density cells and become dense within 24 hours, sinking to the next to densest fraction of cells in the blood.

Reticulocytes are almost absent from the dense cell fractions that contains the largest proportion of crystal containing cells. Hyperdense reticulocytes migrate to lower

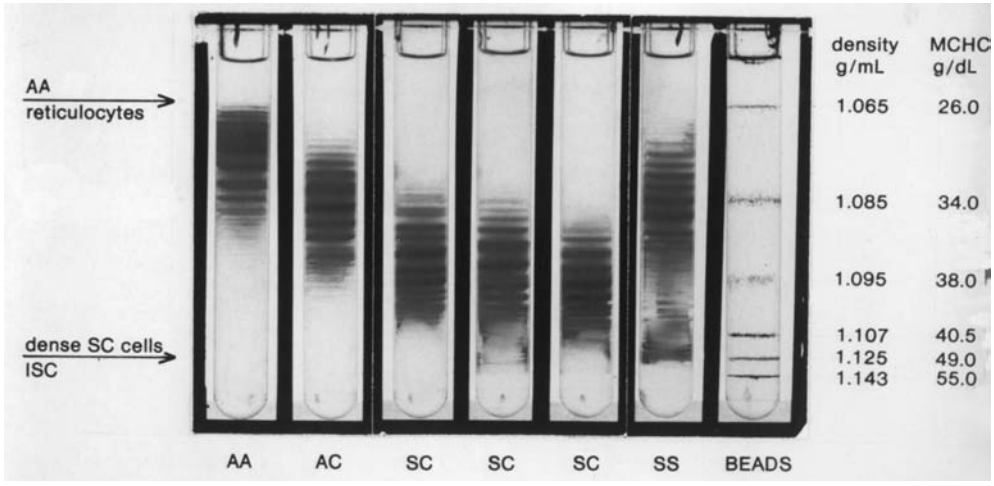

Figure 21.10. Percoll–Strachan (Larex) density separation of whole blood from normal hemolysate (AA), HbC trait (AC), and three different HbSC disease individuals and one sickle cell anemia patient. Beads: Color-coded density beads to establish the density at different levels of the gradient after centrifugation. See color plates.

densities if Cl^- is removed from the media, in concordance with a K:Cl cotransport-mediated phenomena. It seems likely that K:Cl cotransport is responsible for the presence of HbSC disease reticulocytes of unusually high densities.

β-Globin Gene Cluster Haplotypes in HbSC Disease

A Benin haplotype β^S chromosome was present in 56%, Bantu in 25%, Senegal in 6%, and other haplotypes in 12% of HbSC disease cases.[41] No hematological differences among these patients were present.[42] Hematological features of individuals with HbSC disease who had Benin or Bantu β^S chromosomes were similar whether they had a C I or C II haplotype. Most likely, the effect of β-globin gene haplotype on the hematological and clinical features of sickle cell anemia is via haplotype-linked elements that affect the levels of HbF. HbF levels in HbSC disease are lower than in sickle cell anemia, probably because there is less hemolysis and bone marrow expansion in HbSC disease. Another speculative consideration is that the β^C chromosome might not contain the critical genetic elements or polymorphisms that are present in sickle cell anemia and necessary for increased transcription of the γ-globin genes (Chapter 27).

CLINICAL FEATURES OF HbSC DISEASE

In northern Ghana, Burkina Faso, and western Nigeria, approximately a quarter of the population might have HbSC disease. Centuries of population movements have spread the HbS and HbC genes throughout the world, broadening greatly the distribution of the sickle hemoglobinopathies. HbSC disease has an incidence of approximately 1:833 live births in African Americans.[31]

All complications that are found in patients with sickle cell anemia have occurred in individuals with HbSC disease. Nevertheless, most, but not all, of these complications are less frequent and appear at a later age in the course of HbSC disease compared with sickle cell anemia. Hemolysis is less intense so that hemolysis-related complications like leg ulcer, priapism, stroke, pulmonary hypertension, aplastic episodes, and cholelithiasis are less frequent or severe. Disease complications due to blood viscosity, such as osteonecrosis of bone can be as common as in sickle cell anemia; proliferative sickle retinopathy is much more prevalent in HbSC disease than in sickle cell anemia; the mortality of acute chest syndrome might be increased.[43] Painful episodes occur at approximately half the frequency as in sickle cell anemia. The lifespan of HbSC disease patients is shortened when compared with control populations, but is longer than in sickle cell anemia.

Specific treatments that will prevent complications of this disease are not yet available. In the following sections, the clinical aspects of HbSC disease that differ most from those of sickle cell anemia are discussed. For details of treatment and many complications, which differ little among the genotype of sickle cell disease, the reader should consult Chapters 19, 20, and 29–33.

Hematology and Laboratory Findings

HPLC now provides rapid quantitative analysis of hemoglobin fractions and can distinguish HbS, HbC, and many of the variants with which they might be confused (Chapter 28). Blood films can suggest the diagnosis of HbSC disease. Except in the presence of sickle cell–related renal failure or with coincidental medical conditions that can reduce the PCV, patients with HbSC disease do not usually have overt symptoms of anemia. At any age, PCV in HbSC disease is higher than in sickle cell anemia.[44] Median values by age and sex for PCV, MCV, platelet count, and bilirubin are shown in Figure 21.11. PCV rises from 31 to 32 in

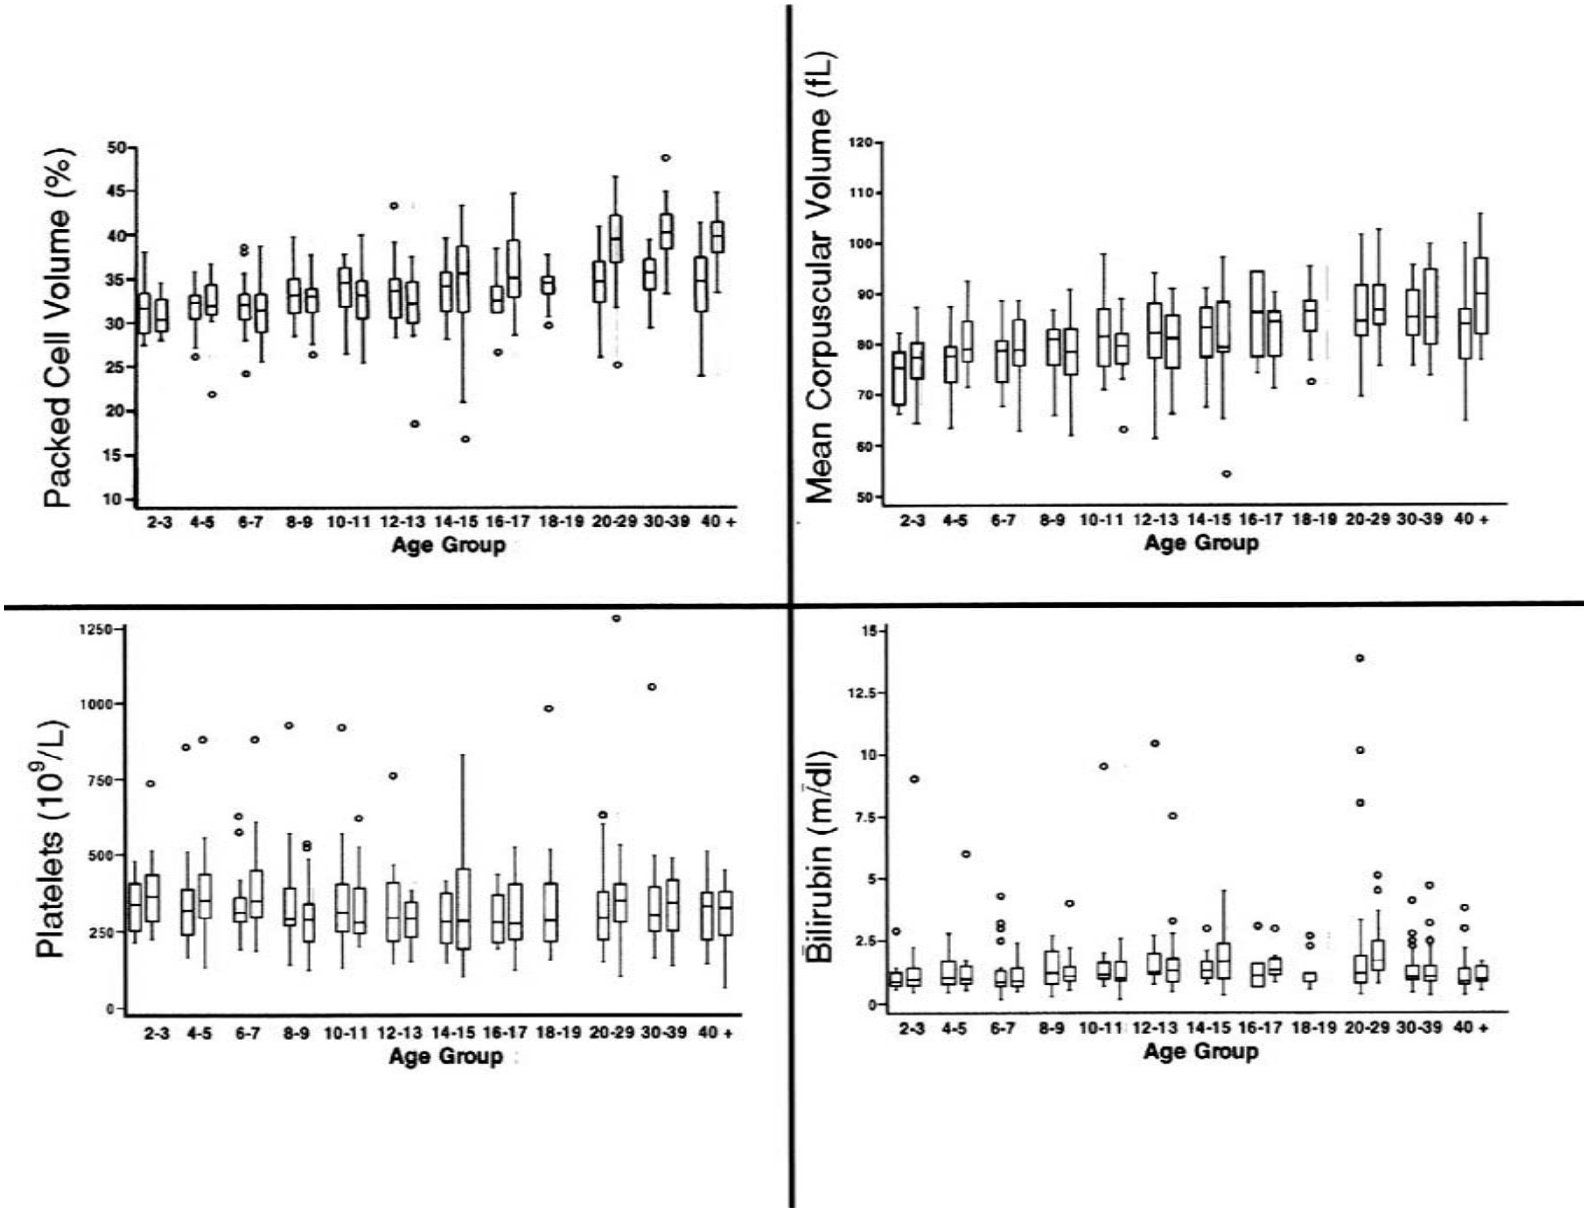

Figure 21.11. PCV, MCV, platelet count, and bilirubin levels in a cross-sectional study of patients with HbSC disease ages 2 years to older than 40 years. PCV, MCV, and reticulocyte counts were available for 586 patients and bilirubin for 467 patients. Box plots show the mean and 25th (bottom of box) and 75th percentile (top of box) of the data.[44]

children aged 2–5 years to approximately 37 in males older than 20 years, a level approximately five points higher than in females with HbSC disease. Many adult men, but fewer adult women, have a normal PCV.[44–46] Individuals with high PCV might be at greatest risk for complications such as proliferative retinopathy and osteonecrosis of the femoral head. Leukocyte counts in HbSC disease are normal or only very slightly elevated. Perhaps this is a result of more persistent splenomegaly, reduced hemolysis, and less proliferative activity of the bone marrow. Platelet counts are also lower in HbSC disease than in sickle cell anemia, perhaps for similar reasons. Some individuals with HbSC disease have mild thrombocytopenia, and this can often be related to an enlarged spleen.

Leukocytosis, thrombocytosis, and reticulocytosis have been linked to the severity of vasoocclusive disease in sickle cell anemia. Mature sickle cells circulate in the company of leukocytes, platelets, and "stress" reticulocytes that display adhesive ligands that facilitate erythrocyte–endothelial interactions. High granulocyte counts are a risk for mortality in sickle cell anemia. Perhaps some of the milder features of HbSC disease are accounted for by the lower numbers of activated neutrophils and platelets.

Bilirubin is usually normal and lactic dehydrogenase (LDH) levels are lower, reflecting mild hemolytic anemia compared with sickle cell anemia. Chromium-51 survival in HbSC disease was 13–26 days and DF ^{32}P mean lifespan was 29 days. Reticulocytes in HbSC disease ranged from less than 1%–7% supporting the lower hemolytic rate. As in sickle cell anemia, red cell volume was only modestly reduced, whereas plasma volume was more substantially elevated. Red cell survival, plasma volume, and PCV were unrelated to splenomegaly or splenic function.

Although hemolysis is only modest, compensation is incomplete. Mild anemia in HbSC disease cannot be entirely accounted for by the rate of red cell destruction because this does not exceed the potential of normal marrow to replace lost cells. In HbSC disease, the PCV and red cell mass average approximately 80%–85% of normal. As hypothesized for sickle cell anemia, it might be that increased P_{50} and enhanced tissue extraction of oxygen blunts erythropoiesis in HbSC disease. Although hemoglobin-oxygen affinity of hemoglobin isolated from HbSC disease red cells is normal, the whole blood P_{50} is increased to 32 mm Hg. Serum erythropoietin levels are higher than normal, but lower than found in sickle cell anemia.[47] These levels might be inappropriately low for the level of anemia and could also be due to subclinical renal disease or an inappropriate marrow erythroid response.

HbSC disease patients usually have HbF levels less than 2% but occasionally the HbF in adults is near 10%. HbF is unlikely to have a major affect on the hematology or clinical features of HbSC disease because of its low level in the majority of patients. In contrast to sickle cell anemia, individuals with HbSC and HbC disease, regardless of haplotype, have similar $^{G}\gamma$-globin chain levels despite different degrees of erythropoietic stress.

α Thalassemia, a known modulator of sickle cell anemia (Chapter 27), has a minor effect on the hematology of HbSC disease. Although coincident α thalassemia reduces the MCV by approximately 5 fl, there is little change in the hemoglobin concentration or HbF level.[48]

Growth and Development

Growth in HbSC disease is delayed, but less so than in sickle cell anemia. With access to reasonable nutrition, Tanner stages of adult sexual development are achieved at 14–16 and 16–18 years of age in young women and boys, respectively, 1–2 years earlier than in children with sickle cell anemia.[49] In some studies, HbSC disease does not appear to affect height, weight, and bone age.[50] A study of 298 children with sickle cell anemia and 157 children with HbSC disease revealed that after age 5 years, HbSC disease children had normal growth.

Mortality

A 1989 report indicated that 95% of patient's with HbSC disease in the United States survived to age 20 years.[51] These individuals were participants in the Cooperative Study of Sickle Cell Disease (CSSCD) (Chapter 19) and many attended comprehensive sickle cell centers, making it possible that they had more regular and skilled care than the general population of HbSC disease. Mortality in this series was greatest in children aged between 1 and 3 years, and was most often a result of pneumococcal sepsis. Another study, reported in 1990, in which 231 individuals with HbSC disease were compared with 785 sickle cell anemia patients, showed an age-specific death rate (per 100 person-years) up to age 30 years of less than one in HbSC disease compared with two–three in sickle cell anemia. Beyond this age, mortality in all patients increased. Nevertheless, the rate in HbSC disease was less than half that of sickle cell anemia.[52] In the largest study of mortality from the United States, the median survival in HbSC disease was 60 years for men and 68 years for women (Fig. 21.12).[53] Jamaican children with HbSC disease, diagnosed by cord blood screening, and so unlikely to represent a biased sample, had a 95% chance of surviving to age 2 years.

Two hundred eighty-four patients with HbSC disease, more than 80% of whom entered the study as children, were followed over a span of 40 years for nearly 3,000 person-years.[48] The median age of death in this study was 37 years and was unaffected by sex. Approximately 10% of patients died, and 60% of these entered the study prior to 1970. No single cause of death predominated. In another study of adults, the median age was 50 years.[54]

It has been theorized that since these reports, the mortality of sickle cell anemia has fallen in developed countries

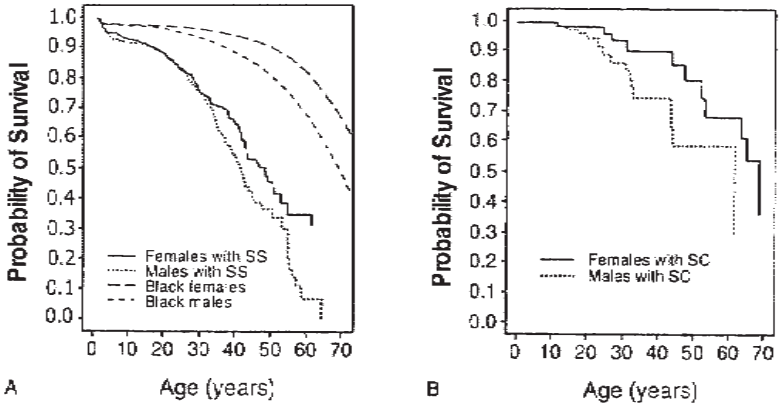

Figure 21.12. Survival curves comparing patients with HbSC disease (**A**) and sickle cell anemia (**B**).[110]

because of the widespread use of prophylactic penicillin, better supportive care for events such as acute chest syndrome and perhaps hydroxyurea. Penicillin prophylaxis is not uniformly used in HbSC disease and studies of hydroxyurea as a treatment for HbSC disease are just starting, so their effects on mortality are not known.

There are few data on risk factors for early death in HbSC disease. Median age of onset for irreversible organ failure like stroke, renal failure, and chronic lung disease, that might contribute to early mortality in HbSC disease is 10–35 years later than in sickle cell anemia.[52] Even in large series of patients, relatively small numbers of deaths occur in HbSC disease, making it difficult to assess the relationship of HbF, leukocyte count, and prior vasoocclusive episodes such as pain and acute chest syndrome to mortality. It is clear that HbSC disease has a pattern of survival that is different from sickle cell anemia. Increased mortality of HbSC disease is apparent only after age 20 years. Overall prognosis of HbSC disease is, therefore, better than that of sickle cell anemia.

CLINICAL EVENTS

Patients with HbSC disease can have all of the problems of sickle cell anemia but usually have a milder clinical course. A survey of 90 Jamaican patients with HbSC disease showed pathology similar to sickle cell anemia, but with generally reduced severity, except for retinal vascular disease. These findings might be a result of reduced hemolysis and higher hemoglobin levels in HbSC disease. In a pediatric cohort, 50% of HbSC patients were found to develop symptoms by age 5 years but 22% remained free of symptoms at age 10 years.[55] Approximately 40% of patients were found to have some chronic organ complication with a mean age of onset of approximately 30 years.[48]

Many individuals with HbSC disease are active in quite strenuous occupations. Some never have the occasion to seek medical attention for the unique events of sickle cell disease and have their diagnosis established incidental to another medical condition. Rarely, the presenting attribute of HbSC disease is calamitous, such as life-threatening acute chest syndrome, multiorgan failure, sepsis, or splenic sequestration. Therefore, although sometimes mild and needing little obvious medical supervision, HbSC disease should not be neglected. Patients with HbSC disease should be detected by neonatal screening so that they and their families can be enrolled in programs providing education about the potential complications of this disorder and the needed level of continued monitoring.

Sickle Retinopathy

Proliferative sickle retinopathy is perhaps the most typical vasoocclusive complication of HbSC disease (Fig. 21.13). More common in this genotype, where it is found in approximately a third of patients, than in sickle cell anemia where only 3% are affected, the pathology of this entity has been delineated in detail.[56,57]

Pathophysiology of Sickle Retinopathy. The primary site of vasoocclusion in sickle retinopathy was located at the precapillary level.[58] Hairpin loops, a neovascular formation that appeared to result from recanalization of occluded vessels and autoinfarcted preretinal neovascular formations are present. Small pigmented lesions consisting of retinal pigment epithelial cells ensheathing channels that resembled autoinfarcted vessels were also seen.

Macular blood flow velocity was compared in 18 patients with sickle cell disease and 45 normal controls and the relation between macular blood flow velocity and red blood cell density was examined.[59] Leukocyte velocity in the macular capillaries was negatively associated with a greater range of red cell density, suggesting that sickle red cell density heterogeneity might slow macular capillary blood flow.

The distribution and relative levels of components in the fibrinolytic system and growth factors in retina and choroid showed increased plasminogen activator inhibitor-1 immunoreactivity in retinal vessels compared with controls, whereas tissue plasminogen activator localization and immunoreactivity were similar.[60] Immunoreactive fibrin was often observed within the lumen of retinal and choroidal vessels and in choroidal neovascularization. Blood vessels containing fibrin generally exhibited elevated plasminogen activator inhibitor-1 immunoreactivity. Von Willebrand factor and basic fibroblast growth factor immunoreactivity were elevated in choriocapillaris and the walls of some retinal vessels. Transforming growth factor–β1 (TGF-β) immunoreactivity was significantly lower in

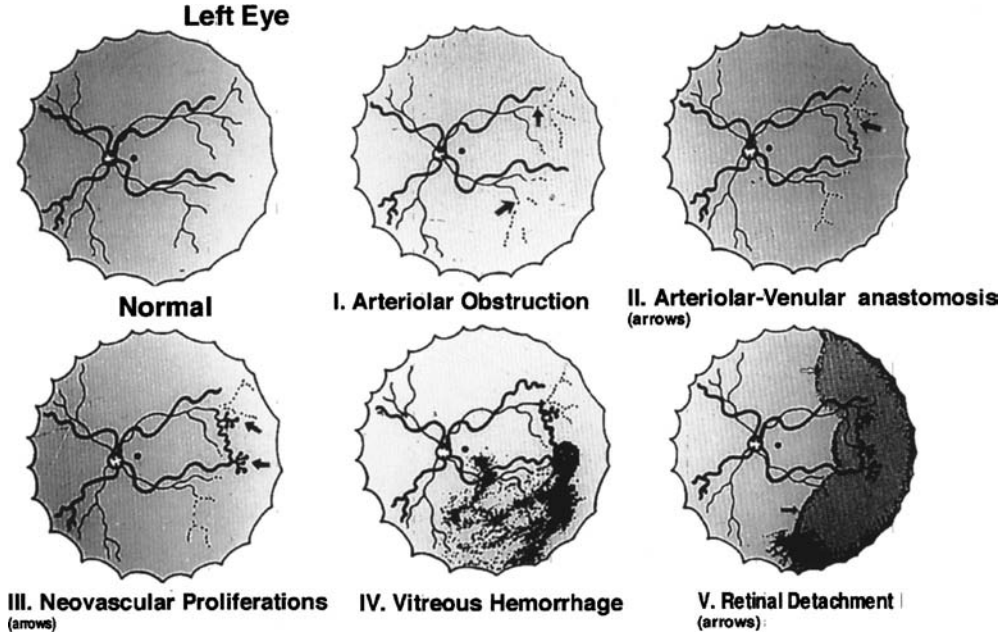

Figure 21.13. Stages of proliferative sickle retinopathy.

sickle cell choriocapillaris than in controls. In chorioretinal-pigmented lesions of an HbSC disease patient, basic fibroblast growth factor, TGF-β1, 2, 3 immunoreactivity was present within migrating retinal pigment epithelial cells. These data suggested that fibrin deposition within retinal and choroidal vessels of sickle cell disease subjects could occur due to elevated plasminogen activator inhibitor–1 activity. Vasoocclusion of choroidal vessels might influence the expression of growth factors in choriocapillaris endothelium, which could stimulate formation of choroidal neovascularization. Fibrosis and gliosis in and near chorioretinal-pigmented lesions, could be stimulated by migrating retinal pigment epithelial cell production of basic fibroblast growth factor and TGF-β.

Pigment epithelium-derived factor (PEDF) is an inhibitor of angiogenesis and a neurotrophic factor in the mammalian eye, and its level is related to retinal neovascularization Using tissue from normal eyes and subjects with sickle cell retinopathy, PEDF was mainly localized to the vitreous condensed at the internal limiting membrane, RPE-Bruch membrane-choriocapillaris complex and choroidal stroma in normal eyes. In sickle retinopathy, the ratio of PEDF/vascular endothelial growth factor (VEGF) was increased in the nonperfused area of the nonproliferative sickle cell retina and in eyes with proliferative sickle cell retinopathy. Elevated PEDF and VEGF immunostaining was present in viable vessels of sea fan neovascular formations and in feeder vessels of sea fans. Only PEDF was present in nonviable sea fans, suggesting that this might play an important role in inhibiting angiogenesis and inducing the regression of sea fans.[61]

Neovascularization is a common consequence of retina vasoocclusion. Morphometric analysis in postmortem ocular tissue from subjects with sickle hemoglobinopathies[62] showed numerous active and autoinfarcted lesions, representing virtually all stages in preretinal neovascularization. They ranged from single small loops extending from arteries and veins along the retinal surface to the typical complex, elevated sea fan formations. Sea fans developed at hairpin loops and at arteriovenous crossings. There was an average of 5.6 connections between sea fans and retinal vessels; of these, 45% were arteriolar, 52.5% were venular, and 2.6% involved capillaries. Autoinfarction appeared to occur initially within the sea fan capillaries. Preretinal neovascularization in sickle cell retinopathy might arise from both the arterial and venous sides of the retinal vasculature and assume a variety of morphological configurations. Multiple feeding arterioles and draining venules are common, and autoinfarction appears to occur initially at the preretinal capillary level rather than at feeding arterioles.

Plasma angiopoietin-1 and angiopoietin-2, soluble Tie-2, VEGF, soluble Flt-1, and von Willebrand factor were measured in patients with HbSC disease or sickle cell anemia who had proliferative and nonproliferative sickle retinopathy. In eight patients who received panretinal laser photocoagulation, plasma was obtained before and 6 months after treatment. Angiopoietin-1 and -2, VEGF, and von Willebrand factor were raised in all sickle cell patient groups compared with controls and only minor changes in were seen after treatment.[63] Angiopoietin-2, erythropoietin, VEGF, and soluble Tie-2 and VCAM were elevated suggesting a proangiogenic state. With painful crisis, only VCAM increased.[47]

Vasoocclusion in the retina has also been studied in transgenic sickle mice and in a rat animal model.[64] Retinal vascular occlusions resulted in nonperfused areas of retina and arteriovenous anastomoses. Intra- and extraretinal neovascularization was observed adjacent to nonperfused

areas. Retinal pigmented lesions were formed by the migration of retinal pigment epithelial cells into sensory retina, often ensheathing choroidal neovascularization. Bilateral chorioretinopathy was present in 30% of animals older than 15 months. These ocular histopathological changes mimicked many aspects of human proliferative sickle cell retinopathy and permitted the detection of choroid abnormalities not previously characterized. Forty-two percent of $\alpha^{H}\beta^{S}[\beta^{MDD}]$ (Chapter 12) mice without any proliferative retinopathy had retinal blood vessels containing red cell plugs visualized by endogenous peroxidase activity and lacked luminal horseradish peroxidase (HRP)–reaction product.[65] In sections from whole eyes of the same animals, foci of photoreceptor degeneration were associated with areas of choriocapillaris nonperfusion. In areas with normal photoreceptors, the choriocapillaris appeared perfused and HRP-reaction product was present.

In animals with proliferative chorioretinopathy, some neovascular formations lacked luminal HRP-reaction product, suggesting autoinfarction. Nonperfused retinal and choroidal vessels were observed in mice without retinal and choroidal neovascularization, whereas, all mice with neovascularization had nonperfused areas. Small foci of HRP loss were associated with areas of nonperfused choriocapillaris. These results suggest that sickle cell–mediated retinal vasoocclusion is an initial event in the chorioretinopathy and outer retinal atrophy.

Density separated, labeled HbSC and sickle cell anemia erythrocytes infused into rats were retained in capillaries. Dense cell retention was inversely dependent on pO_2.[66] Trapping, not adhesion, appeared to be responsible for retention of sickle cells in the normal retinal vasculature because of preferential retention of dense cells with a lower adherence propensity. Paradoxically, given the prevalence of retinopathy in HbSC disease, there was low retention of HbSC cells. Fractionated sickle erythrocytes were infused into rats that were either hypoxic or were given TNFα. Sickle erythrocytes were also preincubated with a peptide that inhibits binding of VLA-4 and α4β7 integrins to their ligands. Hypoxia caused retention of dense but not reticulocyte-rich sickle cells. TNFα significantly increased retention of all types of sickle cells, and this was inhibited by VLA-4 inhibition or by monoclonal antibodies against fibronectin, a ligand for VLA-4. Similar inhibition of retention was seen in retinal vessels when a VLA-4 inhibitor was used.[67]

These studies suggested that the mechanisms for retention of sickle cells in retina and choroid appeared identical and was the result of hypoxia-mediated retention of dense red cells and adherence of sickle reticulocytes after cytokine stimulation. TNFα-stimulated retention of sickle cells in choroid appeared to be mediated by VLA-4, presumably on the surface of some reticulocytes.[68]

The expression of the adhesion molecules ICAM-1, VCAM-1, and P-selectin, and the distribution and number of polymorphonuclear leukocytes were investigated in sickle cell retinopathy and compared with the normal retina. In cryopreserved postmortem ocular tissue from subjects with sickle cell disease and one control subject, increased ICAM-1, VCAM-1, and P-selectin immunoreactivities were observed in sickle cell subjects and the highest ICAM and P-selectin immunoreactivity was associated with intraretinal vessels adjacent to the preretinal neovascular formation in subjects with proliferative sickle retinopathy. VCAM-1 immunoreactivity was highest in intraretinal vessels adjacent to the newly forming sea fans. Old sea fans had the highest levels of VCAM-1. The increase in adhesion molecule immunoreactivity was paralleled by an increase in intraretinal neutrophils that increased with progression of the disease. These data suggest that adhesion molecule mediated leukocyte adhesion might play a role in sickle cell retinopathy.[69]

Table 21.2. Age-related prevalence of proliferative sickle retinopathy in HbSC disease

Age (y)	No. of patients	Percent with retinopathy
0–9	47	0
10–14	77	6
15–19	117	14
20–24	81	27
25–29	67	60
30–39	88	57
>40	56	70
Total	533	32

Using a noninvasive method to assess the velocity, adherence, and arterial/venous transit time of normal and sickle erythrocytes in retinal and choroidal vessels, labeled red cells can be observed in the retina of pigmented rats and on the choroid of albino rats. Normal density sickle cells were transiently retained in retinal vessels. Sickle red cells were retained in larger numbers, in some cases for extended periods of time, suggesting that the choroid–capillaris vasoocclusion can play an important role in sickle retinopathy.[70]

Prevalence. Age-adjusted prevalence of proliferative retinopathy in 533 patients with HbSC disease is shown in Table 21.2. The distinctive "black sea fan," "black sunburst" and salmon patches typify this disorder and characterize the hemorrhagic, infarctive, proliferative, and resolving lesions of sickle retinopathy. Conjoint effects of a higher PCV, increased cell density, and greater blood viscosity in HbSC disease could account for the higher prevalence of retinopathy in HbSC disease than in sickle cell anemia; it is also possible that the lower HbF levels of HbSC disease play a role.

Paradoxically, the high prevalence of proliferative retinopathy in HbSC disease might be an expression of the relative benignity of this genotype. A classification of the peripheral retinal vascular changes in sickle cell

disease, based on the appearance of the peripheral retinal vasculature has been proposed in which vessels are either "normal" (Type I) or abnormal (Type IIa or IIb) based on qualitative changes such as irregular vascular margins, capillary stumps, hyper- or hypofluorescence, and capillary bed thinning.[71] This classification is based on the observation that proliferative retinopathy develops in response to progressive closure of the vessels of the peripheral retina, and, the recession centripetally, of the margin of retinal perfusion.[72,73] Abnormal peripheral retinal vasculature is present in approximately 80% of adults with HbSC disease.[74] By age 17 years, the prevalence of abnormal vascular borders is approximately 60%.[71] More than 260 patients with sickle cell anemia and 154 with HbSC disease were studied with serial fluorescein angiography and retinal photography, beginning at ages 6–12 years. In the teenage years, each year there is a 6% conversion from a normal to abnormal vascular border. The occurrence of sickle proliferative retinopathy was always associated with an abnormal vascular border.

In sickle cell anemia, peripheral retinal vessels are occluded early in the course of disease so that further retinal vascular damage and proliferative lesions cannot develop. The enhanced circulatory competence of the HbSC disease cell could preserve this retinal circulation, permitting the later development of proliferative lesions. If this is true, as hydroxyurea treatment (Chapter 30) makes sickle cell anemia cells more like HbSC disease cells and improves their circulatory competence, the prevalence of proliferative retinopathy could begin to increase in young sickle cell anemia patients treated with this drug.

Diagnosis. Sickle retinopathy is recognizable by its different stages, which include nonproliferative lesions and three stages of proliferative lesions including neovascularization, vitreous hemorrhage, and retinal detachment. Whether or not there is an orderly progression from less to more serious stages that precede retinal detachment and blindness or whether catastrophic changes can arise directly from early stages of proliferative retinopathy is not well characterized. Characteristically, following vasoocclusion in the peripheral vessels of the retina – the nonproliferative stages of retinopathy – neovascular malformations called black sea fans grow from the retinal surface into the vitreous. These fragile new vessels can leak blood into the vitreous, at times in amounts sufficient to reduce vision. Organization of vitreal hemorrhages exerts traction on the inelastic retina, causing tears and allowing vitreal fluid to enter the subretinal space. Retinal detachment, a potential consequence of subretinal fluid invasion, can produce blindness. Of 14 patients with HbSC disease who were selected for study because they had nonproliferative lesions or peripheral retinal arteriolar occlusion or arteriovenous anastomoses, 21% developed new sea fans with an average interval of 18 months (range 8–36 months). Based on these rather small numbers of patients, the authors estimated that approximately 14% of young adults with HbSC disease develop neovascularization each year.[75] Complicating the evaluation of retinopathy in HbSC disease is the propensity for spontaneous regression of proliferative lesions due to autoinfarction.[76] These authors caution, however, that withholding treatment in the hopes of a spontaneous regression is dangerous because the incidence of spontaneous vitreal hemorrhage increased from 28% to 44% in patients observed for 6–77 months.[77]

Table 21.3. Prevalence of ocular lesions in HbSC disease

Ocular lesion	Percent
Nonproliferative	
Salmon patch	17
Iridescent spot	28
Black sunburst	62
Proliferative	
Stage III-Neovascularization	45
Stage IV-Vitreous hemorrhage	21
Stage V-Retinal detachment	10

Progression. Patients picked randomly from a clinic population, were enrolled and followed with annual or semiannual detailed ophthalmological examinations.[78] Initially, 11 patients had stage III retinopathy and their average duration of follow-up was 7 months. Twelve patients had normal findings or stage I or II disease (Table 21.3). The natural history of proliferative retinopathy in HbSC disease compared with sickle cell anemia in patients who presented with stage III disease is shown in Table 21.4. Forty-eight percent had proliferative disease on initial examination and 74% developed stages III–V disease at final examination; there was little change over time in the prevalence of nonproliferative retinopathy in either HbSC disease or sickle cell anemia patients.

In studies from Jamaica, 115 patients with HbSC disease were followed sequentially.[79] Efforts were made to ensure that this was a random sample of HbSC disease patients. Proliferative retinopathy was present in 24% of patients at the initial examination, arose de novo during the study in 18%, and was present at the final examination in 40%. The mean age of patients showing progression was 27.7 years. Of 43 individuals, 58 new lesions were found in 18 patients

Table 21.4. Natural history of proliferative retinopathy in sickle cell disease

Table 21.5. Evolution of proliferative retinopathy in HbSC disease according to patient age

Age (y)	Eyes (no.)	Progression (%)	Regression (%)	Stable (%)
10–19	10	40	30	30
20–29	47	60	17	23
30–39	56	43	27	30
>40	24	29	4	67

younger than 25 years, and the highest risk period was between ages 20 and 24 years. Two thirds of patients with de novo proliferative lesions were aged 15–29 years. Approximately one-third to half of patients had autoinfarction during the course of the study. From ages 10 to 39 years, approximately 7% of individuals in each 5-year age bracket developed proliferative retinopathy per 100 patient-years of observation.[80] In follow-up, progressive disease was most frequent between ages 20 and 39 years, and visual loss occurred in only 9% of patients followed for a mean of 4.5 years.[81] (Table 21.5)

A longitudinal study spanning 20 years was performed in 307 children with sickle cell anemia and 166 children with HbSC disease detected by newborn screening. Participants had annual ophthalmological studies with angiography and angioscopy. Proliferative retinopathy developed in 14 patients with sickle cell anemia and 45 with HbSC disease, unilaterally in 36 patients and bilaterally in 23. The incidence increased with age in both genotypes, with crude annual incidence rates of 0.5 cases per 100 sickle cell anemia and 2.5 cases per 100 HbSC disease patients. By the age of 24–26 years, proliferative retinopathy had occurred in 43% of the subjects with HbSC disease compared with 14% of those with sickle cell anemia. Patients with HbSC disease and unilateral disease had a 17% probability of regression and a 13% probability of progressing to bilateral disease. Those with bilateral had half the chance of regression as those individuals with unilateral disease. Visual loss occurred in only 1 of 82 affected eyes and one required detachment surgery with recovery of normal visual acuity.[82]

In one study, 30% of patients with HbSC disease had retinopathy with a median age of onset of 28 years.[48] Data suggested that the CI β^C haplotype and Benin β^S-globin gene haplotype carriers with the CI β^C haplotype had a delayed onset of retinopathy. The numbers of cases were small and a physiological explanation for these observations was not forthcoming. Similarly, coincident α thalassemia appeared to decrease the incidence of retinopathy, but less than 30 cases were examined.

Treatment Recommendations

Management of sickle proliferative retinopathy is imperfect. Incipient proliferative disease has been treated with focal or panretinal section photocoagulation to forestall advancing pathology and impaired vision. Some of the earliest comparative trials were inconclusive and questioned the role of photocoagulation, but different techniques of treatment and new technologies now make these results difficult to interpret.[83] There are presently no data that conclusively show that prophylactic photocoagulation significantly changes the natural history of retinopathy.[78] In a randomized trial of argon laser scatter photocoagulation, 99 eyes were treated and 75 eyes served as controls, with an average follow-up of approximately 45 months.[84] There was complete or partial regression of sea fans in 81% of treated eyes and spontaneous regression in 46% of control eyes. New sea fans developed in 34% of treated compared with 41% of control eyes. Using the criteria of visual loss, five control eyes and three treated eyes lost vision during follow-up, an insignificant difference similar to that seen in an observational study. Also, the incidence of retinal detachment was not reduced.

Some data suggest that proliferative retinopathy is most prevalent in individuals with higher hemoglobin levels. Phlebotomy to reduce the hemoglobin concentration to 9–10 g/dL has been advocated as a measure to prevent retinopathy or slow its advancement without evidence of the efficacy of this approach.

In summary, proliferative retinopathy occurs often in patients with HbSC disease aged between 15 and 30 years, is progressive, can culminate in visual loss, and does not have a definitive treatment that can eliminate its most severe endpoints. Consultation with ophthalmologists experienced in managing this complication is vital.

Painful Episodes

In a given year, more than half of 806 patients with HbSC disease did not have a painful episode, one-third had a single episode of pain and less than 10% had three or more pain episodes.[85] This rate was approximately 0.4 episodes per patient-year, less than half the rate in sickle cell anemia. Forty percent of Jamaican patients with HbSC disease had at least one pain episode needing hospitalization; 17% never reported a pain crisis. Approximately 60% of HbSC disease patients in Los Angeles reported at least one pain episode.[48]

Acute Chest Syndrome

Acute chest syndrome, with its high morbidity and appreciable mortality, is seen in approximately 30% of patients with HbSC disease.[48] Although this incidence is only 50%–75% that of sickle cell anemia, progression to chronic lung disease is only 0.1 that of sickle cell anemia and the median age of onset is almost one decade later.[52,86] The incidence per 100 patient-years in patients of all ages is 5.2. Typical of this condition, the incidence in children age 5 years or younger is twice that of older individuals. Only steady-state leukocyte count was a risk factor for acute chest syndrome in HbSC disease. When compared with

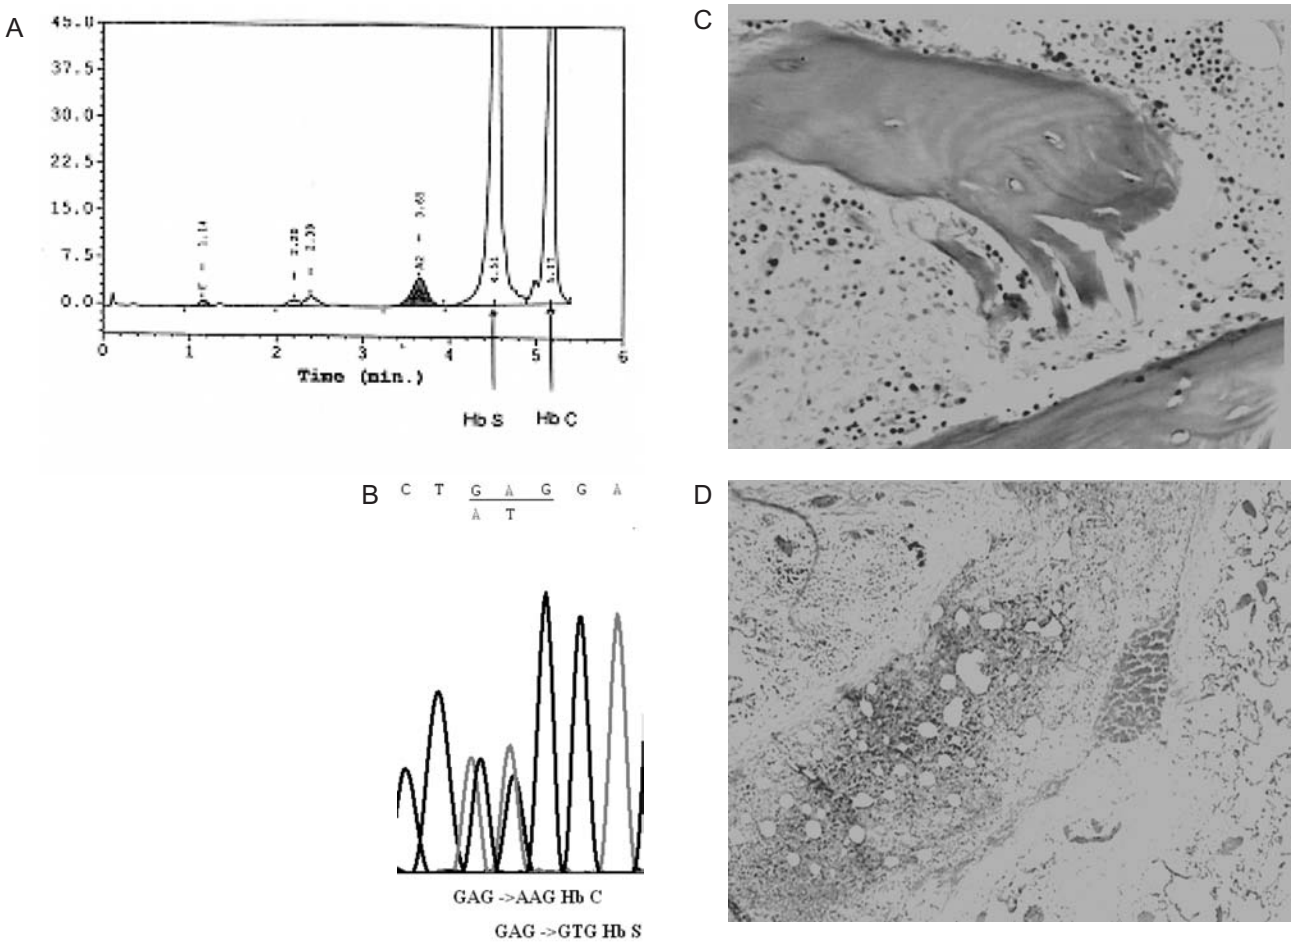

Figure 21.14. A 52-year-old man with HbSC disease and known osteonecrosis and sickle retinopathy who was never hospitalized for painful episodes; he developed severe pain in his extremities and chest and shortness of breath. The hemoglobin level was approximately 10 g/dL and white blood cell count of 25,000/mL^3. The pain soon became unbearable; he became severely hypoxic and comatose and the hemoglobin concentration and platelet count plummeted. Oxygenation was impossible to maintain and despite rapid use of blood transfusions and supportive care he died within hours of presentation with multiorgan failure. **(A)** HPLC separation of HbS and HbC. **(B)** Portion of a DNA sequencing reaction showing compound heterozygosity for HbS and HbC in *HBB* codon 6. **(C)** Bone marrow showing necrotic marrow. **(D)** Lung showing bone marrow emboli in pulmonary arteries.

sickle cell anemia, there were no differences in duration of hospitalization or death rate, but sickle cell anemia patients were more likely to present with severe pain.[87] Nevertheless, severe acute chest syndrome events due to embolization of necrotic bone marrow can occur and can terminate in multiorgan failure and death (Fig. 21.14).

Pulmonary Hypertension

The first reports of pulmonary hypertension in sickle cell disease considered HbSC disease and sickle cell anemia as a group.[88,89] More recently, in an analysis of 43 HbSC patients screened by echocardiography for pulmonary hypertension, the mean age of affected individuals was 52 years. Within this group, anemia, but not markers of hemolysis such as LDH was associated with the pulmonary hypertension phenotype. As with sickle cell anemia, pulmonary hypertension was associated with a higher risk of death.[90]

Spleen

Splenic function is often preserved in HbSC disease, whereas it is rarely preserved in adults with sickle cell anemia. A positive result of retained splenic function is the reduced incidence of infection with encapsulated bacteria. A negative result is the chance for splenic sequestration crises and splenic infarction to occur in adults.

Pocked or "pitted" red cells are found in increased numbers when splenic function declines and is lost, and can be used as a measure of functional asplenia. When pitted red

cell counts were used to evaluate splenic reticuloendothelial function in HbSC disease, there were 4.9 ± 9.1% pitted cells in this disorder compared with 11.8 ± 7.0% in sickle cell anemia; however pitted cells might not always reflect splenic function. Pitted cells increased with age in sickle cell anemia but did not in HbSC disease suggesting they had stabilized splenic function.

Six percent of children with HbSC disease had splenic complications that included acute sequestration crisis, painful infarction, and hemorrhage.[91] Similar events can occur in adults with HbSC disease but are rare in adult sickle cell anemia. Slightly over one half of all adults with HbSC disease had splenomegaly, 36% were asplenic, and 12% had normal spleens when evaluated by spleen scanning. When "pit" counts were related to spleen scans, no patient with HbSC disease younger than age 4 years had functional asplenia, although this abnormality was present in 22% of individuals aged 4–12 years and 45% of individuals older than 12 years.[92]

Coexistent hereditary spherocytosis and HbSC disease were deemed responsible for multiple episodes of splenic sequestration crises in one interesting case report. It was hypothesized that the increased density and reduced deformability of red cells with membrane damage from both hereditary spherocytosis and HbSC disease caused increased splenic trapping and sickling.

Infection

The relative risk of bacteremia is less for HbSC disease patients than for sickle cell anemia patients when correction is made for the total nonhospitalized population at risk, but is much larger than that for the normal population. Gram-negative bacteremia, the systemic infection most commonly found in HbSC disease patients, was less life threatening than the pyogenic bacteremia most commonly found in sickle cell anemia. In children age 4 years and younger, normal "pit" counts suggested that prophylactic penicillin need not be given.[92] Two adolescents with functional asplenia were reported to die of pneumococcal sepsis. Fatal pneumococcal sepsis has been described in children age 5 years and younger who were not receiving penicillin but their state of splenic function was unknown.[93]

Treatment Recommendations

Some authorities question the use of prophylactic penicillin in HbSC disease.[94] A reasonable approach in children who are most susceptible to pneumococcal infection might be to assess splenic function by "pit" counts, the presence of Howell–Jolly bodies or radionuclide scanning. If splenic function is normal, prophylaxis might be withheld; however, as discussed, the evaluation of splenic function is imperfect. Also, a large spleen does not always equate with a normally functional spleen. Pneumococcal vaccines should be given and as in sickle cell anemia, parents instructed to seek immediate medical attention for febrile illnesses.

Osteonecrosis

The incidence of osteonecrosis in HbSC disease is only slightly lower than in sickle cell anemia with an age-adjusted incidence rate of 1.9/100 patient-years for the hip joints and 1.7/100 patient years for shoulders. Shoulder disease was uncommon in patients younger than age 25 years. Osteonecrosis of the femoral heads was almost as prevalent in HbSC disease as in sickle cell anemia but developed later in life.[46,52,95] The estimated age at diagnosis in HbSC disease varied from 36 to 40 years versus 36 years for sickle cell anemia.[48,95] In one study, coincident α thalassemia delayed the age of onset by approximately 15 years.[48]

Leg Ulcers

Compared with sickle cell anemia, leg ulcers are infrequent in HbSC disease and found in only approximately 3% of cases.[48,96] As in the case of priapism, this could be a result of improved nitric oxide (NO) bioavailability because of reduced hemolysis in HbSC disease compared with sickle cell anemia.

Genitourinary

The pathophysiology of renal lesions in HbSC disease is similar to that in HbAS and sickle cell anemia. Hematuria is often present and appears to be more frequent than in HbAS.[2] In HbSC disease, renal concentrating ability is lost at a time intermediate between the loss in sickle cell anemia and HbAS. Maximum concentrating ability in patients with HbSC diseases, mean age 30 years, was 537 mOsm and appeared to decline with age. The two youngest patients, aged 6 and 8 years, had maximally concentrated urines of 640 and 698 mOsms, approximately 60% of normal. In eight children with HbSC disease, mean age 11 years, none had an overnight urine concentration greater than 545 mOsm (normal, 800–1000 mOsm). Seven of eight increased their urine concentration after receiving 1-desamino-8d-arginine vasopressin, although not to normal.[97]

Renal function deteriorates with age but chronic renal failure is half as common as in sickle cell anemia (2%–3%) and its median age of onset is 25 years later.[44,48] In one study, 73% of 27 patients had papillary necrosis based on calyceal blunting by intravenous pyelography, but renal function was normal so the clinical significance of this observation is unclear.[98] Among 25 deaths in 284 HbSC disease patients, three were due to renal failure.[48]

Priapism has been estimated to occur in between 3% and 10% of patients with HbSC disease, a rate far lower than in sickle cell anemia.[48,99] Among other possible explanations, the reduced hemolysis in HbSC disease compared

with sickle cell anemia with better NO bioavailability might explain this observation.[99]

Cerebrovascular Disease

Two percent to 3% of HbSC disease patients had a stroke, and 3 deaths due to stroke were noted among 248 patients.[48,52] This incidence was three–four times less than in sickle cell anemia. In the CSSCD, 0.8% of individuals with HbSC disease compared with 4% of patients with sickle cell anemia had suffered a stroke at study entry.[100]

Pregnancy

Perinatal mortality in HbSC disease has been reported to vary from 28%–nil in the absence of transfusions and from 0 to 9% when transfusions were given.[101] In a heterogeneous collection of patient series with widely different numbers of cases, more recent reports generally had lower mortality. Pregnancy-related complications are higher than in normal controls and not dissimilar to those with sickle cell anemia. The rate of caesarian sections is similar.[102] Stress or pregnancy might result in disease symptoms, and the pregnant HbSC disease patient can be as severely affected as the sickle cell anemia patient. In 95 pregnancies in 43 patients with HbSC disease followed from birth, menarche was marginally delayed compared with controls, but the age at first pregnancy was similar. The prevalence of pregnancy-induced hypertension, preeclampsia, antepartum or postpartum hemorrhage did not differ from controls. Sickle-related complications were similar to those in patients with sickle cell anemia with marginally fewer miscarriages, more live deliveries, and higher birthweight.[103]

Pregnancy and recommendations for its management are discussed in detail in Chapter 19.

HbSC/Hb-G Philadelphia

This genotype has a special phenotype because the hybrid molecule, $\alpha_2^{\text{G-Philadelphia}}\beta_2^{C}$ increases the rate of crystal nucleation compared with native HbC, and HbS enhances this effect in a pathogenetically relevant manner.[16] Heterozygotes for the β^S, β^C, and the $\alpha^{\text{G-Philadelphia}}$ genes have abundant circulating intraerythrocytic crystals and increased numbers of folded red cells with a mild clinical course. This phenotype seems to be the result of increased crystallization and decreased polymerization caused by the effects of the $\alpha^{\text{G-Philadelphia}}$ globin chain on the β^C and β^S gene products. Some of the intraerythrocytic crystals in this syndrome, unlike the typical crystal of HbSC disease, are unusually long and thin and resemble sugar cane (Fig. 21.15). A mild clinical course associated with increased crystallization implies that in HbSC disease polymerization of HbS is pathogenically more important than the crystallization induced by β^C chains.

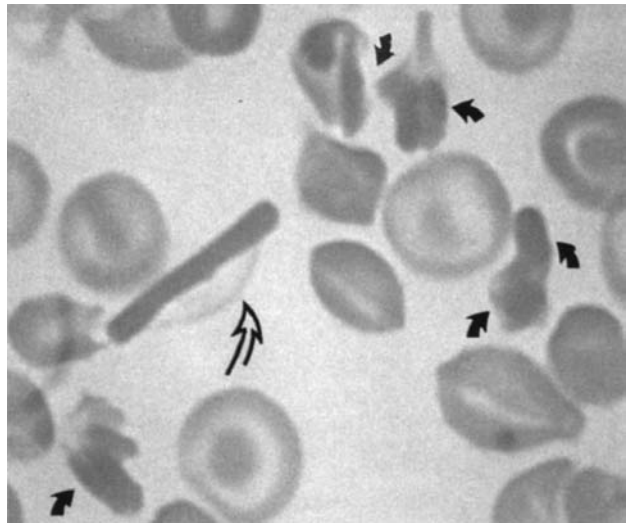

Figure 21.15. Blood smear directly from finger stick blood from a patient with $SC^{\alpha G\ \text{Philadelphia}}$ disease. Open arrow, depicts a "sugar cane" crystal, a shape not observed in HbC disease or HbSC disease blood. The black arrows depict red cells with more classic forms of HbC-dependent crystals.[16]

TREATMENT OF HbSC DISEASE

No currently available treatment is unique for HbSC disease. The special pathophysiological features of HbSC disease might in the future allow a direct attack on some basic disease mechanisms such as K:Cl cotransport (Chapter 9 and 31), but these approaches are still under study. Hydroxyurea can effect changes in the HbSC disease erythrocyte that might be independent of any change in HbF. Early trials of hydroxyurea in HbSC disease are discussed in Chapter 30.

Transfusions are used in HbSC disease for the same indications as in sickle cell anemia. A study was performed on preoperative transfusion in HbSC disease.[104] Eighteen percent of all patients had some postoperative complications. Postoperative events were compared between patients who received preoperative transfusions and those who were untransfused. In patients undergoing intraabdominal surgery, more than a third of untransfused patients had postoperative acute chest syndrome or painful episodes. Although this study was not randomized and both simple and exchange transfusions were used, based on these observations and the larger study of preoperative transfusion in sickle cell anemia,[105] preoperative transfusion should be considered in patients with HbSC disease who face procedures with moderate surgical risk.

Because some patients with HbSC disease have PCVs that approach normal, in emergent situations such as severe acute chest syndrome or stroke, or when preparing a patient for surgery, exchange transfusions might be the most prudent approach to treatment so as not to unduly raise the PCV and increase blood viscosity.

Because of the higher PCV, phlebotomy has been considered one approach to treating HbSC disease. In one patient, the PCV rose following splenectomy and the rate of acute painful episodes increased. Following a phlebotomy program to lower the PCV to presplenectomy values and induce iron deficiency, the symptoms regressed.[106] A controlled trial of this approach has not been reported.

SUMMARY

Positively charged HbC induces cellular changes in HbC trait, HbC disease, and HbSC disease that are a result of cellular dehydration. Although biologically interesting and producing characteristic hematological features in the erythrocyte, only trivial clinical abnormalities are associated with HbC trait and HbC disease. This is not so when HbC is present with HbS. HbSC disease is a clinically important illness with all of the complications of sickle cell anemia, albeit at a reduced rate. An effective treatment would be a major medical advance and clinical trials of agents that can reduce cell density and increase HbF concentration have started.

Sickle Cell Trait

Martin H. Steinberg

INTRODUCTION

Parents of children with sickle cell anemia seldom have the same disease as their offspring. In 1927, 17 years after the first clinical description of sickle cell anemia, it was discovered that almost 10% of African Americans had erythrocytes that sickled when deoxygenated. With the subsequent identification of HbS, and the observation that patients with sickle cell anemia had predominantly HbS in their hemolysates, whereas their parents' had both HbS and HbA, the genetics of sickle hemoglobinopathies was characterized and sickle cell trait (HbAS) was defined.

Almost 40 years ago, reports of sudden death in military recruits with HbAS triggered a push for mandatory screening for HbAS, denial of military service for some carriers, and insurance coverage cancellation for others. An astounding list of complications of HbAS appeared in the literature. The interpretation of these reports often disregarded the distinction between statistically significant associations and coincidence, and almost all lacked any control comparisons. This chapter reviews what is known, what is presumed, and what is erroneous about the pathogenicity, clinical features, and management of HbAS.

PATHOGENESIS

HbAS is usually implies simple heterozygosity for the HbS gene (*HBB* glu6val). Less than half the hemoglobin in the HbAS erythrocyte is HbS; the remainder is mainly HbA. The probability that the mixed hybrid tetramer, $\alpha_2\beta^S\beta^A$, will enter the polymer phase is only half that of the HbS tetramer, $\alpha_2\beta^S{}_2$ (Fig. 22.1A).[1] HbS polymer concentrations sufficient to injure the red cell are prerequisite for the expression of the phenotype of sickle cell disease; in HbAS, high concentrations of HbA preclude clinically significant HbS polymer formation at the oxygen saturation and physiological conditions present in most tissues (Fig. 22.1B). HbS polymer appears in HbAS cells only when oxygen saturation falls below 60%. Even when HbAS blood is completely deoxygenated, the polymer fraction is only 40% of total hemoglobin. HbAS should therefore be clinically benign, and, despite the multitudinous reports of innumerable complications associated with HbAS, very few are confirmed by careful epidemiological studies.

Diagnosis

Indications for detecting HbAS in at risk populations are limited and include genetic counseling, population surveys, evaluating hematuria, planning treatment of hyphema, pregnancy, and perhaps before complicated thoracic surgery.

Detecting HbAS requires the quantification HbS and HbA in a hemolysate. This is best accomplished by high-performance liquid chromatography (HPLC) (see Chapter 28), in which the presence and ratio of HbS to HbA are accurately determined. Isoelectric focusing does not provide quantitative data. DNA-based methods definitively detect the presence of both HbS and HbA genes but are usually unnecessary if all one desires to establish is the presence of HbAS. HbAS cannot be diagnosed by medical history, clinical examination, or routine laboratory testing. Neither hematological indices nor peripheral blood film reviews are useful for diagnosis because both are normal in HbAS. With rare exception, the sickle solubility test has no role as a primary screening test or as the sole means of detecting HbS. This test indicates only the presence of HbS and cannot reliably distinguish between HbAS, sickle cell anemia, and HbS–β^+ thalassemia. Table 22.1 shows the prevalence of HbAS in some locations in African and throughout the world.

Fetal hemoglobin (HbF) levels are usually normal in HbAS. Carriers of HbAS in whom the HbS gene is on a Senegal or Arab–Indian β-globin gene haplotype chromosome (Chapter 27) can have higher HbF levels than other individuals, but they remain within the normal range.[2] HbF and F cells (erythrocytes containing HbF) can be increased in individuals with both HbAS and coincident hereditary persistence of fetal hemoglobin (HPFH) due to point mutations in the γ-globin gene promoters (Chapters 16 and 17).

HbS Concentration in HbAS

Effects of α Thalassemia

The proportion of hemoglobins in the erythrocyte depends on the transcriptional rate of each globin gene, the stability of the mRNA and hemoglobin produced, and the post-translational assembly and stability of the αβ dimer and hemoglobin tetramer.

αβ Dimers rapidly associate into tetramers, and oxyhemoglobin tetramers dissociate into dimers. Hybrid tetramers ($\alpha_2\beta^S\beta^A$) occur in HbAS. Normally, a slight excess of positively charged α chains are always available to bind

Table 22.1. Prevalence of HbAS in world populations

Region/country		Prevalence (%)
Africa	North Africa	1.3–6.3
	West Africa	13.2–24.4
	Central Africa	5.1–24.5
	East Africa	2–38
	Southern Africa	0.8–20
Middle East, Central Asia, & India	India	20 (in affected tribal populations)
	Transcaucasia	0.5–1
	Turkey	13 (Eti-Turks)
	Iran	
	Saudi Arabia	1–60
Europe	Greece	0–32 (mean =11 in the north)
	Italy (Sicily)	2–4
	Portugal	
United States	United States	8–9 (African Americans)
	Amerindians	rare
South America	Brazil	4–8
Caribbean		7–14 (excluding Puerto Rico)
Central America		1–20 (dependent on racial origin of population examined)

Data from Africa are summarized from the work of many investigators and adapted from ref. 24.

non-α chains. Therefore, the steady-state accumulation of hemoglobin tetramers in the erythrocyte depends predominantly on expression of the non-α-globin genes. Hemoglobin dimers are assembled by the electrostatic attraction of α- and non-α-globin chains.[3] β^S-Globin chains are more positively charged than β^A chains, and therefore, bind α chains less avidly, accounting for HbS levels in heterozygotes (and levels of other positively charged hemoglobin variants also) being less than the 50% expected based on gene dosage alone.

HbAS carriers with four α-globin genes usually have 40% ± 4% HbS. The percentage of HbS can be altered by an α-globin gene mutant, a β-globin gene variant *trans* to the HbS gene (or very rarely in *cis*), β thalassemia, iron deficiency anemia, and possibly lead poisoning and megaloblastic anemia.

HbS concentration in HbAS is trimodally distributed, with peaks at 30%, 35%, and 40%.[4] This distribution, with few exceptions, is determined by the number of α-globin genes. Mild forms of α thalassemia are extraordinarily common where HbS is prevalent (Chapters 13 and 14). Individuals with HbAS who have α thalassemia exhibit HbA/HbS ratios less than 40%. The ratio of α/β globin biosynthesis in three families with a proband with HbAS–α thalassemia is shown in Figure 22.2. As α thalassemia reduces the pool of available α-globin chains, β^A- and β^S-globin chains must compete for those available and β^A chains dimerize twice as effectively with α chains as do β^S chains. When α gene triplication or quadruplication increases the number of α-globin chains, the HbS level increases beyond 40% due to the augmented pool of available α-globin.[5] These relationships are shown in Table 22.2. Individuals with the $-\alpha^{4.2}$ deletion have lower HbS levels than those with the more common $-\alpha^{3.7}$ deletion because of the greater α-globin chain deficit associated with the former type of α thalassemia (Chapter 13). Homozygotes for the $-\alpha^{4.2}$ with HbAS deletion have approximately 20% HbS.

Rare individuals with HbAS have only a single α-globin gene, or HbH disease.[6,7] They have HbS levels of approximately 20%, mild anemia, and marked microcytosis,

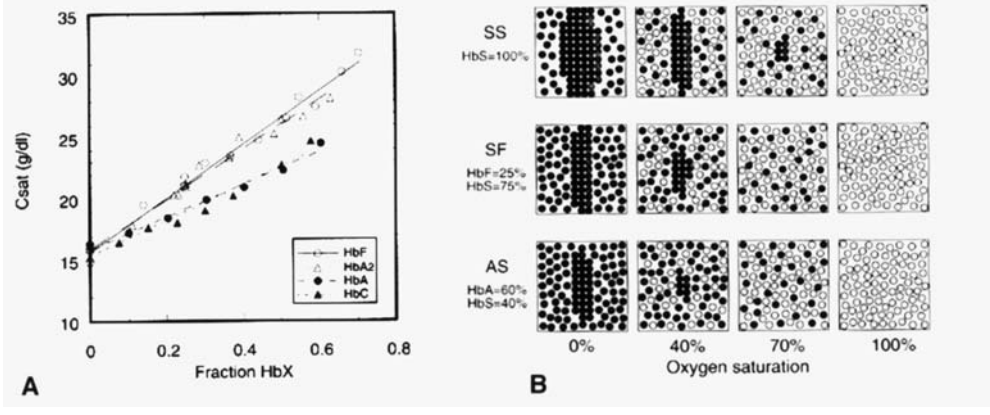

Figure 22.1. (A) Solubility of deoxygenated hemoglobin mixtures. Other hemoglobins prevent HbS polymerization by increasing HbS solubility (Csat). The percentage of increase in solubility reflects the likelihood of the other hemoglobin type being included in the deoxy HbS polymer. Neither the γ-globin chain of HbF nor the δ-globin chain of HbA_2 is incorporated into the polymer phase, so HbF and HbA_2 inhibit polymerization more than do HbA and HbC. From ref. 71, with permission. **(B)** Effects of HbA and HbF on HbS polymerization. Closed circles indicate fully deoxygenated hemoglobin and open circles indicate fully oxygenated hemoglobin. Polymer is indicated by stacked closed circles. (From ref. 71, with permission.)

Table 22.2. Hematology and percentage of HbS in HbAS with α thalassemia or β thalassemia

α-Globin genotype	Hemoglobin (g/dL)	MCV (fL)	α/β* biosynthesis	HbS§ (%)
ααα/αα	N	N	–	45
αα/αα	N	N	1	40
-α/ααα	N	N	–	40
-α/αα	N–low N	75–85	0.85	35
--α /αα$^{\text{codon 62 GTG>TG}}$##	12	73	–	28
--/αα¶	?	?	?	?
-α/-α	N–low N	70–75	0.75	30
--/-α	7–10 g/dL	50–60	0.50	20–25
HbAS with β$^+$ Thalassemia in Trans or in Cis				
β$^+$ Thalassemia Cis	12–13	65	1.50	10
β$^+$ Thalassemia in Trans (see Chapter 23)				

Modified from ref. 4. N signifies normal levels. * Ratio of radioactivity incorporated into α-globin chains vs. β-globin chains during incubation of reticulocytes with radioisotopes. The normal α/β ratio is 1 ± 0.15. Lower ratios suggest the presence of α thalassemia and higher ratios, β thalassemia. ## This single case is associated with a novel frameshift mutation.[116] ¶ This genotype has not been reported with HbAS. § Remainder of hemoglobin predominantly HbA.

Most values represent means from several studies. Although approximately 50 patients with HbAS and the αα/αα genotype, 40 with the -α/αα genotype, and 20 with the -α/-α have been studied, far fewer with the other genotypes have been examined, so the data presented should be interpreted with caution. HbS with β$^+$ thalassemia assumes a normal α-globin genotype.

but no detectable HbH. It might be that in the presence of only a single normal β-globin gene, the high affinity of α-globin chains for the limited β^A-globin chains and the instability of a β^S teramer preclude HbH (β_4) formation. Heterozygotes for HbC (*HBB* glu6lys) and HbE (*HBB* glu26lys) have similar reductions in the level of the variant hemoglobin when α thalassemia coexists (Chapters 18 and 21).

Occasionally, α thalassemia is caused by a point mutation in either the α_1 or α_2 gene (*HBA1, HBA2*) (Chapter 13). When these mutations are present in individuals with HbAS, the level of HbS is likely to be dependent on the suppression of α-globin synthesis and the particular α-globin gene that is affected, but few data are available.

Iron deficiency selectively inhibits the translation of α-globin mRNA and can produce an acquired form of α thalassemia. Depending on its severity, iron deficiency can mimic HbAS–α thalassemia by depressing HbS levels and causing microcytic erythrocytes. In vitro and perhaps in vivo, lead can do the same.

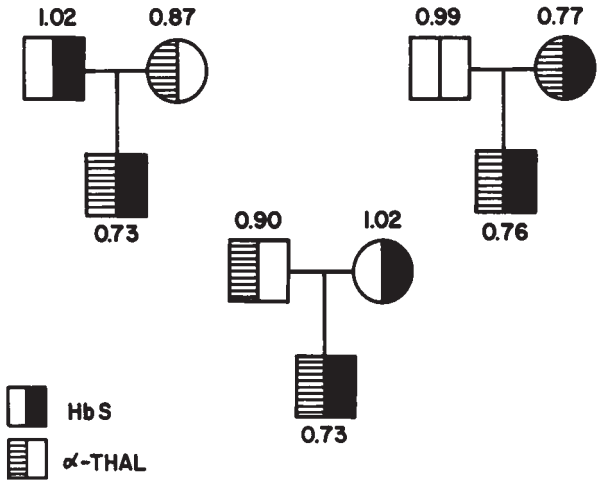

Figure 22.2. $\alpha/\beta^A + \beta^S$ biosynthesis in three families in which there was a proband with HbAS–α thalassemia. Shown beneath each individual is the $\alpha/\beta^A + \beta^S$ biosynthesis ratio. The normal ratio is 0.85–1.25.

Effects of Variant Hemoglobins, β Thalassemia and HPFH

α-Globin variants. HbG Philadelphia (*HBA2* or *HBA1* asn68lys), an α-globin chain variant is the most common hemoglobin variant found with HbAS (Chapter 24). This mutation is usually on a chromosome with a -α$^{3.7}$ deletion. Compound heterozygotes with HbAS and HbG-Philadelphia are not anemic and have no hemolysis but might have mild microcytosis. HbG-Philadelphia can be separated from normal hemoglobins by HPLC. When HbAS or HbC trait appears with HbG-Philadelphia, the HPLC and electrophoretic patterns can be confusing as normal α-globin chains and α^G-globin chains combine with non-α-globin chains to form hybrid and normal hemoglobin tetramers. These species can be resolved by HPLC that in contrast to electrophoresis can separate HbS from HbG. Other α-globin chain variants can be found with HbAS, and like the example of HbG-Philadelphia, their initial resolution could be puzzling, but, like HbG-Philadelphia with HbAS, they are clinically insignificant. Some of these variants include Hb Memphis (glu23gln), Hb Montgomery (leu48arg) Hb Mexico (gln54glu), Hb Stanleyville-II

(pro77arg), Hb Nigeria (ser8cys), HbG-Georgia (pro95leu), and Hb Hopkins-II (his112asp). (The Globin Gene Server http://globin.cse.psu.edu/ provides up-to-date information on hemoglobin variants and thalassemias.)

β-Globin Variants. HbS can coexist as a compound heterozygote with many other β-globin chain variants, including HbD Ibadan (*HBB* thr87lys), HbD Iran (*HBB* glu22gln), HbG San Jose (*HBB* glu7gly), Hb Osu-Christianbourg (*HBB* asp52asn), HbE, HbG Galveston (*HBB* glu43ala), Hb Korle-Bu (*HBB* asp73asn; also known as HbG-Accra), and Hb Richmond (*HBB* asn102lys). The resulting phenotypes depend on the pathogenicity of the β-globin variant but usually resemble uncomplicated HbAS (Chapter 23). HbC-Harlem (*HBB* glu6val; asp73asn) migrates like HbC at alkaline pH, is present at a concentration of approximately 40% of the hemolysate, and gives a positive test for sickling (Chapter 23). It can be separated from HbC at acidic pH. HbC-Harlem heterozygotes do not have abnormal hematology or symptoms.

β Thalassemia, HPFH, Fusion Hemoglobins. Compound heterozygotes with β^+ thalassemia and HbS synthesize more HbS than HbA because of the reduced expression of the β thalassemia gene. Rarely, a β thalassemia mutation can be *cis* to the β^S-globin gene. A C→T mutation at position -88 5′ to the β-globin gene was found in a HbS gene on a Benin haplotype chromosome.[8] Affected patients had a normal α-globin genotype with α:β synthesis consistent with β thalassemia trait. They were mildly anemic with microcytosis, high HbA_2 concentration, and HbS levels of 10%–11%. This HbS level is much lower than those found in HbAS with HbH disease (Table 22.2).

Point mutations that produce HPFH can be found *cis* and *trans* to the HbS gene. They are not associated with a clinical phenotype but can produce confusing HPLC and electrophoretic findings. Depending on the mutation causing HPFH, there can be minor increases in HbF of approximately 5% or major increases that exceed 20% of the total hemoglobin. Individuals with HbAS who inherit the -202 C→T mutation 5′ to the $^A\gamma$ globin gene have 2%–4% HbF and more than 90% $^A\gamma$ chains.[9] Mutations associated with these conditions are shown in Table 22.3. The compound heterozygous conditions of HbS-deletion HPFH and HbS–δβ thalassemia are discussed in Chapter 23.

Hb Lepore (Chapters 16 and 17) is the product of a poorly expressed fusion gene with δ- and β-globin chain components. Hb Lepore migrates like HbS on electrophoresis at alkaline pH and like HbA at acidic pH but is separable from HbA and HbS by HPLC. Heterozygotes have approximately 10% Hb Lepore and the phenotype of β thalassemia trait. Hb Lepore heterozygotes should not be confused with HbAS or the very rare cases of HbAS–HbH disease or β thalassemia *cis* to HbAS. The anti-Lepore variants HbP Nilotic (HbP Congo) and Hb Lincoln Park exhibit the same electrophoretic behavior as HbS and form approximately 20% of the hemolysate. Unlike Hb Lepore, they do not cause a thalassemia phenotype. Hb Parchman, only reported once, migrates electrophoretically like HbS but forms less than 2% of the hemolysate.

Table 22.3. Nongene deletion hereditary persistence of HbF and HbAS[24]

Mutation	HbF	HbA	HbS	$^G\gamma$ (%)
-202 C→G 5′ $^G\gamma$	20	30	50	100
-202 C→T 5′ $^A\gamma$	2–4	60	40	10
-175 T→C 5′ $^G\gamma$	30	30	40	
-175 T→C 5′ ^{A}	40	20	40	85
-158 C→T 5′ $^G\gamma$ in *cis*				

HbAS has been described with the γβ fusion hemoglobin, Hb Kenya (Chapters 16 and 23). Carriers are not anemic but could have mild microcytosis. The hemolysate contains approximately 20% Hb Kenya and 60%–70% HbS; the remainder is HbA_2 and HbF.

SYMPTOMATIC "HbAS"

With some exceptions, carriers of HbAS do not have the clinical features of sickle cell disease. Nevertheless, sometimes, what appears at first to be HbAS is accompanied by disease symptoms. In addition to the rare conditions discussed, it is formally possible that genetic polymorphisms in the many genes that could affect the phenotype of sickle cell anemia might lead to symptoms in HbAS, but, to date, such associations have not been studied.

Variant Hemoglobins

HbS-Antilles (*HBB* glu6val; val23Ile) migrates like HbS, giving the electrophoretic appearance of HbAS. In contrast to HbAS, HbS-Antilles is associated with sickle cell disease in the heterozygote. Its presence should be considered in patients with HbAS who have hemolytic anemia and vasoocclusive disease (Chapter 23). Heterozygotes have 40%–50% HbS-Antilles, and sickling tests are positive. Erythrocyte damage and symptoms are seen in heterozygotes because the additional val23Ile mutation in HbS-Antilles allows this variant to polymerize even when it forms only half of the hemoglobin.

A baby girl presented with symptomatic sickle cell disease despite a prior diagnosis of HbAS. One β-globin gene contained the HbS mutation and an additional *HBB* leu68phe mutation. This variant, Hb Jamaica Plain, had severely reduced oxygen affinity, suggesting destabilization of the oxy conformation at ambient partial pressures of oxygen.[10]

Pyruvate Kinase Deficiency

A unique cause of symptomatic HbAS was found with the coexistence of erythrocyte pyruvate kinase deficiency in a carrier of the HbS gene. This patient, a 42-year-old Guinean

woman, had an HbS level of 44%, packed cell volume of 25, reticulocytes of 203×10^9/L, cholelithiasis, and a 35-year history of hospitalizations approximately five times yearly for painful episodes.[11] Erythrocyte density profiles resembled that seen in HbSC disease. The P_{50} was 41.5 mm Hg (normal ~25). Severe pyruvate kinase deficiency was present.

High 2,3-BPG levels, a consequence of the metabolic block caused by pyruvate kinase deficiency, increased P_{50} and decreased hemoglobin oxygen affinity allowing HbS polymerization. Intraerythrocytic HbS polymer was inferred by hysteresis – different P_{50} values during deoxygenation and reoxygenation – of the hemoglobin–oxygen dissociation curves. HbS polymerization under physiological conditions evidently increased cell density, caused hemolytic anemia, and provoked vasoocclusive episodes. Although it would be useful to know in greater detail the clinical features of the vasoocclusive disease in this patient, this case seems to be an exceptional example of a truly symptomatic individual with HbAS. It suggests that metabolic abnormalities can influence the phenotype of HbAS and, by extension, sickle cell disease.

Hereditary Spherocytosis

Rarely, HbAS and hereditary spherocytosis coexist.[12,13] The dominant phenotype is that of hereditary spherocytosis.[14] Patients with this combination have been reported to developed acute splenic sequestration crises and the post-splenectomy specimens showed erythrostasis and sickling. Perhaps these unusual events – sequestration crises are not a feature of HbAS – were the result of the splenomegaly of hereditary spherocytosis and the high mean corpuscular Hb concentration of HbS-containing hereditary spherocytosis erythrocytes.

HEMOGLOBIN VARIANTS MASQUERADING AS HbAS

Many variants of the β- and α-globin chain will migrate like HbS under the conditions of alkaline electrophoresis. Most, but not all, of these variants can be resolved by more sensitive analytical methods such as HPLC, and in principle, all can be distinguished by DNA analysis. None, except the rare variants like HbS Antilles, and Hb Jamaica Plain, with the HbS mutation and other mutations in the same β-globin gene, will polymerize. HbG Makassar (*HBB* glu6ala) cannot be separated from HbS by HPLC, isoelectric focusing, hemoglobin electrophoresis, or globin chain electrophoresis. It is present at a level of approximately 45% and has no pathological consequences.

CLINICAL FEATURES

Does HbAS interfere with any physical activities? Is it a risk factor for increased morbidity and mortality? Again, with some exceptions, there is little evidence for the pathogenicity of HbAS under conditions of ordinary living.

Hematology

Table 22.2 presents hematological data compiled from various studies of people with HbAS and either normal α-globin genotype or with α thalassemia or β^+ thalassemia. In some studies, the packed cell volume in HbAS was slightly reduced but still normal; in others, it did not differ from the packed cell volume in controls.[15,16] The disparity might have been due to differences in methodology and the examination of diverse populations with different age ranges. Differences from normal are very small and are unlikely to be clinically significant.

Hemolysis is absent in uncomplicated HbAS in which the reticulocyte count and studies of red cell survival were usually normal. The popular Variant II^{TM} HPLC method of hemoglobin variant detection used in the United States is associated with increases in HbA_2 when HbS is present because of the coelution of glycosylated HbS.[17] A modification of this method, the Variant II HbA_2/HbA_{1c}, improves the reliability of HbA_2 measurement in the presence of HbS.[18] Gene deletion α thalassemia is associated with very small differences in HbA_2 levels that vary according to the numbers of α-globin genes.[17]

Mortality, Rhabdomyolysis, and Sudden Death

In diverse cross-sectional, longitudinal, hospital and community-based studies of thousands of subjects with HbAS, carriers did not have excess risk of mortality.[19–23] Evidence that Africans with HbAS have increased mortality rates is also lacking, but adequate data are not available.[24]

Exercise-related sudden death, or near death, in previously healthy, young athletes is always a tragic event. When an athlete dies and has HbAS, a causal relationship is often assumed, and the case reported in the medical literature and lay press. What is lacking, and needed to interpret the clinical significance of these reports and the concerns they engender, is a careful epidemiological study of exertional rhabdomyolysis, associated and not associated with sudden death, in the universe of athletes (90% of deaths in athletes are due to unsuspected cardiovascular disease). Although studies of military recruits showed that death after exertional heat illness and rhabdomyolysis was increased in carriers of HbAS, their incidence of exertional heat illness was not.

Reports of sudden death or life-threatening episodes during exercise in HbAS abound and have been extensively reviewed.[25] Most deaths were attributed to exertional heat illness, with rhabdomyolysis and idiopathic sudden death accounting for equal numbers of cases. Case reports and small clusters of unexpected sudden death in people with HbAS in special situations – military recruits undergoing basic training and athletes engaging in physically

stressful sports – raised the possibility that under extremely rigorous conditions, HbAS could be associated with a higher risk of sudden death.[25]

Over a span of 5 years, during which 2.1 million recruits underwent basic training in the U.S. Armed Forces, the risk of sudden unexplained death in black recruits with HbAS compared with those without the trait was 27.6.[26] Compared with all recruits – blacks without HbAS, and whites – the relative risk was 40. Other HbAS mortality studies suffer from design flaws, principally low power due to small sample size. The risk increased progressively with increasing age from a death rate of 12 per 100,000 at ages 17–18 years to 136 per 100,000 at ages 31–34 years. Perhaps the increasing prevalence of isosthenuria with age in HbAS and the accompanying possibility of dehydration when access to fluids was limited might account for this observation. It was not possible to tell if the fractional percentage of HbS was associated with sudden death. Coincident α thalassemia in individuals with HbAS might be associated with better-preserved urine-concentrating ability.[27] Using percentage of HbS as a surrogate for α thalassemia, studies suggested that α thalassemia was underrepresented in individuals with sudden death.[25,28]

In summary, HbAS is not a risk factor for a higher mortality rate in the general population, and restraint during the rigors of conditioning should eliminate any hazard in special groups.

Treatment Recommendations

A prudent course for all exercising individuals includes gradual conditioning, liberal fluid intake, and avoidance of overexertion under all conditions, especially when temperature and humidity are high. When that strategy was adopted by the U.S. military in recruit conditioning and training, the death rate in the HbAS was said to fall to that of the recruit population overall. Unfortunately, the abandonment of this policy was associated with a return to an increased number of deaths in carriers of HbAS.

Thromboembolism

Individuals with HbAS might have increased coagulation system activity and a higher prevalence of prothrombotic mutations, but most studies reporting such association are small, poorly controlled, and inconclusive.[29,30] In one study, individuals with HbAS had increased levels of d-dimers, thrombin–antithrombin complexes, and prothrombin fragment 1.2 compared with controls.[31] The differences between HbAS and controls were small and might be attributable to a few cases with very high values. This study only included 23 individuals with HbAS, nearly half of whom appeared to be atypical with mild anemia and with a hemoglobin concentration of less than 12 g/dL.

In contrast to individuals of African descent in whom the factor V Leiden mutation is rare, in Iranians who have an HbS gene this prothrombotic mutation appears to be common.[32]

Two careful studies suggest that middle aged African Americans with HbAS have an increased risk of thromboembolic disease. In a study of 65,000 hospitalized veterans, 2.2% of individuals with HbAS had pulmonary embolism compared with 1.5% of controls, a statistically significant, albeit small, difference.[19] This study examined men nearly exclusively, and, the currently used sensitive methods to diagnose pulmonary embolism were not available. A recent case-control study examined 515 hospitalized African Americans with either deep venous thrombosis or pulmonary embolism and compared them with 555 outpatient controls. The prevalence of the HbS allele was 0.070 for cases and 0.032 for controls. The odds of a case having HbAS were approximately twice that of a control, indicating that the risk of venous thromboembolism is increased approximately twofold among individuals with HbAS. The odds ratio for pulmonary embolism was 3.9. The proportion of cases of pulmonary embolism attributable to HbAS was approximately 7%. The prevalence of sickle cell disease was also increased among cases compared with controls, but in most of these cases there was an underlying reason for thromboembolism.[33]

Treatment Recommendations

These studies show that African Americans with HbAS have an increased risk of venous thromboembolic disease. Although it was implied that African Americans should know if they carry HbAS, given its benignity, it is difficult to see how screening the adult population for HbAS would alter the management of thromboembolic disease. The importance of knowing if a patient with thromboembolic disease has HbAS is also unclear as the treatment implications of such knowledge seem nil.

Pregnancy and Contraception

It was thought that fertility was increased in women and perhaps in men with HbAS; however, this supposition is not supported by more recent studies.[34–37]

According to many reports, pregnancy complications are more frequent in HbAS. Some studies suggest that the risks for bacteriuria, pyelonephritis, and urinary tract infection might be increased as much as twofold. In a well-designed prospective study of 162 pregnancies with HbAS and 1,422 controls, the preeclampsia rate in HbAS was doubled, endometritis occurred more frequently, and gestational age and birth weight were reduced in infants.[38] In contrast, a retrospective study, in which HbAS was ascertained by solubility testing, showed no difference in the prevalence of preeclampsia in HbAS and controls.[39] A recent retrospective study using data collected from 1991 to 2006 showed that among 36,897 pregnancies, perinatal mortality and preeclampsia were not increased in HbAS.[40]

In a recent retrospective cohort study, asymptomatic bacteriuria, acute cystitis, and pyelonephritis had a similar prevalence in HbAS (n = 455) and matched pregnant control patients (n = 448). Although HbAS carriers had significantly higher rates of pyelonephritis, many affected patients had risk factors such as previous pyelonephritis or noncompliance with therapy.[41]

In a retrospective case-control study, 180 pregnant women with HbAS were compared with controls. Women with HbAS had significantly shorter average duration of pregnancy (233 ± 45 days vs. 255 ± 34 days), lower birth weight infants (2,114 ± 1,093 g vs. 2,672 ± 942 g), and a higher rate of fetal death (9.7% vs. 3.5%). Acute ascending amniotic infection and meconium histiocytosis were noted more frequently.[42] The authors speculate that placental infarction led to intrauterine hypoxia. Patients in this study might not represent the African American population overall. They had a high prevalence of comorbid conditions such as hypertension, diabetes, and obesity and the fetal loss rate in the population from which cases and controls were drawn was approximately twice the national average. Also, it was not clear that comorbidities and hematological findings, such as the prevalence of α thalassemia, were similar in HbAS and control pregnancies. In contrast, a retrospective study of more than 5,000 pregnancies showed that HbAS was associated with lower risk of preterm delivery at less than 32 weeks and increased odds of multiple gestations.[43]

The effect of maternal age on pregnancy outcomes is controversial. Some studies showed a reduced birth weight of infants born to older mothers but others did not. Pregnancy outcomes did not seem to be affected by age. Although some studies reported increased complications of many types, including prematurity and premature rupture of membranes, they often lacked appropriate controls. In Nigerian women, pregnancy outcomes were similar in HbAS and controls and HbAS women had fewer attacks of malaria.[44] Iron supplementation to pregnant African women with HbAS is of little benefit, perhaps because of an increased risk of malaria, but those results are inconclusive.

Mothers with HbAS were more likely to have HbAS children than those with only HbA.[45–47] This maternal segregation distortion could be another means of maintaining a high prevalence of HbAS.

Treatment Recommendations

Despite some uncertainties, the available data suggest that HbAS might be associated with increased risks of certain complications of pregnancy, mainly urinary tract infections, low birth weight, and possibly increased fetal loss. These observations suggest that screening for HbAS in at risk pregnancies might be useful if affected individuals are provided a higher level of antenatal care.

The scanty literature available does not suggest that any means of contraception is more hazardous in HbAS than in the general population but definitive studies have yet to be reported.

Growth and Development

Many investigators have questioned whether HbAS influences growth and development, and although some have found differences in physical and intellectual development, the best evidence suggests that children with HbAS and matched controls are similar. HbAS is not associated with an increased chance of sudden infant death syndrome.[48]

Exercise Capacity

Whether or not athletes with HbAS are at special risk of sudden death and should be treated differently from their peers is a subject of continued debate and the expression of strong opinions without the addition of new definitive studies.[49–54] It is questionable whether HbAS affects the physiological responses to exercise or impairs exercise tolerance and performance. Forty-eight people with HbAS, aged 4–21 years, underwent progressive ergometer stress testing at their voluntary maximal performance and the results were compared with 184 controls. Equivocal ischemic changes on electrocardiographic exmination were seen in four individuals with HbAS. The maximum workload and heart rate were lower in the HbAS subjects, but there were no complications of the exercise program.[55] One study comparing the response to incremental exercise in people with HbAS and controls revealed no differences in cardiovascular function but did reveal lower blood lactate concentrations in HbAS.[56] When anaerobic exercise and exercise metabolism after force-velocity tests were compared in sedentary adults with HbAS and closely matched controls, there were no differences between the groups.[57] Under laboratory conditions, when eight HbAS and eight normal individuals were subjected to an incremental exercise test, maximal oxygen uptake and ventilatory thresholds were similar, and no difference in whole blood, plasma, or red blood cell lactate concentrations were found, suggesting that lactate production and clearance is quite similar during exercise. Lactate uptake by HbAS erythrocytes is more rapid during exercise.[58] At supramaximal exercise, an increase in red cell rigidity was seen in HbAS, but it is not known if this has any clinical significance.[59,60]

Concurrent α thalassemia does not effect the oxygen response to exercise in HbAS.[61] Before and after basic training, a group of HbAS and control subjects had similar responses to exercise testing.[62,63]

In some circumstances and among some African tribes, hypoxia at high altitudes appeared to affect performance in vigorous exercise and cause changes in the splenic circulation.[64] In other studies at simulated altitude and moderate hypoxic environment, the cardiopulmonary and gas exchange responses of persons with HbAS during brief episodes of exhaustive exercise were comparable to those of

controls.[65] Acute stressful exercise at an altitude of 1,270 m and a simulated altitude of 2,300 m were not associated with differences in cardiopulmonary and gas exchange between subjects with HbAS and controls. Vigorous arm exercise was associated with sickled cells in effluent venous blood, and the frequency of such cells increased fourfold at simulated altitudes of 4,000 m.[66] Performance was unimpaired, and sickled cells were not detected in arterial blood and hemolysis was not detectable. Ventilatory responses to three episodes of heavy exercise was similar in HbAS and controls.[49]

When athletes with HbAS, with and without coincident α thalassemia, were exercised on a bicycle ergometer and levels of soluble intercellular adhesion molecule–1 and vascular cell adhesion molecule–1 were measured, the HbAS group had higher vascular cell adhesion molecule–1 basal concentrations, and incremental exercise resulted in a significant increase in all subjects. Levels remained elevated in the HbAS group during recovery, and individuals with HbAS–α thalassemia had a more rapid return to baseline.[67]

Many other studies show minimal or no adverse effects of HbAS during exercise.[58,68,69] After prolonged intense exercise, prothrombin time, antithrombin III activity, and plasma fibrinogen were similar in individuals with HbAS and controls.[70] Black athletes with HbAS are well represented in elite competitive sports. The percentage of African semimarathon runners with HbAS was similar to that of the general population.[63]

Treatment Recommendations

Based on the total body of work on exercise ability and capacity, there is no reason to restrict exercise of any type in persons with HbAS. All individuals engaged in strenuous exercise, trained or untrained, should be properly conditioned, clothed, have unrestricted access to fluids, appropriate rest periods, moderation of the exercise routine when harsh atmospheric conditions like excessive heat and humidity are present, and rapid treatment should symptoms develop. Any restraints applied to carriers of HbAS need not differ from those used to forestall ill effects of exercise in the general population.

Flying and Scuba Diving

There are many reports of splenic infarction during flight in unpressurized aircraft at altitudes of 3,000–5,000 m. In the early reports, the diagnosis of HbAS was often made by tests that today would be considered inadequate, and some cases reported could have been instances of HbSC disease or HbS–β^+ thalassemia rather than HbAS. Commercial aircraft are pressurized to 2,500 m and splenic infarct – and any other complication of HbS polymerization – is unlikely to occur under that condition. As of 1996, the US Department of Defense stopped preinduction testing for HbAS and as of 2003 HbAS carriers were not restricted from flight or undersea duty.

Scuba diving, in which divers breathe compressed air, provides an environment with increased pO_2 and poses no known risk to carriers of HbAS.

Genitourinary System

Hyposthenuria. The kidney medulla is one of the few sites where under physiological conditions, HbAS erythrocytes are placed in jeopardy. Low pO_2, low pH, and high solute concentration provide a milieu where sickling of even the HbAS erythrocyte can occur.[71] Damage to the countercurrent urine-concentrating mechanism and the vasculature of the renal medulla leads to a defect in urine-concentrating ability and hyposthenuria in most adults with HbAS and hematuria in some individuals. These abnormalities might result from microvascular injury in the vasa recta of the renal medulla. A defect in urine acidification, which in sickle cell anemia is related to the severity of the concentration defect, is not seen in HbAS.

The polymerization tendency of HbS might determine the extent of the urine-concentrating defect in HbAS.[27] To test this hypothesis, urinary-concentrating ability was examined following overnight water deprivation and intranasal arginine vasopressin in HbAS subjects separated into two groups – one with a normal α-globin gene complement and one with either heterozygous or homozygous -$\alpha^{3.7}$ gene deletion α thalassemia. The ability to concentrate urine was most impaired in subjects with normal α-globin genotype and least impaired in subjects with homozygous α thalassemia. Urine osmolality was 882 ± 37 mOsm/kg H_2O in α thalassemia homozygotes and 672 ± 38 mOsm/kg H_2O in the heterozygotes. In all subjects, urinary osmolality correlated linearly and inversely with percentage of HbS. A similar correlation was found between urine-concentrating ability and HbS polymerization tendency at 0.4 oxygen saturation (Fig. 22.3), suggesting that HbS polymer, a function of percentage of HbS, is responsible for the urine-concentrating defect of HbAS.

Hematuria. Hematuria occurs episodically in approximately 5% of people with HbAS. Some studies suggest that hematuria is most common at higher HbS levels. Bleeding is more frequent from the left kidney, perhaps because of the anatomy of venous system, and men are affected four times as often as women. Although von Willebrand syndrome has been reported in HbAS, no association has been established between any coagulation abnormality and HbAS hematuria.

Papillary necrosis can cause hematuria, sometimes with renal colic. This might be more frequent in HbAS and is perhaps another consequence of sickling in the renal medulla.[72,73] Autosomal dominant polycystic kidney disease might be more prevalent and progress to renal failure more rapidly in individuals with HbAS.[74]

Medullary Carcinoma. Renal medullary carcinoma, a rare and aggressive tumor, has a unique association with HbAS.[75–82] In a retrospective analysis spanning 20 years, 33 black patients, aged 11–40 years, who presented with hematuria and pain had renal medullary carcinoma. Nine patients had proven HbAS, and one had HbSC disease, but all tumor specimens contained sickled cells. The tumors were lobulated with satellite cortical nodules and widespread metastases. Histologically, the tumors had a reticular, yolk sac–like or glandular cystic appearance, with a desmoplastic stroma, hemorrhage, necrosis, neutrophil infiltration, and lymphocyte sheathing (Fig. 22.4). Characteristic findings of renal medullary carcinoma on computed tomography and magnetic resonance imaging include an infiltrative renal mass with associated retroperitoneal adenopathy and caliectasis.[83] Chemotherapy was uniformly unsuccessful, and survival after diagnosis was approximately 4 months.[67]

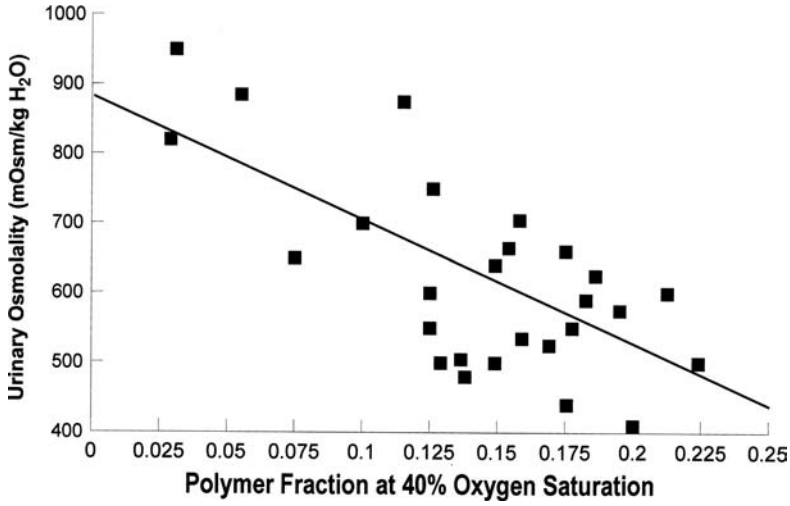

Figure 22.3. Relationship between maximum urine-concentrating ability and polymer fraction at 40% oxygen saturation in individuals with HbAS and 4, 3, and 2 α-globin genes. (From ref. 27 with permission.)

The diagnosis of HbAS for 23 of the patients was based only on histological findings because diagnostic tests documenting HbAS were not available. If HbAS was present in all 33 patients, the conclusion that the condition predisposes to this rare tumor seems inescapable. It has been hypothesized that the medullary cancers could originate in terminal collecting ducts, where epithelial cell proliferation has been noted in HbAS. Perhaps rapid cell proliferation and oxygen radicals produced by cell sickling, coupled with preexisting mutations in genes controlling cell growth, predispose to carcinogenesis. In three cases, the *ABL* gene was amplified.[81] Gene expression studies suggested that the tumor signature resembled that of urothelial tumors rather than renal cell carcinoma.

Genitourinary Lesions Probably Not Caused by HbAS. Other renal or genitourinary system disorders, such as nephrotic syndrome, pyelonephritis, hypotonic bladder, hypertension, renal failure, renal cortical infarction, renal vein thrombosis, and testicular infarction undoubtedly occur in some carriers of HbAS, but there is no evidence of their being caused by HbAS. Priapism, a serious complication of sickle cell anemia, is not associated with HbAS. Renal allograft survival in HbAS is equivalent to that in the general population.

Treatment Recommendations

No treatment can reliably stop hematuria in people with HbAS and radical treatments, such as nephrectomy, should be avoided.[84] Induced hypotonicity, alkalinization, and epsilon amino caproic acid, an antifibrinolytic agent, have all been used to control severe hematuria but controlled trials have never been reported. Epsilon amino caproic acid can be dangerous in some situations by inducing clot formation and causing obstructive uropathy.

Although often recurrent and sometimes producing anemia, hematuria is usually benign and self-limited. Nevertheless, hematuria could arise from more ominous causes than a damaged renal medulla. Renal and bladder cancer – especially medullary cancer in young patients – stones, glomerulonephritis, and infection should be excluded during the evaluation of hematuria.

SPLEEN

Young black men with HbAS who resided at altitudes up to 1,600 m for many years had normal splenic function as assessed by radionuclide scanning and by the number of

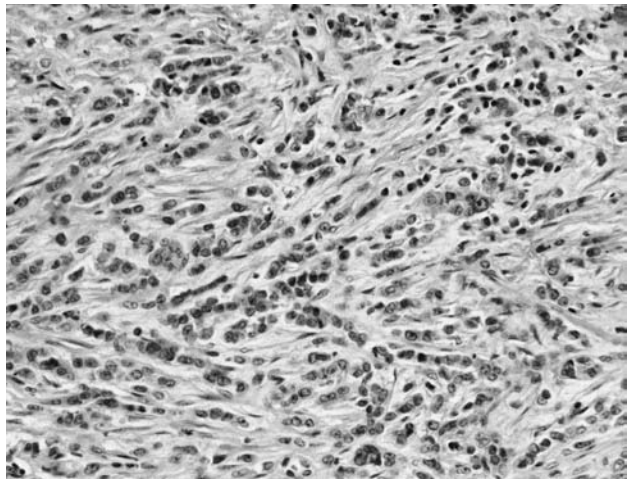

Figure 22.4. Renal medullary carcinoma showing epithelioid cells and spindle cells in a background of fibrosis and small lymphocytes ($\times$ 400). Kindly provided by R.S. Figenshau.[79]

red cells with "pits."[85] Splenic infarction can occur in individuals with HbAS when they encounter hypobaric conditions.

Splenic infarcts in African Americans with HbAS are rare, or rarely reported. Splenic infarction was not mentioned in a report of African runners with HbAS who competed at altitudes of up to 4,100 m. Especially interesting are reports of splenic infarction in Caucasians with HbAS.[86,87] Caucasian men might be overrepresented in reports of altitude-induced splenic syndrome and splenic infarcts at sea level. Twenty of 29 reported cases of splenic syndrome were in Caucasian men.[88] Most, but not all, episodes occurred shortly after ascent to approximately 3,000 m. These curious observations have led to much speculation.[28] A reasonable supposition is that an African HbS gene within the Caucasian gene pool became isolated from accompanying genes that in Africa evolved along with the HbS gene and modulated its effects. The hypothesized modulating genes could affect the mean corpuscular HbS concentration, which might differ between black and nonblack HbAS carriers. Inconclusive evidence suggests that Caucasian carriers with splenic infarction have a higher HbS concentration than black carriers and that a high mean cell HbS concentration increases the risk of intrasplenic sickling and organ damage. One Caucasian splenic infarction patient had an HbS level of 46.5% and had five α-globin genes (Table 22.1). In a report in which both father and son had a splenic infarct, the HbS levels were 41% and 45.6%. In another study, however, HbS levels in a small series of nonblack carriers differed little from those in most black carriers of HbAS. If HbS levels are truly higher in Caucasian carriers, it might be a consequence of the absence of α thalassemia and the reduced cation exchange and lower cation content in Caucasians erythrocytes, a deficit most marked in men (splenic infarction is rarely reported in women), or, differences in other "protective" genes associated with the HbS gene in black patients.

Treatment Recommendations

Fear of splenic damage should not dissuade carriers of HbAS from activities at altitude. Physicians should be aware, however, that in this setting, splenic infarction should be considered as a cause of left upper quadrant pain in any racial and ethnic group. Fortunately, most often splenic infarction is a self-limited process and needs no special treatment.

EYE

In nonhemoglobinopathic individuals, hyphema, or hemorrhage into the anterior chamber, usually clears uneventfully with topical medical therapy. Among individuals with traumatic hyphema, carriers of HbAS might be overrepresented.[89] The naturally low pO_2 in the anterior chamber causes erythrocyte sickling in HbAS and impedes cellular outflow through the trabecular meshwork and Schlemm canal, raising intraocular pressure. High pressure in the anterior chamber can reduce vascular perfusion pressure elsewhere in the eye, injuring the optic nerve and retina and causing hemorrhage and impairing vision.[90] Anterior segment hypoxia and acidosis set in place the vicious circle of erythrostasis typical of sickle cell disease. Secondary open-angle glaucoma can result from poorly treated hyphema.

Many ocular abnormalities, including internuclear ophthalmoplegia, transient monocular blindness, vitreous hemorrhage, and optic atrophy have been described in HbAS, but any association with HbAS is likely to be fortuitous.[91–93] Chronic open-angle glaucoma is no more common in HbAS than in age- and sex-matched controls.

Although proliferative retinopathy, akin to the type known to occur in sickle cell disease has been described in HbAS, in all cases, a known cause of proliferative retinopathy such as diabetes, was present, perhaps predisposing to the development of retinal lesions. Uncomplicated HbAS is not associated with sickle retinopathy.[94]

Treatment Recommendations

Black patients and others at risk of carrying the HbS gene who present with hyphema should be screened for HbAS without delay. A sickle solubility test will do, because it is important at this point to find out only whether HbS is present. Management of hyphema in HbAS is beyond the scope of this chapter; it should be supervised by an ophthalmologist who understands the special problems that can arise when the hyphema and HbAS coexist. Intraocular pressure can be controlled medically in perhaps two thirds of the cases. Anterior chamber hypertension of greater than 24 mm Hg for consecutive 24-hour periods and repeated but transient increases above 30 mm Hg should be reduced by paracentesis, which can be repeated if necessary. Normal pressure during the first 24 hours of observation suggests, but does not establish, that medical treatment will suffice.[95]

BONES AND JOINTS

Reports of osteonecrosis in HbAS make an unconvincing case for their association. Bone infarction has also been described with HbAS, also with no evidence of association beyond coincidence.[96]

NERVOUS SYSTEM

Children with HbAS had greater arterial tortuosity on magnetic resonance imaging and magnetic resonance angiography compared with controls, and this was related to the percentage of HbS.[97] The authors speculated that this was a sign of mild vasculopathy; however, the clinical implications of this observation are unknown. Cerebral infarcts

have been reported in HbAS.[98] Most of the reports are of one or two cases so that given the ubiquity of both HbAS and stroke, a causal relationship cannot be established. In a retrospective study in Guadeloupe, in 295 patients hospitalized for stroke, HbAS appeared to be more prevalent in individuals with hemorrhagic stroke and less prevalent in individuals with infarctive stroke.[99] The truth of the assertion that HbAS is a risk factor for stroke cannot yet be established.[98]

SURGERY AND ANESTHESIA

Untold numbers of patients with HbAS have safely undergone anesthesia and surgery. In a matched-pair analysis of patients with HbAS and control subjects, the frequency of anesthetic, surgical, and postoperative complications was similar; however, most patients were young, and few intraabdominal and thoracic procedures were included.

Use of a tourniquet in orthopaedic procedures appears safe in HbAS (and in sickle cell anemia).

Treatment Recommendations

Most evidence suggests that anesthetic risk is not increased by HbAS, and the choice of anesthesia need not be limited.[100,101] Thus, there is no rationale for routine preoperative screening for HbAS.[102]

With open heart surgery or complicated intrathoracic surgeries, in which hypoxia might be intrinsic to the procedure, preoperative transfusion was recommended.[100,101] Screening for HbAS might be prudent under those circumstances, but there are no well-controlled studies on the preoperative management of intrathoracic surgery in HbAS.

MALARIA

The selection pressure from *Plasmodium falciparum* malaria is expressed primarily in children, and where malaria is endemic, HbAS children have reduced mortality.[103,104] HbAS retards the development of cerebral malaria in children aged younger than 5 years, and it reduces their death rate.[105] Although the clinical features, haptoglobin levels, parasite counts, and most laboratory measurements are similar in children with and without HbAS, trait carriers are transfused more often. It is estimated that HbAS is almost 90% protective for severe *P. falciparum* malaria with lesser protection against mild disease.[106]

When homozygous α thalassemia and HbAS coexist, the protection against *P. falciparum* malaria afforded by each trait individually was lost, an example of negative epistasis.[107] It was suggested that this might be explained by the reduction in HbS concentration caused by α thalassemia or effects on the erythrocyte membrane altering merozoite invasion.

Children with HbAS have an imbalanced distribution of immunoglobulin G2 (IgG2) antibodies to merozoite surface protein 2 (MSP2) and a higher frequency of infection with multiple *P. falciparum* strains. In Gabonese children with HbAS, Fc gamma receptor IIa (CD32) polymorphism and the rate of in vitro invasion of red blood cells from subjects with HbAS and controls with multiple *P. falciparum* strains were investigated. Lower levels of IgG2 subclass antibodies to MSP2 peptides were independently associated with the Fc gamma receptor IIa-R131 allele and with HbAS, suggesting that IgG3 antibody responses to MSP2 epitopes could be exacerbated by lower IgG2 levels. Longer persistence of ring forms in HbAS might reflect slower multiplication, longer circulation, and enhanced phagocytosis of these nonpathogenic forms and could contribute to the protection against malaria.[108] Some aspects of malaria and hemoglobinopathies are discussed in Chapter 26.

OTHER CONDITIONS

The grab bag of other diseases reported in individuals with HbAS has been reviewed and new "associations" continue to appear.[109] Early reports of impaired pulmonary function in HbAS have been refuted by more carefully controlled studies of diffusing capacity for CO and spirometry at simulated altitudes up to 7,500 m and pulmonary function at rest and after exhaustive exercise in men with HbAS who had been living above 1,600 m for many years. Reports of sickle cell disease–like "crises," complicated migraine with occlusion of branches of the middle cerebral artery, venous thrombosis, and retroperitoneal fibrosis could not be linked etiologically to HbAS.

Leg ulcers have been associated with HbAS in Jamaica. Of 250 patients with chromic leg ulcers, 20% had HbAS, whereas 11% of the general population carried the HbS gene. There are no data to support an increase in leg ulceration in HbAS carriers in temperate climates.

Erythrocyte glucose-6-phosphate dehydrogenase (G6PD) deficiency is common in many populations in which HbAS is found. Hemizygotes with the common African type of G6PD deficiency rarely encounter clinical difficulties. In a study of more than 65,000 hospitalized African-American men, nearly 1% had both HbAS and G6PD deficiency. Morbidity from pneumonia and mean age of death were similar for the group with HbAS alone and the group with both HbAS and G6PD deficiency.

TRANSFUSION OF HbAS BLOOD

Minor changes distinguish HbAS from normal blood under storage conditions, but transfused HbAS erythrocytes are equivalent to normal cells in safety, effectiveness, and survival. Cryopreserved red cells from individuals with HbAS could hemolyze when deglycerolized but a special deglycerolization protocol can prevent this; thus, when cryopreservation of rare blood types is undertaken, knowing if the donor has HbAS is useful.

Table 22.4. Recommendations for counseling and management of HbAS

Counseling permits informed family planning
Antenatal diagnosis for sickle cell disease is available
Occupational choice should be unrestricted
Flying in commercial aircraft is safe
Unexplained pain should not be ascribed to HbAS
Hematuria is usually benign and self-limited but should be carefully evaluated
Hyposthenuria is present in most adults with HbAS
When strenuous exercise is undertaken, fluid intake should match expected losses
Surgical intervention might be needed in hyphema
Pregnancy can have complications such as urinary tract infection
Surgery is safe
Morbidity from most associated diseases is not increased
Duration and quality of life are normal
Clinically significant anemia is not a complication
Microcytosis in HbAS is usually a sign of α thalassemia but should be evaluated.

Blood from donors with HbAS cannot be consistently leukodepleted with any available filter but cell sickling upstream of the filters was not observed.[110–112] This might be due to the low pO_2 and pH of stored blood and HbS polymerization.[113,114] Universal leukodepletion has become the standard in the United States, France, and Canada. Because HbAS carriers are a large fraction of donors in many locales, the loss of their units could seriously reduce blood supplies. Studies have suggested that storage of HbAS whole blood in large-capacity oxygen-permeable bags increases oxygen tension and allows more effective leukoreduction.[114] Units from HbAS donors should be avoided when transfusing large amounts of blood into anemic hypoxic neonates.

SCREENING AND COUNSELING

Screening for HbAS has limited indications and in most cases should be reserved for individuals likely to carry the HbS gene. The U.S. Armed Forces do not screen before induction but might conduct screening afterward. Although the screening of individuals assigned to flight duty might be prudent to detect asymptomatic individuals with sickle cell disease such as HbS–β^+ thalassemia and HbSC disease, screening the general population for HbAS serves no purpose.

Before screening prospective parents, they should be educated about sickle cell disease and HbAS and receive nondirective counseling. Antenatal diagnosis for sickle cell disease is possible in instances in which a pregnancy is at risk for an affected fetus (Chapter 28).

A byproduct of neonatal screening for sickle cell disease is the identification of babies with HbAS. The value of finding HbAS in newborns is questionable; nevertheless, notifying the parents is reasonable so they can be informed about the implications of the condition and offered further family testing.[115]

Table 22.4 summarizes an approach for counseling and management of individuals with HbAS.

INTRODUCTION

The Genotypic Complexity of Sickle Cell Disease

The sickle hemoglobin gene (*HBB* glu6val) and β thalassemia alleles are often geographically coincident. Consequently, compound heterozygotes with HbS–β thalassemia are commonplace. The incidence of this genotype is dependent on the populations' ratio of carriers of an HbS gene to carriers of β thalassemia. In the United States, and in Africa where the HbS predominates, sickle cell anemia (homozygous for *HBB* glu6val) is the prevailing genotype of sickle cell disease. Wherever β thalassemia is more frequent than sickle cell trait (HbAS) – Greece, Italy, and other Mediterranean countries are examples – HbS–β thalassemia predominates. Some β thalassemia variants, such as δβ thalassemia and Hb Lepore and gene deletion hereditary persistence of fetal hemoglobin (HPFH), can interact with HbS producing different interesting phenotypes. α Thalassemia is present in 30% of African Americans with sickle cell anemia and might be even more common in some populations from the Middle East and Indian subcontinent. Individuals with sickle cell anemia–α thalassemia have distinctive hematological and clinical features. Compound heterozygotes of HbS with other mutant α- or β-globin genes are also present in any population with a high prevalence of HbS. Depending on the other globin gene mutation, these conditions can resemble the clinically benign HbAS or have a phenotype with hemolytic anemia and vasoocclusive complications. Rare variants, often with intriguing phenotypes, have both the sickle mutation and an additional mutation in the same β-globin gene.

This chapter will examine the molecular, diagnostic, laboratory, and clinical aspects of compound heterozygous genotypes of sickle cell disease, excluding HbSC disease, which is discussed in Chapter 21. Unless there are special features associated with a genotype discussed in this chapter, its clinical aspects will be covered in chapters on sickle cell anemia (Chapter 19) and HbSC disease (Chapter 21) and in other chapters in which management is discussed (Chapters 20, section VIII, Chapters 29–33).

Whatever the hemoglobin genotype responsible for a sickle hemoglobinopathy, the treatment of its complications is nearly always the same. The critical clinical issue is to establish the correct genotypic diagnosis before counseling and when discussing prognosis.

HbS–β Thalassemia and HbS–β Thalassemia-like Conditions

β Thalassemia is classified as β^0 thalassemia or β^+ thalassemia (Chapter 16). In the former, the thalassemia-causing mutation totally abolishes expression of the affected gene; in the latter, there is a reduction in β-globin gene expression that depends on the thalassemia mutation. Lacking recent blood transfusion, HbA is not present in HbS–β^0 thalassemia; the hemolysate contains only HbS, fetal hemoglobin (HbF), and 4%–6% HbA_2. Therefore, the phenotype of HbS–β^0 thalassemia mimics that seen in sickle cell anemia and is equally variegated.

In HbS–β^+ thalassemia, HbA levels range from less than 5%–45% of the hemolysate. Given the primacy of the HbS concentration in determining the phenotype of the resulting disease, individuals with only traces of HbA have a disease resembling sickle cell anemia or HbS–β^0 thalassemia; most patients with HbA levels of 20% or more have a phenotype milder than that of HbSC disease or sickle cell anemia.

Because of the confounding influences of genetic modifiers like γ-globin gene expression, α thalassemia, and other more obscure modulators of sickle cell disease (Chapter 27), rigid genotype–phenotype correlations are difficult to establish in all instances of HbS–β thalassemia. Among the different genotypes of HbS–β^+ thalassemia, higher levels of HbA are usually associated with a milder phenotype and in all types of HbS–β thalassemia, as in sickle cell anemia, higher HbF concentrations temper the disease.

Pathophysiology

β Thalassemia Mutations in HbS–β Thalassemia

The pathophysiology of the sickle–β thalassemias is similar to the pathophysiology of sickle cell anemia (Chapters 8–11) with the major determinant of severity being the magnitude of the reduction in β^A-globin chain production caused by the thalassemia mutation. Different β thalassemia–causing mutations have been described in association with HbS and many of these are shown in Table 23.1. The β thalassemia mutations extant in each population determine the phenotypes of HbS–β thalassemia present. HbS–β thalassemia has a different clinical spectrum in different racial and ethnic groups because β thalassemia mutations vary among populations. HbS–β thalassemia is most common in selected Italian and Greek populations, in Turks,

* In many instances, few patients or only a single patient was studied so that the values reported may not necessarily be representative of the genotype.

§ Indicates those examples of HbS–β thalassemia in which information is scanty and only one or two cases are reported. Also, patient ages could differ among groups, confounding the interpretation of hemoglobin level, MCV, HbF, and HbA_2. Sometimes, no hematological values are available. Data reported were assembled from the following references and are summarized in http://globin.cse.psu.edu.[58,82–92]

¶ Mean age of patients was approximately 10 years.

§§ One individual, age 9 months, was studied. HbA_2 was 6%.

Iranians, and other Middle Eastern nationalities, in tribal groups of the Indian subcontinent and in blacks of African descent. "Mild" β-globin gene promoter mutations are prevalent in blacks, accounting for the preponderance of milder forms of HbS–β^+ thalassemia in this racial group.

As with sickle cell disease caused by other genotypes, the pathophysiology of the HbS–β thalassemias is ultimately linked to HbS polymerization and modulated by coincident genetic factors, such as the ability to make large amounts of HbF and by the cellular concentration of HbS. Two interrelated elements modulate the polymerization tendency of HbS in HbS–β thalassemia. They are mean corpuscular HbS concentration and the concentration of HbA. In both HbS–β^0 thalassemia and HbS–β^+ thalassemia, reduced β-globin chain accumulation reduces mean corpuscular hemoglobin (MCH) and mean corpuscular volume (MCV). In HbS–β^+ thalassemia, HbA concentration is the major determinant of mean corpuscular HbS concentration. HbA dilutes HbS and, depending on its concentration, variably inhibits polymerization-induced cellular damage. HbA is

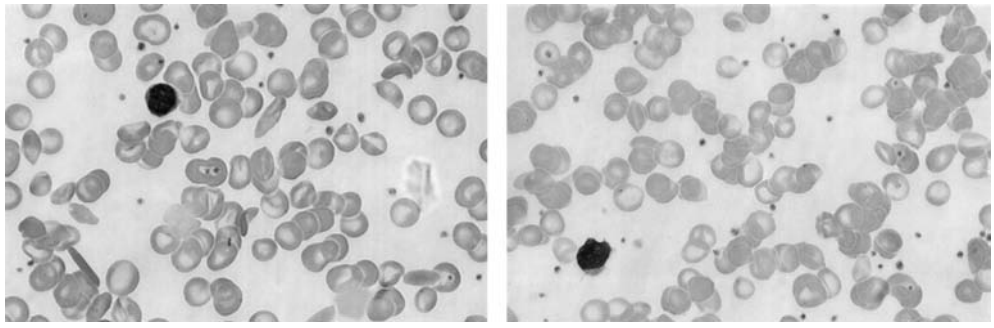

Figure 23.1. Blood films in two patients with HbS–β^0 thalassemia. In the left panel, the patient has an HbF level of 5%. Sickled cells are prominent beside microcytosis. In the right panel, with an HbF of 2%, microcytosis and hypochromia are prominent and few typical sickled cells are seen. Despite similar HbF levels, for unknown reasons, the numbers of sickled cells are quite different. This suggests the possibility of different cellular distributions of HbF or other genetic modifiers. See color plates.

only a "dilutent" and does not have the enhanced benefit of HbF, which is not incorporated into the polymer phase of HbS (Chapters 6, 7).

In HbS–β^0 thalassemia, compared with sickle cell anemia, the effects of thalassemia on sickle erythrocytes – microcytosis, hypochromia, sometimes high levels of HbF – improve the circulatory competence of these cells, marginally reduce hemolysis, and cause a small increase in total hemoglobin concentration. This suggests that as with sickle cell anemia-α thalassemia (see later) a reduction in hemolysis and improved anemia might lead to fewer of the disease complications attributable to intravascular hemolysis, although perhaps increasing the viscosity-vasoocclusive events of sickle cell disease.[1] Nevertheless, despite a few reports, comprehensive data are not yet available in HbS–β thalassemia.[2] Hemolysis-related complications have been described in HbS–β thalassemia. Reduced nitric oxide bioavailability, oxidant stress, and endothelial dysfunction are key contributors to the proliferative vasculopathy of sickle cell disease and its complications (Chapter 11). Similar to what has been found in sickle cell anemia,[3–6] in patients with HbS–β thalassemia, and normal left ventricular function, a complex vasculopathy with endothelial dysfunction, increased arterial stiffness, and a global effect on cardiovascular function was present.[7]

Table 23.2. Laboratory differentiation of sickle cell anemia, sickle cell anemia–α thalassemia and HbS–β^0 thalassemia*

Diagnosis	Hemoglobin (g/dL)	MCV (fL)	HbA_2 (%)	HbF§ (%)	α/β@

Diagnosis

Hematological Evaluation of HbS–β^0 Thalassemia

Microcytosis and hypochromia, noticed on blood films but best determined using automated blood cell counters, and elevated concentrations of HbA_2 are often the first clues to diagnosis of HbS–β thalassemia. Nevertheless, alone they are insufficient for diagnosis. HbS–β^0 thalassemia resembles, in many respects, sickle cell anemia, and in some cases of HbS–β^0 thalassemia the MCV is near normal and the HbA_2 is only elevated marginally. Compounding the possibilities for diagnostic confusion is that sickle cell anemia–α thalassemia is a nearly exact phenocopy of HbS–β^0 thalassemia. Iron deficiency also causes microcytosis in sickle cell anemia, but here, the level of HbA_2 is normal or low. Hematological studies, including the determination of MCV and MCH, quantification of HbS, HbA_2, HbF, and when present, HbA levels, form the cornerstone of diagnosis. Blood films from two patients with HbS–β^0 thalassemia are shown in Figure 23.1. Family studies and the demonstration by DNA analysis of heterozygosity for the sickle β-globin gene and the presence of a β-thalassemia mutation are important confirmatory analyses and are critical when antenatal diagnosis and genetic counseling are at issue.

Some hematological distinctions among these three phenocopies are shown in Table 23.2 and comparative pedigrees are displayed in Figure 23.2. Most cases of HbS–β thalassemia are accompanied by reduced MCV and MCH and increased concentration of HbA_2. Depending on the reticulocyte count, the HbF level, and the nature of the particular β thalassemia mutation, the MCV could be normal or in the lower range of normality. HbA_2 levels are low in early childhood and cannot be relied on for diagnostic discrimination at this stage of life. When the HbF level is very high, HbA_2 levels are often reduced, further compromising the utility of

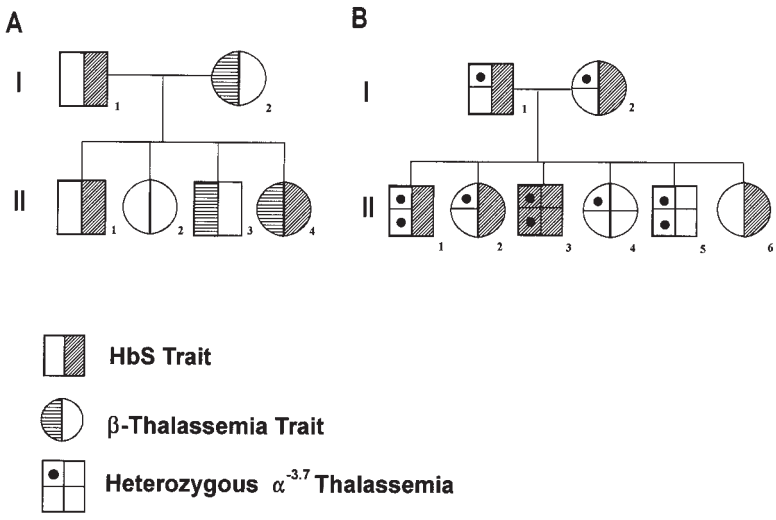

Figure 23.2. Pedigrees of families with HbS–β thalassemia **(A)** and sickle cell anemia with α thalassemia **(B)**. II 4 in family A and II 3 in family B have nearly identical hematological findings with microcytic erythrocytes and increased HbA_2 levels. Nevertheless, A II 4 has HbS–β thalassemia and B II 3 has sickle cell anemia with homozygous α thalassemia-2. The latter individual has inherited an HbS gene from each parent and an α thalassemia gene from each parent. As shown in the pedigree, because the β-globin genes and α-globin genes are on different chromosomes they are inherited independently and individuals can have HbAS (or sickle cell anemia) without α thalassemia or with one or two α thalassemia genes. The HbS and β thalassemia genes are allelic.

this measurement. Although high HbA_2 levels are typical of heterozygous β thalassemia, the increase is in part dependent on the reduction of β-globin chain synthesis. HbA_2 is also high when α thalassemia is present with sickle cell anemia. This increase is proportional to the reduction in α-globin chain synthesis and is a result of the differential affinities of non-α-globin chains for the limited numbers of α-globin chains. HbA_2 levels and MCV in sickle cell anemia, HbS-β^0 thalassemia, and sickle cell anemia–α thalassemia are shown in Figure 23.3. Although HbA_2 levels are highest in HbS–β^0 thalassemia, lowest in sickle cell anemia, and intermediate in sickle cell anemia–α thalassemia, in an individual, they have little discriminatory value and diagnostic utility. HbF levels span a very wide range in all three genotype, rendering them diagnostically useless.

Hematological Evaluation of HbS–β^+ Thalassemia

Family studies, hematological evaluation, and measuring the percentage of HbA, HbS, and HbA_2 by high-performance liquid chromatography (HPLC) are usually sufficient for establishing the presence of HbS–β^+ thalassemia. When a sickle solubility test is the sole means of diagnosis – it should never be! – or when protein-based methods, such as hemoglobin electrophoresis or HPLC, are uncritically interpreted, HbS–β^+ thalassemia might be confused with HbAS or even go unsuspected.

In HbS–β^+ thalassemia, the presence of HbA simplifies the diagnosis. Yet, the rare case with very high HbA levels – the highest level reported is 45% – might be confused with HbAS and in instances in which HbA is quite low – the lowest levels are less than 5% – its presence can be overlooked. Representative hematological findings in the different genotypes of HbS–β^+ thalassemia are presented in Table 23.1. During newborn screening for sickle cell disease, small amounts of HbA might be undetected, leading to a false diagnosis of sickle cell anemia and emphasizing the need for confirmatory testing after the initial screening.[8]

Individuals with HbS–β^+thalassemia and very low levels of HbA are often mistakenly diagnosed as having HbS–β^0 thalassemia. Four β^+ thalassemia mutations, all producing a severe phenotype, have been described at IVS-1 position 5, and two of these have been associated with severe HbS–β^+ thalassemia, masquerading as HbS–β^0 thalassemia (Table 23.1).[9] IVS-1 position 5 is part of the consensus sequence for the donor splice site of exon 1. When mutated, splicing efficiency is greatly reduced and only a small amount of mRNA is correctly spliced.

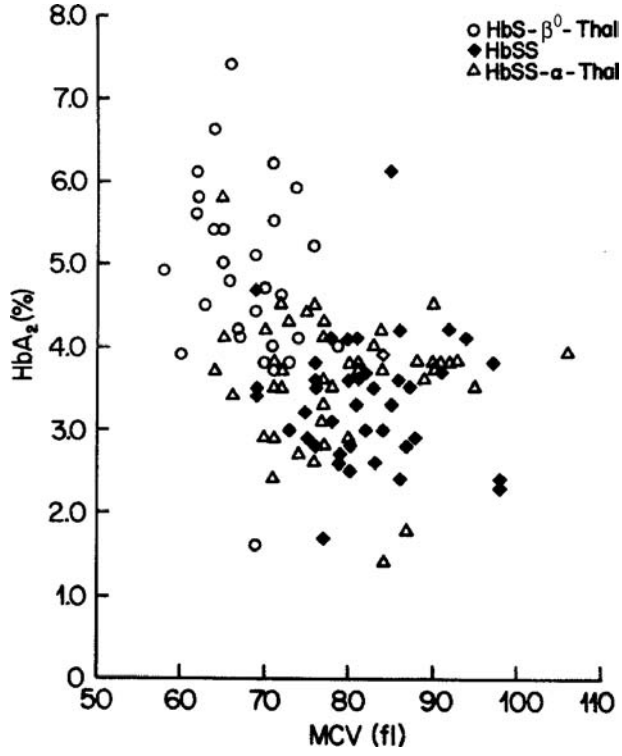

Figure 23.3. HbA_2 levels and MCV in HbS–β^0 thalassemia, sickle cell anemia–α thalassemia, and sickle cell anemia. Considerable overlap among these genotypes makes it difficult to rely on HbA_2 for diagnostic purposes in an individual case. Most reported methods of HbA_2 analysis by HPLC result in higher levels of HbA_2 when HbS is present. The data reported here are not based on HPLC.

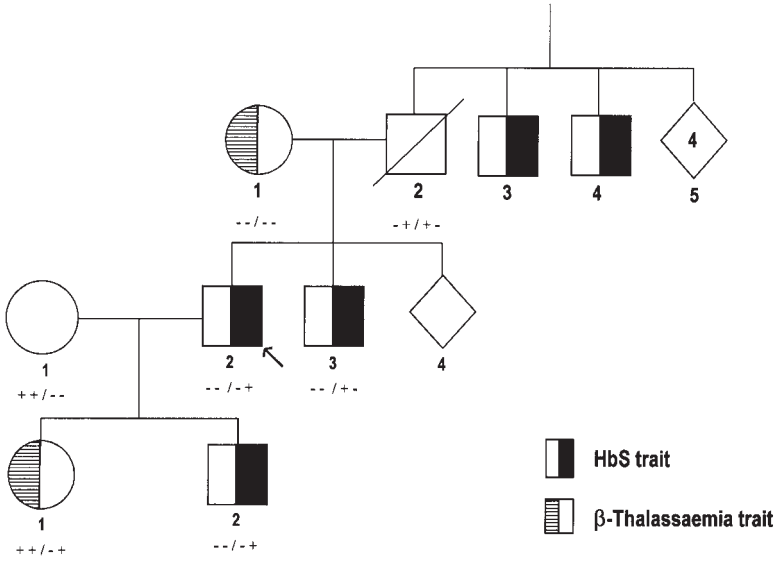

Figure 23.4. Inheritance of sickle cell trait and β thalassemia unlinked to the β-globin gene cluster. The two Hinc II/ψ β restriction length polymorphisms are shown with +/-.[12]

Molecular Evaluation

In any instance when antenatal diagnosis is contemplated or family counseling is needed, DNA-based molecular analysis is required (Chapter 28). The most confusing diagnostic problem is the differentiation of HbS–β^0 thalassemia from sickle cell anemia–α thalassemia. Microcytosis and the elevated HbA_2 level in sickle cell anemia–α thalassemia cause great confusion with HbS–β^0 thalassemia. Differentiating between these genotypes is critical during genetic counseling because hematological, HPLC or electrophoretical studies, and, for the case of sickle cell anemia–α thalassemia, family studies, cannot distinguish among these conditions.

In HbS–β^0 thalassemia, DNA analysis will show that the patient is heterozygous for the HbS gene and that the other β-globin gene contains a β thalassemia mutation. In sickle cell anemia–α thalassemia, patients are homozygous for the HbS gene and have an α thalassemia mutation, most often a deletion of one or more α-globin genes (Chapter 13).

Hb Monroe (*HBB* IVS-1 position -1, G-C), initially described in a Tunisian patient and called Hb Kairouan, has been described in several families as a compound heterozygote with HbS. IVS-1 position -1 is between the A and G of β-globin gene codon 30 (AGG), which normally codes for arginine; in Hb Monroe it is converted to a threonine codon (ACG). The mutation has dual effects: it impairs the use of the normal 5′ splice site by 98%, and the threonine residue causes hemoglobin instability. In HbS–Hb Monroe disease, Hb Monroe is not detectable by isoelectric focusing, and only in some patients is 0.6%–1.6% Hb Monroe found by HPLC.[10] Patients with HbS–Hb Monroe appear to have all the clinical and hematological features of HbS–β^0 thalassemia.

Two Moroccan adults with HbAS were found to have the -88 C-T β^+ thalassemia mutation in c*is* to the sickle mutation. Both had a normal α-globin gene haplotype. A reticulocyte count of approximately 3%, mild anemia, and microcytosis (Table 23.1), without iron deficiency suggested the presence of mild hemolysis. HbA_2 levels were 6%–7%, HbF approximately 3% and HbS, 10%–11%. In one individual, the α/β globin biosynthesis ratio was 1.35 and the ratio of $\beta^S/\beta^A+\beta^S$ was 0.17.[11] Further studies of cloned DNA in the patient's family confirmed that the thalassemia mutation was in the same gene as the HbS mutation. Analysis of polymorphisms 5′ to the β^S gene revealed a Benin haplotype chromosome, strongly suggesting that the thalassemia mutation arose anew on the HbS chromosome rather than from a recombination between a β thalassemia and an HbS chromosome. It was not clear why HbS levels were as low as they were because analysis showed a reduction of β-globin mRNA similar to that found in simple heterozygotes for the -88 C-T mutation. The authors speculated that the reduction in HbS was caused by a posttranslational event and that even without α thalassemia, the β^S chains competed less well than the β^A chains for α-globin chains.

Two Portuguese patients with HbAS had a β thalassemia determinant that was not linked to the β-globin gene (Fig. 23.4).[12] Extensive analysis of the β-globin gene DNA failed to find a thalassemia-causing mutation. Carriers had very mild microcytic anemia and increased HbA_2 levels; in vitro translation of mRNA showed an α/β ratio of 1.6. Examples of *trans*-acting β thalassemia mutations are rare.[13]

Clinical Features

Although it is possible to generalize about genotype–phenotype relationships in HbS–β thalassemia, as with sickle cell anemia, genotype–phenotype association correlations are often difficult to establish because of the many genetic and environmental modulators that impact this disease (Chapter 27).

HbS–β^0 Thalassemia

HbS–β^0 thalassemia (and HbS–β^+ thalassemia with very low levels of HbA), with some exceptions, has a pathophysiology and panoply of clinical complications very similar to sickle cell anemia. In HbS–β^0 thalassemia, the average packed cell volume (PCV) and hemoglobin concentration are higher than in sickle cell anemia, a likely result of the reduction in mean cell HbS concentration and improved red cell survival. Based on current understanding of the role of hemolysis as a risk factor for death and some

complications of disease,[1,14] it might be expected that the mild reduction of hemolysis in HbS–β^0 thalassemia compared with sickle cell anemia would be beneficial in some areas. That supposition has not yet been confirmed by clinical studies. Conversely, one might expect that disease complications associated with blood viscosity might be more prevalent. In one study of HbS–β^0 thalassemia, osteonecrosis was more common than in sickle cell anemia.[15] Bacteremia occurred half as often in HbS–β^0 thalassemia as in sickle cell anemia.

An exception to the nearly uniform severe phenotype of HbS–β^0 thalassemia is the rare patient with very high HbF and HbA_2 levels. This has been associated with several small deletions that affect the 5′ portion of the β-globin gene, and, perhaps because of competition of the transcriptional apparatus for gene promoters, is typified by very high HbA_2 and HbF levels (Chapter 16). Both HbA_2 and HbF inhibit the polymerization of HbS. In families with HbS–β^0 thalassemia caused by a −1.4-kb 5′ β-globin gene deletion, the combined total of HbF and HbA_2 was more than 20% of the total hemoglobin. This was associated with a milder than expected phenotype; nevertheless, other observations suggested that all individuals with this genotype might not be similarly affected. One young child with HbS–β^0 thalassemia caused by a 532-bp deletion in the 5′ part of the β-globin gene had 29% HbF and 6% HbA_2; however, this patient's age precluded an assessment of the phenotype.

HbS–β^+ Thalassemia

The clinical features of HbS–β^+ thalassemia depend on the β thalassemia mutation and the deficit of β^A-globin chains (Table 23.1). Rare cases of HbS–β^+ thalassemia are asymptomatic, and some are quite severe; however, for the most part the phenotype of HbS–β^+ thalassemia lies between these extremes.

In one HbS–β^+ thalassemia study, the median PCV was 32 in all patients younger than age 10 years. Males aged 10–19 years and those aged 20 years and older had PCVs of 36 and 40, respectively, approximately four–six points higher than age-matched females. In all patients, the MCV was 70–72 fL compared with approximately 90 fl in sickle cell anemia. Leukocyte and platelet counts were also reduced compared with sickle cell anemia patients.[16] These data were from African American patients in whom the preponderance of β^+ thalassemia mutations is "mild" (Table 23.1 and Chapter 16).

The Cooperative Study of Sickle Cell Disease in the United States examined clinical differences among the common sickle hemoglobinopathies. Approximately 3% of patients with HbS–β^+ thalassemia died during 6–8 years of observation compared with 8% of patients with sickle cell anemia, 4% with HbS–β^0 thalassemia, and 3% with HbSC disease.[17] Patients with HbS–β^+ thalassemia had pain rates approximately half those observed in HbS–β^0 thalassemia and sickle cell anemia and similar to those of patients with HbSC disease.[18] Osteonecrosis of the femoral head rarely appeared in children with HbS–β^+ thalassemia and was less frequent in adults with this genotype (5.8%) than in sickle cell anemia (10.2%). Bacteremia was approximately half as frequent in HbS–β^+ thalassemia as in sickle cell anemia and similar to its incidence in HbSC disease. At any age, the incidence of acute chest syndrome in HbS–β^+ thalassemia was less than in sickle cell anemia or HbS–β^0 thalassemia, which did not differ, and it was similar to that in HbSC disease.[19] Strokes occur in all genotypes of HbS–β thalassemia but less often than in sickle cell anemia.[20] As in patients with sickle cell anemia, individuals with HbS–β thalassemia without overt stroke can have abnormal transcranial Doppler flow velocity and silent cerebral infarction, although in one small study patients' cognitive function seemed unimpaired.[21]

HbS–β^+ thalassemia patients with more than 20% HbA usually have milder clinical disease than those with sickle cell anemia and HbSC disease, and some patients can be asymptomatic with the diagnosis established incidental to other medical problems. Now and then, the presence of HbS is not recognized at all because the patient seems normal hematologically. Sometimes, the mildness of this genotype leads it to be confused with HbAS. Nevertheless, microcytosis and reticulocytosis are virtually always present in HbS–β^+ thalassemia, whereas reticulocytosis is not a feature of HbAS. Failing to recognize mild HbS–β^+ thalassemia can be a serious omission when surgery is planned or pneumonia-like disorders are treated because individuals with this genotype can encounter severe and devastating problems.[22] Some observations suggest that the mortality rate of acute chest syndrome is higher in HbS–β^+ thalassemia than in sickle cell anemia.[23–25]

Splenic enlargement is more likely to persist into the adult years in HbS–β thalassemia; in some studies it is present in more than half the affected patients. As a result, adults can have splenic sequestration episodes. An enlarging spleen in adults can also lead to hypersplenism with falling blood counts and splenic infarction.

In Greek patients with HbS–β thalassemia, detailed studies of renal function showed multiple abnormalities that were similar in all respects to those found in sickle cell anemia. Similarly, polymorphisms of the *UGT1A1* gene (Chapter 27) modulated serum bilirubin concentration.[26]

HbS–β Thalassemia with α Thalassemia

Although some reports suggest a milder phenotype in HbS–β thalassemia with α thalassemia,[27] when more than a few cases are available for analysis, any influence of coexistent α thalassemia on the phenotype of HbS–β^0 thalassemia or β^+ thalassemia is difficult to detect. The numbers of observations are still too small to provide firm conclusions. Not all reports used gene mapping to detect α thalassemia. When the coincidence of these disorders was based on the less reliable use of hematological, electrophoretical,

and globin biosynthesis studies, there were no clinical or hematological differences compared with patients with HbS–β^0 thalassemia, except for the presence of balanced globin biosynthesis ratios. No clinical and hematological differences were observed when heterozygous or homozygous α thalassemia-2 was ascertained by α-globin gene mapping.

HbS–Hereditary Persistence of Fetal Hemoglobin and δβ Thalassemia

Pathophysiology

HPFH connotes the continued expression of HbF into adult life (Chapters 16 and 17). These conditions are, like all genetic abnormalities of globin, genetically and hematologically heterogeneous. They can be divided into two classes: HPFH caused by extensive deletions within the β-like globin gene complex and HPFH caused by point mutations within the promoters of the γ-globin genes. The δβ thalassemias, also caused by large gene deletions, are closely related to gene deletion HPFH. Compound heterozygotes with HbS-deletion HPFH and δβ thalassemia can be found in populations of African and Mediterranean ancestry, and some mutations described in HbS–HPFH and δβ thalassemia are shown in Table 23.3. Nongene-deletion HPFH in sickle cell anemia is difficult to recognize when lacking family studies with enumeration of F cells and determination of the HPFH mutation, so there is no reliable description of its phenotype. Therefore, we will consider mainly the HbS-deletion HPFH and δβ thalassemia syndromes. Nongene-deletion HPFH is more commonly suspected when it is present with HbAS or exists without an abnormal hemoglobin or β thalassemia.

A pancellular distribution of HbF in HbS-deletion HPFH retards HbS polymerization to the extent that hemolytic and vasoocclusive diseases are absent or very minimal. Although HbS–δβ thalassemia and HbS-deletion HPFH can have similar total HbF levels, in the former condition all cells are not equally endowed with HbF so that mild hemolytic anemia is present.

Diagnosis

In blacks, the prevalence of HbS-deletion HPFH is approximately 0.0001.[28] HbF levels are 20%–30%, and nearly equal concentrations of HbF are present in all erythrocytes leading to the designation, pancellular HPFH. Anemia and reticulocytosis are absent or mild, irreversibly sickled cells are absent, target cells are present, and HbA_2 levels are low or normal because the HPFH chromosome lacks the δ-globin gene. Thirteen unselected patients with HbS–HPFH, diagnosed because the proband had a parent with heterozygous HPFH, but not by molecular analysis, were compared with patients with sickle cell anemia and HbS–β^0 thalassemia. In all groups, patients were aged between 9 and 12 years, and all individuals had HbF levels of more than 20%. Their hematological findings are summarized in Table 23.4. Differentiating among these genotypes was possible based on the hematological findings, although the patients with sickle cell anemia and HbS–β^0 thalassemia were selected for this comparison by their high HbF levels. When HbS-gene deletion HPFH is compared with unselected cases of sickle cell anemia and HbS–β^0 thalassemia that have more ordinary HbF levels, the differentiation among these genotypes is even more dramatic.

Hb Kenya is caused by a γβ fusion gene, the product of nonhomologous crossing over between the γ- and β-globin

Table 23.4. Comparisons of HbS Gene–deletion HPFH, sickle cell anemia with high HbF, and HbS–β thalassemia

	HbS-HPFH	Sickle cell anemia	HbS–β thalassemia

Reticulocytes (%)	1.9	7.3	3.6

Adapted from ref. 28; values given are means.

genes (Chapter 16). In compound heterozygotes with HbS, there was approximately 18% Hb Kenya, evenly distributed among the red cell population and HbF averaged approximately 8%. Hb Kenya acted as a deletion HPFH determinant, and vasoocclusive symptoms were not reported. Red cell morphology was normal, and anemia was absent or minimal.[29]

In HbS–δβ thalassemia, the HbF level is 15%–25%. Its cellular distribution is not uniform as it is in HbS-deletion HPFH, but instead HbF is unevenly spread among red cells, or, is heterocellular. Anemia is mild with the hemoglobin level averaging 10–12 g/dL, reticulocytes are approximately 2%, and the MCV is low normal. HbA_2 levels are normal or low because of the deleted δ-globin gene.

Some individuals with sickle cell anemia have very high HbF levels and seem not to have deletion HPFH, δβ thalassemia, or a Senegal haplotype chromosome (Chapter 27). Few of these patients have been carefully studied, but it is likely that some will have a nondeletion HPFH mutation. In a patient with sickle cell anemia who was heterozygous for the Benin and the "MOR" haplotype and lacked the −158 C−T polymorphism, HbF was 24%–29%. The presence of a C−T mutation at −202 5′ to the $^{A}\gamma$ globin gene was suspected to cause this marked increase in HbF. Individuals with HbAS who also inherited this mutation had 2%–4% HbF and more than 90% $^{A}\gamma$ chains.

In some cases of sickle cell anemia with unusually high HbF levels, the increase in HbF might not be linked to the β-globin gene-like cluster. Other instances could be associated with already identified or still obscure *cis*-acting elements linked to the β-globin gene that might modulate γ-globin gene expression or with *trans*-acting elements that modulate HbF expression (Chapter 27).

Clinical Aspects

HbS-deletion HPFH is not associated with hemolytic anemia or acute vasoocclusive disease, although osteonecrosis has been described. The phenotype of HbS–δβ thalassemia also seems mild. Vasoocclusive problems can occur but less often than in sickle cell anemia or HbS–β thalassemia. Splenomegaly is common.

HbS–Hb Lepore

Hb Lepore, the name given to a small group of hemoglobin variants that result from unequal crossing over between δ- and β-globin genes (Chapter 16), is characterized by the deletion of both these genes from the chromosome and their replacement by a poorly expressed, δβ hybrid, or, Hb Lepore gene. HbS–Lepore was first described in Greece but has since been found in many other geographical areas. Hb Lepore moves electrophoretically like HbS but is easily separated from HbS, HbA, and HbF, but not HbA_2, by HPLC. In heterozygotes, it accounts for approximately 10% of the total hemoglobin causing, in essence, a $\delta\beta^{+}$ thalassemia with levels of Hb Lepore equivalent to the levels of HbA in the IVS-1, 110 G-A HbS–β^{+} thalassemia.

Compound heterozygosity for HbS and Hb Lepore is an uncommon condition, most often described in Mediterranean populations, and best diagnosed by family studies that document heterozygous Hb Lepore in a parent or sibling. Failure to note the presence of Hb Lepore by protein-based hemoglobin diagnostic studies can result in the confusion of this genotype with sickle cell anemia or HbS–β^{0} thalassemia, but HPLC can now simplify this distinction, and DNA analysis can authenticate the presence of the Hb Lepore gene.[30] Because compound heterozygotes with HbS–Hb Lepore have only a single β-globin gene, amplification of the β-globin gene and allele-specific hybridization or restriction endonuclease cleavage can falsely suggest homozygosity for the HbS gene when in actuality, the patient is hemizygous at the β^{6} codon.

Unsurprisingly, reported patients with HbS–Lepore have heterogeneous phenotypes. Compared with sickle cell anemia and HbS–β^{0} thalassemia, there is less anemia, and a reduction in MCV, HbA_2, and reticulocyte counts. Symptoms can vary and splenomegaly is common. Only a few clinical studies of HbS–Lepore disease have been conducted, making it difficult to define completely its clinical spectrum. On average, the hemoglobin level is 11–13 g/dL, HbS and Hb Lepore comprise 70%–80%, and HbF makes up 10%–20% of total hemoglobin.

Residues δ22 (ala) and δ87 (gly) inhibit polymerization of HbS (Chapter 6). When HbA_2 and HbF levels are high, their combination might cause a mild phenotype. Hb Lepore Boston, the type most often reported with HbS, contains the δ87 glycine residue whereas Hb Lepore Hollandia contains δ22 alanine. It is possible that the presence of Hb Lepore not only reduces the concentration of HbA but also inhibits polymerization, accounting for the milder than expected phenotype.

Treatment Recommendations

With few exceptions, individuals with HbS–β thalassemia-like disorders should be managed like those with sickle cell anemia. Although serious pneumococcal infection is less common in HbS–β^{+} thalassemia with high levels of HbA

Table 23.5. Sickling hemoglobins with two amino acid substitutions in the β-globin chain

Hb name	Amino acid substitution	Variant with same mutation	*HBB* mutation	Phenotype
S-Antilles	val23Ile	HbS (---)	GTT→ATT	Migrates ~HbS. Heterozygote affected; compound heterozygote with HbS or HbC severely affected
C-Ziguinchor	pro58arg	HbS (Dhofar)	CCT→CGT	Migrates ~HbC on electrophoresis. 30%–40% in the heterozygote. Normal hematology, target cells
C-Ndjamena	trp37gly	Hb Howick	TGG-GGG	Migrates like HbC on isoelectric focusing; faster than HbS on HPLC; phenotype appears severe
Jamaica Plain	leu68phe	New mutation (Rockford/ Loves Park)	CTC-TTC	Migrates like HbS on isoelectric focusing, not separable from HbS by HPLC. Moderate to severe disease in simple heterozygote
C-Harlem	asp73asn	HbS (Korle-Bu)	GAT→AAT	Migrates like HbS at alkaline pH and like HbC at acidic pH. Compound heterozygote with HbS, ~sickle cell anemia, Heterozygote ~40%, normal hematology
S-Providence	asn82asp	HbS (Providence)	AAG→AAT or AAC	Migrates like HbA. Hematology normal
S-Cameroon	glu90lys	HbS (Agenogi)	GAG-AAG	HbAS; 38% HbS-Cameroon
S-Oman	glu121lys	HbS (O-Arab)	GAA→AAA	Migrates ~HbC. Heterozygote has ~15% HbS-Oman
S-South End	lys132asn	HbS (Yamagata)	GAG-GTG	Migrates like HbA on HPLC. Severe sickle cell disease when present with HbS
S-Travis	ala142val	HbS (---)	GCC→GTC	Migrates between HbS and HbF at alkaline pH and between HbA and HbS at acidic pH. Unstable, ~15% in heterozygote. Hematology normal

Shown are the non-HbS mutation and amino acid substitution. All cases have the *HBB* glu6val HbS mutation (http://globin.cse.psu.edu[9]). The mutations have been proven by gene analysis in only a few instances.

and might be no more common than in the general population, it does occur.[31] Little consensus exists on the use of prophylactic penicillin to prevent pneumococcal sepsis in HbS–β^+ thalassemia or other "mild" compound heterozygous forms of sickle cell disease.[31–33] A decision to use prophylactic penicillin in HbS–β thalassemia can be based on an approach similar to that for HbSC disease and is discussed in Chapters 19 and 21. In essence, this decision is predicated on an evaluation of splenic function, which if normal, argues for withholding prophylaxis. Pneumococcal vaccinations should be given and parents instructed to seek immediate medical attention for febrile illnesses.

Patients with HbS–β thalassemia and like disorders have a higher prevalence of proliferative retinopathy than do individuals with sickle cell anemia. They should be monitored like patients with HbSC disease (Chapter 21).

Continued and sometimes advancing splenomegaly predisposes affected individuals to splenic infarction, splenic sequestration episodes, and hypersplenism. These complications raise the issue of splenectomy and its timing during the evolution of the disease. Delaying splenectomy until the first recurrence of an episode of splenic sequestration seems reasonable. Hypersplenism or subacute splenic sequestration can be associated with worsening anemia and the need for transfusion. This might then dictate the need for splenectomy. Splenic infarcts can be painful, recurrent, and associated with intrasplenic hemorrhage. They may, depending on the severity of symptoms, also require splenectomy.

When general anesthesia is planned, based on observations in HbSC disease and in sickle cell anemia, using preoperative transfusion in patients with HbS–β^+ thalassemia who face procedures with moderate surgical risk, such as abdominal surgery, appears prudent.[34,35] Preoperative transfusions are likely to reduce the incidence of serious complications such as the acute chest syndrome.

SICKLING HEMOGLOBINS WITH TWO SUBSTITUTIONS IN THE β-GLOBIN GENE

Nine variant hemoglobins have been described with both the *HBB* glu6val mutation and an additional amino acid substitution in the same β-globin chain (Table 23.5). Some of these variants were likely to have arisen from crossing-over between a chromosome with the HbS mutation and a chromosome containing the other mutation. Hb Korle-Bu (*HBB* asp73asn) and HbO-Arab (*HBB* glu121lys) are sufficiently common to suggest that crossing-over between these genes and HbS genes account for the origin of HbC-Harlem (*HBB* glu6val; asp73asn) and S-Oman (*HBB* glu6val; glu121lys), respectively. For Hb Jamaica Plain (*HBB* glu6val; leu68phe), analysis of parental alleles suggested a new mutation on the proband's HbS gene.[36] In six instances (Table 23.5), the hemoglobin variant with the second

mutation was characterized before the description of the HbS variant.

HbS-Antilles

HbS-Antilles (*HBB* glu6val; val23ile) was found in a black family from Martinique. Twenty-four heterozygotes with 40%–50% HbS-Antilles had hemolytic anemia with hemoglobin levels of 11 g/dL, reticulocytes of 4.5%, and MCV of 90 fL. Irreversibly sickled cells were present in the blood film. Heterozygotes for HbS-Antilles had recurrent painful episodes and splenomegaly. Three compound heterozygotes with HbS died with severe anemia and one child with HbS-Antilles/HbC had severe disease.

Like the erythrocytes of HbS homozygotes, HbS-Antilles red cells had reduced oxygen affinity but solutions of HbS-Antilles also had a low P_{50}. This variant had a C_{sat} – a measure of hemoglobin solubility – of 11.9 g/dL compared with 18.4 g/dL for HbS and 24.1 g/dL for an equal mixture of HbS and HbA. HbS-Antilles erythrocytes sickled at physiological pO_2. Ten percent to 20% of HbS-Antilles erythrocytes had increased density. The percentage of HbS-Antilles cells that sickled at pO_2 between 0 and 70 mm Hg was identical to HbSC disease erythrocytes. At a pO_2 between 40 and 90 mm Hg, the polymer fraction in HbS-Antilles cells was calculated to be similar to that present in erythrocytes of sickle cell anemia. These findings show that this variant polymerized more readily than HbS at any pO_2. HbS-Antilles polymerizes even when it comprises only half of the cellular hemoglobin, accounting for cellular damage and the symptoms of sickle cell disease in heterozygotes (Chapter 22) and the very severe phenotype in compound heterozygotes with HbS or HbC.

HbS-Oman

This variant, containing the HbS and HbO-Arab mutation, migrates more slowly than HbC when electrophoresed at alkaline pH because of an additional positive charge; β121 lys appears to stabilize the sickle polymer. C_{sat} was 11 g/dL, nearly identical to that of HbS-Antilles and lower than that of HbS. In all cases described to date, HbS-Oman has been associated with either heterozygous or homozygous α thalassemia-2 (Fig. 23.5). Homozygotes for this variant have not been described but are predicted to have very severe disease, resembling homozygotes with HbS-Antilles and perhaps made even worse by the presence of α thalassemia. Two different phenotypes appear to exist.[37] Patients with HbS-Oman–heterozygous α thalassemia-2 had more than 20% of the variant hemoglobin, low hemoglobin levels, MCV approximately 73 fL, splenomegaly, and vasoocclusive episodes including acute chest syndrome. Their sickle cells had a peculiar morphology described as "yarn/knitting needle" believed to be a consequence of one or two domains of HbS-Oman polymerization. Individuals with HbS-Oman–homozygous α thalassemia-2 had approximately 14% variant hemoglobin and further reduction of MCV. They were asymptomatic but had microcytosis. Interaction of this highly charged variant with the membrane, a general feature of hemoglobins with high positive charges like HbC and HbA_2, promotes dense cell formation and polymerization even at the relative low concentrations of HbS-Oman found in heterozygous HbS-Oman–heterozygous α thalassemia-2.

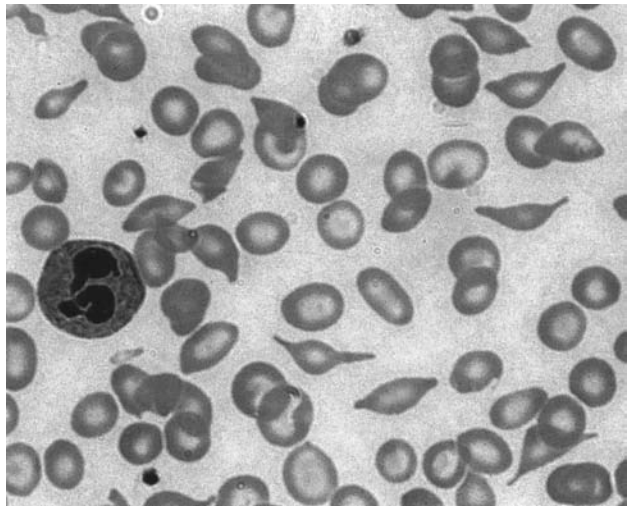

Figure 23.5. Erythrocytes in different genotypes of HbS-Oman disease. The peculiar shape of the irreversibly sickled cells has been called "yarn/knitting needle" and it presumed due to the polymerization of HbS-Oman in one or two domains.[37]

HbS-HbC Harlem

A compound heterozygote with HbS and HbS-HbC-Harlem had 50% HbS, 43% HbC-Harlem, and 7% HbF. Hematological findings were similar to those in sickle cell anemia, with vasoocclusive episodes and osteonecrosis of the hips requiring surgery. Heterozygous HbC-Harlem emulates HbAS. Equal mixtures of HbC-Harlem and HbS had gelling properties identical to 100% HbS, predicting that compound heterozygotes would resemble sickle cell anemia. Compound heterozygotes for HbAS and Hb Korle-Bu, however, do not differ from individuals with HbAS trait alone, indicating that in that variant, the β73 asp-asn substitution does not promote HbS polymerization.

Hb Jamaica Plain

An infant who was thought to have HbAS developed symptoms of sickle cell disease with hypoxia. The blood contained 27% of a variant hemoglobin that behaved like HbS. Genetic studies showed that the *HBB* leu68phe mutation occurred on the paternal HbS gene. Hb Jamaica Plain had reduced O_2 affinity, which was thought to account for its

polymerization in the heterozygous carrier and the symptoms of sickle cell disease.[36]

HbS-South End

Another interesting variant is HbS-South End (*HBB* glu6val; lys132asn), described only in a compound heterozygote with HbS.[38] Severe sickle cell disease was present in the adult carrier of HbS-HbS-South End who, because HbS-South End comigrated with HbA on electrophoresis, was initially diagnosed as having HbS–β^+ thalassemia. It was presumed, but not proven experimentally, that the *HBB* lys132asn mutation in the HbS gene caused reduced oxygen affinity as it did when found as the simple heterozygote in Hb Yamagata.[39,40]

COMPOUND HETEROZYGOTES OF HbS WITH β-GLOBIN CHAIN VARIANTS

Examples Without a Clinical Phenotype

Many β-globin chain variants have been described as compound heterozygotes with HbS. In most examples, only one or a few cases have been reported and gauging the true extent of any hematological or clinical abnormalities is difficult because confounding genetic and acquired abnormalities are not always excluded. Most of these compound heterozygous combinations are not associated with any clinical disease, and if there are hematological abnormalities present, they are minor. Only when the site and type of amino acid substitution permits participation in the polymerization of HbS or the variant is unstable or is synthesized in vastly reduced amounts, as with Hb Monroe, is a clinically apparent phenotype apt to be present. Approximately one third of the β-globin chain variants found with HbS as compound heterozygotes do not separate from HbS by the alkaline electrophoresis as reported in the initial descriptions so the individuals who have these hemoglobins can be mistaken for patients with sickle cell anemia and counseled erroneously or treated incorrectly. More current methods of hemoglobin separation and family studies can usually resolve any confusion that might arise. Some compound heterozygotes with HbS that do not have a clinically significant phenotype are listed in Table 23.6.

Examples with a Clinical Phenotype

Some examples of compound heterozygosity for HbS and other β-globin gene variants associated with hematological or clinical findings are described only once or twice. Their associated phenotype is likely to be incompletely characterized. Often enough, the phenotype is ostensibly the result of the abnormal properties of the variant associated with HbS, usually instability, rather than due to the polymerization of HbS so that, strictly speaking, these examples might not be a type of sickle cell disease (Table 23.7).

HbO-Arab. HbO-Arab is a relatively common variant in blacks and individuals of Arabic descent and in both populations it has been associated with HbS. Together, the two variants can cause severe sickle cell disease. Because HbO-Arab migrates with HbC when electrophoresed at alkaline pH, HbS-O-Arab disease was confused often with HbSC disease. HPLC can separate HbC from HbO-Arab. Patients with unusually severe "HbSC disease" should be carefully evaluated for the presence of HbO-Arab. The β121 residue, also affected in HbD-Los Angeles, is a contact point in the HbS polymer, and substitutions at this residue increase the nucleation rate for polymer formation.

Thirty-nine patients with HbS-O-Arab have been reported, making an assessment of the clinical phenotype possible.[41] Individuals with HbS-O-Arab disease have hematological and clinical findings indistinguishable from patients with sickle cell anemia. In 13 African Americans with HbS-O-Arab disease, aged 3–63 years, mean hemoglobin concentration was 8.7 g/dL, reticulocytes 5.8%, and HbF 6.7%. Blood films showed target and sickled cells. Acute chest syndrome, stroke, leg ulcers, and painful episodes along with all of the other complications of sickle cell disease occurred in all patients. Four patients died: Two children died of pneumococcal sepsis, a teenager died of acute chest syndrome, and an adult from multiorgan failure.

HbD-Los Angeles (Punjab). Compound heterozygosity of HbD-Los Angeles (*HBB* glu121gln) with HbS, first described in Caucasians, produces hematological and clinical manifestations similar to those of sickle cell anemia. The β121 glutamine residue facilitates polymerization of HbS. This mutant, widespread throughout the world, is most common in Caucasians of Northern India. It is a typical HbD when evaluated by the older method of electrophoresis, but it can be separated from HbS and HbA by HPLC.

HbS-Oman and HbS-O-Arab, where the β 121 substitution is in *cis* or in *trans*, respectively, to the HbS mutation and where both conditions are associated with vasoocclusive disease, illustrate the clinical importance of mutations that stabilize the HbS polymer. In contrast, the *HBB* 73 residue, altered in Hb Korle-Bu, does not affect polymerization. Heterozygotes for HbC-Harlem, where the β 73 mutant is in *cis* to the sickle mutation, resemble HbAS. Only the HbS-HbC-Harlem compound heterozygote has sickle cell disease, and this is because of homozygosity for the HbS mutation and not the β 73 mutation in trans.

Hb Quebec-Chori. Hb Quebec-Chori (*HBB* thr87ile) migrated like HbA on alkaline electrophoresis and by isoelectric focusing, allowing the compound heterozygous state with HbS to be confused with HbAS. Reverse-phase HPLC and electrospray ionization mass spectroscopy separated this variant β-globin chain from β^A. Mixtures of Hb Quebec-Chori with HbS had the same delay time of

Table 23.6. Compound heterozygotes of HbS with β-globin chain variants lacking a clinical phenotype

Name	*HBB* Mutation	Properties
Hb Deer Lodge	his2arg	Migrates like HbS on alkaline electrophoresis. Compound heterozygotes appear like "sickle cell anemia"
HbG-San Jose	glu7gly	Migrates between HbF and HbS
Hb Saki	leu14arg	Migrates like HbA
HbJ-Baltimore	gly16asp	Separable by HPLC
Hb Sinai-Baltimore	val18gly	Migrates ~HbA
HbD-Iran	glu22gln	Separable from HbA, ~ to HbA_2 on HPLC
Hb Knossos	ala27ser	Migrates like HbA. A "thalassemic" variant. 40% in compound heterozygote with HbS
Hb Muscat	leu32val	Migrates like HbA. 48% in compound heterozygote with HbS
Hb Athens-Georgia	arg40lys	50% 'HbA' on HPLC
HbG Galveston	glu43ala	Migrates like HbS at alkaline pH, like HbA at acidic pH. Possibly mistaken for sickle cell anemia
Hb Maputo	asp47tyr	Migrates like HbS at alkaline pH, like HbA at acidic pH
Hb Osu-Christiansborg	asp52asn	Separable from HbA, ~ to HbA_2 on HPLC. Possibly mistaken for sickle cell anemia on electrophoresis.
Hb Ocho Rios	asp52ala	Migrates like HbS at alkaline pH
Hb Korle-Bu	asp73asn	Common variant
Hb Mobile	asp73val	Can be confused electrophoretically with HbS
Hb Pyrgos	gly83asp	Migrates faster than HbA
HbD-Ibadan	thr87lys	Migrates like HbS at alkaline pH, like HbA at acidic pH
Hb Caribbean	leu91arg	Migrates between HbS and HbA
HbN-Baltimore	lys95glu	Separable by HPLC, common in blacks
Hb New Mexico	pro100arg	Migrates like HbS at alkaline pH, between HbS and HbC at acidic pH. High oxygen affinity variant with mild erythrocytosis. 54% with HbS
Hb Richmond	asn102lys	Migrates as 2 bands between HbS and HbA
HbP-Galveston	his117arg	Separable on HPLC
Hb Iowa	gly119ala	Migrates ~HbF at alkaline pH. In neonate, electrophoresis was confused with HbSF pattern and sickle cell anemia was considered
Hb Hofu	val126glu	Migrates faster than HbA. 23% with HbS, mild anemia. This might be due to α thalassemia. No symptoms despite HbS of ~70%
Hb Sesirade	ala129val	Unstable, 45% variant; Hb12.7
Hb K-Cameroon	ala129?	Amino acid substitution unclear, ?asp, ?glu
Hb Camden	gln131glu	Migrates faster than HbA at alkaline pH, near HbF at acidic pH
Hb K-Woolwich	lys132gln	Separable by HPLC
Hb McKees Rock	tyr145term	Migrates like HbA. High O_2 affinity variant
Hb Rainier	7tyr145cys	Migrates like HbA. High O_2 affinity variant

Many of these rare variants have not been examined by modern methods of HPLC so that their separation for other hemoglobins is reported only for electrophoresis or isoelectric focusing (http://globin.cse.psu.edu).

polymerization as pure HbS. A bulky hydrophobic isoleucine residue substituted at β87 might strengthen the hydrophobic environment in the acceptor pocket for β6 val, stabilize a lateral contact between HbS polymer strands, and accelerate polymerization. Other work has shown the importance of this site in polymer formation. Participation of this variant with HbS in the polymerization process caused vasoocclusive symptoms and the hematological phenotype of sickle cell disease in the compound heterozygote with HbS. Associated with a nonfunctional enlarged spleen, vasoocclusive episodes, mild anemia, reticulocytosis, sickled cells in the blood, HbS-Hb Quebec-Chori mimics sickle cell anemia and not HbAS. This rare condition, described in the literature twice, provides a cautionary note on the evaluation of clinically symptomatic instances of HbAS (Chapter 22). In one case, hydroxyurea treatment was associated with an increase of HbF.[42]

HbI-Toulouse. HbI-Toulouse (*HBB* lys66glu) was described in a boy with HbAS, splenomegaly, a hemoglobin level of 10.5 g/dL, reticulocytes of 7%, and MCV of 110 fL.

Table 23.7. Compound heterozygotes of HbS with β-globin chain variants with a clinical phenotype

Name	*HBB* Mutation	Phenotype
Hb Monroe	IVS-1–1 G→C; arg→thr	Severe HbS–β^0 thalassemia
HbO-Tibesti	val11ile; glu121lys	Severe, like HbS-O-Arab
HbE	glu26lys	Mild sickle cell disease
Hb Volga	ala27asp	Unstable, hemolytic anemia; Hb Volga elutes ∼HbA on HPLC ∼19%
Hb Lufkin	gly29asp	Migrates faster than HbA. Mildly unstable. ∼45% in compound heterozygote with HbS. Mild hemolysis
Hb I-Toulouse	lys66glu	Migrates faster than HbS
Hb Quebec-Chori	thr87Ile	Causes sickle cell disease. 60% of hemolysate
Hb San Diego	val109met	Difficult to separate from HbA. High oxygen affinity variant with erythrocytosis
Hb Showa-Yakushiji	leu110pro	Unstable variant expressed as a β^0 thalassemia allele. 60% HbS, 36% HbF, Hb 10.7. MCV 63 fL
HbD-Los Angeles (Punjab)	glu121gln	Detectable by HPLC. Fourth most common Hb variant
HbO-Arab	glu121lys	Detectable using HPLC
Hb Shelby	gln131lys	Migrates like HbF at alkaline pH and between HbS and HbC at acidic pH. Mild instability, anemia, microcytosis, ∼10 variant
Hb North Shore	val134glu	"Thalassemic" variant causing HbS–β^+ thalassemia-like phenotype
Hb Hope	gly136asp	Separable by HPLC

(http://globin.cse.psu.edu)[95]

Similar findings were present in a simple heterozygote for this variant, suggesting that it was the characteristics of this unstable hemoglobin rather than HbS responsible for the phenotype.

Hb San Diego. Hb San Diego (*HBB* val109met) is a high oxygen affinity variant described in diverse ethnic backgrounds and often results from a new mutation. It has been postulated that the ethnic diversity of this variant is a result of the mutation occurring at a CpG "hot spot" where deamination of methylcytosine leads to a C-T transition. In a compound heterozygote with HbS, approximately 70% of the hemolysate was Hb San Diego. Mild erythrocytosis with a hemoglobin of 18.8 g/dL and PCV 58 was caused by the high oxygen affinity variant and not by sickle cell disease.

Hb Shelby. Hb Shelby (*HBB* gln131lys), a mildly unstable variant, is associated with hemolytic anemia when present with HbS.[43] It appears to interact similarly with HbS and HbA. At age 4 years, the proband with HbS-Hb Shelby had a hemoglobin level of 9.8 g/dL, 14% reticulocytes, and MCV of 70 fL. Hb Shelby formed 43% of the hemolysate. Splenomegaly or vasoocclusive symptoms were absent. It is not clear why anemia was present in this compound heterozygote. Based on studies of simple heterozygotes for Hb Shelby, the phenotype of this combination most likely is due to Hb Shelby and not HbS polymerization.

Hb Hope. Hb Hope (*HBB* gly136asp) is mildly unstable and has reduced oxygen affinity. When present with HbS, it is associated with mild hemolytic anemia with a hemoglobin concentration of approximately 10 g/dL but normal reticulocyte counts and no symptoms of vasoocclusive disease.[44] In compound heterozygotes, approximately 50%–58% of the hemolysate was Hb Hope.[51] Cr red cell survival was reduced approximately 30%, and Heinz bodies were present in half the red cells. Hb Hope did not appear to affect HbS polymerization because the minimum gelling concentrations of mixtures of Hb Hope with HbS and HbA with HbS were similar. Lack of reticulocytosis was thought to result from the low oxygen affinity of Hb Hope. Again, the phenotype of this combination does not appear to be due to HbS polymerization.

Hb North Shore. Hb North Shore (*HBB* val134glu) is associated with the phenotype of mild β thalassemia. A patient with HbAS and Hb North Shore had mild hemolytic anemia, MCV of 71 fl, HbA_2 of 4.9%, and an α/β synthesis ratio of 3. These findings suggested that HbS polymerization did not contribute to the phenotype that was likely to be a reflection of the 'thalassemic' properties of this variant.[45]

Others. Severe sickle cell disease was associated with compound heterozygosity for HbS and two β-globin variants: HbC-Ndjamena (*HBB* glu6lys; trp37gly) and HbO-Tibesti (*HBB* val11ile; glu121lys) (Chapter 24, Table 24.8). The former contains the HbC mutation and the latter, the HbO Arab mutation, so it is not surprising that a clinically significant phenotype is found with these combinations.

HbSE Disease

HbSE disease was first reported from southern Turkey and has since been reported in the Middle East, India and Pakistan, Southeast Asia, North America, and the Caribbean.[46]

Table 23.8. Effects of α thalassemia in sickle cell anemia

Cellular
Reduced HbS polymer
Decreased cation exchange
Decreased erythrocyte density
Increased erythrocyte deformability
Prolonged erythrocyte lifespan
Clinical
Clinical events
Increased osteonecrosis
Increased splenic sequestration
Possible increased painful episodes
Increased incidence of acute chest syndrome
Fewer leg ulcers
Reduced incidence of pulmonary hypertension
Reduced incidence of priapism
Normalized transcranial Doppler flow studies
Fewer cerebrovascular accidents
Laboratory
Reduced hemolysis and increased PCV
Reduced lactate dehydrogenase, aspartate transaminase
Reduced reticulocytes

In Oman, HbSE disease was found in 0.05% of more than 600 children, a prevalence second only to sickle cell anemia, which was present in 0.2%.[47] Worldwide, HbS and HbE are the two most common variant hemoglobins, and with population migrations and intermarriages, increasingly more patients with HbSE disease will be encountered.

Hematological Findings and Diagnosis. In 26 patients with HbSE disease the hemoglobin level was either normal or mildly decreased with a mean of 11.2 +/− 1.8 g/dL in 24 individuals including children.[46] Hemoglobin levels as high as 14.6 g/dL in a 22-year-old African American man and 14.3 g/dL in a 31-year-old Turkish man were observed. Their MCV was slightly below the normal range. Data on variables that might affect the wide range of MCV, including the α-globin genotype, the degree of reticulocytosis, possible coexistent iron deficiency, or other chronic diseases were not always available. In 18 patients, reticulocyte counts varied from 0.5% to 4.3%. HbS accounted for 62.8% +/− 7.4%, and Hb E accounted for 33.3% +/− 3.6% of the hemolysate in 22 patients. HbF level varied from undetectable to 5.2%. Similarly heterogeneous hematological findings are seen in Hb S–β^+-thalassemia although in this genotype, the severity of the β^+-thalassemia mutation is the major determinant of the hematological and clinical phenotype.

The clinical laboratory diagnosis of HbSE can be problematic. HbE cannot be distinguished from some variant hemoglobins, such as HbC, by some still commonly used clinical laboratory electrophoretical techniques, but it is separable by HPLC, and DNA-based diagnostics are definitive. The level of HbS in the hemolysate is comparable to the level present in many patients with HbS–β^+ thalassemia.

Clinical Features. Although generally thought to be benign, HbSE disease can be symptomatic. Review of the literature showed that nine patients, aged 18 years and younger, were generally well; nevertheless, among 17 patients aged 20 years and older, nine presented with symptoms and findings usually ascribed to sickle cell disease.[46] Some patients had mild anemia, reticulocytosis, and hyperbilirubinemia, indicative of hemolysis. Other reported events in patients with HbSE disease included painful episodes, avascular necrosis of the hip and shoulder, acute chest syndrome, sickle cell retinopathy, bone marrow necrosis, hematuria, splenic infarction, splenic sequestration, splenomegaly, and cholelithiasis. Two patients developed acute chest syndrome, one following parvovirus B19 infection, accompanied by markedly elevated lactate dehydrogenase and hyperbilirubinemia. These sickling-related complications appeared mostly in adults who were aged 20 years or older. As asymptomatic patients with HbSE are less likely to be reported, these results are not necessarily representative of all patients with this genotype. In 12 cases of HbSE disease from six families reported from Oman, seven were aged younger than 20 years.[47] Only three individuals had symptoms of sickle cell disease.

Although patients with HbSE disease might have a relatively mild clinical course, they can develop all of the complications of sickle cell disease. Concomitant α thalassemia exerts significant effect on the clinical manifestations of patients with sickle cell anemia, and α thalassemia is likely to be present in some patients with HbSE disease. Hemoglobin subunit assembly is facilitated by electrostatic attraction between the positively charged α-globin chains and the negatively charged β-globin chains, predicting that with limiting amounts of available α-globin chains, the assembly of $\alpha\beta^S$ dimers is favored over the assembly of $\alpha\beta^E$-dimers. Consequently, the proportion of HbS might increase further, potentially causing more clinical complications. So far, none of the published reports on HbSE disease recorded the patients' α-globin genotype. Other genetic modifiers might also dictate whether patients with HbSE disease will develop sickling-related complications.

In summary, the previously held assumption that HbSE disease is a clinically benign disorder might not be entirely true. Perhaps half of patients older than 20 years have significant sickling-related complications, including the potentially serious acute chest syndrome. Although this high proportion of symptomatic adult patients with HbSE disease is possibly due to reporting bias, it underscores the importance of proper recognition and follow-up of patients with HbSE disease and the need to provide appropriate treatment when they develop sickling-related symptoms and complications.

Treatment Recommendations

Firm recommendations are hampered by the lack of knowledge of the natural history of HbSE disease. During the

newborn period, patients should be vaccinated against pneumococcal and *Haemophilus influenzae* infections. The currently available and limited data show that children with HbSE disease are clinically well. Therefore, the need for penicillin prophylaxis and folic acid supplement is uncertain, and the same approach as recommended for HbSC disease might be applied. HbE is an oxidatively unstable hemoglobin and is more reactive than HbS in drug-induced oxidation. The coinheritance with pyrimidine 5′ nucleotidase deficiency or exposure to elevated temperature of 39°C–41°C in vitro have been reported to exacerbate HbE instability and hemolysis. If possible, avoiding prescribing oxidant drugs or compounds to these patients is advisable.

For surgery under general anesthesia, appropriate precautions have to be taken during the pre-, intra-, and postoperative period to guard against the development of sickling-related complications, especially acute chest syndrome. Preoperative exchange transfusions to reduce HbS concentration to less than 30% seems prudent. Simple transfusions in patients with hemoglobin levels near normal could be associated with an untoward rise in PCV and blood viscosity, suggesting that exchange transfusions might be preferable.

Hydroxyurea, used to treat sickle cell anemia has been used successfully in patients with HbS–β^+ thalassemia. When serious and/or repeated sickling-related complications occur in HbSE disease, a trial of hydroxyurea might be indicated.

SICKLE CELL ANEMIA–α THALASSEMIA

Early accounts of sickle cell anemia–α thalassemia were limited by the inability to definitively detect the common gene deletion α thalassemia. Because of this and the small number of patients studied, these reports could not accurately define the effect of α thalassemia on the phenotype of sickle cell anemia. DNA-based diagnosis of α thalassemia and its application to the study of large groups of patients have permitted the definition of the phenotype of sickle cell anemia–α thalassemia.[48–51] As the role of hemolysis as a major determinant of some subphenotypes of sickle cell anemia has emerged, the effects of α thalassemia as a genetic modulator of sickle cell disease have come into sharper focus (Chapter 27).

Among African Americans and other individuals of African descent with sickle cell anemia, 30%–40% are heterozygous and 2%–3% are homozygous for the common -$\alpha^{3.7}$ kb–deletion type of α thalassemia.[51] This genotype is also prevalent in Saudi Arabia and India. Some instances of sickle cell anemia with microcytosis without evidence of β thalassemia or gene-deletion α thalassemia could reflect the presence of nondeletion types of α thalassemia. Although uncommon in blacks, these mutations are not rare on the Arabian peninsula, the Middle East, and in North Africa and can be found with sickle cell anemia (Chapter 13) Infrequently, the $\alpha^{4.2}$-kb deletion and HbH disease have been found in individuals with the HbS gene.

Sickle cell anemia has also been described with triplicated α-globin loci. Few cases have been reported, and although they do not seem to differ from sickle cell anemia with a normal α-globin gene haplotype, it is not yet possible to know if the phenotype of the disease is affected.[52]

An extensive literature on the interaction of α thalassemia with sickle cell anemia is available and the following seems clearly established: α Thalassemia affects the cellular abnormalities, hematological values, and clinical features of sickle cell anemia; the extent of this effect is dependent on the α-globin gene haplotype; in a single patient the changes produced by α thalassemia can be subtle and difficult to detect; and differences among groups of patients are clear and clinically relevant.

Cellular Effects

α Thalassemia has multiple effects on the sickle erythrocyte that culminate in its improved cellular survival (Table 23.8). Reduced cellular hemoglobin content, a primary consequence of α thalassemia, is calculated to diminish the polymerization potential of HbS and the cascade of cellular damage that emanates from this phenomenon. Smaller sickle cells could also have rheological advantages that increase their survival. In sickle cell anemia–α thalassemia, the numbers of dense cells are reduced and fewer irreversibly sickled cells – cells that are least deformable and shortest lived – are present. The oxygen affinity of sickle cells, intrinsically low because of HbS polymer, might be increased in sickle cell anemia–α thalassemia by the improvement in cellular hydration and reduction in mean cell HbS concentration. Higher oxygen affinity should reduce the fraction of deoxy HbS, further retarding polymerization.

α Thalassemia reduces the density and increases the deformability of oxygenated sickle erythrocytes. When sickle cells of equal density were isolated from individuals with four, three, and two α-globin genes, they were equally deformable, showing that the improved deformability associated with α thalassemia was due to the presence of fewer dense cells. Improved deformability is probably related also to reduced cytoplasmic viscosity caused by a lower mean cell HbS concentration and the advantages of an increased cell surface:volume ratio. As PCV is the prime determinant of blood viscosity, the rheological benefit of enhanced deformability of the individual cell is lost when the PCV in sickle cell anemia–α thalassemia cell is increased due to improved cell survival. Whole blood viscosity in sickle cell anemia–homozygous α thalassemia-2 at a standard PCV of 45 was lower than viscosity of sickle cell anemia blood at the same PCV. When these groups were compared at the patient's original PCV, viscosity was higher in sickle cell anemia–α thalassemia.[53] An additional

Table 23.9. Effects of α-globin haplotype on the hematological features of sickle cell anemia

Genotype	Number	Hemoglobin (g/dL)	Reticulocytes (%)	MCV (fL)	HbF (%)	HbA_2 (%)
αα/αα	299	8.1	11.4	92	6.2	2.9
-α/αα	152	8.6	9.0	83	5.7	3.3
-α/-α	66	9.2	6.7	72	5.1	3.8

The values reported are averages of studies that used gene mapping to ascertain the α-globin genotype. The series differed in the mean ages of the patients studied. One series combined the -α/αα and -α/-α genotype together for hemoglobin, MCV, and HbF levels; only nine -α/-α patients were in this series, and in this table these data were analyzed with the -α/αα genotype. The HbF differences are not significant; however, the patients were not segregated by β haplotype. In patients with α thalassemia and the Senegal haplotype, HbF levels are higher than in the other groups. The other differences are statistically significant.

benefit anticipated from increased cell surface: volume ratio is protection against deoxygenation-induced K^+ efflux induced by polymerization-provoked membrane distortion (Chapter 9). α Thalassemia protects against deoxygenation-induced cation leak and the rapid dehydration of reticulocytes that generates irreversibly sickled cells.[54] Effects of α thalassemia on red cell surface area to volume relationships might explain the lack of effect of α thalassemia on the severity of anemia in young children when persistent splenic function in childhood might condition sickle erythrocytes by removing excessive membrane.[55]

Hematological Effects

Hematological manifestations of sickle cell anemia–α thalassemia are a direct consequence of the cellular changes and are summarized in Table 23.9. Patients of African descent with sickle cell anemia–α thalassemia had increased levels of HbA_2, microcytosis, reduced reticulocyte counts, and higher hemoglobin levels. Patients homozygous for the $-\alpha^{3.7}$-kb deletion had more pronounced changes than heterozygotes for this haplotype. It was suggested that the lower mean corpuscular HbS concentration associated with α thalassemia resulted in retarded HbS polymerization, which reduced red cell injury. Higher hemoglobin levels and reduced reticulocyte counts suggested that hemolysis was likely to be reduced and studies of red cell survival in sickle cell anemia–α thalassemia confirmed this notion.[56]

HbA_2 levels are elevated in sickle cell anemia–α thalassemia, an effect that confounds its distinction from HbS–β^0 thalassemia. It is likely that δ-globin chains compete more effectively than β^S chains for the limited numbers of α-globin chains that are present in α thalassemia, favoring the assembly of HbA_2 over HbS.

Sickle cell anemia–α thalassemia was first thought to be associated with increased HbF levels, but subsequent studies have failed to confirm this observation, which was likely to have been the result of the examination of few patients. Hypothetically, γ-globin chains might compete more favorably than β^S chains for the reduced number of α chains available in sickle cell anemia–α thalassemia and increase HbF levels. Several large studies of sickle cell anemia–α thalassemia found little influence of α thalassemia on HbF concentration in sickle cell anemia, and other investigators found that α thalassemia reduced HbF in sickle cell anemia. It was hypothesized that the presence of both α thalassemia and HbF allowed some sickle erythrocytes to survive longer, masking the usual F cell enrichment characteristic of sickle cell anemia and reducing the total HbF level. When patients were stratified based on the β-globin gene haplotype, no effect of α thalassemia on HbF was observed.[57,58] HbF levels are unaltered by α thalassemia in children with sickle cell anemia and the Arab–India haplotype.[59]

Clinical Effects

α Thalassemia–related reduction in mean cell hemoglobin concentration lowers the polymerization tendency of HbS, forestalls erythrocyte injury, and leads to the production of smaller, less dense, more deformable cells. These cells have an increased survival and anemia is therefore improved. This reduction in hemolysis decreases the incidence of disease complications that are a consequence of the hemolysis-induced vasculopathy, but appears to increase the complications that are more dependent on blood viscosity (Chapters 11 and 19).

In one study, patients with sickle cell anemia–α thalassemia did not have an increased risk of pulmonary hypertension.[2] Priapism is more common in individuals with sickle cell anemia than in those with sickle cell anemia–α thalassemia or HbSC disease.[60,61] Age-adjusted comparisons showed that sickle cell anemia–α thalassemia and HbSC disease were more frequent among control patients than in patients with leg ulcers.[62] Coexistent α thalassemia protects patients with sickle cell anemia from stroke and is also associated with reduced cerebral blood flow.[63,64] The 'no stroke' group also had HbF levels twice as high as the stroke group but, even when controlling for the effects of HbF, α thalassemia was associated with a lower risk of stroke. Likewise, the prevalence of α thalassemia was significantly higher in children with normal transcranial Doppler flow rates than in patients with high flow velocity.[65] Chronic transfusions, by reducing plasma hemoglobin and other markers of hemolysis, might affect the risk of stroke by retarding hemolysis.[66] In several studies of stroke in sickle cell disease, stroke was associated with lower hemoglobin concentration.[20] None of 48 patients with homozygous α thalassemia-2 had a stroke. Although patients with silent cerebral infarct were more anemic than controls, there was

Table 23.10. Association of α-globin gene variants with HbS

Variant	*HBA* mutation*	Phenotype
Hb Memphis	glu23gln	Migrates like HbS at both alkaline and acidic pH
Hb Montgomery	leu48arg	Migrates between HbS and HbA at alkaline pH
Hb Mexico	gln54glu	With sickle cell trait, ~20% Hb Mexico and 50% hybrid hemoglobin
Hb G-Philadelphia	asn68lys	Migrates like HbS at alkaline pH and HbA at acidic pH. Usually, when found with HbS, mutation is linked to $-\alpha^{3.7}$ chromosome
Hb Stanleyville-II	α_2 asn78lys	Separable by HPLC or electrophoresis. Migrates like HbC at alkaline pH and HbA at acid pH and therefore, might be confused with HbSC disease
Hb Nigeria	ser81cys	Migrates faster than HbA and hybrid with β^S migrates faster than HbS at alkaline pH
HbG-Georgia	pro95leu	Migrates ~HbS at alkaline pH
Hb Hopkins-II	his112sp	Migrates ~HbA
Hb Oleander	α_2 glu116gln	20%–30% HbS; 9%–14% Hb Oleander and HbS hybrid (Also found with $-\alpha^{3.7}$ chromosome)
Hb Chicago	leu136met	Not separated by electrophoresis

* It is usually not known which of the two α-globin genes contain the mutation. (http://globin.cse.psu.edu; Chui DHK, personal communication).

no association of α thalassemia, reticulocyte count, aspartate transaminase, or bilirubin with this phenotype.[67]

Bayesian network modeling was used to estimate severity in patients with sickle cell anemia, sickle cell anemia–α thalassemia, and HbSC disease. A disease severity score ranking patients from least severe (0) to most severe (1), defining severity as risk of death within 5 years, was constructed. Subjects with sickle cell anemia were at greatest risk compared with subjects with sickle cell anemia–α thalassemia.[14]

Blood flow is optimal at the PCV found in most patients with sickle cell anemia. Presumably, as the PCV rises, viscosity-associated reductions in flow in some vascular beds promote sickle vasoocclusion. In sickle cell disease, the intrinsically abnormal properties of dense and poorly deformable sickle erythrocytes vastly increase blood viscosity at any given PCV. The common complications of acute painful episodes, acute chest syndrome, and avascular necrosis of bone might be particularly dependent on blood viscosity, and their incidence is increased by the presence of α thalassemia.[64] For example, osteonecrosis of the humeral and femoral heads had an incidence of 4.5–4.9 cases per 100 patient-years in sickle cell anemia–α thalassemia when compared with 2.4 cases for sickle cell anemia without α thalassemia.[15,68]

Cardiovascular function was examined in patients with sickle cell anemia who were homozygous for the common α thalassemia-2 deletion.[69] These individuals had increased left ventricular wall thickness with higher heart rates and blood pressure during exercise compared with patients with sickle cell anemia. The abnormalities noted in sickle cell anemia–α thalassemia suggested that the lower hemoglobin level in sickle cell anemia protects cardiac function. The inheritance of α thalassemia was associated with a 13% prevalence of macroalbuminuria compared with 40% in patients without α thalassemia.[70]

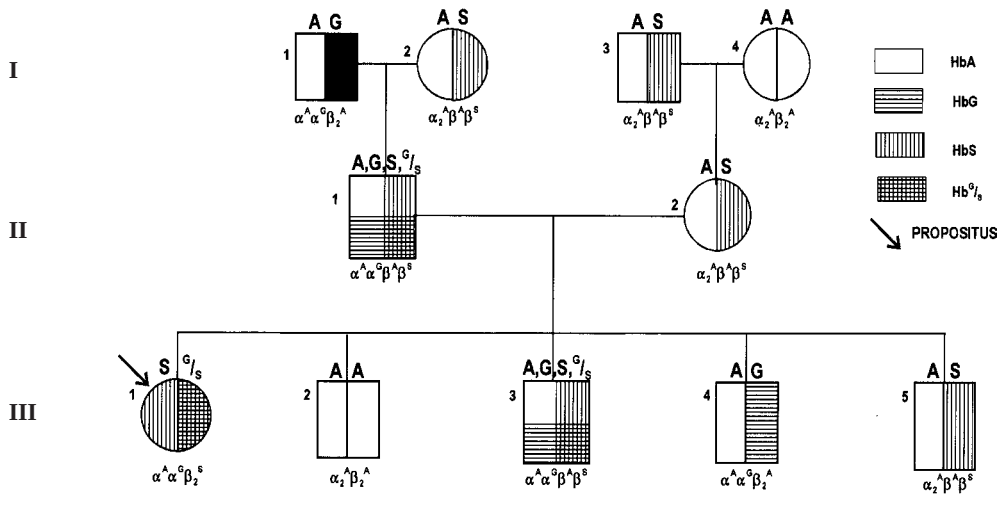
Reduced hemolysis in sickle cell anemia–α thalassemia predicts that cholelithiasis should be less common in this genotype, but any effect is outweighed by the genotype of the *UGT1A1* promoter.

α Thalassemia might increase the incidence of acute splenic sequestration episodes in children and adults with sickle cell anemia. Improved rheology of sickle erythrocytes in the presence of α thalassemia could preserve splenic function,[71] setting the stage for acute sequestration episodes at a later age than expected. A positive aspect of α thalassemia–related preserved splenic function, at least in individuals with the Arab–Indian haplotype and high HbF levels, is a reduction in bacterial infection.[59,72]

α Thalassemia was initially thought to increase survival in sickle cell anemia.[73,74] Other studies do not confirm this observation, and, in some studies, α thalassemia was a risk for increased morbidity and mortality.[48,75–78] α Thalassemia and markers of hemolysis were important elements of the modeling of near-term death.[14] Perhaps differences in the analytical approaches in these studies account for the variability of the results.

HbS with α-Globin Chain Variants

Separate inheritance of β- and α-globin genes permits a dizzying array of combinations of sickle cell disease and HbAS with α-globin gene variants and α thalassemia. In this section, the interactions of sickle cell anemia with α-globin gene variants are considered (Table 23.10). When variants of the α-globin gene are present, hybrid tetramers



Case	A	G	S	S&G	S/G	A_2	G_2*	F
II-1	37.5	...	...	47.7	12.8	+	1.5	0.9
III-1	...	...	62	...	32.9	+	1.7	3.4
III-3	45.1	...	...	41.0	11.9	+	1.2	0.8
III-4	65	31.6	...	...	...	1.4	1.2	0.8

Figure 23.6. Pedigree of an extended family in which HbG-Philadelphia is present with sickle cell trait and sickle cell anemia. Below the pedigree, the percentage of different hemoglobin fractions is shown. (Redrawn from ref. 96.)

containing variant α-globin chains and normal α-globin chains are present. In the presence of β-globin chain mutants such as HbS and HbC additional hybrid tetramers form that can display unique electrophoretical or HPLC patterns. This often provides a clue or the diagnosis of disorders in which both α- and β-globin chain variants are present.

Many examples of the coincidence of HbG-Philadelphia (*HBA* asn68lys) and sickle cell anemia or HbAS have been described. In Figure 23.6, a pedigree and the hemoglobin fractions found in a family in which HbG-Philadelphia was present with sickle cell anemia and HbAS is shown. Figure 23.7 shows separation by HPLC of HbG-Philadelphia from HbS and HPLC separations of other variant hemoglobin from HbS. In sickle cell anemia, diagnostic confusion can occur because the hybrid molecule, $\alpha^{A}\alpha^{G}\beta_2^{S}$ might be confused with HbC if electrophoresis alkaline pH is the sole diagnostic method. Clinically and hematologically, sickle cell anemia–HbG-Philadelphia resembles sickle cell anemia and not HbSC disease. HbG-Philadelphia has been described in patients with HbSC disease in whom it was associated with a mild phenotype, perhaps because of the antipolymerization effect of the *HBA* asn68lys mutation.[79]

Sickle cell anemia has also been described with the α-globin gene variants Hb Montgomery (*HBA* leu48arg) and Hb Chicago (*HBA* leu136met).[80] An example of isoelectric focusing of these variants is shown in Figure 23.8.

Hb Memphis (*HBA* glu23gln) was described as migrating with HbS when electrophoresed at both alkaline and acidic pH. In older adults with sickle cell anemia, red cell survival was 11 days but vasoocclusive episodes were absent. The hemoglobin level was 9.5 g/dL, reticulocytes 5%–24%, MCV 88 fL, and HbF 6% and sickled cells were present in the blood. Curiously, in neither the proband nor three children in the family of the proband who had HbAS and Hb Memphis was there evidence of hybrid molecules that are typical of other α-globin gene variants. These observations anteceded the era of DNA-based diagnosis.

Hb Stanleyville-II (*HBA* pro77arg) was described in a boy from Zaïre with findings that were typical of sickle cell anemia, with 70% HbS and 30% Hb Stanleyville-II. A brother with sickle cell anemia had a more severe disease. Individuals with HbAS and Hb Stanleyville-II were well and had the expected distribution of HbA, Hb Stanleyville-II, and hybrid molecules. It was proposed that the mutation to arginine stabilized HbS fiber formation.

A report of a 3-year-old patient with sickle cell anemia and Hb Hopkins-II (*HBA* his112asp), a variant with high oxygen affinity, revealed mild anemia and reticulocytosis, no sickled cells in the blood, reduced MCV, and normal splenic function.

Mild sickle cell anemia was reported in a 34-year-old patient homozygous for the HbS gene and heterozygous for Hb Matsue-Oki (*HBA1* asp75asn).[81] This α_2-globin gene variant affects a contact site between deoxy HbS polymer strands. $\alpha^{\text{Matsue-Oki}}{}_2\beta^{S}{}_2$ tetramers formed 28% of the hemolysate and migrated on cellulose acetate electrophoresis like HbC. Hb Matsue-Oki migrates like HbS, and heterozygotes have between 12% and 24% of this variant. Although no clinical information was provided in the

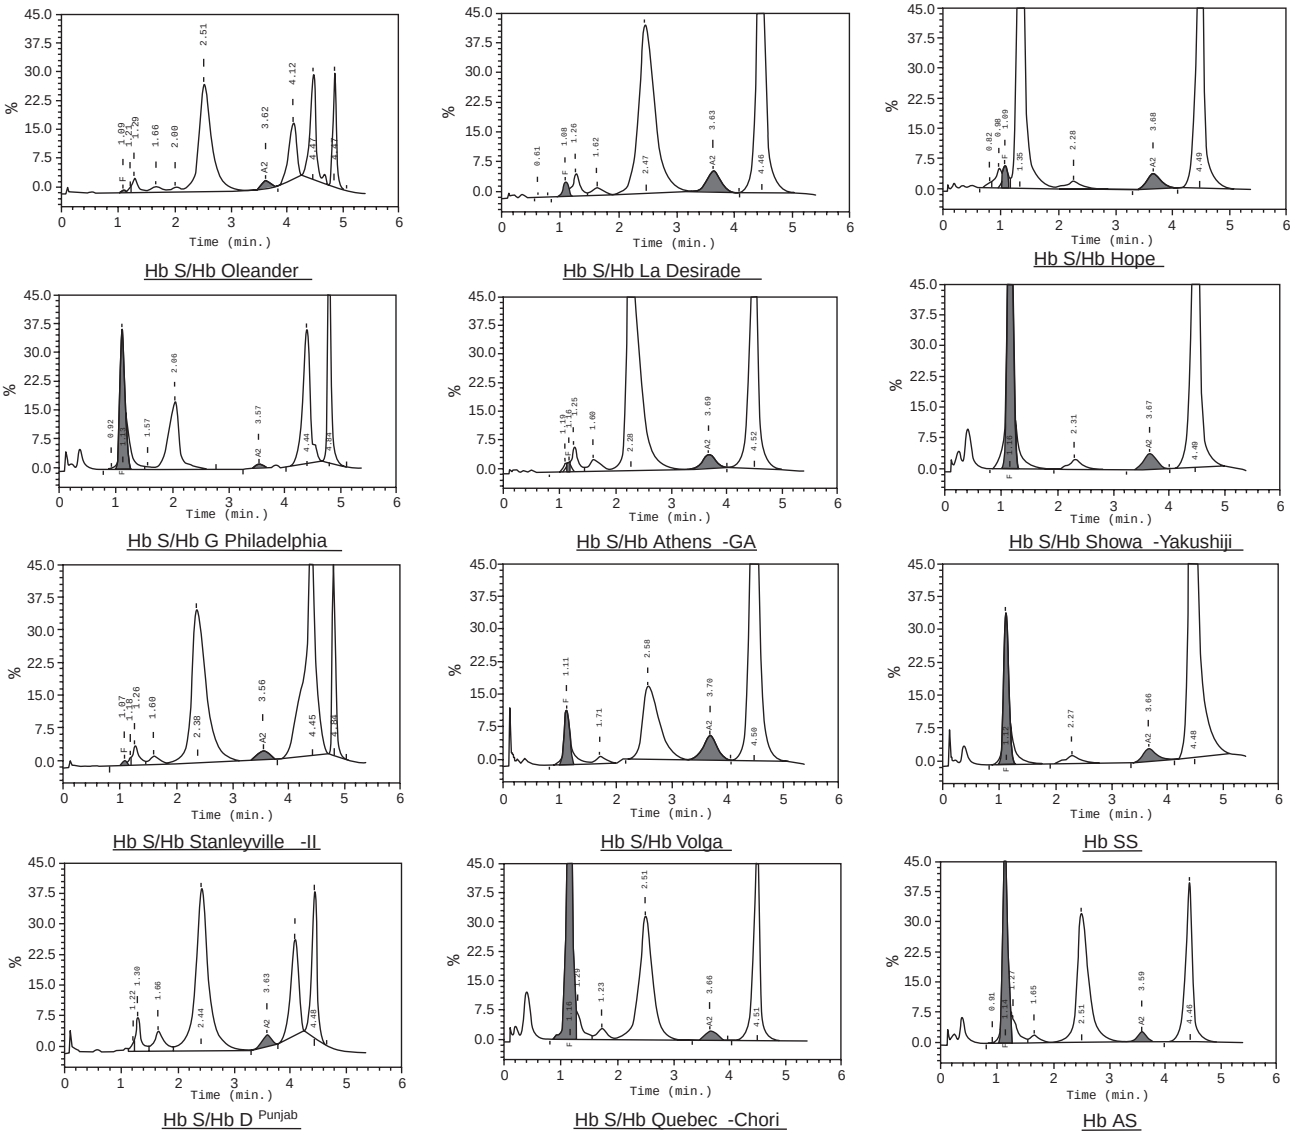


Figure 23.7. HPLC separation of variant hemoglobin found with HbS. Representative HPLC tracings of some common and rare hemoglobin variants associated with HbS. All hemoglobins were verified by DNA sequencing. For comparison, tracings from an HbS homozygote and carrier of HbAS are shown. Retention times obtained with the Beckman Variant II system are shown in or above the peaks. Note that the retention of some variants such as Hb Quebec-CHORI (*HBB* thr87ile) and Hb Volga (*HBB* ala27asp) cannot be resolved from HbA. α-Globin variants such as Hb Oleander (*HBA* glu116gln) and Hb G Philadelphia have peaks representing hybrid tetramers. Hb Showa-Yakushiji (*HBB* leu110pro) is hyperunstable and no protein can be recovered, therefore, HPLC is identical to sickle cell anemia.

initial report of this compound heterozygote, it was implied that the phenotype was milder than that of HbSC disease, with which it might be confused.

HbS with Other Globin Variants

Variants of the γ-globin chains and the δ-globin chain are also found with homozygosity and heterozygosity for the HbS gene. Although they might cause diagnostic confusion, they are not associated with hematological or clinical sequelae. γ-Globin gene variants are usually detected in infants in whom they can form up to 30% of the total hemoglobin and similar proportions of the HbF fraction. As γ-globin gene expression diminishes, these variants are reduced to a minor fraction of the small amount of remaining HbF and are usually undetectable.

HbA_2', (*HBD* gly16arg) is found in approximately 1% of individuals of African descent and is the most common δ-globin gene variant. Migrating more slowly than HbA_2 on electrophoresis at alkaline pH, it is often found in sickle cell anemia and HbAS (Chapter 22).

Individuals with HbAS have been described with the βδ-globin gene crossover variant Hb P-Nilotic (Congo) (β through residue 22, δ from residue 50). Pedigrees, in which

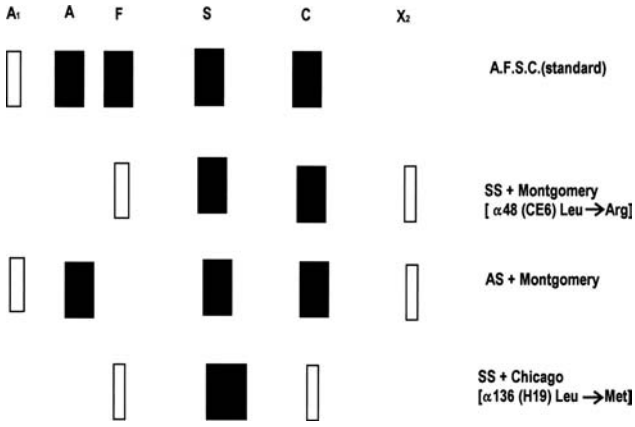

Figure 23.8. Isoelectric focusing of hemolysates from sickle cell trait and sickle cell anemia with Hb Montgomery and sickle cell anemia with Hb Chicago. These α-globin gene variants display confusing patterns by hemoglobin electrophoresis and isoelectric focusing. Redrawn from ref. 80.

the affected but hematologically normal individual had HbS, HbA, and HbP-Nilotic, confirm that the chromosome with the fusion gene contained a normal β-globin gene. In the compound heterozygote with HbS, there was 40% HbS, 35% HbA, 22% HbP-Nilotic, and 2.3% HbA_2.[29]

CONCLUSION

HbS can be present with different forms of α or β thalassemia and dozens of abnormal hemoglobins. Phenotypes associated with these genetic combinations can be pernicious or benign, and the management of clinically significant phenotypes should follow the guidelines proposed for sickle cell anemia or HbSC disease. The correct delineation of the genotype is clinically important for genetic counseling.

SECTION SIX

OTHER CLINICALLY IMPORTANT DISORDERS OF HEMOGLOBIN

Martin H. Steinberg

Three chapters discuss rare inherited hemoglobinopathies including unstable hemoglobins, hemoglobins with altered oxygen affinity, hemoglobins easily oxidized, and a miscellaneous group of hemoglobin variants with interesting biological properties, some of which are clinically important. Acquired disorders of hemoglobin can arise from heme iron oxidation due to inherited abnormalities of hemoglobin-reducing enzymes or because of exposure to exogenous oxidizing agents.

Rare hemoglobinopathies have taught us much about the structure-stability-function relationships of hemoglobin. Hemoglobin mutants have provided the most comprehensive list of mutations of any system in human biology, creating a map for understanding mutation in other genetic loci. Globin gene mutations – these include nearly every class of mutation so far described – provided an early catalog of the possible mechanisms of genetic disease.

An accounting of globin gene mutations in early 2008 listed 1,326 unique mutations (http://globin.cse.psu.edu/). Here, we discuss some rare hemoglobin mutations. As comparatively few globin residues are critical for maintaining the structural integrity and functional utility of the molecule, most hemoglobin mutations are not associated with hematological or clinical abnormalities and so escape detection. Some mutations, although not medically important, illustrate interesting biological and anthropological principles.

Abnormal hemoglobins with high or low oxygen affinity, variants that have their heme iron oxidized to the ferric form causing methemoglobinemia (HbM), or hemoglobin variants that are unstable are abnormalities seen rarely by the general physician and infrequently encountered in the practice of hematology. High oxygen affinity hemoglobin variants cause erythrocytosis; low oxygen affinity variants can be accompanied by cyanosis and anemia; HbM variants present with cyanosis. Patients with unstable hemoglobins can have hemolytic anemia that might worsen during infection and when certain drugs are given. Because these uncommon variants are unusual causes of erythrocytosis, cyanosis, and hemolytic anemia, their presence is often unsuspected. When present, their identification can prevent hazardous diagnostic tests, forestall potentially dangerous treatments, permit reassurance of the patients, and allow family counseling.

In evaluating these disorders, tests for hemoglobin instability are useful and measurement of the hemoglobin–oxygen dissociation curve is vital when a hemoglobin variant is suspected of causing erythrocytosis or cyanosis. Methemoglobins are suspected by observing an abnormal brown coloration of the blood and spectrophotometric recording of the visible spectrum of the hemolysate. Mutation detection by DNA analysis is the only way of definitively diagnosing rare hemoglobin variants.

24

Unstable Hemoglobins, Hemoglobins with Altered Oxygen Affinity, Hemoglobin M, and Other Variants of Clinical and Biological Interest

Martin H. Steinberg and Ronald L. Nagel

INTRODUCTION

Mutations of hemoglobin can be polymorphic (>1% of a population), like HbS, HbE, HbC, and the thalassemias, or rare. Our first edition listed 750 unique hemoglobin variants; this number is now more than 1,000.[1] In this chapter we address rare mutations. Some are associated with clinical disease; others are interesting solely for the biological principles they illustrate. A current listing of variant human hemoglobins is maintained in the HbVar database at http://globin.cse.psu.edu/, and the journal *Hemoglobin* (Taylor & Francis, Philadelphia) is a rich source for reports of new variants. Both are invaluable resources for clinicians and investigators with interests in unusual hemoglobin disorders.

Globin gene mutations, which include nearly every class of mutation so far described, except trinucleotide repeats and other nucleotide expansions associated with neuromuscular disorders, provided an early catalog of the mutations that can cause genetic disease. Clinically important but rare mutants affect hemoglobin stability causing premature red cell destruction; interfere with normal oxygen binding kinetics producing erythrocytosis; and permit heme iron oxidation, causing cyanosis. Most rare variants have no phenotype and are of biological and diagnostic interest only.

Comparatively few globin residues are critical for maintaining the structural integrity and functional performance of the molecule (Chapter 6). Hemoglobin gene mutations are, as a rule, not associated with hematological or clinical abnormalities and escape detection, especially when they are chromatographically silent.

Large-scale population screening programs have defined the worldwide prevalence of medically important hemoglobinopathies and thalassemias. Most of the hemoglobin variants known today were discovered as a byproduct of this extensive effort. Unlike some thalassemia mutations and HbS, HbE, and HbC, almost none of these variant hemoglobins are polymorphic because they are genetically neutral and their carriage does not provide a selective advantage. Sometimes, in population isolates, there is a founder effect leading to a higher than expected prevalence of a particular mutation. The geographical distribution of hemoglobin variants in the Americas, Europe, Africa, the former USSR, the Middle East, India, southeast Asia, China, Japan, the Antipodes, and Oceania have been cataloged.[2] It is unlikely that new globin mutations that reach polymorphic frequencies will be found. In unexamined population isolates, some new variants present at high frequency might yet be uncovered and sporadic examples of new and already described variants will continue to be unearthed.

Mutation Distribution

More than 90% of hemoglobinopathies result from point mutations. Some globin gene codons are associated with as many as seven different mutations; others have one or no described mutations, suggesting both mutational "hot spots" and sites resistant to mutation.

Mutations have been described in approximately 75% and 95% of α- and β-globin gene codons. Multiple different mutations are described in amino acid residues that are functionally important so that a clinical phenotype brings the substitution to clinical attention. For example, seven mutations have been described at β99, all associated with high oxygen affinity variants and erythrocytosis. Four of the six variants of α141 for which information is available have increased oxygen affinity. Six mutations at β92 are all associated with unstable hemoglobins and hemolytic anemia. In contrast, the five mutations described at the β22 codon are all stable and functionally normal. It is not known if these sites are particularly prone to mutational events or if we are witnessing a bias of ascertainment in which some these mutations are identified because of their obvious phenotype.

Only 20% of the possible globin gene mutations have been described. Clinically silent variants are still likely to escape notice, and many variants that cause a change in the charge of the molecule, simplifying their detection, have been already delineated. Neutral substitutions in which the charge of the molecule is unchanged and a phenotype is not present are rarely detected.

Among hemoglobin mutants, β-globin gene variants are most frequently described whereas α-, γ-, and δ-globin gene variants are reported 65%, 20%, and 10% as often, respectively. This preponderance of β-globin gene variants might reflect the fact that with only two β-globin genes, the intracellular concentration of β-globin variants exceeds that of α-globin variants so they are more likely to be clinically apparent (Chapter 13). For example, a high oxygen affinity variant present at 40%–50% total hemoglobin, the level of most β-globin gene mutants, is more likely to cause clinically apparent erythrocytosis than a similar α-globin

Table 24.1. Sites of globin mutation that are associated with increased oxygen affinity. In addition to single amino acid substitutions, these mutations can include small deletions and insertions of amino acids, reading frameshifts, fusion globins, and elongated globin chains

α1β2 interface contacts (sliding contact) connecting α1β1 and α2β2 dimers
α1β1, α2β2 interface
Mutations that reduce 2,3-BPG binding
Heme pocket mutations
Miscellaneous

gene variant present at the usual level of 20%–25%. Some α-globin variants might go unnoticed because of their low levels in the blood. Certain α-globin mutations are more likely to be lethal because α chains are also essential for the functional hemoglobins of the embryo and fetus (Chapter 7). α-Globin chains must also bind three types of non-α-globin chains, β-, γ-, and δ-globin chains to form tetramers, increasing their chance of being functionally incompetent if mutated.

Very low concentrations of HbA_2 and HbF in adults often preclude the detection of an abnormal variant of the δ and γ-globin genes (Chapter 7). Only rarely do γ-globin chain abnormalities have a clinical phenotype in neonates and this usually is due to methemoglobinemia and cyanosis. Structural variants of the embryonic ε- and ζ-globin chains have not been described.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

High Oxygen Affinity Hemoglobins

Globin gene mutations can increase the affinity of the hemoglobin molecule for oxygen and cause erythrocytosis transmitted as a dominant trait. Approximately 100 high oxygen affinity variants have been reported.[3] Although familial erythrocytosis is a valuable clue to the presence of a high oxygen affinity hemoglobin variant, new mutations cause isolated cases. These α- or β-globin chain mutations are expressed clinically in the heterozygote; they might be lethal in homozygotes if they affect the α-globin chain as this will affect embryonic and fetal hemoglobins. Several homozygotes for β-globin high oxygen affinity variants have been described and these individuals might have more severe disease.[4–7] High oxygen affinity hemoglobins have also been described with β^0 thalassemia, and as HbA is not present, they mimic homozygosity for the variant.

Pathophysiology. Stabilization of the relaxed (R) state of the hemoglobin tetramer (high oxygen affinity) or destabilization of the tense (T) state (low oxygen affinity) is caused by mutations in critical areas of the globin chain affecting the R-T transition (Table 24.1) (see Chapter 6).

The increased avidity for oxygen (low P_{50}) of these variants reduces oxygen delivery to tissues stimulating erythropoietin production and increasing red cell mass. Patients with high oxygen affinity hemoglobins and the erythrocytosis that results from relative tissue hypoxia had normal urine erythropoietin levels but showed increases in erythropoietin when phlebotomized to a normal red cell mass. They might be reasonably compensated for the low P_{50} by the increased red cell mass and probable increases in tissue blood flow, along with changes in perfusion patterns in selected regions of the body that negate any adverse effect of increased blood viscosity. Oxygen consumption and arterial pO_2 are normal but occasionally there is reduced mixed venous pO_2 and decreased resting cardiac output.

Diagnosis. The diagnosis of high oxygen affinity hemoglobins is suggested by the following: isolated erythrocytosis without accompanying leukocytosis, thrombocytosis and splenomegaly that is typical in polycythemia vera; a family history of erythrocytosis; reduced P_{50} (partial pressure of oxygen where hemoglobin is half-saturated Fig. 24.1). DNA sequencing defines the mutation. Not unexpectedly, the *JAK2* V617F mutation found in most individuals with polycythemia vera is absent in patients with high oxygen affinity hemoglobin variants.[8]

Determination of the red cell oxygen equilibrium curve (Fig. 24.1) is the benchmark for the diagnosis of erythrocytosis due to high oxygen affinity hemoglobins. The oxygen-binding characteristics of hybrid tetramers ($\alpha_2\beta^A\beta^{var}$) are likely to be intermediate between purified HbA and purified variant and the shape of the hemoglobin oxygen dissociation curve can at times be biphasic. Measurement of blood P_{50} confirms the shift in the hemoglobin–oxygen dissociation curve. Rarely, the whole blood P_{50} is normal, requiring study of dialyzed purified hemoglobin. An accurate P_{50}

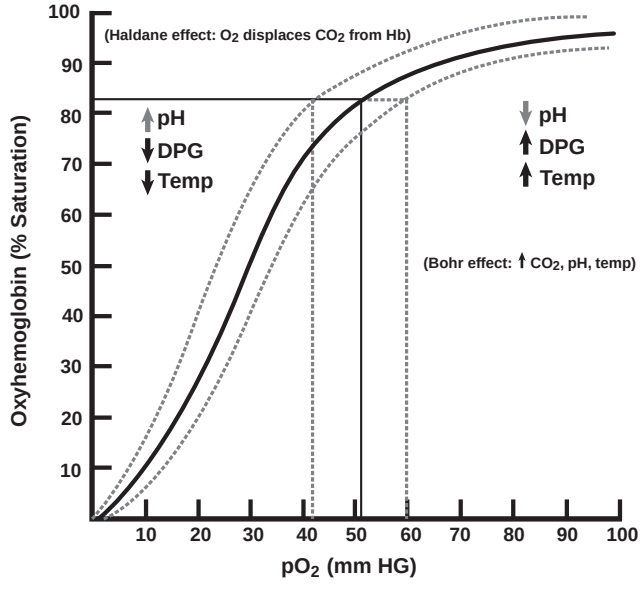

Figure 24.1. Hemoglobin–oxygen dissociation curve. As the P_{50} drops (the curve is left-shifted) the affinity of hemoglobin for oxygen increases. An increased P_{50} decreases hemoglobin–oxygen affinity.

value cannot be "calculated" from pO_2 data and directly measuring the saturation of hemoglobin and pO_2 is necessary. P_{50} measurements are not widely available but can be done with several instruments.

Both erythrocytes and purified dialyzed hemoglobin will have high oxygen affinity and 2,3-BPG concentrations should be normal, suggesting that altered oxygen affinity is not caused by reduced levels of this heterotopic modulator of hemoglobin function (Chapter 6). When 2,3-BPG mutase deficiency is present, red cell levels of 2,3-BPG will be low and whereas erythrocytes or whole blood will have high oxygen affinity red cells, the oxygen affinity of the purified hemolysate stripped of this intermediate will be normal.

In addition to high oxygen affinity hemoglobins, disorders expressed in the erythrocyte that cause isolated erythrocytosis include, 2,3-BPG mutase mutations that reduce the synthesis of this modulator of hemoglobin–oxygen affinity, some instances of methemoglobinemia and chronic carbon monoxide poisoning (Chapter 25).

The search for the mutation is initiated by high-performance liquid chromatography (HPLC) analysis of hemoglobin but normal studies do not exclude the diagnosis of a high-affinity hemoglobin that can migrate with HbA. As with all evaluations for abnormal hemoglobins, determining the DNA sequence of the globin genes provides the definitive information.

Some examples of high oxygen affinity hemoglobins, illustrating the varying mechanisms and heterogeneous clinical findings seen with these variants, are discussed later. A detailed understanding of the structure of hemoglobin and the importance of each residue in determining function allows a molecular explanation of most of the clinical abnormalities observed.

α-Globin Chain Variants. Because of a gene dosage effect, most stable α-globin variants form approximately 25% of the total hemoglobin. As a result, the clinical effects of α-globin variants are less striking than those of similar β-globin variants that usually comprise 50% of total hemoglobin, although coincident thalassemia can modulate the concentration of variant hemoglobins.

The first report of a high oxygen affinity hemoglobin was that of a patient aged 81 years with erythrocytosis, an abnormal hemoglobin detected by hemoglobin electrophoresis, and erythrocytes with increased oxygen affinity (Hb Chesapeake; *HBA* arg92leu). Fifteen members of the proband's family were similarly affected.[9] Hb Chesapeake represented approximately 20% of the total hemoglobin. With a P_{50} of 19 mm Hg (normal ~26 mm Hg), Hb Chesapeake produced moderate erythrocytosis. The mutation affected an invariant residue that stabilized the R-state at the $\alpha_1\beta 2$ area of contact, making the T conformer less favored.

Hb Nunobiki (*HBA1* arg141cys) is one of four mutations of this invariant residue, all of which exhibit high oxygen affinity and moderate to mild erythrocytosis. This group of mutations represents an interesting cluster of variants that illustrate the effects of different mutations at the same amino acid residue. As a mutant of the 3′ *HBA1* gene that is expressed to a lesser extent than 5′ *HBA2* gene, Hb Nunobiki makes up approximately 13% of the hemolysate and is accompanied by only mild erythrocytosis. High oxygen affinity is due to the breaking of the C terminal–C terminal salt bridge indispensable for the stabilization of the T-state, favoring the R-state.

β-Globin Chain Variants. All possible single base mutations of the β99 site disturbing the $\alpha 1\beta 2$ area of contact have been described and include Hb Kempsey (*HBB* asp99asn), Hb Yakima (asp99his), Hb Radcliffe (asp99ala), Hb Ypsilanti (asp99tyr), Hb Hotel-Dieu (asp99gly), Hb Chemilly (asp99val), and Hb Coimbra (asp99glu). As expected for stable β-globin chain variants, all are present at 40%–50% of the hemolysate, exhibit moderately high oxygen affinity, and are characterized clinically by erythrocytosis. Other properties of this group of mutants include: moderately decreased response to 2,3-BPG with Hbs Kempsey and Radcliffe and slightly decreased response to 2,3-BPG in Hb Hotel Dieu. Hbs Ypsilanti and Radcliffe form stable hybrid tetramers in the hemolysates in which the abnormal β chains coexist with normal β chains.

Six of the possible seven mutations of the C-terminal CAC (tyr) codon have also been described. One of them, Hb Cochin-Port Royal (tyr146arg), has nearly normal oxygen affinity but decreased 2,3 BPG interaction and Bohr effect.

Three mutations of β82 lys have been described: Hb Rahere (lys82thr), Hb Helsinki (lys82met), and Hb Providence (lys82asn). All have moderately high oxygen affinity and moderate erythrocytosis. These mutants have drastically reduced 2,3-BPG binding due to the elimination of one of the normal binding sites for this allosteric effector.

Hb Porto Alegre (*HBB* ser9cys) has high oxygen affinity and a tendency to aggregate (see later) but erythrocytosis is not present. Oligomerization of this mutant diminishes heme–heme interaction and increases the oxygen affinity.

Hb Tak (*HBB* 147[+AC], modified C-terminal sequence 147thr-lys-leu-ala-phe-leu-leu-ser-asn-phe-157tyr-COOH) is elongated by 11 amino acid residues. It forms 40% of the hemolysate and has a very high oxygen affinity with no cooperativity and no allosteric interaction with pH or 2,3-BPG. The C-terminal of the β-globin chain is actively involved in the conformational changes of the hemoglobin molecule by stabilizing the T-state. By having these stabilizing interactions disrupted, Hb Tak is totally frozen in the R-state. It is also slightly unstable. Despite these severe functional abnormalities, the heterozygous patient did not have erythrocytosis. The extreme biphasic nature of the hemoglobin–oxygen affinity curve observed in mixtures of Hb Tak and HbA suggested that hybrid tetramer ($\alpha_2\beta^A\beta^{Tak}$) formation is absent. The top portion of the oxygen equilibrium curve is normal and begins to be abnormal only below 40% saturation. Because physiological oxygen exchange occurs most commonly above that level of saturation, the

tissues might not be hypoxic, removing the stimulus for increased erythropoiesis.

Clinical Aspects. Patients with high-affinity hemoglobins and erythrocytosis have a benign clinical course and rarely have complications, apart from a ruddy complexion. Splenomegaly is typically absent. Hemoglobin concentration and packed cell volume are increased variably, and usually only moderately, suggesting that modulation by variations in other genes might affect the physiological response to hypoxia. Some patients with Hb Malmo (*HBB* his97gln) have been reported to be symptomatic and to benefit from phlebotomy and the transfusion of normal blood, but this is an exception.

Many cases of high oxygen affinity hemoglobins are diagnosed during a routine hematological examination or when the family of a proband known to have erythrocytosis is examined. In very limited studies, exercise capacity in the laboratory and the indices of working capacity and cardiac tolerance were similar in patients with high oxygen affinity hemoglobins and controls. It has been suspected that carriers' of these variants could have enhanced athletic performance under some circumstances and this has lead to the unfortunate and sometimes fatal use of erythropoietin or transfusion to enhance performance in competitive athletics.

If high-affinity hemoglobins are diagnosed early, unnecessary invasive diagnostic procedures and inappropriate therapeutic interventions such as cardiac catheterization can be avoided. Patients have received phosphorus-32 treatment based on a mistaken diagnosis of polycythemia vera.

Increased morbidity or mortality in mothers or their offspring with high oxygen affinity hemoglobins has not been observed, suggesting that the affinity of the mother's hemoglobin is irrelevant with respect to oxygen delivery to the fetus. Low ambient pO_2, as in unpressurized airplanes and ascent to altitude, does not represent a risk because high-affinity hemoglobins are avid for oxygen. Hypothetically, carriers would be less prone to "the bends" during deep sea diving because of slower oxygen release during ascension.

Treatment. Patients with high oxygen affinity hemoglobins have reasonable compensation for their abnormality with adequate tissue oxygen delivery despite increases in blood viscosity. Intervention is therefore rarely required. Exercise studies before and after phlebotomy in patients with Hb Osler (*HBB* tyr145asn), a variant with a P_{50} of 10–11 mm Hg and a hemoglobin concentration of approximately 22 g/dL, did not show impairment after phlebotomy.[10] Limited studies have suggested that phlebotomy does not improve exercise performance.

Although individuals seldom benefit from phlebotomy, unknown factors might interfere with their normal compensation for high hemoglobin oxygen affinity, and increased blood viscosity might become a burden. Prudence dictates that before embarking on a regimen of chronic phlebotomy, one should be conservative and review the hematological and physiological findings at 6-month intervals during the first few years after diagnosis. In older patients special attention should be directed to the adequacy of blood flow to the heart and central nervous system.

Variants with Low Oxygen Affinity

Hemoglobin variants with reduced affinity for oxygen are in many respects the clinical obverse of high oxygen affinity variants. Expressed in the heterozygotes, with homozygosity likely to be embryonic lethal, these variants, which are far less common than variants with high oxygen affinity, are associated with anemia and at times are accompanied by cyanosis.

Pathophysiology. Alterations of critical molecular regions directly involved in the R-T transition result in the stabilization of the T-state or destabilization of the R-state. Low oxygen affinity hemoglobins deliver more oxygen to the tissues per gram of hemoglobin, and this is reflected by an oxygen–hemoglobin dissociation curve shifted toward the right of normal, and an increase in P_{50} (Fig. 24.1). When hemoglobin has a right-shifted or low affinity curve, the difference between oxygen binding in the lungs at pO_2 levels of 100 mm Hg and unloading in the tissues at 40 mm Hg can be twice as great as the differences in a hemoglobin with a normal oxygen equilibrium curve. Patients with moderately right-shifted oxygen equilibrium curve (P_{50} between 35 and 55 mm Hg) could be anemic. With a further right shift (P_{50} ~80) anemia is not present.

A right-shifted oxygen equilibrium curve leads to an increase in the synthesis of 2,3-BPG and decrease in its destruction.

Diagnosis. Approximately half as many low oxygen affinity variants have been described compared with high oxygen affinity variants. The first report of such a hemoglobin was Hb Kansas (*HBB* asn102thr) in a patient who presented with asymptomatic cyanosis without anemia or hemolysis. Detection of a low oxygen affinity hemoglobin is part of the differential diagnosis of patients with cyanosis. Before undertaking extensive diagnostic procedures in cases of cyanosis that are not clearly due to cardiovascular or pulmonary disease, obtaining hemoglobin HPLC and measuring blood P_{50} is advisable. A search for low affinity hemoglobins as an explanation for anemia without cyanosis is less compelling but if other investigations prove fruitless, unexplained normocytic anemia without reticulocytosis might be evaluated by measuring P_{50}.

A simple bedside test to distinguish cyanosis due to low oxygen affinity hemoglobins and cardiopulmonary cyanosis from that of methemoglobinemia, M hemoglobins, and sulfhemoglobinemia (Chapter 25) is to expose blood to pure oxygen. Blood from carriers of low oxygen

affinity hemoglobins or patients with cardiopulmonary disease will turn from purple-greenish to the bright red. Blood of patients with methemoglobinemia, sulfhemoglobinemia, and M hemoglobins will remain abnormally colored.

Clinically apparent cyanosis is only observed in carriers of low oxygen affinity variants with greatly right-shifted curves and in whom the variant comprises a substantial portion of the hemolysate. Cyanosis is present from birth in some low oxygen affinity hemoglobins due to α-globin chain mutants. In carriers of β-globin chain mutants, cyanosis can appear from the middle to the end of the first year of life as γ-globin gene expression and HbF synthesis wanes and is replaced by β-globin gene expression and HbA. Globin gene sequencing is the sole means of definitive diagnosis

Clinical Features. Three low oxygen affinity variants have been described at β102. Hb Kansas, the best-studied variant, has a whole blood P_{50} of approximately 70 mm Hg, decreased cooperativity, and a normal Bohr effect. The β102 asn residue is invariant among β-globin chains and participates in the only hydrogen bond between asn102 and asp 94 across the α1β2 interface in oxyhemoglobin. This bond is broken when the molecule assumes the T-state. The new thr residue is incapable of forming this bond and low oxygen affinity results from destabilization of the R conformer. The changes induced by this substitution at the α1β2 interface allow Hb Kansas to dissociate into αβ dimers, the near opposite of the high oxygen affinity Hb Chesapeake.

Hb Beth Israel (*HBB* asn102ser) was found in a patient with cyanosis of the fingers, lips, and nail beds. The P_{50} was 88 mm Hg and arterial blood was only 63% saturated despite a normal pO_2. The hemolysate also had a low oxygen affinity and a normal Bohr effect. Erythrocyte 2,3-BPG was mildly elevated. The molecular mechanism of reduced oxygen affinity is the same as for Hb Kansas, although the defect might be more disruptive locally as the serine side chain is shorter than that of threonine.

Hb Bologna (*HBB* lys61met) was informative as it was present as a compound heterozygote with β^0 thalassemia and comprised 90% of the hemolysate. During development, the effects of this mutation were unlikely to be manifest because of high HbF concentrations and adults were neither cyanotic nor anemic despite Hb Bologna forming nearly 50% of the hemolysate and having a P_{50} of 37.6 mm Hg.

Hb Bruxelles (phe42del) is a deletion of the most conserved amino acid residue of hemoglobin. Phenylalanine residues at β41 and β42 are conserved in all normal mammalian non-α-globin chains and are indispensable for the structural integrity and oxygen-binding functions of the molecule. From age 4 years, the index case of Hb Bruxelles had severe hemolytic anemia and cyanosis, requiring blood transfusion once. Later in life, her hemoglobin concentration stabilized at 10 g/dL. Reasons for this "switch" of phenotype are unknown. Other mutations of β41 and β42, which are predominately unstable hemoglobins, are discussed later.

In individuals with low oxygen affinity variants, the oxygen saturation measured using pulse oximetry can be spuriously reduced.[6,11] Attention should be paid to measurement of blood oxygen saturation when any hemoglobin variant is present. Blood oxygen saturation can be measured using an arterial blood gas analyzer, by pulse oximetry, and by using a CO oximeter. The first method measures blood partial pressure of dissolved oxygen and provides the paO_2 and saO_2. The convenient pulse oximeter provides a transcutaneous measure of absorbance at two wavelengths (660 and 940 nm) but is inaccurate when dyshemoglobins, such as methemoglobin (hemoglobin with oxidized [Fe^{+3}] heme iron), carboxyhemoglobin, and sulfhemoglobin are present. CO oximetry, the most accurate of all the methods, can be inaccurate in cases of M hemoglobins.[12]

Oxygen saturation calculated from pH and pO_2 should be interpreted with caution as the algorithms used assume normal hemoglobin oxygen affinity, normal 2,3-BPG concentrations, and no dyshemoglobin such as methemoglobin or hemoglobinopathies. CO oximeter reports should include the dyshemoglobin fractions besides the oxyhemoglobin fraction. In cases of an increased methemoglobin fraction, pulse oximeter values trend toward 85%, underestimating the actual oxygen saturation. Hemoglobin M variants can have normal methemoglobin levels and increased carboxyhemoglobin or sulfhemoglobin fractions measured by CO oximetry.

Treatment. Treatment for these variants is not needed. The importance of the early diagnosis is to avoid unnecessary work-up and to alleviate concern for the patient and family.

UNSTABLE HEMOGLOBINS

Globin chain mutations can cause hemoglobin tetramer instability and intracellular precipitation of its globin subunits. These mutants, sometimes called collectively, congenital Heinz body hemolytic anemia, cause intraerythrocytic precipitates that are detectable by supravital staining, and that appear as globular aggregates called Heinz bodies (Fig. 24.2). The inclusions reduce variably the life of the erythrocyte by binding to the membrane, decreasing cell deformability, and increasing membrane permeability. Erythrocyte enzyme deficiencies can also cause Heinz bodies and hemolysis. More than 135 unstable variants of both the β- and α-globin chains with widely varying clinical severity have been reported (Fig. 24.3), usually as heterozygotes, although some homozygous cases have been reported. Anemia, reticulocytosis, pigmenturia, and splenomegaly are the major clinical features.[13]

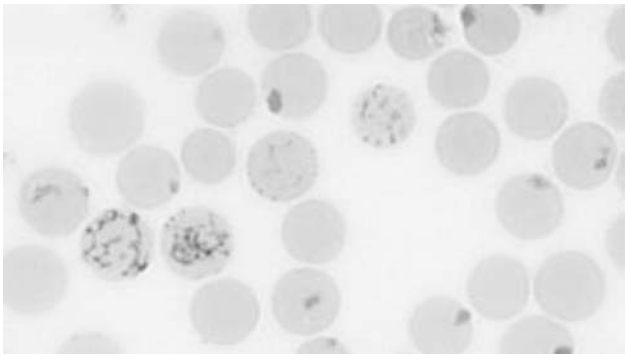

Figure 24.2. Heinz bodies. Heinz bodies are the large, single basophilic inclusions inside erythrocytes. Other red cell inclusions represent reticulocytes. (See color plate 24.2.)

Table 24.2. Sites of globin mutation that are associated with unstable hemoglobins. In addition to single amino acid substitutions, these mutations can include small deletions and insertions of amino acids, reading frameshifts, fusion globins, and elongated globin chains

Weakening or modification heme–globin interactions
Interference with the secondary structure of a globin subunit
Interference with the tertiary structure of the subunit
Altered subunit interactions interfering with the quaternary structure

Pathophysiology

Mutations that change the primary structure of globin, depending on the substitution and its location, can alter the secondary (α-helical), tertiary (folding of the globin chain) or quaternary (interactions within the hemoglobin tetramer) structure of hemoglobin by mechanisms shown in Table 24.2.

Heme–globin interactions are vital for oxygen delivery but also contribute to molecular stability. For example, introduction of a charged amino acid residue into the heme pocket, a site normally formed by residues with nonpolar side chains, deletions involving residues that directly interact with the heme, mutations other than to a tyrosine residue of the (F8) proximal histidine or (E7) distal histidine, all cause molecular instability.

Disruption of the secondary structure reduces subunit solubility and is often a result of the introduction of proline residue that cannot be accommodated into α-helix except in its first two positions. α-Helices comprise approximately 70% of the globin subunit and must be folded into a globin motif. Introduction of water into the molecule destroys its stability and this can be caused by substitution of a charged residue, for example, leucine, for a nonpolar residue, like arginine.

Loss of intersubunit contact hydrogen bonds or salt bridges in the α1β1 contact area will also reduce stability. Dissociation of α1β1 dimers into monomers is normally minimal as it generates methemoglobin and consequent instability. Dissociation of chains along the α1β1 contact generates α- and β-globin chains that uncoil, loosening their heme–globin interaction and favoring methemoglobin formation. Mutations affecting the α1β1 interface tend to be more unstable than those affecting the α1β2 contact.

Heme loss is inhibited by maintaining heme iron in the reduced ferrous (Fe^{2+}) state by the action of methemoglobin reductases and detoxification of oxygen radicals. Therefore, dimerization and the dispersion and precipitation of free heme is minimalized. Hemoglobin dimers autoxidize and lose heme more readily than tetramers. Generation of methemoglobin increases the thermoinstability of hemoglobin, suggesting that the pathways and events accompanying the conversion of ferrous to ferric heme are important for hemoglobin stability.

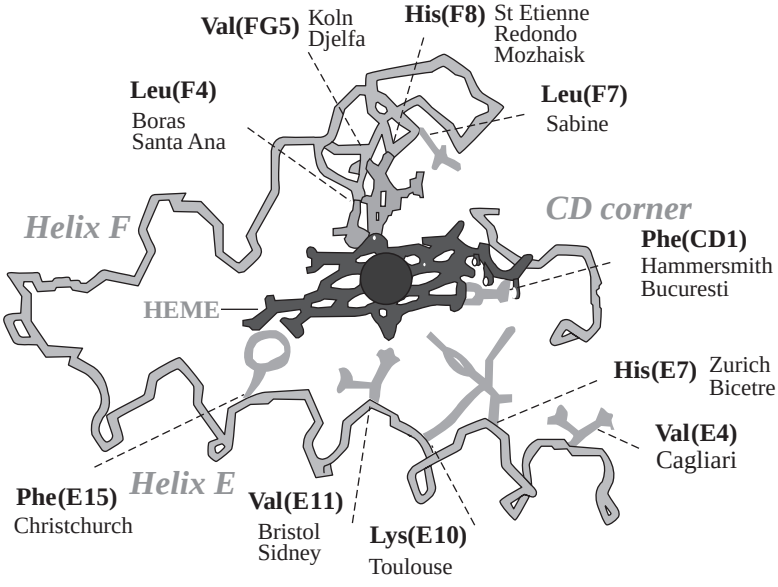

Figure 24.3. Mutation sites of some unstable hemoglobins. Mutations shown are near the heme moiety.

Heinz bodies are the product of hemoglobin denaturation. First suggested to be heme-depleted globin chains, these inclusions were subsequently identified as hemichromes, derivatives of ferric hemoglobin that have the sixth coordination position occupied by a ligand provided by the globin. Hemichromes are generated when the heme is dissociated from the heme pocket and rebinds elsewhere in the globin after the α or the β chains have denatured. Irreversible hemichromes are a stage in the formation of Heinz bodies. Membranes prepared from the red cells of patients with Hb Köln (*HBB* val98met) who have had a splenectomy contain aggregates composed of disulfide-linked spectrin, band 3 (Chapter 9), globin and

Table 24.3. Some hemoglobin variants with elongated globin chains

Variant	Mutation	Mechanism	Phenotype
NH_2-Terminal Extension			
South Florida[51]	*HBB* val1met	Initiator met retained, chain extended by 1 residue	Acetylated at the NH_2 terminus and appears as HbA_1C
Doha[52]	*HBB* val1glu	Initiator met retained, chain extended by 1 residue	21% in heterozygote, acetylated
Long Island	*HBB* his2pro	Initiator met retained, chain extended by 1 residue	No clinical phenotype but appears as HbA_1C
Thionville[53]	*HBA1* val1glu	Initiator met retained, chain extended by 1 residue	50% in heterozygote, acetylated
Insertions			
Catonsville[54]	Insertion between α37 and α38	glu inserted	Increased O_2 affinity, unstable
Zaïre	Insertion between α116 and 117	5 residues inserted	Normal
Grady	Insertion between α118 and 119	3 residues inserted	Normal
Koriyama[55]	Insertion between β95 and 96	5 residues inserted by possible out of frame base pairing. In Hb Gun Hill the same 15-bp segment is deleted	Severe instability and anemia. Resembles a thalassemic hemoglobinopathy
COOH-Terminal Extensions			
α-Globin gene termination mutants	See Chapter 13	Termination codon mutations	α Thalassemia
Tak	β147 (+AC)	2-bp insertion and frameshift	∼Normal
Wayne	α139 (−A)	1-bp deletion and frameshift	See Table 24.5

high-molecular-weight complexes composed in part of denatured spectrin.

Hemichrome can bind band 3 of the erythrocyte membrane. Decreased deformability of the erythrocyte leads to preferential trapping in the spleen where Heinz bodies are removed. The coincident loss of small amounts of membrane gradually converts discoid cells into spherocytes that are eventually removed from the circulation. Membrane damage might also result from lipid peroxidation and protein cross-linking due to free radical formation that is a result of Fenton chemistry.

When the mutation is such that heme dissociates from the abnormal globin chain, as in the example of Hb Köln, the partially heme-deficient molecule is susceptible to reversible and irreversible hemichrome formation with subsequent denaturation. Precipitates tend to be pale, and the pattern found during hemoglobin electrophoresis was characterized by multiple bands unless stabilized by the addition of hemin. Dipyrroluria was present, suggesting that free heme was converted to dipyrroles rather than bilirubin.

By different mechanisms, hemoglobin chains might be extended beyond their expected length. Small insertions and deletions are caused by slipped mispairing at the replication fork of DNA at the site of direct repeats or inverted repeats. Nonsense to missense mutations at the termination codon, reading frameshifts, failure to cleave the initiator methionine residue from the amino terminus of globin, amino acid insertions, and combined deletions and insertions have been reported. Although many resulting variants are not associated with hematological abnormalities, some are accompanied by hemolytic anemia that can be severe. Not unexpectedly, distortion of tertiary structure because of chain elongation can provoke different degrees of globin instability. Table 24.3 highlights other variants with extended globin chains.

Almost without exception, the deletion of one or more amino acid residues results in an unstable globin. When one or two residues are missing, the clinical phenotype is usually mild with slight anemia. When more than one or two amino acids are deleted the phenotype is apt to be more severe. Hb Bruxelles (*HBB* phe41 or 42del) is accompanied by severe Heinz body hemolytic anemia.

Alpha hemoglobin-stabilizing protein (AHSP) binds free α-globin chains protecting them from precipitation (Chapter 4). In vitro studies suggest that the impaired interaction of AHSP with α-globin variants where the mutation lies in the molecular sites where ASHP binds α globin might affect the stability of the variant.[14,15] In these studies, recombinant Hb Groen Hart (*HBA* pro119ser), Hb Diamant (*HBA* pro119leu), and α-globin termination mutants had impaired interactions with AHSP. These observations suggest an additional mechanism for unstable α-globin variants.

Hyperunstable hemoglobins are an uncommon class of variants where the mutation, usually in the third exon of

the globin gene, leads often to a truncated globin that is barely detectable or undetectable. These hemoglobins, creating the phenotype of dominant inherited thalassemia, are discussed in Chapter 16.

Chronic hemolysis has been associated with dysregulated nitric oxide (NO) biochemistry and reduced NO bioavailability. This subject is discussed in Chapter 11.

Diagnosis

Multiple tests are used to diagnose unstable hemoglobins. Patients with unstable hemoglobins might have characteristically dark urine or pigmenturia. This is due to the presence of dipyrroles that are also present in Heinz bodies. The absence of pigmenturia does not exclude the diagnosis of unstable hemoglobin and the severity of the hemolysis is unrelated to pigmenturia. For example, carriers of Hb Köln and Hb Zürich (*HBB* his63arg) can have pigmenturia but hemolysis can be severe with Hb Köln and is usually very mild with Hb Zürich. The P_{50} of unstable hemoglobins is quite variable and can be normal, low, or high. This is a result of different mutations variously affecting heme–globin interaction, and the tertiary and quaternary structures of the molecule.

Blood Smear and Heinz Body Preparation. Abnormalities of the blood smear are often present but are nonspecific. They might include anisocytosis, basophilic stippling, Howell–Jolly bodies, nucleated red blood cells and microspherocytes. Fragmented cells can appear to have had "a bite" taken from them and are thought to result from the phagocytosis of Heinz bodies during passage of the cell through the spleen. The mean corpuscular hemoglobin concentration can be as low as 25 g/dL because of heme loss or Heinz body formation. Some reported values for reticulocytes might be factitiously high as inclusion bodies are mistaken for reticulocytes.

Heinz bodies in circulating red cells are usually found only after splenectomy or during an acute hemolytic episode (Fig. 24.2). Under such circumstances, more than 50% of the cells typically contain one large, spherical inclusion. Heinz body detection requires the incubation of erythrocytes with a supravital stain such as new methylene blue or crystal violet. They appear as single or multiple inclusions of 2 μ in diameter or less and often appear membrane attached. Heinz bodies can be found in fresh blood, but usually, incubation for 24 hours without glucose is required for their formation. A normal control should always be run simultaneously.

Hemoglobin Stability Tests. The isopropanol test, a good screening test for unstable hemoglobins, can give false positive results when the sample contains more than 5% HbF.

In the heat denaturation test, a hemolysate is incubated for 1 or 2 hours at 50°C. Hemoglobin instability is suggested by a visible precipitate. Although simple, the results of this test vary because of different concentrations of the abnormal variant and different temperatures need for their denaturation. A control with a normal, stable hemolysate is vital for correct interpretation.

Detection of the Variant Hemoglobin and Mutation Analysis. If clinical and hematological studies suggest an unstable variant, the determination of the molecular defect becomes the final step in diagnosis. Approximately a quarter of unstable hemoglobins are not detectable by commonly used methods of hemoglobin separation, and an unstable variant might be reflected only by a diffuse peak. DNA analysis is the best approach to defining the globin mutation. New mutations are common, thus a family history need not be present.

Clinical Aspects

The presence of an unstable hemoglobin should always be prime consideration when hemolytic anemia is present and its cause is not clearly defined. Chronic hemolysis due to unstable hemoglobins can be associated with all of the known complications of hemolysis such as aplastic crisis, jaundice with cholelithiasis, leg ulcers, pulmonary hypertension, splenomegaly, and hypersplenism, along with special features of unstable hemoglobins such as pigmenturia and drug-induced and fever-associated increases in anemia.[16,17] Dusky cyanosis has been described in some patients with unstable hemoglobins predisposed to methemoglobin formation. In one case where the γ-globin chain of HbF was affected (HbF-Poole; *HBG2* trp130gly), hemolytic anemia was present in the newborn but disappeared as the γ- to β-globin switch was completed. Sometimes, the disease is seen in early childhood; it can be found in adults incidentally or when fever or drug treatment induces hemolysis.

Many unstable hemoglobin variants produce mild hemolytic disease with minimal or no anemia in the steady state and a reticulocyte count between 4% and 10%. Splenomegaly might or might not be present. Most patients with mild disease are first seen during a hemolytic crisis induced by drugs or infection. More than one-half of the unstable variants are associated with no hematological abnormality and were detected through screening programs.

Although most differences in clinical phenotypes are explained by nature of the amino acid substitution, as in many single gene disorders, other genetic and some environmental factors might modulate the severity of disease. For example, investigation of the basis for intrafamilial variation in drug-related hemolysis with Hb Zürich disease suggested that tobacco smoking ameliorated hemolysis, probably because the high affinity of Hb Zürich for CO stabilized the hemoglobin tetramer.

B19 parvovirus infection can temporarily shut down erythropoiesis, rapidly worsening the anemia and causing aplastic crisis. Anemia might also increase during infection and after treatment with oxidant drugs such as

sulfonamides. The intensity of hemolysis is variable and is dependent on the mutation and fraction of abnormal hemoglobin present.

Hb Köln, described in multiple kindreds, is the most common unstable hemoglobin and is characterized by anemia, reticulocytosis, splenomegaly, and 10%–25% Hb Köln. It is not associated with oxidant drug-induced hemolysis. The independent occurrence of this variant in so many apparently unrelated individuals suggests that the Hb Köln mutation, located at a methylated CpG dinucleotide sequence of the β-globin gene, can act as a "hotspot" for mutation through the deamination of the methylcytosine nucleotide to form thymine.

Hb Zürich has also been reported often. This variant, forming approximately 25% of the hemolysate, is accompanied by mild anemia exacerbated by oxidant drugs, pigmenturia, and increased affinity for CO. The latter protects the β-globin heme group from oxidation and increased instability. Carriers have a special susceptibility to sulfonamide-induced hemolytic crisis. Hb Hasharon (*HBA2* asp47his) is another more common variant affecting the α-globin chain, found in Ashkenazi Jews, and causing hemolysis in newborns but not in most adults. This variant comprises 15%–20% of the hemolysate and inclusion bodies were not found.

Some unstable hemoglobins are linked to α- or β-thalassemia genes: the α-chain mutants Hb Suan-Dok (*HBA2* leu109arg) and Hb Petah Tikva (*HBA* ala110asp) coexist in *cis* with α thalassemia and some β-chain mutants like Hb Leiden (*HBB* glu6 or 7del), Hb Duarte (*HBB* ala62pro), and HbG-Ferrara (*HBB* asn57lys) coexist with a β^0-thalassemia mutation in trans.

Miscellaneous. A 10-year-old girl with hemolytic anemia due to Hb Bristol-Alesha (*HBB* val68met) had moyamoya and transient ischemic attacks. The authors suggested that chronic hypoxemia might be the cause of occlusive moyamoya in unstable hemoglobinopathies or in hemoglobins with altered oxygen affinity.[18]

Hyperunstable Hemoglobins

Some uncommon globin mutations are hyperunstable. Although these mutants are synthesized in normal amounts, they are unable to form stable tetramers or even dimers and are rapidly catabolized. These variants therefore have features of both an unstable hemoglobins and thalassemias and have been called thalassemic hemoglobinopathies.[19] The dominant phenotype is that of severe, dominantly inherited β thalassemia because the effected globin chain fails to accumulate and participate in tetramer formation. These mutations are discussed in Chapters 13 and 16.

Treatment. Unstable hemoglobinopathies are generally mild disorders and do not require therapy except for supportive and preventive measures. Administration of folic acid to prevent megaloblastic arrest of erythropoiesis might be warranted, although access to a nutritious diet is probably satisfactory. The possibility of fever-associated hemolysis should be recognized and oxidant drugs should be avoided, including acetaminophen and sulfonamides, especially when history suggests they can provoke hemolysis, and there are other management considerations. Chronic hemolysis is associated with a high incidence of cholelithiasis although this alone is not an indication for surgery.

Severe hemolysis raises the question of splenectomy. Undoubtedly, the spleen plays an important pathophysiological role in the destruction of Heinz body containing red cells. This must be balanced with the role of the spleen as a defense against pneumococcal infections early in life and the need for antipneumococcal vaccines and prophylactic penicillin in cases in which splenectomy is performed in childhood. On balance, splenectomy might be beneficial for some severe unstable hemoglobinopathies, and partial correction of the anemia is sometimes achieved. Nevertheless, predicting the response to splenectomy is difficult. Hydroxyurea has been used to stimulate HbF production and help repair anemia in two cases of unstable hemoglobin disease.[20]

M HEMOGLOBINS

Cyanosis is the major clinical feature of amino acid substitutions causing methemoglobinemia. These rare disorders are not noted for their clinical severity; misdiagnosis, and unneeded treatment are their major hazards. Other causes of methemoglobinemia are discussed in Chapter 25.

Pathophysiology

In the M (met) hemoglobins, the mutant globin chain creates an abnormal microenvironment for the heme iron, displacing the equilibrium toward the oxidized or ferric (Fe^{3+}) state (Fig. 24.4). A combination of Fe^{3+} and its abnormal coordination with the substituted amino acid generates a visible spectrum that resembles but is clearly different from methemoglobin not due to a globin gene mutation, where the heme iron is oxidized but an associated amino acid substitution is absent (Chapter 25).

In the Iwate prefecture of Japan, "black children" had been observed for more than 160 years and this was associated with a brownish colored hemoglobin in the hemolysate of a patient that was eventually characterized as HbM Iwate (*HBA* his87tyr).[21] Four β-, two α-, and two γ-globin HbM variants have been reported. In five of the eight described HbM variants, the mutation involves the substitution of the distal (E7) or proximal (F8) histidine interacting with the heme iron via tyrosine. With HbM Milwaukee (*HBB* val67glu), the longer side chain of the glutamic acid residue can reach and perturb the heme iron.

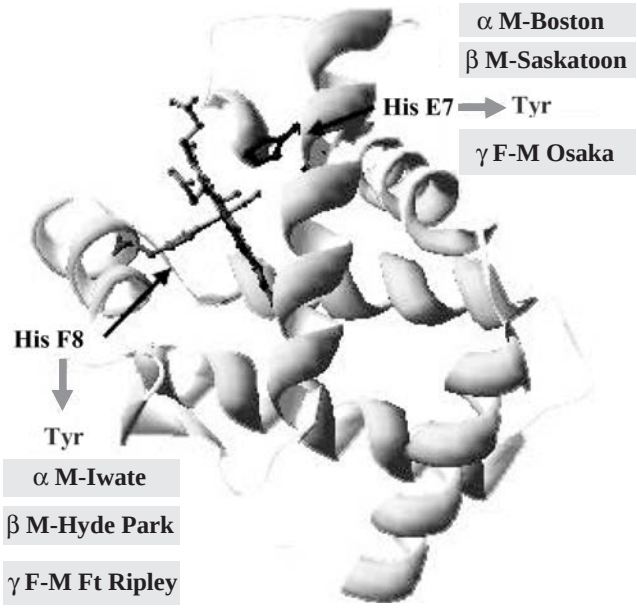

Figure 24.4. Mutation sites of some hemoglobin M variants.

Some properties of M hemoglobins are shown in Table 24.4. The strength of attachment of ferric heme to globins differs among M hemoglobins. The γ-globin gene HbM variants, HbF-M Osaka (*HBG2* his63tyr), and HbF-M Fort Ripley (*HBG* his92tyr) have been associated with neonatal "cyanosis" that disappears with maturation.

HbM Milwaukee is the sole example of an M hemoglobin not caused by mutation of the proximal or distal histidine residues but by the nearby β67 (E11) val. When this residue is replaced by a residue with an appropriate side chain, as happens with the glutaminyl residue, it perturbs the heme iron and generates an M hemoglobin. Other mutations of that site, such as Hb Bristol (val67asp) or Hb Sidney (val67ala), are unstable or have low affinity but do not lead to heme iron oxidation. X-ray crystallography showed that the carboxylic group of the new glutaminyl residue in Hb Milwaukee occupies the sixth coordination position of the iron, and that the proximal histidine maintains its role as the tenant of the fifth coordinating position, stabilizing the abnormal ferric state of HbM Milwaukee.

Oxygen-binding Properties and the R→T Transition of M Hemoglobins. HbM Milwaukee, Hyde Park (*HBB* his92tyr), and Hb Boston (*HBA* his58tyr) all adopt deoxy or deoxy-like conformation upon the deoxygenation of the two normal chains although the abnormal chains cannot off load oxygen. This, and crystallographic, electron paramagnetic resonance, and nuclear magnetic resonance spectroscopy, and 2,3-BPG binding studies affirm that after two heme groups become deoxygenated, the entire molecule adopts the deoxy T conformation.

A normal Bohr effect and P_{50} strongly suggest that in HbM Milwaukee, HbM Saskatoon (*HBB* his63tyr), and HbM Hyde Park the molecule adopts the R-state when the two normal chains are oxygenated, a finding supported by nuclear magnetic resonance studies of HbM Milwaukee. In contrast, HbM Iwate is in the crystallographic T configuration when its normal heme groups are in the ferric state, explaining its decreased oxygen affinity; the molecule does not shift to the R-state when the normal heme groups are liganded and remains in the low affinity T-state. A similar situation probably exists in HbM Boston, as the habit of the deoxy crystal remains intact after oxygenation, suggesting that no conformational change has occurred that would require a different crystal structure.

HbM Saskatoon and HbM Boston have different properties despite the common substitution of the distal histidine because the former variant does not change its conformation when oxygenated, whereas the latter variant does. Why properties of the β-globin chains differ from that of the α-globin chain when their distal histidine is substituted is unresolved.

Iron Oxidation and Spectral Characteristics. In all M hemoglobins, the affected heme groups are stabilized in the ferric state and have an abnormal microenvironment. They exhibit an abnormal visible absorption spectrum that can be easily distinguished from methemoglobin. This characteristic separates these variants from some unstable hemoglobin mutants that also have a tendency to form methemoglobin.

Heme iron in the abnormal subunits of the M hemoglobin exhibit abnormally low redox potential. They are oxidized more rapidly by molecular oxygen and are resistant, to a variable degree, to reduction by dithionite. Differences exist in the rate of reduction of the five M hemoglobins with various reductases, including the enzyme active in the normal erythrocyte, NADH-cytochrome

Table 24.4. Hematological features of HbM variants of the α- and β-globin chains

Variant	Percent	Hb (g/dL)	Reticulocytes (%)	P_{50}	Bohr effect
HbM Hyde Park (Milwaukee-2)(β)	23–32	10–13	4–6	Normal	Present
HbM Iwate (α)	19	17	–	Decreased	Decreased
HbM Boston (α)	20–30	–	–	Decreased	Decreased
HbM Milwaukee (β)	50	14–15	1–2	Decreased	Present
HbM Saskatoon (β)	35	13–16	0.8–3.2	Normal	Present
HbM Chile (β)	17	13.2	1.2	–	–

b_5 reductase (*CYB5R3*). HbM Iwate, HbM Hyde Park, and HbM Boston are not reduced at all; HbM Milwaukee is reduced slowly and HbM Saskatoon is reduced normally by this reductase. These last two variants might be less oxidized in vivo than expected. Full ferric conversion might occur only in vitro, due to the high autoxidation rate of these abnormal hemoglobins. Older red cells might, nevertheless, have fully oxidized abnormal chains consistent with the presence of clinically apparent cyanosis.

Clinical Aspects and Diagnosis

Clinically, the skin and mucous membranes of HbM carriers have an appearance similar to but not identical with cyanosis, sometimes called pseudocyanosis. Skin and mucosal surfaces are brownish/slate colored, more like methemoglobinemia, but not as slate blue-purple as true cyanosis. This distinction is subtle and might not be apparent without simultaneously comparing the two conditions. Skin reflects hemoglobin molecules with an abnormal ferric heme and abnormal spectrum, because cyanosis is caused by the presence of more than 5 g/dL of deoxyhemoglobin. Pseudocyanosis is present from birth in α-globin chain abnormalities and from the middle of the first year of life in the β-chain mutants. A mixture of the abnormal pigment and true cyanosis, due to hemoglobin desaturation of the normal chains, is observed in the low oxygen affinity HbM Boston and HbM Iwate. Pseudocyanosis, is not associated with dyspnea or clubbing and carriers have a normal life expectancy. A mild hemolytic anemia and reticulocytosis has been observed in HbM Hyde Park and can be explained by the instability of the hemoglobin induced by partial heme loss.

HbM should be considered in all patients with abnormal homogeneous coloration of the skin and mucosa, particularly if pulmonary and cardiac function is normal. The diagnosis can be suspected by observing an abnormal brown coloration of the blood in a tube. To distinguish this coloration from methemoglobin, the addition of KCN to the hemolysate is useful. KCN will turn blood containing methemoglobin red, but has little if any effect on HbM-containing hemolysates. Lack of color conversion with KCN is diagnostic of HbM.

A spectrophotometrical recording of the visible spectrum of the hemolysate is critical for the diagnosis. M hemoglobins do not have an absorbance peak at 630–635 nm, which is typical of methemoglobin A (Fig. 24.5). In the presence of HbM, accurate measurement of oxygen saturation and CO hemoglobin is difficult with most instruments. Absorption maxima at different wavelengths of all hemoglobin M variants have been reported.

Treatment. Treatment is neither possible nor necessary. A correct diagnosis is most important because this will forestall therapeutic and diagnostic misadventures.

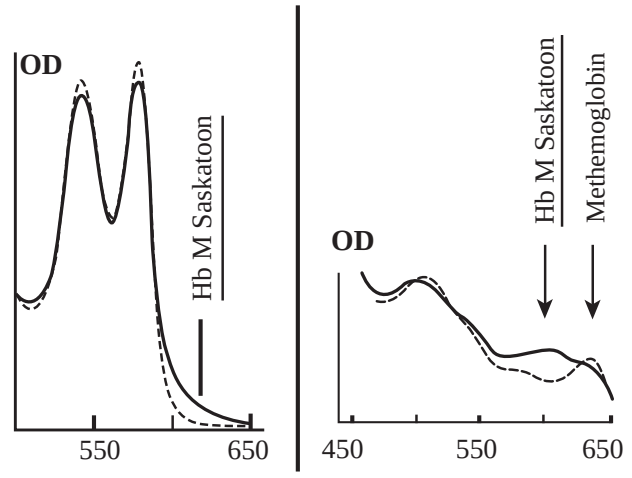

Figure 24.5. Absorption spectra of HbM Saskatoon. The left panel shows a fresh hemolysate and the right panel, a hemolysate totally oxidized.

RARE MUTATIONS WITHOUT A PHENOTYPE OR WITH MINOR HEMATOLOGICAL CHANGES

Posttranslational Modifications

Posttranslational modifications of globin are broadly illustrative of the secondary changes possible in all proteins and form an interesting group of hemoglobinopathies.

Deamidation. Under certain conditions, mutant asparaginyl residues can be deamidated to aspartate and result in two species of globin caused by a single mutation (Table 24.5).[22] Aspartic acid to asparagine mutants could be deamidated, reducing levels of the asparagine-containing globin. Usually, deamidation occurs when a histidine residue is adjacent to the asparagine substitution or when changes in the tertiary structure of a variant globin can bring a histidine into the proximity of an asparagine residue. Other factors favoring asparagine deamidation are glycine, serine, or alanine residues with nonbulky side chains on either side of the asparagine or brought near the asparagine, a basic or acidic residue on one side and a serine or cysteine on the other side of asparagine and peptide chain flexibility. Not all aspartic acid to asparagine mutants are subject to posttranslational deamidation. Two abnormal hemoglobins can be present when variants susceptible to deamidation are analyzed: a native form containing the encoded asparagine and a deamidated form containing aspartic acid. When a variant of this type is present in a compound heterozygote with another variant hemoglobin, a confusing HPLC profile with three hemoglobin bands representing two globins resulting from the asparagine substitution and another from the other β-globin gene variant can exist.

Oxidation. A young girl with hemolytic anemia was found to have two unstable hemoglobins: Hb Sidney (*HBB* val67asp) and a new variant called Hb Coventry (*HBB* leu141del) that formed less than 10% of the hemolysate.

Table 24.5. Hemoglobin variants with deamidated asparaginyl residues

Variant	DNA mutation	Phenotype
La Roche-sur-Yon (*HBB* leu81his)	CTC→CAC (?)	Unstable, decreased P_{50}, mild hemolysis. leu81his facilitates β80 asn deamidation
Providence (*HBB* lys82asn)	AAG→AAC/T (?)	Increased O_2 affinity but normal packed cell volume
Redondo (*HBB* his92asn)	CAC→AAC (?)	Heme loss, unstable, hemolysis, migrates like HbS and HbA_2
Osler (*HBB* tyr145asn)	TAT→AAT	Increased O_2 affinity, migrates like HbJ and HbA
J Sardegna (*HBA* his50asn)	CAC→AAC	Functionally normal. Present in 0.09% of Sardinians
J-Singapore (*HBA*2 ala79gly)	GCG→GGG	Normal, ∼22%. The *HBA*2 ala79gly mutation allows deamidation of α78 asn[56]
Wayne (*HBA* 139 -A)	-A in either *HBA2 or HBA1* with 5 codon elongation	Normal hematology, either ∼14% or ∼6% present

As the patient also had HbA, three β-globin genes were postulated, one being a βδ gene.[23] Another patient with unstable hemoglobin hemolytic anemia was also found with three putative β-globin chains: Hb Atlanta (*HBB* leu75pro), Hb Coventry, and β^A. These observations, and a third instance of Hb Coventry in a similar clinical setting, suggested that this variant was widespread and only became apparent when present with another unstable hemoglobin. It was proposed that the two mutations were in a single β-globin gene (*HBB* leu75pro; leu141del), that was the product of a βδ anti-Lepore gene, the leucine 141 being deleted in the crossover event.[24] Two genetic events must have occurred to explain these findings; a de novo β75 leu→pro mutation and a sister chromatid exchange in a somatic cell. When DNA techniques were applied to study the structure of the β-globin gene cluster and the nucleotide sequence of the β-globin genes, only two normal β-globin genes were found. The expected leu75pro mutation was found but the codon for β141 was intact in genomic DNA and in mRNA. Mass spectroscopy demonstrated the peptide containing β141 leucine to contain a novel amino acid of 129 D instead of the 113 D of the leucine peptide and was postulated to be hydroxyleucine. Hydroxyleucine cannot be detected by amino acid analysis so its presence remains conjectural. It was proposed that perturbation of the heme pocket by the leu75pro mutation in the E helix, perhaps via the generation of activated oxygen species, lead to oxidation of some β141 leucine residues. This notion provides a parsimonious explanation for the existence of the Hb Coventry anomaly in the same globin chain as Hb Atlanta and other unstable variants.[25]

Acetylation. Hb Raleigh *(HBB* val1ala) is acetylated and migrates with HbA_1C.[26] Proteins with an NH_2-terminal alanine are often acetylated. Acetylation of a retained N-terminal methionyl occurs when normal cleavage of this residue malfunctions (see later). Acetylated hemoglobins can be mistaken for Hb A_1C.

N-Terminal Elongated Globins

Several mutations of the NH_2-terminal valine of both the α- and β-globin chain and a *HBB* his2pro mutation result in a globin elongated by one residue because of the failure to cleave the initiator methionyl (Table 24.3). A hematological phenotype is not present but the NH_2-terminal methionine is acetylated and appears as HbA_1C by some methods of hemoglobin separation.

Interesting β-Globin Gene Variants with Point Mutations

Hemoglobin G Coushatta (HBB glu22ala). This β-globin chain variant has no clinical or hematological manifestations and has been found in geographically separated racial and ethnic groups.[27] It is common in China and North American Coushatta Indians and has also been described in Japan, Korea, and Turkey. It is the most common variant hemoglobin described along the Chinese Silk Road. Its presence in Asia, the Old World, and in American Indians raised the question of whether this variant had a unicentric origin and spread to the New World over the ancient Bering land bridge or originated multicentrically in Asia and in Amerindians. When the haplotype of the β-globin gene cluster was examined in Louisiana Coushatta Indians and native Chinese who carried Hb G Coushatta, these groups had different haplotypes and β-globin gene framework associated with the identical HbG Coushatta mutation. Both the HbG Coushatta mutation (GAA→GCA) and the codon 2 CAC→CAT polymorphism are normal δ-globin gene sequences, suggesting the possibility of gene conversion. HbG Coushatta had at least two independent origins

Table 24.6. Mutations encoded on *HBA*$_2$ and *HBA*$_1$

Variant	*HBA2*	Genotype	%	*HBA1*	Genotype	%
J-Paris (ala12asp)	GCC→GAC	$\alpha^X\alpha/\alpha\alpha$	24	GCC→GAC	$\alpha\alpha^X/\alpha\alpha$	20.7
Hekinan (glu27asp)	GAG→GAC	$\alpha^X\alpha/-\alpha$	27.9	GAG→GAT	$\alpha\alpha^X/\alpha\alpha$	13.9
G-Philadelphia (asn68lys)*	AAC→AAA	$\alpha^X\alpha/\alpha\alpha$	25.1	AAC→AAG	$\alpha\alpha/-\alpha^{X*}$	33.4
J-Broussais (lys90asn)	AAG→AAT	$\alpha^X\alpha/\alpha\alpha$	25	AAG→AAC	$\alpha\alpha^X/\alpha\alpha\alpha$	18
Manitoba ser102arg)	AGC→CGC	$\alpha^X\alpha/\alpha\alpha$	18.7	AGC→AGA	$\alpha\alpha^X/\alpha\alpha^X$	23.9
J-Meerut (ala120glu)	GCG→GAG	$\alpha^X\alpha/\alpha\alpha$	23	GCG→GAG	$\alpha\alpha^X/\alpha\alpha$	18.4

* This variant is usually present on the $-\alpha^{3.7}$ rightward deletion chromosome.

that could be due to two separate mutations at codon β22, a mutation at this codon and a β→δ gene conversion or two β→δ gene conversion events.[28] The β-globin gene haplotype predominant in Thailand and in Koreans suggesting yet other possible origins for this ostensibly genetically "neutral" variant.[29,30,31]

Hemoglobin Vicksburg (HBB leu75del). It was proposed that Hb Vicksburg arose as a stem cell mutation on a β^+-thalassemia chromosome.[32] When first studied, only Hb Vicksburg was present, then both HbA and Hb Vicksburg were found, and finally, only HbA was present. This suggested that over time there were at least two clones of erythroid progenitors contributing to erythropoiesis.[33] A leucine deleted in Hb Vicksburg recalls the origin of Hb Coventry so it remains possible that a technical artifact was responsible for the failure to find a β75 leucine residue when Hb Vicksburg was present.

Support for the notion of a somatic mutation leading to traces of abnormal hemoglobin comes from studies of the stable variant, Hb Costa Rica (*HBB* his77arg). Six percent to 8% Hb Costa Rica was found in a young woman but not in any of her relatives. A mutation corresponding to the CAC→CGC transversion expected to code for this variant could not be detected in her genomic DNA. Yet, small amounts of Hb Costa Rica mRNA were present in reticulocytes. Globin gene structure was normal. A somatic mutation causing genetic mosaicism was hypothesized. In follow-up studies in which burst-forming unit erythrocytes were grown from the blood of this patient, only 12%–15% of these erythroid colonies contained both HbA and Hb Costa Rica mRNA, whereas the remainder had mRNA only for HbA.

HBB mutations in *cis* to a β^+-thalassemia mutation was the explanation for unusually low levels of HbS and the rare variant, Hb Dhofar (*HBB* pro58arg).[34]

Interesting α-Globin Gene Variants with Point Mutations

Mutations can occur in either or both the 5′ *HBA2* or the 3′ *HBA1* genes. Where information is available, mutations are equally divided between both α-globin genes.[35] Depending on whether they are encoded on the *HBA2* or the *HBA1* gene, there is a small difference in the levels of stable α-globin gene mutants. *HBA2* mutants usually form approximately 24% and *HBA1* mutants approximately 20% of the hemolysate, a difference explained by the transcription rate of each α-globin gene, translational efficiency of the mRNA from each gene, the assembly of αβ dimers, the presence of deleted or triplicated α-globin loci, and the presence of nondeletion types of α thalassemia (Chapter 13). Some identical amino acid substitutions encoded on both the α_1- and α_2-globin genes, often by different mutations, are shown in Table 24.6.

Hemoglobin G-Philadelphia (HBA asn68ys). HbG Philadelphia is the most common α-globin gene variant in blacks and is found in approximately one in 5,000 African Americans. A clinical phenotype is not present, but because it is usually found with α thalassemia and can be present on many different α-globin gene arrangements, its level in the hemolysate varies widely and it has a bimodal or trimodal distribution.[36,37] Interactions of HbG-Philadelphia with sickle cell anemia are discussed in Chapter 23. Most often, in the black population, HbG-Philadelphia is present on the $-\alpha^{3.7}$ chromosome as an AAC→AAG transversion. It is also found in Italians on the *HBA2* gene in a normal α-globin gene locus ($\alpha^G\alpha/\alpha\alpha$) where the mutation is AAC→AAA.[38,39] Different proportions of HbG-Philadelphia found with different α-globin gene haplotypes are shown in Table 24.7. In addition to the α-globin genotypes shown, it is likely that HbG-Philadelphia will be found in trans to chromosomes with both α-globin genes deleted and associated

Table 24.7. Levels of HbG-Philadelphia in different α-globin genotypes

α-Globin genotype	% HbG-Philadelphia
$\alpha^G\alpha/\alpha\alpha$	25
$-\alpha^G/\alpha\alpha$	33
$-\alpha/\alpha^G\alpha$	33
$-\alpha/-\alpha^G$	50
$-\alpha^G/-\alpha^G$	100
$-\alpha^T/-\alpha^{G*}$	100
$-/-\alpha^{G\dagger}$	HbG+HbH

* α^T denotes a dysfunctional α-globin gene that is not expressed because of a frameshift and new in-phase termination codon.

† In HbG/HbH disease, both HbH and HbG are present.

with triplicated and quadruplicated α-globin loci. In the latter case, the percent of HbG should be lower than usual.

Other α-globin gene variants present at levels near 50% are probably also present on an α thalassemia-2 chromosome. HbJ-Tongariki (*HBA* ala115asp) is commonly found in Melanesians and always on a $-\alpha^{3.7}$ chromosome. Heterozygotes have approximately 50% and homozygotes, nearly 100% of this variant. This mutation was likely to have occurred on a $-\alpha^{3.7}$ thalassemia chromosome that is prevalent in Vanuatuans.

Hb Setif (HBA2 asp22tyr) Pseudosickling and Hemoglobin Oligomerization. Only hemoglobin variants with the *HBB* glu6val mutation polymerize when deoxygenated and cause vasoocclusive disease. Hb Setif, a variant found in North Africa and the Middle East, forms pseudosickled cells in vitro but not in vivo, when it is oxygenated. This is due to the aggregation of Hb Setif.[40–44] Pseudosickled Hb Setif cells can be distinguished from sickled HbS-containing cells by many physical characteristics although they have several features in common. The C_{sat} of a 40%/60% hemolysate of Hb Setif/HbA at 290 mOsm was 24 g/dL at 24°C. During incubation in NaCl buffer at 450 mOsm, polymer in pseudosickled cells required more than 30 minutes to begin formation; after 24 hours, nearly all cells contained aggregated Hb Setif. In contrast, HbS polymer forms in fractions of a second to seconds. Deoxygenation promotes HbS polymerization but inhibits pseudosickling of Hb Setif cells. Pseudosickled Hb Setif cells have been described as twisted cigars with a monotonous morphology in contrast to the eclectic conformation of sickle cells (Fig. 24.6). In common with HbS erythrocytes, cell deformability decreased with increasing Hb Setif concentrations and increasing osmolality of the suspending buffer, whereas the amount of Hb Setif polymer increased under these conditions.

Pseudosickling of Hb Setif is strictly an in vitro phenomenon. Whether Hb Setif was present at levels of less than 20%, attributable to mild instability, or found at concentrations near 40%, because of a coexistent α thalassemia deletion, there was no evidence of hemolysis and vasoocclusive disease. Urine-concentrating ability in carriers of Hb Setif seemed unimpaired, whereas this is abnormal in sickle cell trait and sickle cell anemia.

Hemoglobin Porto Alegre (*HBB* ser9cys) contains an extra thiol group oriented toward the molecule's exterior and spontaneously oligomerizes during storage by forming intermolecular disulfide bridges. Although other substitutions introducing a cysteine residue have been described, only Hb Mississippi (*HBB* ser44cys), Hb Harrow (*HBB* phe118cys), and Hb Ta-Li (*HBB* gly83cys) are also known to form low concentrations of oligomers.[45] None of these variants are associated with cell sickling.

HbI (HBA2 lys16glu). HbI has been encoded on both *HBA2* and *HBA1* of a single individual and considered an example of concerted evolution (the parallel development of related closely linked genes). In a hematologically normal black woman, 65% of the hemolysate was HbI. Her α-globin gene haplotype revealed a normal α-globin gene locus and an α-globin gene locus with the common $-\alpha^{3.7}$ deletion. Genetic studies showed she transmitted to a daughter who had only HbA, the $\alpha^{-3.7}$ deletion, suggesting that HbI was encoded on the normal α-globin gene locus. When mRNAs from the *HBA1* and *HBA2* were selectively isolated and translated in vitro, both encoded a glutaminyl residue at position 16, whereas the *HBA1* mRNA also encoded normal mRNA, the product of the chromosome with the $\alpha^{3.7}$ deletion. These observations suggested a gene conversion event between the highly homologous α-globin genes. Two of the

* Variants with the sickle cell mutation and another amino acid substitution are discussed in Chapter 23. Details and references at http://globin.cse.psu.edu.

three α-globin genes present in the proband produced HbI, accounting for the very high concentration of the variant.

A report of HbI associated with "sickled" cells contains many unknowns, including the structure of the abnormal globin and whether there is some sort of hemoglobin polymer in the cell. Some features of HbI appear to resemble those of Hb Setif.

Five stable α-globin variants formed by mutations of codon 6, Hb Sarawa (asp6ala), Hb Dunn (asp6asn), Hb Ferndown (asp6val), Hb Woodville (asp6tyr), and Hb Swan River (asp6gly) are all present at a concentration of 10%. Four stable to mildly unstable α-globin variants at codon 27 mutations, Hb Fort Worth (glu27gly), Hb Spanish Town (glu27val), Hb Shuanfeng (glu27lys), and Hb Hekinan (glu27asp) are present at concentrations of 4%–14%. In no case has it been established whether the mutant is on *HBA2* or *HBA1* or whether the α-globin gene loci are duplicated. Other than Hb Dunn, whose asparaginyl residue might be deamidated, it is not clear why these variants with uncommonly low blood levels are clustered at these sites.

Two Point Mutations in a Globin Chain

Examples of two point mutations in a single β-globin chain, where one mutation codes for HbS, are discussed in Chapter 23. β-Globin gene variants with two amino acid substitutions in *cis* are shown in Table 24.8. There are two putative origins for these double-substitution variants: recombination between homologous chromosomes each containing a different mutation and a new mutation in a gene already containing one mutation. When both mutations are common in a population, like HbC and HbN-Baltimore that in *cis* characterize Hb Arlington Park, or HbE and HbD-Los Angeles that are found in HbT-Cambodia, then the doubly substituted variant most likely arose by recombination. De novo mutation could explain instances where a rare variant is present along with a polymorphic one, such as HbC or HbE. Occasionally, both mutations are rare.

Hb Medicine Lake (β98 val→met; β32 leu→gln) has the phenotype of severe β thalassemia because the β-globin chain, containing both the Hb Köln and the β32 mutation, is likely to be highly unstable and rapidly catabolized (Chapter 13). Lacking a detectable protein, it was not possible to explore directly the properties of the abnormal hemoglobin containing the β32 CTG→CAG mutation. It was predicted that because the leu→gln mutation does not alter the charge of the β subunit, the electrophoretic mobility of Hb Medicine Lake might not differ from Hb Köln. A hydrophilic glutamine residue contains an uncharged polar side chain that could distort the B helix. Also, perturbation of the adjacent β31 leucine that contacts the heme group could result in instability. A definitive assessment of the inheritance of Hb Medicine Lake was not possible, but the most plausible cause of this abnormal hemoglobin was a new mutation in the germ cell of the father or in the proband.

Seven variants of *HBG1* contain the ile75thr polymorphism (HbF-Sardinia, Chapter 6) and an additional mutation. Curiously, no α-globin chain or *HBG2* variants with two point mutations have been described.

Table 24.9. βδ and γβ fusion chains

Variant	Crossover	Features
Miyada	β through 12 δ from 12	17% in heterozygotes; normal hematology
P-Congo	β through 22 δ from 116	Normal hematology
P-Nilotic*	β through 22 δ from 50	Normal hematology
P-India	β through 87 δ from 116	23% in heterozygotes
Kenya	$^{A}\gamma$ through 81 β from 86	6% in heterozygotes; 5% HbF ($100\%^{G}\gamma$); normal hematology
Hong Kong	within 54 bp of CAP site and exon 1	Protein is identical to δ globin. β-globin like in 5′ untranslated portion. HbA^{2} 16–20%[56]
Parchman	δ through 12 β from 22–50 δ from 86	1.6%; stable; found in a patient with α thalassemia

* Hb Lincoln Park is identical to HbP-Nilotic but is associated with reticulocytosis. It contains a deletion of δ137 valine and was hypothesized to result from multiple crossing over events.

References to variant described before 2000 can be found in http://globin.cse.psu.edu.

Nonthalassemic Fusion Globins

Anti-Lepore βδ fusion globins and Hb Kenya, a γβ fusion globin, are not usually associated with hematological abnormalities because a normal β-globin gene is present on the chromosome along with the hybrid gene. These variants are shown in Table 24.9.

NOVEL COMPOUND HETEROZYGOUS CONDITIONS

With the widespread use of hemoglobin screening and increasingly sensitive methods of hemoglobin separation, many interesting but rare compound heterozygous conditions have been described. Although most of these have no hematological abnormalities they could, if not correctly diagnosed, lead to misinformed genetic counseling. As expected, most of these compound heterozygotes include HbS, HbC, and HbE but other interesting combinations have been reported.

RECOMBINANT HEMOGLOBINS

Recombinant hemoglobins can be produced in bacterial and yeast expression systems and in transgenic animals. Hundreds of variants have been engineered and used to study hemoglobin structure, function,[46] HbS polymerization, and its inhibition[47] and for potential therapeutic purposes.[32] As hemoglobin-based blood substitutes, recombinant hemoglobins could provide a shelf-storable oxygen carrying solution for use in surgery, trauma, and other emergencies without the need for blood typing and cross matching. Free hemoglobins have been difficult to develop as blood substitutes. They must not scavenge NO and form methemoglobin (Chapters 10 and 11), they should overcome the very high oxygen affinity of free hemoglobin, they should not readily dissociate into dimers, and they should be retained in the vasculature.[48] None of these conditions have been sufficiently realized to the point of producing a product for late phase clinical trials.

A recombinant human β-globin variant with gly16asp, glu22ala, and thr87gln was designed as an antisickling protein. The gly16asp substitution increased affinity for α-globin, whereas the other mutations inhibited deoxyHbS polymerization. This variant binds oxygen cooperatively and has an oxygen affinity that is comparable with HbF. Delay time experiments showed that it is a potent inhibitor of HbS polymerization. When knockout transgenic mice that expressed only this variant were bred with knockout transgenic sickle mice, hematological abnormalities and organ pathology were abolished, suggesting the value of a variant like this in diminishing the pathology of sickle cell disease.[49]

Dyshemoglobinemias

Neeraj Agarwal, Ronald L. Nagel, and Josef T. Prchal

Hemoglobin can bind gases other than oxygen (O_2). These include carbon monoxide (CO) and nitric oxide (NO). Carboxyhemoglobin (COHb) precludes normal O_2 transport and is toxic. Nitrosohemoglobin has critical physiological functions discussed in Chapter 10. Normal hemoglobin can be oxidized to methemoglobin and sulfhemoglobin by exogenous agents and these hemoglobin forms can also be found as a result of germline mutations. In aggregate, these modified hemoglobins, referred as dyshemoglobinemias, are the basis of a group of acquired and genetic disorders that are rare but can have serious clinical implications.

METHEMOGLOBINEMIA

Methemoglobin is formed when the iron of the heme group is oxidized or converted from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. The ferric hemes of methemoglobin are unable to reversibly bind O_2. In addition, the presence of ferric heme increases the O_2 affinity of the accompanying ferrous hemes in the hemoglobin tetramer.[1] This leads to a left shift in the hemoglobin–O_2 dissociation curve, which impairs tissue delivery of O_2. Normally, methemoglobin is generated and then reduced physiologically to maintain a very low steady-state blood methemoglobin level of 1% or less of the total hemoglobin. The half-life of methemoglobin is approximately 1 hour if the reductase mechanism is normal.[2] Methemoglobinemia occurs when there is imbalance between methemoglobin production and methemoglobin reduction. Methemoglobinemia can have both inherited and acquired causes; hemoglobin oxidation has been recently reviewed.[3]

Pathophysiology of Methemoglobinemia

Production of Methemoglobin. O_2 binds the ferrous form of iron present in hemoglobin to form oxyhemoglobin. During this process, one electron is partially transferred from iron to the bound O_2, forming a ferric–superoxide (Fe^{+3}-O_2) anion complex.[4] At the time of tissue delivery of O_2, some leaves as a superoxide (O_2^-) radical. The partially transferred electron is not returned to the iron moiety, thus leaving the iron in the ferric state and forming methemoglobin (Fig. 25.1). This physiological autooxidation of hemoglobin occurs spontaneously at a slow rate, creating 0.5%–3% methemoglobin per day.[5] Oxidation of heme iron can occur by other nonphysiological means. These include 1) reactions with free radicals and endogenous compounds, including hydrogen peroxide (H_2O_2), NO, O_2- and hydroxyl radical ($OH^•$);[6,7] and 2) oxidation by exogenous compounds or their metabolic derivatives.

Antioxidant protein 2, the product of the *PRDX6* gene, is present in high concentrations in red cells and prevents methemoglobin formation. This member of the peroxiredoxin protein family binds to hemoglobin and prevents spontaneous and oxidant-induced methemoglobin formation. Mutations of this gene or its acquired deficiency are potential candidates responsible for congenital and acquired methemoglobinemia; however, to our knowledge, this has not been yet described.[8]

Reduction of Methemoglobin. The ferric form of methemoglobin can be reduced to the ferrous form via the following metabolic pathways.

1) Cytochrome b5 reductase (*CYB5R3*) pathway: Cytochrome b5 reductase (previously termed diaphorase and NADH methemoglobin reductase) is the only physiologically meaningful way of reduction of methemoglobin. Cytochrome b5 reductase, a housekeeping enzyme and a member of the flavoenzyme family of dehydrogenases–electron transferases, is involved in the transfer of electrons from reduced nicotine adenine dinucleotide (NADH) generated by glyceraldehyde-3-phosphate reduction in the glycolytic pathway to cytochrome b5.[9,10] In red cells, NAD is reduced to NADH during glycolysis. Flavine adenine dinucleotide (FAD) is a noncovalently bound prosthetic group in the cytochrome b5 reductase, which acts as an acceptor and donor of electrons. NADH donates an electron and reduces FAD to FADH.[11–13] In turn, FADH reduces the heme protein of the cytochrome b5, which donates an electron to reduce methemoglobin to ferrous hemoglobin (Fig. 25.2).

Besides reducing methemoglobin to hemoglobin by donating an electron, cytochrome b5 also serves as an electron donor in cells with mitochondria. In these cells, a reaction catalyzed by stearyl–coenzyme A (CoA) desaturase transfers electrons from cytochrome b5 to stearyl-CoA in the outer mitochondrial membrane and endoplasmic reticulum.[14] These reactions play an important role in fatty acid desaturation and drug metabolism.

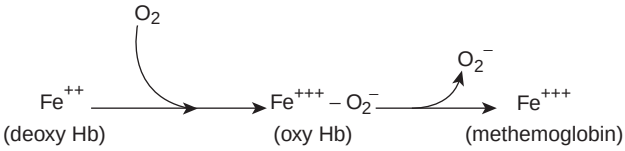

Figure 25.1. Generation of methemoglobin from hemoglobin: O_2 binds easily to the ferrous form of iron present in hemoglobin (Hb Fe^{2+}) to form oxyhemoglobin. During this process, one electron is partially transferred from iron to the bound O_2, forming a ferric–superoxide (Fe^{3+}–O_2) anion complex. At the time of tissue delivery of O_2, some of the O_2 leaves as a superoxide (O_2^-) radical. The partially transferred electron is not returned to the iron moiety, thus leaving the iron in the ferric state and forming methemoglobin (Hb Fe^{3+}).

2) NADPH-methemoglobin reductase pathway: Normally NADPH, an essential coenzyme for this reductase (an electron donor), is generated by glucose-6-phosphate dehydrogenase (G6PD) in the hexose monophosphate (pentose phosphate) shunt. There is no electron carrier in red blood cells to accept an electron directly from NADPH-methemoglobin reductase. This is possible, however, in the presence of the pharmacologically provided electron acceptors such as methylene blue or riboflavin that can link electron transfer from NADPH coenzyme of this reductase to methemoglobin.[15–18] Because these electron acceptors are not physiological, NADPH-methemoglobin reductase does not play a role in vivo in the reduction of methemoglobin. Nonetheless, this is a very important pathway during treatment of toxic methemoglobinemia when the physiological pathway is overwhelmed (Fig. 25.3).

Hereditary Methemoglobinemia

In 1845, Francois[19] reported the first case of congenital methemoglobinemia in a patient with chronic congenital cyanosis without obvious cardiac or pulmonary disease. A familial incidence of "autotoxic cyanosis" and methemoglobinemia was later described by Hitzenberger[20] and accounts of the early work on this disorder have been published.[21–23]

There are three types of hereditary methemoglobinemia. Two, cytochrome b5 reductase deficiency and cytochrome b5 deficiency, are inherited as autosomal recessive traits. The third type, inherited as an autosomal dominant disorder, is caused by globin gene mutations (HbsM), is discussed in Chapter 24. Due to the rarity of hereditary methemoglobinemia, it is not clear which of these forms is most common. Nevertheless, even discounting endemic Navajo, Athabascan, and Yakutsk congenital methemoglobinemia due to cytochrome b5 reductase deficiency, the published reports of congenital methemoglobinemia due to cytochrome b5 reductase deficiency far exceed cases of HbM. Furthermore, in our experience in a referral laboratory, more than 20 subjects with unrelated hereditary methemoglobinemia were due to cytochrome b5 reductase deficiency compared with only one case of HbM. Only a single, well documented family with methemoglobinemia (and other systemic defects) due to cytochrome b5 deficiency has been reported.

Cytochrome b5 Reductase Deficiency. The gene for cytochrome b5 reductase (*CYB5R3*) is on chromosome 22 and is 31 kb in length, containing nine exons and eight introns.[24,25] There are more than 40[3,26–28] mutations described that result in either type I or type II cytochrome b5 reductase deficiency. Although most of the mutants have been found in Caucasians, five unique mutations were found in Chinese,[29] at least three in Thai,[30,31] two in African Americans,[32] and one in an Asian Indian.[33] The cytochrome b5 reductase mutations that cause endemic methemoglobinemia in Yakutsk, Navajo, and Athabascans have not been defined, due in part to the reluctance of tribal authorities to consent to studies. An additional mutation of cytochrome b5 reductase (T116S) is not a disease-causing mutation but a high-frequency African-specific polymorphism that does not cause any appreciable disruption of the cytochrome b5 reductase secondary structure.[34]

The cytochrome b5 reductase gene has several potential transcripts generating multiple isoforms. Differences at the 5′ end of rat liver and reticulocyte cDNAs indicate the use of alternative promoters for the production of all forms of cytochrome b5 reductase.[35] Two putative promoters with different characteristics have been well described. A constitutive promoter region has similarities with housekeeping genes as it does not contain a TATA box or CAAT box but instead contains five GC box sequences (GGGCGG and CCGCCC), representing potential binding sites for the transcription factor Sp1.[25] The erythroid-specific promoter region contains several possible regulatory elements found in erythroid promoter regions, including a TATA box, CAAT-like sequences, two binding sites for the erythroid-specific transcription factor GATA-1, and a GT box.[36] Two additional promoter regions have been identified but not yet fully characterized.[37]

Multiple isoforms of cytochrome b5 reductase are generated from a single gene by a combination of alternative promoters and alternative initiation of translation.[36–38] One isoform, found in nonerythroid cells and reticulocytes but not in mature erythrocytes, is a membrane-associated isoform located on the endoplasmic reticulum membrane and the outer mitochondrial membrane.[39,40] This

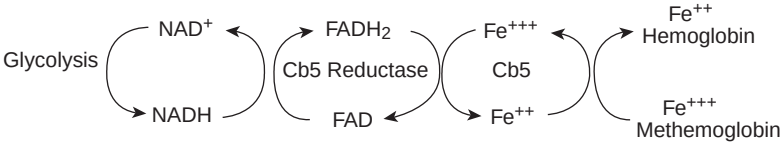

Figure 25.2. Physiological reduction of methemoglobin to hemoglobin: NADH is generated from glycolysis and reduces FAD to $FADH_2$. $FADH_2$ reduces ferric (Fe^{3+} to ferrous (Fe^{2+}) form in the cytochrome b5, which in turn reduces methemoglobin (Fe^{3+}) to hemoglobin (Fe^{2+}).

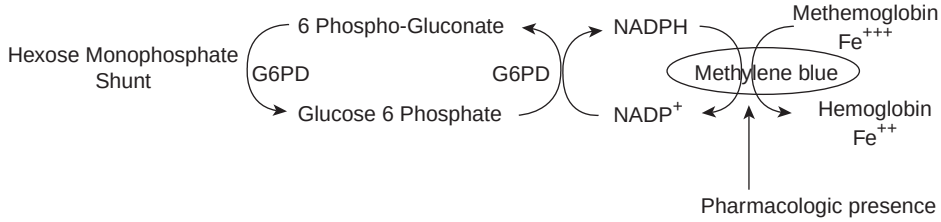

Figure 25.3. Reduction of methemoglobin by methylene blue: NADPH is generated by glucose-6-phosphate dehydrogenase (G6PD) in the hexose monophosphate shunt (pentose phosphate pathway). NADPH, in the presence of pharmacologically supplied electron acceptor such as methylene blue, reduces methemoglobin (Fe^{3+}) to hemoglobin (Fe^{2+}).

membrane-bound isoform consists of a 275–amino acid hydrophilic moiety that contains the active site and a hydrophobic domain at the N-terminal end that anchors the protein to the membrane.[41–43] Two other isoforms are found only in erythroid cells.

The isoform involved in methemoglobin reduction in erythroid cells is soluble and consists of the same 275 hydrophilic amino acids found in the ubiquitously expressed membrane-associated isoform.[18,44] The other erythroid-specific isoform is membrane-associated with an N-terminal hydrophobic sequence that differs from the sequence found in the ubiquitously expressed isoform.[36] Although it contributes only 20%–25% of erythrocyte cytochrome b5 reductase activity in adult humans, it represents a greater proportion in infants.[45]

In type I cytochrome b5 reductase deficiency (see later) only erythrocytes have decreased enzyme activity. This enzyme is heat labile and presumably is unstable and easily degraded. Thus, although cytochrome b5 reductase is abnormal in all cells in type I deficiency, only mature red cells, which cannot synthesize proteins and replace the enzyme, are significantly affected. Because cytochrome b5 reductase is coded by a single gene, it is hypothesized that type I cytochrome b5 reductase deficiency results from mutations producing an unstable enzyme, whereas mutations in type II deficiency (see later) either affect the catalytic function or cause underproduction of the enzyme, resulting in a generalized decrease in functional cytochrome b5 reductase activity.[46]

Type I Cytochrome b5 Reductase Deficiency. Most cases of enzymopenic congenital methemoglobinemia are type I, in which the functional deficiency of cytochrome b5 reductase is limited to erythrocytes. Homozygotes or compound heterozygotes[47,48] have methemoglobin concentrations of 10%–35% and appear cyanotic. Homozygotes, because of the chronic nature of their methemoglobinemia, are usually physiologically adapted to their disease state and are asymptomatic even with methemoglobin levels up to 40%.[49] Headache and easy fatigability are occasionally reported symptoms. Life expectancy is normal and pregnancy is unaffected. Significant compensatory erythrocytosis (polycythemia) is rarely observed. The cyanosis is of cosmetic significance only and can be treated with methylene blue or ascorbic acid, both of which facilitate the reduction of methemoglobin through alternate pathways.[50]

In contrast to the asymptomatic, chronically methemoglobinemic homozygotes (or compound heterozygotes) for type I cytochrome b5 reductase deficiency, heterozygous individuals are at risk for developing acute, symptomatic methemoglobinemia after exposure to exogenous methemoglobin-generating agents. Cohen and colleagues[51] report of acute toxic methemoglobinemia in US military personnel receiving malarial prophylaxis in Vietnam is a classic description of this phenomenon.

This form of cytochrome b5 reductase deficiency is distributed worldwide but is endemic in the Athabascan Alaskans,[52,53] Navajo Indians,[54] and Yakutsk natives of Siberia.[55,56] The Navajo Indians and the Athabascan Indians of Alaska are known to share a common ancestor; thus, the high frequency of cytochrome b5R deficiency suggests a common origin for all three of these populations. It remains to be determined if the molecular defect resulting in cytochrome b5R deficiency is identical in these populations. In other ethnic and racial groups the defect occurs sporadically. Although cyanosis is difficult to detect due to skin pigmentation, type I deficiency has been reported in two unrelated African American families.[57]

Point mutations in patients with type I cytochrome b5R deficiency all have been missense mutations, resulting in an amino acid substitution. Most of these mutations are found in the 5′ end of the cytochrome b5 reductase gene.[58,59] A one mutation, a G to A transition in exon 8 (E212K) in an African American family, occurs in the 3′ end.[32] As discussed, the T116S polymorphism in exon 5 in African Americans with type I cytochrome b5 reductase deficiency[34] is unlikely to be the disease-causing mutation as the amino acid substitution causes no readily appreciable disruption of the enzyme secondary structure and is not associated with methemoglobinemia. Rather, it is one of the most common African-specific polymorphisms known.

Type II Cytochrome b5 Reductase Deficiency. Unlike type I mutations that are confined to the red cell, type II mutations are associated with cytochrome b5 reductase deficiency of all cells. Type II cytochrome b5 reductase deficiency represents 10%–15% of cases of enzymopenic congenital methemoglobinemia and has a sporadic

distribution. In addition to methemoglobinemia and cyanosis, the affected infants have mental retardation and developmental delay with failure to thrive and typically die during the first year of life.[60] Other associated neurological features include microcephaly, opisthotonus, athetoid movements, strabismus, seizures, and spastic quadriparesis. The mechanism resulting in the neurological problems is currently unknown but might be due to abnormal lipid elongation and desaturation in the central nervous system[61] or perhaps due to impairment of ferric-iron reduction of other cellular globins.[57] Type II mutations have been reported in both the 5′ and 3′ ends of the cytochrome b5 reductase gene[62–68] and are heterogeneous, including deletions, point mutations, splicing site mutations, and premature stop codons.

Cytochrome b5 Deficiency. Deficiency of cytochrome b5 is an extremely rare disorder that causes congenital methemoglobinemia. Only one well-documented case of cytochrome b5 deficiency has been described, compared with more than 500 reported cases of cytochrome b5 reductase deficiency,[69] and the large number of uncounted subjects affected in the endemic areas. This patient, a product of an Israeli consanguineous marriage, was also a male pseudohermaphrodite. Further analysis revealed that he was homozygous for a splicing mutation in the cytochrome b5 gene, resulting in a premature stop codon and a truncated protein molecule.[70] Another family with probable cytochrome b5 deficiency was described prior to the recognition of this entity;[71] however, the inheritance pattern in this family was autosomal dominant.

Acquired Methemoglobinemia

Most cases of methemoglobinemia are acquired, resulting from increased methemoglobin formation due to exposure to exogenous agents (Table 25.1).[72–75] Medication overdose or chemical ingestion causes methemoglobinemia by increasing the production of methemoglobin. Perhaps even more often, standard doses of medication cause methemoglobinemia in either normal individuals or those with partial deficiencies of cytochrome b5 reductase.[51,76] Use of multiple drugs together has also been implicated in the development of methemoglobinemia.[77] In one study of 138 cases of acquired methemoglobinemia, use of dapsone accounted for 42% of all affected patients, with a mean level of methemoglobin of 7.6% (range 2%–34%).[78] Xylocaine and related compounds appear to be the most common cause of drug-induced acquired methemoglobinemia; the most severe cases were seen after the use of 20% benzocaine spray for topical anesthesia (mean peak methemoglobin level 44%, range 19%–60%). Benzocaine is used during commonly performed endoscopic procedures such as bronchoscopy and endoscopy.[79] The estimated incidence in a population undergoing transesophageal echocardiography was 0.115%.[80] The molecular mechanism underlying this association has not been elucidated, as previous or subsequent exposure might not be associated with methemoglobinemia. The true incidence of drug-induced methemoglobinemia due to less frequently used agents is not known. Furthermore, it is unknown whether the development of methemoglobinemia is dose related or idiosyncratic. During surgery, methemoglobinemia should be suspected in the presence of clinical "cyanosis," a normal paO_2 and/or the presence of "chocolate brown blood."

Table 25.1. Drugs and agents that might cause methemoglobinemia

Anesthetics (local): benzocaine, lidocaine, procaine, prilocaine
Antimalarials: chloroquine, primaquine, quinacrine
Aniline dyes
Chlorates
Dapsone
Diarylsulfonylureas
Doxorubicin
Metoclopramide
Nitric and nitrous oxide
Nitrates and nitrites (amynitrate, isobutyl nitrite, nitroglycerine, sodium and silver nitrate)
Nitrobenzenes (shoe and floor polish and in paint solvents)
Nitroethane (nail polish remover, propellent, fuel additive)
Nitrofurantoin (furadantin)
Pyridium (phenazopyridine)
Phenacetin (acetaminophen)
Phenylhydrazine
Rasburicase
Sulfonamides (sulfacetamide, sulfamethoxazole, sulfanilamide, sulfapyridine)

Infants, especially those born premature, are particularly susceptible to development of methemoglobinemia because their erythrocytes contain only 50%–60% of adult cytochrome b5 reductase activity.[81–83] Although cytochrome b5 reductase levels rise to those of an adult within months of birth, young infants are unusually vulnerable to developing toxic methemoglobinemia following exposure to a number of otherwise relatively harmless medications, local ointments, and dyes used on diapers. This problem can be especially severe upon ingestion of nitrates. Nitrates do not oxidize hemoglobin directly; intestinal bacteria convert the nitrates to nitrites, which then oxidize hemoglobin to methemoglobin. In the United States, formula and food prepared from well water contaminated with nitrates have been implicated in development of methemoglobinemia in infants and children.[84–86] The nitrate nitrogen concentration of water should be less than 10 ppm to avoid methemoglobinemia. Methemoglobinemia does not occur in breast-fed infants of mothers who ingest nitrate-contaminated water because nitrates do not concentrate in breast milk. Methemoglobinemia has also been associated with diarrheal illnesses in infants without known exposure to toxins.[87,88] The exact mechanism leading to methemoglobinemia is unknown but could be

due to metabolic acidosis induced by diarrhea, increased endogenous nitrite production, milk intolerance, or unique bacterial pathogens producing nitrites.[89] Other predisposing factors associated with development of methemoglobinemia in infants with diarrhea are low admission weight percentiles, failure to thrive, and diarrhea lasting for more than 7 days.[90,91] Administration of over-the-counter local anesthetic for teething has also been reported to cause methemoglobinemia in infants.[92]

Systemic infection can predispose to methemoglobinemia. NO is a free radical that is synthesized from L-arginine by NO synthases (Chapter 10). During bacteremia and sepsis, proinflammatory cytokines and bacterial lipopolysaccharide stimulate the production of inducible nitric oxide synthase (*NOS2*) from a variety of cell types including endothelial cells.[93–95] Increase in circulating NO leads to increased production of methemoglobin.[96,97] Symptomatic methemoglobinemia can also occur as a result of concomitant use of drugs predisposing to methemoglobinemia during infection and inflammation. Methemoglobinemia has been described in a burn patient with necrotizing fasciitis after prolonged application of topical 0.5% silver nitrate solution.[98] Methemoglobin production is enhanced by reactions with free radicals and endogenous compounds including H_2O_2. Reduced glutathione (GSH) in red cells helps in decreasing the level of methemoglobin by eliminating free radicals and H_2O_2. Intercellular parasites such as *Plasmodium* sp. are associated with reduced levels of erythrocyte GSH. A progressive decrease in GSH level has been shown to occur with increasing parasitemia.[99] Oxidative stress caused by medications used to treat malaria such as primaquine can also contribute to development of methemoglobinemia. Prophylaxis with primaquine alone, in absence of malarial infection, has been shown to cause mild asymptomatic methemoglobinemia.[100]

Clinical Features of Methemoglobinemia

Most individuals with congenital, chronically elevated methemoglobin concentrations are generally asymptomatic even with methemoglobin levels up to 40% of total hemoglobin.[49] Headache and easy fatigability are occasionally reported. The main clinical feature is "cyanosis" or a slate-blue color of the skin and mucous membranes, a finding that is due to the different absorbance spectrum of methemoglobin compared with oxyhemoglobin and is of only cosmetic importance. Significant polycythemia (erythrocytosis) is rarely observed.[51] Life expectancy is not shortened and pregnancies occur normally. Although cyanosis associated with cytochrome b5 reductase deficiency is readily corrected with methylene blue, this therapy is not effective for methemoglobinemia due to HbM disease.

In comparison to the general lack of symptoms in patients with chronic methemoglobinemia, patients with acute acquired methemoglobinemia are symptomatic due to acutely impaired O_2 delivery to tissues that does not allow sufficient time for physiological compensation to occur. Early symptoms include headache, fatigue, dyspnea, and lethargy. At higher levels, respiratory depression, altered consciousness, shock, seizures, and death can occur.[73] Most individuals presenting with acute acquired methemoglobinemia are not heterozygous for cytochrome b5 reductase deficiency.[101]

Cyanosis is clinically detected when the absolute concentration of methemoglobin exceeds 1.5 g/dL, which is equivalent to 8%–12% methemoglobin at normal hemoglobin concentrations.[49] In contrast, the more common cause of cyanosis, due to decreased hemoglobin O_2 saturation, is observed when the absolute level of deoxygenated hemoglobin exceeds 4–5 g/dL, as in severe respiratory failure or cardiac abnormalities due to right-to-left shunts. This form of cyanosis cannot be clinically differentiated from that due to methemoglobinemia, and laboratory analysis is required for its distinction from methemoglobinemia and sulfhemoglobinemia (see later).

The general lack of symptoms other than cyanosis, and the normal life expectancy in patients with cytochrome b5 reductase deficiency applies only to the more common type I disease in which the enzymatic deficiency is limited to the red cells. All cells are affected in patients with type II disease who exhibit neurological and developmental abnormalities.[60]

Diagnosis of Methemoglobinemia

Methemoglobinemia can be clinically suspected by the presence of clinical "cyanosis" in the face of normal paO_2. Unlike deoxyhemoglobin, the dark color of the blood in methemoglobinemia does not change with the addition of O_2. Historically pulse oximetry has been considered inaccurate in monitoring O_2 saturation in the presence of methemoglobinemia; however, the presence of methemoglobin can be suspected when the O_2 saturation as measured by pulse oximetry is significantly less than the O_2 saturation calculated from arterial blood gas analysis ("saturation gap").[78,102]

The laboratory diagnosis of methemoglobinemia is based on analysis of its absorption spectra, which have peak absorbance at 631 nm. A fresh specimen should always be obtained, as methemoglobin levels tends to increase with storage. The standard method of assaying methemoglobin utilizes a microprocessor-controlled, fixed-wavelength cooximeter. This instrument interprets all readings in the 630-nm range as methemoglobin so that false positives can occur in the presence of other pigments including sulfhemoglobin and methylene blue.[103,104] Hence, methemoglobin detected by the cooximeter should be confirmed by the specific Evelyn–Malloy method.[105] This assay involves the addition of cyanide, which binds to the positively charged methemoglobin, eliminating the peak at 630–635 nm in direct proportion to the methemoglobin

concentration. Subsequent addition of ferricyanide converts the entire specimen to cyanomethemoglobin for measurement of the total hemoglobin concentration. Methemoglobin is then expressed as a percentage of the total concentration of hemoglobin.

Recently, a new eight-wavelength pulse oximeter, Masimo Rad-57 (the Rainbow-SET Rad-57 Pulse CO-Oximeter, Masimo Inc, Irvine, CA), has been reported to be accurate in measuring carboxyhemoglobin and methemoglobin. The Rad-57 uses eight wavelengths of light instead of the usual two and is thereby able to measure more than two species of human hemoglobin.[106] It is approved by the US Food and Drug Administration for the measurement of both carboxyhemoglobin and methemoglobin. In addition to the usual SpO_2 value, the Rad-57 displays SpCO and SpMet, which are the pulse oximeter's estimates of carboxyhemoglobin and methemoglobin percentage levels, respectively. In a study on healthy human volunteers in whom controlled levels of methemoglobin and carboxyhemoglobin were induced, the Rad-57 measured carboxyhemoglobin with an uncertainty of $\pm$ 2% within the range of 0%–15% and measured methemoglobin with an uncertainty of 0.5% within the range of 0%–12%.[106]

Distinguishing the hereditary forms of congenital methemoglobinemia requires interpretation of family pedigrees followed by biochemical analyses. Cyanosis in successive generations suggests the presence of HbM disease, whereas normal parents but possibly affected siblings imply the presence of the autosomal recessive cytochrome b5 reductase deficiency or, rarely, cytochrome b5 deficiency.

Incubation of blood with methylene blue distinguishes cytochrome b5 reductase deficiency from HbM disease as this results in the rapid reduction of methemoglobin through the NADPH–flavin reductase pathway in cytochrome b5 reductase deficiency.[107–109]

Measurement of the level of cytochrome b5 reductase activity, or cytochrome b5 if cytochrome b5 reductase activity is normal, is required to distinguish cytochrome b5 reductase deficiency from cytochrome b5 deficiency; however, the assay for cytochrome b5 is not commercially available.

Assays of Enzyme Activity. Types I and II cytochrome b5 reductase deficiency are distinguished by clinical phenotype and analysis of enzymatic activity in erythroid and nonerythroid cells. Reports of decreased cytochrome b5 reductase activity are difficult to compare because several different assays of cytochrome b5 reductase activity, varying in their substrate and in their normal values, have been used.[6,47,57,65,66,110,111] These assays also vary in their technical difficulty. The first widely accepted cytochrome b5 reductase activity assay used a difficult to produce and standardize methemoglobin–ferrocyanide complex and its reduction by an enzyme containing tissue homogenate.[110] The most rigorous cytochrome b5 reductase enzyme activity is based on partial purification of the enzyme by ultracentrifugation and uses the physiological enzyme substrate (cytochrome b5 prepared by a recombinant DNA technology)[42]; this assay is not readily available and is too complex for nonspecialized research laboratories. The most convenient assay uses readily available ferricyanide[111] and easily differentiates type I and type II cytochrome b5 reductase deficiency because patients with type I deficiency have normal enzyme activity in platelets, fibroblasts, Epstein–Barr virus–transformed lymphocytes, and granulocytes whereas, in type II deficiency, the activity in nonerythroid tissues is markedly to moderately decreased.[32,57,64,111] Because the enzyme defect is also found in fibroblasts and amniotic cells, analysis of cytochrome b5 reductase activity in cultured amniotic cells for the purpose of prenatal diagnosis of type II disease is possible.[112,113]

Two families with "type III" deficiency have been described in whom cytochrome b5 reductase activity was allegedly decreased not only in erythrocytes but in also in platelets and leukocytes.[114,115] The existence of this entity is difficult to accept because these individuals did not exhibit the neurological abnormalities characteristic of type II deficiency. Reevaluation of one of the patients with a rigorous assay using recombinant cytochrome b5 confirmed sufficient b5 reductase activity in the platelets, leukocytes, and fibroblasts and this analysis was consistent with the presence of type I deficiency.[116]

Treatment of Methemoglobinemia

Treatment of methemoglobinemia depends on the clinical setting. Is the onset acute and due to drugs or other toxic agents or is there congenital life-long methemoglobinemia? All patients with hereditary methemoglobinemia should avoid exposure to aniline derivatives, nitrates, and other agents that could, even in normal individuals, induce methemoglobinemia (Table 25.1). Known heterozygotes for cytochrome b5 reductase deficiency should be similarly counseled.[117] Treatment of HbM disease is neither possible nor necessary.

Hereditary methemoglobinemia. In most cases, congenital methemoglobinemia results in chronic cyanosis, except when acute methemoglobinemia occurs in heterozygotes for cytochrome b5 reductase deficiency, in which case it should be treated like acquired methemoglobinemia. Treatment of the cyanosis in these individuals is indicated for cosmetic reasons only. Options include methylene blue (100–300 mg/day orally) or ascorbic acid (300–1,000 mg/day orally in divided doses). Concerns about kidney stone formation with ascorbic acid therapy remain unproven but high-dose therapy can be associated with the theoretical nephrolithiasis risk. Riboflavin (20–30 mg/day) has also been used with some success,[118] although clinical experience with its use is very limited. Although effective for the cyanosis, neither methylene blue nor ascorbic acid has any effect on the neurological abnormalities in type II

disease. Theoretically, a bone marrow or liver transplant would alleviate these neurological problems if they were due to a problem with circulating fatty acids; however, these approaches have not yet been tested.

Acquired Methemoglobinemia. Offending agents in acquired methemoglobinemia should be discontinued (Table 25.1). This condition can be life-threatening when methemoglobin comprises more than 30% of total hemoglobin. Blood transfusion or exchange transfusion might be helpful in patients who are in shock. In lesser degrees of methemoglobinemia, no therapy other than discontinuation of the offending agent(s) might be required. If the patient is symptomatic, which is often the case in deliberate or accidental overdoses or toxin ingestion, specific therapy is indicated.

Methylene blue is given intravenously in a dose of 1–2 mg/kg over 5 minutes. Methylene blue, as mentioned previously, provides an artificial electron acceptor for the reduction of methemoglobin via the NADPH-dependent reductase pathway (Fig. 25.4). The response is usually rapid; the dose can be repeated in hourly, but this is frequently not necessary. Maximum cumulative dose should not exceed 7 mg/kg as overdose can cause dyspnea and chest pain, as well as hemolysis in some susceptible subjects.[119,120] Because cooximetry detects methylene blue as methemoglobin, this technique cannot be used to follow the response of methemoglobin levels to treatment with methylene blue. If needed, the more specific Evelyn–Malloy method should be used to discriminate between methemoglobin and methylene blue and to follow response to therapy with methylene blue.

Methylene blue should not be administered to patients with G6PD deficiency because the reduction of methemoglobin by methylene blue is dependent on NADPH generated by G6PD (Fig. 25.3). As a result, methylene blue can be ineffective and is potentially dangerous because it has oxidant potential that could further produce hemolysis.[121] To avoid these problems, pretreatment screening of populations with a high incidence of G6PD deficiency (e.g., African Americans, patients of Mediterranean descent, and southeast Asians) is reasonable, although not usually practical. If methylene blue is contraindicated, only moderate doses of ascorbic acid, 300–1,000 mg/day orally in divided doses, should be given, as this drug can also cause oxidant hemolysis in G6PD-deficient patients when given in very high doses. Hyperbaric O_2 and exchange transfusion have been used with success in severe cases.[122]

Marked methemoglobinemia can occur after treatment of dermatitis herpetiformis or *Pneumocystis carinii* infection with dapsone. Cimetidine, used as a selective inhibitor of N-hydroxylation, might be effective in this setting when taken on a regular basis and lowers the methemoglobin level by more than 25%.[117,123] Because it works slowly, cimetidine is not helpful for the management of acute symptomatic methemoglobinemia arising from the use of dapsone.

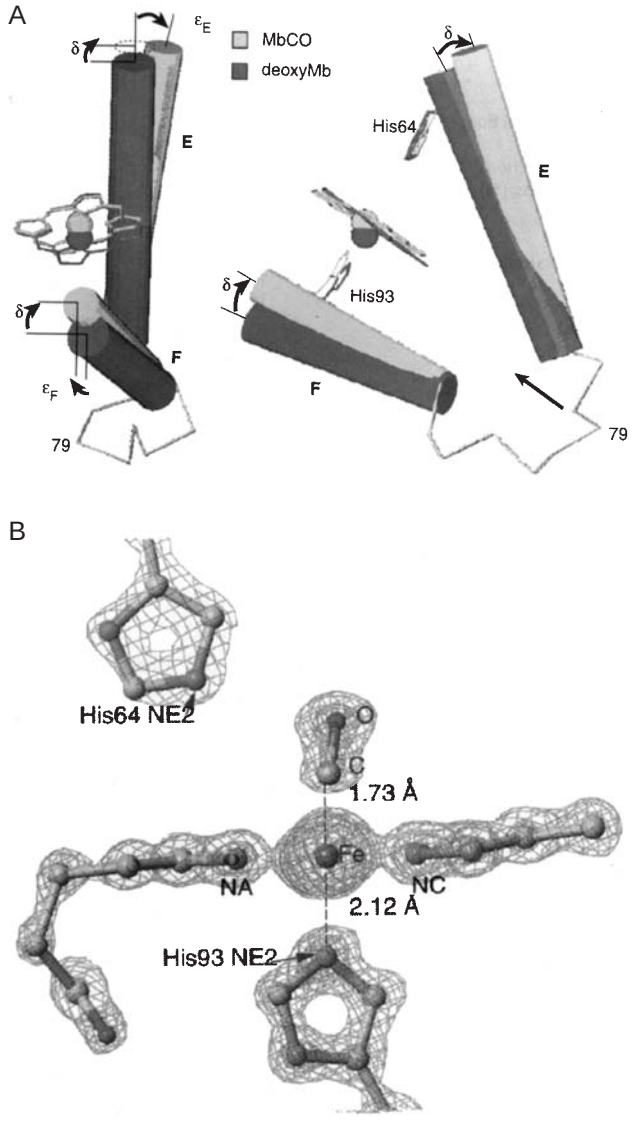

Figure 25.4. CO binding to myoglobin. **(A)** Binding of CO at the heme group. **(B)** CO binding to heme is possible because the E helix (and His 64) moves away, making space for the CO molecule without the need for bending.

CARBON MONOXIDE POISONING: CARBOXYHEMOGLOBINEMIA

CO, a toxic gas, is unusually dangerous because it is odorless, colorless, and tasteless, increasing the probability of serious and life-threatening accidents when high concentrations are unknowingly present in the environment.[124]

Epidemiology

CO intoxication is one of the most common causes of morbidity due to poisoning in the United States. Although deaths from CO poisoning had decreased in the United States, the total burden (fatal and nonfatal) might not have significantly changed in the past two decades.[125] In the United States, CO poisoning results in approximately 40,000

emergency department visits per year.[126,127] Approximately 500 accidental deaths due to CO poisoning are reported to occur annually in the United States and the number of intentional CO-related deaths is 5–10 times higher.[128,129] To examine unintentional, nonfire-related CO exposures, the Centers for Disease Control and Prevention analyzed 2001–2003 data on emergency department visits from the National Electronic Injury Surveillance System All Injury Program and 2001–2002 death certificate data from the National Vital Statistics System.[130] This analysis determined that each year, approximately 15,000 U.S. residents' visit emergency departments for unintentional, non-fire-related CO exposure and approximately 500 die from this exposure. Primary sources of CO were home appliances, and the majority of exposures occurred during the fall and winter months, when persons are more likely to use gas furnaces and heaters. During warmer months, boating activities were another source of exposure. Males were more likely to die from CO poisoning than females, which was consistent with previous findings.[131] Death rate was highest among persons aged older than 65 years. The increased death rate in elderly can be attributed to delayed diagnosis because symptoms often resemble those of associated comorbidities.[132]

The exhaust produced by the typical home-use 5.5-kW generator contains as much CO as that of six idling automobiles.[133] A survey of generator use after the 2004 Florida hurricane season reported that 4.6% of persons using generators had used them inside their home or garage. During this 2004 Florida hurricane season (13 August–25 September 2004), there were 167 persons requiring treatment for CO poisoning in 10 hospitals and six deaths were attributed to CO poisoning.[134]

Although most of the aforementioned causes more often result in acute CO intoxication, cigarette smoking is a common cause of chronic CO intoxication and can increase the COHb level by as much as 15%. By increasing hemoglobin–O_2 affinity, COHb can cause erythrocytosis (polycythemia) in smokers. Houses with defective heating exhaust systems and vehicles that leak CO into the passenger compartment, either because of mechanical failure or driving with the rear hatch-door open, are the second most common cause of chronic CO exposure. Occupations that involve a high risk for CO intoxication include garage work with improper ventilation, toll booth attendants, tunnel workers, firefighters, and workers exposed to paint remover, aerosol propellant, or organic solvents containing dichloromethane.[135]

Pathophysiology of CO Poisoning

CO has low solubility in water and is relatively inert because of its extremely high bond enthalpy. Still, it combines with high affinity with the heme of hemoglobin – and with lesser affinities to myoglobin and cytochromes – at the iron core, a site that it shares with O_2.[136] Its affinity to cytoglobin and neuroglobin has not yet been studied. Binding of CO to hemoglobin is the basis of its toxicity. An excellent summary of CO chemistry is provided by Bunn and Forget.[137]

At equilibrium in physiological conditions, CO affinity for hemoglobin is approximately 240 times greater than that of O_2. This very high equilibrium constant is the result of reaction kinetics. Contrary to popular belief, CO reacts more slowly than O_2 with the heme of hemoglobin. At 20°C and pH 7.0, the "on" rate for CO is 20 mol/L/sec compared with 470 mol/L/sec for O_2. The steric constraints present in the heme pocket make it more difficult for CO to reach the heme group. Indeed, x-ray crystallography and neutron crystal structure showed that the Fe-C-O geometry was not "linear," but "bent," an unfavorable position for CO binding.[138] Once CO is bound to heme, its "off" rate is only 0.015 mol/L/sec in contrast to 35 mol/L/sec for O_2.[136] This extraordinarily slow-release process produces a very high affinity constant of CO for heme and a life-threatening danger for individuals exposed to high levels of CO. An alternative picture has been proposed of the steric mechanisms involved in the inhibition of CO binding to heme proteins.[139] These investigators compared unliganded myoglobin and CO myoglobin at a resolution of 1.15 Å, and found perfect linearity of the Fe-C-O complex, not a "bent" configuration. This geometry was possible because a concerted motion of heme, iron, and helices E and F relieved the steric constraints (Fig. 25.4). Once two molecules of CO are bound to hemoglobin, the molecule switches to the relaxed (R) state, further endangering those exposed to CO, and the two globin chains that remain capable of binding O_2 will be in their high-affinity conformation. This high ligand affinity will make more difficult the delivery of O_2 to the tissues by the remaining O_2 binding sites. As a consequence of this phenomenon, called the Darling–Roughton effect,[1] the hemoglobin O_2 affinity increases in parallel with increasing CO levels.

In the absence of environmental CO, the blood of adults contains approximately 1%–2% COHb. This represents approximately 80% of the total body CO, the remainder probably sequestered in myoglobin and other heme binding proteins. This CO is endogenously produced,[140] originating from the degradation of heme by the rate-limiting heme oxygenase–cytochrome P-450 complex, which produces CO and biliverdin. CO levels in expired air have been used as an index of hemolysis, although the difficulty of standardization and the availability of simpler means of assessing red cell destruction have hampered the widespread use of this technique.[141,142] Further degradation of biliverdin to bilirubin by biliverdin reductase renders a stoichiometry in which one molecule of hemoglobin, by oxidation of the α-methane bridge of the tetrapyrrole ring, generates one molecule of CO and one molecule of biliverdin.

Endogenous CO levels differ among individuals. Caloric restriction, dehydration, infancy, and the genetic variations reported in Japanese and Native Americans generate higher endogenous levels of CO. Hemolytic anemia,

hematomas, and infection tend to increase CO production up to threefold. Fetuses and newborns have double the normal adult levels of COHb, and levels can be much higher with hemolytic disease of the newborn. Not all endogenous CO is the product of normal metabolism. Drugs such as diphenylhydantoin and phenobarbital, by inducing the cytochrome P-450 complex, increase CO production, as does any drug that causes hemolysis. Endogenous CO production might have important physiological consequences.[143] Like its analog, NO, CO can bind to the heme of soluble guanylate cyclase and to the iron/sulfur centers of macrophage enzymes. Guanylate cyclase regulates cyclic guanosine-3′,5′-monophosphate, a second messenger involved in many cellular functions. The exact physiological significance of CO in these reactions remains to be determined.

Exogenous sources of CO include atmospheric CO, which is a product of incomplete combustion and oxidation of hydrocarbons, and natural sources.[144] High-altitude polycythemia (erythrocytosis) and hypoxemia prolong CO excretion that increases COHb levels and further compounds our imperfect adaptation to high altitude associated with decreased tissue O_2 delivery.[145]

Although the normal adult level of COHb is less than 1% or 2%, this low concentration is rarely found in urban centers because of air pollution. Hemolysis can produce COHb levels of more than 2%. Levels more than 3% must have an exogenous origin, except for rare conditions as occur in carriers of abnormal hemoglobins such as Hb Zurich. The affinity of Hb Zurich for CO is approximately 65 times that of normal hemoglobin.[146] The U.S. Environmental Protection Agency considers an acceptable exposure time to be 1 hour to 25 ppm CO or an 8 hours exposure to 9 ppm. This exposure would raise the COHb by 1.5%. Pregnant women and fetuses are particularly at risk,[147] because they already have higher levels of COHb. CO readily crosses the placenta and half life of CO in the fetus is as much as five times longer than it is in the mother. This results in approximately 15% higher fetal COHb level than the maternal COHb level.[148] The O_2 affinity of HbF is shifted to the left[149,150] owing to its lack of 2,3-BPG binding, making the Darling–Roughton effect particularly pernicious, yet another reason why cigarette smoking during pregnancy is hazardous to the fetus.

Clinical Features of CO Poisoning

Acute intoxication with CO rapidly affects the central and peripheral nervous systems and cardiopulmonary functions. Cerebral edema is common, as are alterations of sensory and peripheral nerve function. CO induces increased permeability in the lung resulting in acute pulmonary edema. Cardiac arrhythmias, generalized hypoxemia, and respiratory failure are the common causes of CO-related death; COHb levels more than 40% are found in these cases. In survivors, considerable neurological deficits might remain. Patients with less severe acute cases have the same type of clinical features as patients with chronic intoxication. Myocardial ischemia, lactic acidosis, convulsions, and coma can sometimes occur. An interesting complication observed several days after the exposure to CO are patches of necrotic skin induced by localized hypoxia. Levels of COHb that can elicit any of these symptoms vary widely among patients. Acute CO intoxication in children[151] is responsible for approximately 400 deaths a year, is more severe, and sometimes has unique symptomatology resembling gastroenteritis. Surviving children are more likely to have severe sequelae such as leukoencephalopathy (white cerebral matter destruction), and severe myocardial ischemia.[152]

Chronic intoxication in adults might result in irritability, nausea, lethargy, headaches, and sometimes a flu-like condition. Higher COHb levels produce somnolence, palpitations, cardiomegaly, and hypertension and could contribute to atherosclerosis. Chronic CO poisoning can produce erythrocytosis, the magnitude of which varies with the level of COHb. By increasing red cell production, chronic CO poisoning can mask the mild anemia of acquired or congenital hemolytic disorders.

Diagnosis and Treatment of CO Poisoning

CO poisoning is a clinical diagnosis that is confirmed by laboratory testing. Signs and symptoms consistent with CO poisoning in certain circumstances should raise the suspicion of its presence. A higher index of suspicion should attend the simultaneous presentation of multiple patients from the same family or housing complex. The eight-wavelength pulse oximeter (Masimo Rad-57) has been reported to be accurate in measuring CO.[106] Because CO has a relatively short half-life in vivo, the levels obtained in the emergency setting often do not correlate directly with symptoms.

The most important step in the treatment for CO poisoning is prompt removal of patients from the source of CO followed by administering 100% supplemental O_2 via a tight-fitting mask. The CO molecule reversibly binds to hemoglobin and is eliminated through the lungs. The serum elimination half-life of CO is 5 hours when breathing room air and 30 minutes with O_2 therapy (100% O_2 at 3 atm).[148]

For mild to moderate cases of CO poisoning, which more often happens with chronic intoxication, removing the patient from the source of environmental CO is usually curative. If the COHb level is high, breathing 100% O_2 will increase the rate of CO removal.

In severe cases of CO poisoning, which more often occur with acute intoxication, after identification and removal of the source of CO, 100% O_2 should be administered with cardiac monitoring. Endotracheal intubation should be done in any patient with impaired mental status and other interventions should be dictated by the symptomatology.

Hyperbaric O_2, which has complications of its own such as bronchial irritation and pulmonary edema, should be reserved for exceptional cases of CO intoxication. Most often, by the time the patient is brought into a hyperbaric chamber, the simple breathing of 100% O_2 has reduced COHb sufficiently to make it unnecessary. Because of conflicting evidence, there is no absolute indication for the use of hyperbaric O_2 treatment for patients with CO poisoning. Hyperbaric O_2 might be indicated in patients who have obvious neurological abnormalities, have a history of loss of consciousness with their exposure, have cardiac dysfunction, have persistent symptoms despite normobaric O_2, or have metabolic acidosis.[153] Locations of hyperbaric chambers throughout the world and in the United States can be found at the Undersea and Hyperbaric Medical Society web site, www.uhms.org under "chamber directory."

Pregnant women exposed to CO are at particularly high risk. CO poisoning is especially dangerous to the fetus because CO readily crosses the placenta and half-life of CO in the fetus is as much as five times longer than it is in the mother. For these reasons treatment with hyperbaric O_2 should be carried during pregnancy when the COHb levels exceed 15%. In limited number of studies done on pregnant patients, hyperbaric O_2 does not seem to adversely affect the fetus.[154,155]

SULFHEMOGLOBINEMIA

Definition and Pathogenesis

Sulfhemoglobin is a modification of the hemoglobin molecule that produces a bright green color because a sulfur atom is incorporated into the porphyrin ring. It has been associated with the use of certain "oxidant" medications, with drug abuse,[156–161] with occupational exposure to sulfur compounds,[162] and with exposure to polluted air.[163] Heme modification by the addition of sulfur is associated with a drastic right shift in the hemoglobin–O_2 dissociation curve in the physiologically relevant PO_2 range, rendering the molecule totally ineffective for O_2 transport.[164] Fully sulfurated tetramers seem to have no cooperativity. In most cases, only a fraction of the hemes are modified and full saturation of the unaltered hemes in the lungs and enhanced O_2 unloading in tissues would be expected. Because this right shift would ameliorate any decrease in functional hemoglobin mass, sulfuration of hemes might have little physiological significance as long as sufficient proportion of hemoglobin with some unmodified hemoglobin subunits remains.

An understanding of the molecular basis of the right-shifted oxygenation curve emerges from isoelectric focusing data. In a clinical sample that contained only 12% modified heme[165] the distribution of these hemes among partially sulfurated tetramers resulted in a larger percentage of the tetramers being abnormal. Between 24% and 48% of the hemoglobin tetramers in a clinical sample were abnormal and contributed to the shift of the hemoglobin–O_2 dissociation curve.[166] The actual effect that these partially modified molecules have on this curve depends on their conformation. Because the half-sulfurated, half-liganded tetramers have an isoelectric point between deoxyhemoglobin and oxyhemoglobin and bind 2,3-BPG under conditions when oxyhemoglobin does not, their conformation must be closer to the T-state (deoxy state) than that of oxyhemoglobin. Whereas in methemoglobinemia some tetramers have subunits fixed in an oxidized R-like state (Darling–Roughton effect),[1] in sulfhemoglobinemia some tetramers have subunits fixed in a deoxidized T-like state because they remain unliganded at physiological pO_2. In the former case, a left-shifted oxygenation curve and impaired O_2 delivery results, whereas in the latter case, a right-shifted curve and enhanced O_2 delivery occur. The slightly higher 2,3-BPG in the blood of patients with sulfhemoglobinemia probably reflects increased binding to the T-like sulfurated tetramers rather than an actual increase in free 2,3-BPG.[166,167]

Clinical Presentation, Diagnosis, and Treatment

Sulfhemoglobin in concentrations greater than 0.5 g/dL also causes "cyanosis" with a normal paO_2 and might be erroneously measured as methemoglobin. Sulfhemoglobin can be distinguished from methemoglobin by its peak absorption at 620 nm, which unlike methemoglobin is not abolished by the addition of cyanide. Sulfhemoglobin and methemoglobin have been reported to coexist in a number of cases of drug-induced acute toxic methemoglobinemia.[156–161] The lists of chemicals and drugs reported to produce these syndromes overlap. Acetanilid, usually in the form of Bromo Seltzer, and phenacetin were the main offenders in 62 cases of sulfhemoglobinemia seen at the Mayo Clinic in 1951.[157] The aryl hydroxylamine metabolites of these drugs can serve as reducing agents in a cyclic process capable of generating both sulfhemoglobin[165] and methemoglobin.[168] The origin of the sulfur atom in the former case remains unclear, but both H_2S generated by intestinal flora[169] and glutathione[170,171] have been suggested. Laboratory assays used for detection of methemoglobinemia are often inadequate to detect sulfhemoglobin, so it is likely that sulfhemoglobinemia is underdiagnosed.[172] Although acetanilid was removed from Bromo Seltzer a number of years ago and the Food and Drug Administration removed phenacetin from the United States market, sulfhemoglobinemia is not likely to vanish. Sulfonamides, dapsone, and sulfur-containing ointments are reported offenders[162,173,174] and are still widely used. Some drugs reported to produce methemoglobin, including acetaminophen, might be found to also produce sulfhemoglobin when more careful analysis is done. Sulfhemoglobinemia, which has been associated with constipation, possibly because sulfides produced by an expanded intestinal flora when stasis exists, converts methemoglobin

to sulfhemoglobin. Treatment of this cause of sulfhemoglobinemia is to treat constipation.

Accidents involving occupational exposure to hydrogen sulphide (H_2S) are expected to increase.[175] Because exposure of red blood cells to H_2S produces sulfhemoglobin within minutes, it is likely that occupational exposure to H_2S poisoning in industrial societies, particularly emerging ones, will increase. A fatal case of a shrimp fisherman exposed to high levels of ambient H_2S emanating from the dithionite-treated catch has been reported.[165] In Alberta, Canada, there were 221 cases of exposure to H_2S over 4 years, with an overall mortality of 6%. Hospital admission was required for 65% of the victims.[175] Acute problems were coma, ataxia, and respiratory insufficiency with pulmonary edema. Sulfhemoglobin is seldom suspected in this setting and thus likely underdiagnosed. Increased interest in occupational and environmental pollutants and screening of populations at risk could reveal many more subclinical cases. Although CO_2 was thought to be the cause of death in the Lake Nyos African disaster that claimed nearly 2,000 lives as a cloud of toxic gases erupted from the bottom of this tropical lake, H_2S was among the liberated gases that could have modified hemoglobin and contributed to this calamity.[176] Significant exposure to H_2S can occur in workers at sulphurous thermal baths. Blood sulfhemoglobin levels has been shown to be a reliable measure of individual exposure to H_2S.[177] One case report described the false diagnosis of "methemoglobinemia," which on further analysis, because of refractoriness to methylene blue, was found to be sulfhemoglobinemia.[72] The patient had applied 4 oz of dimethyl sulfoxide to her abdomen to treat interstitial cystitis. Within 24 hours she developed fatigue, cyanosis, and dyspnea with mild exertion.

Although sulfhemoglobinemia is probably a relatively nontoxic syndrome in individuals with HbA, it might prove to be a surprisingly toxic syndrome in individuals with HbS, especially compared with methemoglobinemia, which would be expected to ameliorate sickling because of left-shifted hemoglobin dissociation curve associated with methemoglobinemia. The presence of sulfurated subunits will shift the conformation of HbS tetramers toward the unliganded, polymerizing T form, even in the presence of high pO_2, thus leading to polymerization of HbS. Microvascular occlusion could be exacerbated by these tetramers remaining in the polymerizing conformation in both the arterial and venous circulation. This hypothetical scenario has yet to be reported.

Congenital sulfhemoglobinemia has been reported but is rare and a fraction of sulfhemoglobin has been described with an unstable hemoglobin.[137]

Diagnosis of sulfhemoglobinemia is suspected when a patient who is cyanotic with normal to near-normal O_2 tension and the clinical and laboratory diagnosis of methemoglobinemia does not respond to therapy with methylene blue. With the eight-wavelength pulse oximeter capable of measuring methemoglobin more accurately, diagnosis of sulfhemoglobinemia will likely be made earlier without requiring waiting for therapy with methylene blue treatment to fail. With equivalent amounts of abnormal pigment, the patient with sulfhemoglobinemia appears more cyanotic than the patient with methemoglobinemia as a result of spectral differences between the pigments, but is less symptomatic as a result of the differences in P_{50}. This is fortunate, as there is no known treatment analogous to methemoglobin reduction for reconverting sulfhemoglobin to functional hemoglobin; exchange transfusion is the sole therapeutic option, if therapy is needed.

In summary, sulfhemoglobin is a green-pigmented protein that can be accurately identified by spectrophotometry and isoelectric focusing. At low concentrations, sulfurated tetramers are shifted toward the deoxy or T form, producing a right shift of the O_2 equilibrium curve. For this reason, dyspnea is absent unless the levels of sulfhemoglobin are extraordinarily high. Mild cases that are typically undiagnosed might be revealed in screening studies looking for toxic effects of drugs and environmental pollutants. Awareness of this entity and modern, widely used, simple equipment could allow us to determine the true prevalence of sulfhemoglobinemia.

CONCLUSIONS

COHb, methemoglobin, and sulfhemoglobin are present in normal red cells in very low concentrations. Mutations or environmental conditions can increase the concentrations of these liganded or oxidized hemoglobins, producing a dyshemoglobinemia. Although rare, increased levels of dyshemoglobins can be life threatening so that their presence should be identified in a timely fashion to permit effective treatment. The distinction between environmental and genetic dyshemoglobinemia is often blurred because many acquired dyshemoglobins are, in effect, the consequence of both an environmental challenge and a genetic predisposition.

SECTION SEVEN

SPECIAL TOPICS IN HEMOGLOBINOPATHIES

Martin H. Steinberg

Three chapters in this section, Population Genetics and Global Health Burden, Genetic Modulation of Sickle Cell Disease and Thalassemia, and Developments in Laboratory Methods to Detect Hemoglobinopathies, cover diverse subjects.

Without endemic malaria, the genes for HbS, HbC, HbE, and the thalassemias would not exist at polymorphic frequencies as the selective pressure from *Plasmodium falciparum* is so strong. Weatherall and Williams discuss the "Malaria hypothesis," and the evidence that carriers of thalassemia and HbS, HbC, and HbE are protected from *P. falciparum* infection, although the mechanisms behind such protection are incompletely understood. The health burden of hemoglobinopathies and thalassemia is great, particularly in developing countries, and it is likely to increase as development proceeds. Many obstacles to providing genetic services are discussed, among them, the prioritization of scant healthcare resources and the problems posed by communicable disease and malnutrition, leaving hemoglobin disorders underserved.

Hemoglobinopathy detection is often a part of the evaluation of anemia and microcytosis. It should first be determined, using hemoglobin high-performance liquid chromatography, whether a variant hemoglobin is present, how abundant the variant is, and whether the variant is relevant to the clinical picture. With background information from the patient's history, studies of informative family members, physical examination, blood counts, and erythrocyte indices, high-performance liquid chromatography can suggest the genotype of sickle cell disease. Thalassemia mutations are multitudinous and only DNA-based studies can pinpoint the genotype of this disease. For purposes of genetic counseling, especially when antenatal diagnosis is being considered, DNA-based diagnostics are required, although these tests are not required for managing disease complications in an individual. An accurate prognosis is often facilitated by knowing the genotype of the disease.

Mutations of the β-globin gene usually change only one hemoglobin component and stable variants usually have a concentration of 40%–50%. In contrast, α-globin gene variants should produce abnormal major and minor hemoglobins because, with rare exceptions, all hemoglobin molecules contain α-globin chains. Mutation of a single α-globin gene usually creates variants forming 20%–25% of the total hemoglobin, and a variant minor hemoglobin fraction, but the actual amounts of different hemoglobin types that accumulate can vary. γ-Globin gene mutants are important only in the fetus and usually "disappear" postnatally, when γ-globin gene expression is nearly extinguished. α-Globin chain abnormalities are expressed at birth and can produce signs of disease neonatally. Characteristically, β-globin chain mutations are clinically apparent only after the first few months of life, although their mutations can be detected beforehand.

Although a prototypical mendelian, single gene disease, the clinical heterogeneity of sickle cell anemia resembles that of a complex multigenic trait. Similarly, genotype–phenotype correlations are often difficult to establish in thalassemia. Modifying genes must affect the pathogenesis of these disorders and modulate their phenotypes. Candidate gene association studies have linked several genes and pathways with some subphenotypes of sickle cell anemia, including stroke, leg ulceration, priapism, pulmonary hypertension, and osteonecrosis. Genome-wide association studies now permit an "unbiased" assessment of all genes that could modulate disease. To be successful, this work requires precise definitions of phenotypes or heritable quantitative traits, samples of sufficient size to provide reasonable power to detect associations, knowledge of linkage disequilibrium patterns in the study populations, the availability of economically feasible high-throughput genotyping platforms, and sophisticated analytical techniques. These conditions have now been largely met, and some results are beginning to be published but this remains a "discovery" process.

Although it is still early in this quest, we can envision a time when disease diagnosis might include the use of tests for polymorphic modifier genes that will allow the treating physician to predict the future level of severity and complications likely to occur in an individual. This knowledge would help rationalize the use of antenatal diagnosis and the selection of patients for risky treatments and procedures. It might also allow a prediction of drug response, preclude exposing some patients to toxic therapies, and identify new pathways to which therapy could be targeted.

26

Population Genetics and Global Health Burden

David J. Weatherall and Thomas N. Williams

It is now widely accepted that the hemoglobinopathies are the most common monogenic diseases in humans. In this chapter we discuss the possible reasons for their very high frequency and uneven distribution among the world's population and describe recent attempts to determine their global health burden and how this might be managed.

FREQUENCY AND DISTRIBUTION

Frequency

A number of attempts have been made to review or determine the global frequency and annual birth rates of homozygotes or compound heterozygotes for the important inherited disorders of hemoglobin.[1–8] Composite data from these reports for the frequency and distribution by World Health Organization (WHO) regions are summarized in Table 26.1 and similar data for the estimated annual birth rate of severe forms of hemoglobinopathy are summarized in Figure 26.1. As we will discuss later in this chapter, such summaries are based on imperfect data and should be viewed with some caution; nevertheless, it is now generally acknowledged that as a group the hemoglobinopathies represent the most common monogenic diseases of humans.

Any explanation for the extremely high gene frequencies of the inherited disorders of hemoglobin must take into account a number of unusual features about their world distribution. The high-frequency regions stretch across the tropical belt of the Old World or areas into which there has been a high rate of migration from this region. None of the hemoglobinopathies have been found in the indigenous populations of the New World despite the fact that some of its populations have existed in tropical conditions over thousands of years. Furthermore, the different hemoglobinopathies are unevenly distributed in the tropical belt of the Old World. For example, HbS reaches its highest frequencies in Africa, parts of the Middle East, and the Indian subcontinent but is not observed further east, whereas HbE occurs at extremely high frequencies in Southeast Asia, Myanmar, Bangladesh, and parts of the eastern borders of the Indian subcontinent, yet does not extend further west (Fig. 26.2), and every population with a high frequency of different forms of thalassemia has its own particular set of mutations. These observations, which suggest that these conditions have arisen de novo with local expansion, are not compatible with older theories about their distribution, which suggested that it reflects massive population movements in an eastward or westward direction.[4]

As well as the heterogeneous distribution of the hemoglobinopathies, there are certain other generalizations that can be made about their frequency, which also have to be taken into account in any explanation for why these conditions are so common. The sickle cell (HbS) and β thalassemia genes (Figs. 26.2 and 26.3), although they occur at varying frequencies in different populations, rarely are found in more than 20% of the population. The α^0 thalassemias occur at similar frequencies to the β thalassemias. On the other hand, the α^+ thalassemias occur at much higher frequencies, achieving up to 70%–80% of the population in some regions (Fig. 26.4) and, similarly, the carrier rates for HbE greatly exceed those of HbS, reaching as high as 70% in some parts of Asia including northern Thailand and Cambodia. Further details of these gene frequencies, together with the appropriate references and data that underline these generalizations are reviewed in more detail elsewhere.[4]

In short, the hemoglobinopathies only occur at very high frequencies in warm or tropical climates, their distribution is extremely heterogeneous, and the maximum population frequencies that are achieved appear to vary considerably between different forms of thalassemia and structural hemoglobin variants.

Why Do the Hemoglobinopathies Occur at Such a High Frequency?

The high-frequency populations for the hemoglobinopathies are mainly those of developing countries or countries that have only recently made the demographic and epidemiological transitions from the effects of extreme poverty. There is considerable evidence that genetic diseases and congenital malformations occur more frequently in countries with a low per capita gross national income for which a number of explanations have been put forward. These include increased rates of consanguinity, increased parental age, population migration, and natural selection.[6]

Although it is difficult to obtain accurate data, it is clear that consanguineous marriage is still practiced in many parts of the world and may be acceptable to a minimum of 20% of the world's population.[9,10] This practice is especially common throughout the eastern Mediterranean, North Africa, and the Indian subcontinent, and to a lesser extent in parts of South America and subsaharan Africa.[9–11] There is clear evidence that the birth prevalence of autosomal

Table 26.1. Percent carrier frequencies for common hemoglobin disorders, by WHO region (1–7)

Region	HbS	HbC	HbE	β Thalassemia	α^0 Thalassemia	α^+ Thalassemia
Americas	1–20	0–10	0–20	0–3	0–5	0–40
Eastern Mediterranean	0–60	0–3	0–2	2–18	0–2	1–80
Europe	0–30	0–5	0–20	0–19	1–2	0–12
Southeast Asia Africa	40	0	0–70	0–11	1–30	3–40
Western Pacific	0	0	0	0–13	0	2–60

Note: Many of these data are derived from small population samples.

recessive diseases is increased by this mechanism in these populations.[6] The percentage of pregnant women aged older than 35 years is also high in middle- and low-income countries, although the major consequence of this appears to be an increase in the number of live births of infants with chromosomal defects or developmental abnormalities.[6] A large population movement from areas of high frequency for single gene effects also has the effect of introducing these disorders into new populations, as evidenced by the spread of the hemoglobin disorders to the Americas, the Caribbean, and Europe by the slave trade and later migrations. Although all of these mechanisms might undoubtedly have been responsible for increasing the frequency of autosomal recessive disorders and others over time, they cannot account for the remarkably high gene frequencies of the hemoglobinopathies in these populations, and the evidence is now overwhelming that the principle factor in maintaining these high gene frequencies is natural selection working through the relative protection of heterozygotes for the common hemoglobinopathies against *Plasmodium falciparum* malaria.

NATURAL SELECTION AND THE HEMOGLOBINOPATHIES; THE MALARIA HYPOTHESIS

Historical Background

The notion that variation in host response to infection might have a genetic basis is not new;[12,13] however, it was not until the late 1940s, and through the remarkable insight of J.B.S. Haldane, that a plausible genetic protective mechanism was first suggested.

During the period just after World War II, independent studies in Italy and in Mediterranean immigrants in the

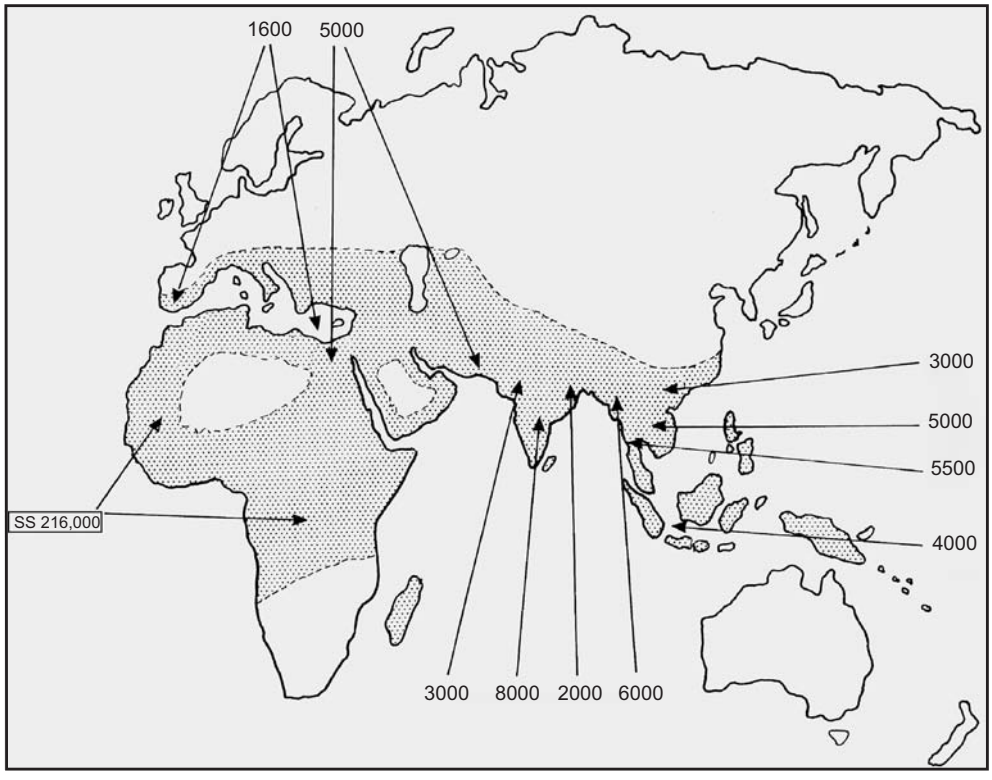

Figure 26.1. Estimated annual births of hemoglobinopathies. Data from references 2–5. The SS box shows sickle cell disease in Africa; other figures are for β thalassemia. These data are currently being revised and extended; in many cases they may underestimate the birth rates. (From ref. 4.)

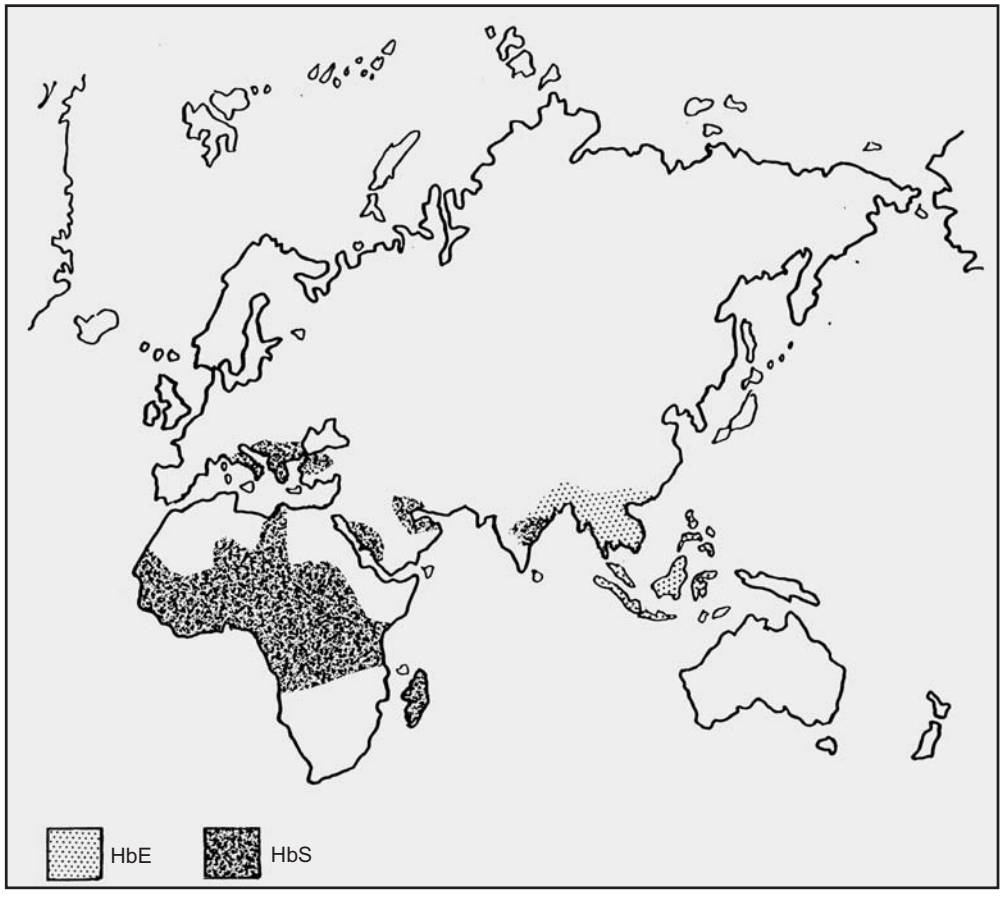

Figure 26.2. The world distribution of hemoglobins S and E. (From ref. 4.)

United States highlighted a remarkably high frequency of thalassemia in these populations.[14,15] Influenced by the intense interest in human mutation rates following studies of the survivors of the atomic bombs in Hiroshima and Nagasaki, workers on both sides of the Atlantic suggested that this might reflect a high rate of mutation and, because they appeared to be restricted to certain populations, that the mutation rate might differ between different ethnic groups.

At the 8th International Congress of Genetics in Stockholm in 1948, Neel and Valentine, to explain the high frequency of thalassemia in immigrant populations in the United States, calculated a mutation rate for thalassemia of 1:2500. Haldane felt that this was unlikely and that these remarkable gene frequencies were more likely to be the result of heterozygote selection. Furthermore, he went on to suggest, "The corpuscles of anemic heterozygotes are smaller than normal, and more resistant to hypertonic solutions. It is at least conceivable that they are also more resistant to attacks by the sporozoa which cause malaria, a disease prevalent in Italy, Sicily and Greece, where the gene is frequent."[16]

In essence, what became known as the "malaria-hypothesis" intimated that diseases like thalassemia can be considered balanced polymorphisms – conditions in which the gene frequency for the advantageous heterozygous state increases until it is balanced by the loss of disadvantaged homozygotes from the population. Haldane's great contribution to this field was to encourage geneticists and hematologists to analyze the high frequency of common genetic diseases of the blood as putative polymorphisms of this kind. Although, over the years, the hypothesis has stood the test of time, as we shall see in subsequent sections it has not always been easy to substantiate Haldane's ideas in human populations.

It is beyond the scope of this chapter to review in detail all the population and experimental work that has followed from Haldane's original idea. In particular, it has not been possible to review the evidence suggesting that polymorphisms other than the hemoglobinopathies have also come under selection by malaria. Readers who wish to explore this aspect of the topic further are referred to several recent reviews.[17–19]

Malaria in Human Populations

Malaria has decimated large populations in the past and is still one of the world's most common causes of mortality. Currently, close to 50% of the world's population are at risk of transmission, more than 3 billion people live in malarious areas and the disease causes between 1 and 3 million deaths per year.[20] Four different species of

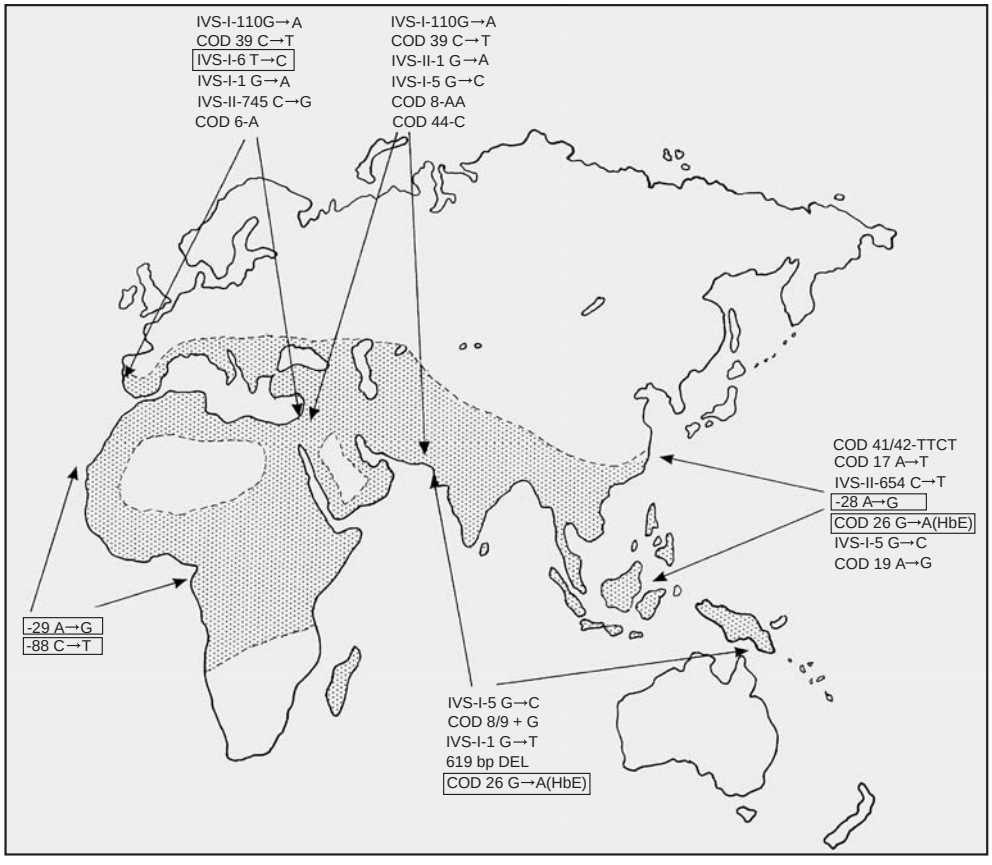

Figure 26.3. The world distribution and different mutations that cause β thalassemia. Those shown in boxes are milder mutations. Hemoglobin E is included in the milder mutation because of its β thalassemic phenotype. (From ref. 4.)

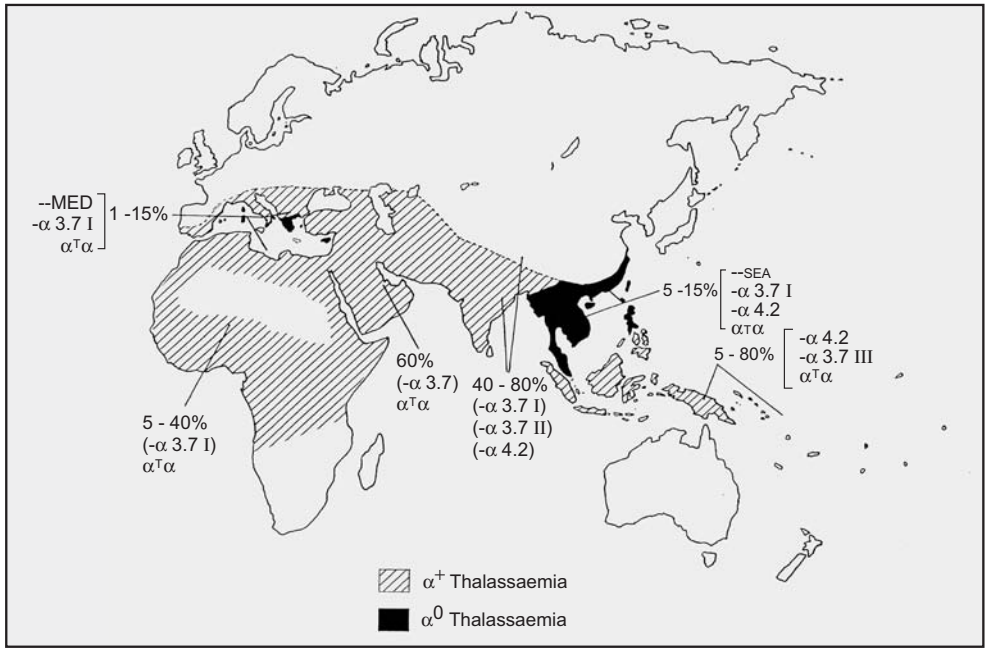

Figure 26.4. The world distribution of the α thalassemias. The α^0 thalassemias are only found at high frequencies in Asia and some Mediterranean countries. The α^+ thalassemias have a much broader distribution. Some of the different subtypes of α^0 and α^+ thalassemia are shown. - -SEA indicates the Southeast Asian deletion form of α^0 thalassemia. $-\alpha^{4.2}$ or $-\alpha^{3.7}$ relate to different forms of α^+ thalassemia with their particular deletion sizes, $-\alpha^{3.7}$ is further subdivided into types I, II, and III, again depending on the different deletion sizes. α^T denotes nondeletion α thalassemia. (From ref. 4.)

Plasmodium cause human infections: *P. falciparum, P. vivax, P. ovale,* and *P. malariae*. Although the majority of deaths are caused by *P. falciparum* malaria, *P. vivax* malaria is a common cause of chronic ill health, particularly in children.

Infection occurs when a female anopheline mosquito inoculates sporozoites into humans where they mature in the liver and are then released into the blood stream as merozoites. The latter invade red cells, causing both their destruction and also adhesion to the walls of blood vessels.

The complex interactions of malarial parasites and red blood cells, that have to be understood for a full appreciation of the complexities of the potential protective effects of the hemoglobin disorders have been reviewed recently.[18,19]

Hemoglobin S

Because, paradoxically, it was the structural hemoglobin variants, notably HbS, for which Haldane's hypothesis was first explored we will consider this condition first and then discuss how far his hypothesis has stood up in the case of the thalassemias (see Chapter 22).

Early studies on the relationship of the high frequency of the HbS gene to *P. falciparum* malaria are summarized elsewhere.[21] In short, analyses of parasite rates and densities in children with the sickle cell trait (HbAS) and non-affected controls, together with observations of the rarity of sickling in patients with severe malaria and the distribution of the sickle cell gene combined to provide convincing evidence that HbAS offers at least some degree of protection against severe malarial infection. More recent studies in east and west Africa suggest that the greatest impact of HbS is against fatal or severe malaria, that is profound anemia or cerebral malaria, having no discernible effect on infection rates per se.[22–24] Indeed, case-control studies suggest that HbS heterozygotes have a level of protection of approximately 60%–80% against the severe complications of malaria.

Some progress has also been made in determining the mechanisms of protection of those with HbAS against *P. falciparum* malaria, although many questions remain unanswered. Early studies demonstrated that in those with HbAS the rate of sickling is significantly greater in parasitized than in unparasitized red cells,[25] findings that were later confirmed and extended under more physiological conditions.[26] These studies suggested that the parasites cause a "suicidal infection;" because parasitized HbAS red cells sickle and are more likely to be removed from the circulation. At approximately the same time it was also demonstrated independently by two groups that parasitized HbAS cells maintained at low oxygen tension do not support the growth of malaria parasites as effectively as normal cells at similar oxygen tensions.[27,28] Later it was suggested that this effect might be due to the increased loss of potassium or water from the HbAS cells.[29]

Recent studies have also been compatible with the early suggestion[21] that there might also be an immune component involved in the protection of individuals with HbAS. In a cohort study of mild clinical malaria in Kenya, the protection attributable to HbAS showed a significant increase with age.[30] Compatible with these findings, it was demonstrated in two studies that those with HbAS had significantly higher titers of immunoglobulin G antibodies to a variety of malarial antigens than normal children.[31,32]

Thus although there are a number of feasible mechanisms at both the cellular and immunological levels for protection of HbAS individuals against *P. falciparum* malaria the precise mechanisms of these complex interactions that result in such a remarkable protective effect remain to be determined.

Hemoglobin C

Although early studies were not convincing, more recent work conducted in West Africa indicates that the relatively high frequencies of HbC in that region have been maintained by resistance to *P. falciparum* malaria (see Chapter 21).[33] In this case there is evidence that protection is greater in homozygotes (90%) than in heterozygotes (30%), suggesting that, unlike the sickle cell mutation, HbC may be an example of a transient polymorphism – one that would move to fixation under continued selective pressure. This hypothesis is based on the assumption that, in itself, homozygosity for HbC has no adverse consequences. If this were the case, however, it is difficult to understand why the frequency of HbC is not higher in African populations. Furthermore, the fitness (in the Darwinian sense) of homozygotes for this variant is not completely established; further work will be required to confirm this interesting suggestion.

Although a number of early studies suggested that the protective mechanism of HbC might be mediated through the inability of parasites to grow and develop in affected red cells, this mechanism is not supported by studies of parasite densities in vivo (summarized in ref. 19). More recently it has been shown that the expression of PfEMPI, an important parasite-encoded red cell adhesion protein, is reduced in HbC-containing red cells, an effect that is most marked in homozygotes.[34,35] It should be remembered, however, that HbC-containing red cells have a number of abnormal properties including rheological abnormalities and increased levels of oxidant stress; clearly, the final story about the definitive protective mechanism remains to be determined.[36]

Hemoglobin E

Because of its extremely high frequency in Asia, HbE has always seemed to be a good candidate for a malaria-protection polymorphism (see Chapter 18). Many of the early population studies that were conducted failed to show a clear relationship between HbE and malaria.[4] It is possible that some of these studies may have been bedeviled

by the very high frequency of α thalassemia that occurs in many populations with a high frequency of HbE.

Recent extended linkage-disequilibrium analyses of the HbE gene suggest that it is of relatively recent origin and must have come under intense selection.[37] In keeping with this observation it has been found that the presence of HbE trait is associated with a reduced severity of disease in adults admitted with acute *P. falciparum* malaria.[38] Furthermore, in vitro culture studies using mixtures of normal and variant red cells have shown that those from HbAE individuals, although not those from HbE homozygotes or different forms of α thalassemia, are more resistant to invasion by the parasite.[39]

Although these findings are suggestive, a major gap in our information about HbE and malaria is the absence of adequate data from case-control studies of the kind that have been so successful in demonstrating the magnitude of the protective effects of HbS and HbC. Thus, although it seems almost certain that HbE is in some way protective against malaria, a great deal more work needs to be done before we will have any clear understanding of the magnitude of the effect or its mechanism.

α Thalassemia

The frequency of α^+ thalassemia in the southwest Pacific follows a clinal distribution from north/west to south/east, with the highest frequency in northern Papua New Guinea and the lowest in New Caledonia (see also Chapters 13 and 14). This distribution shows a strong correlation with malarial endemicity; similar relations are not observed with other genetic polymorphisms in this region.[40] The possibility that α thalassemia has been introduced from the mainland populations of Southeast Asia, and that its frequency has been diluted as populations moved south, has been largely excluded by finding that the molecular forms of α thalassemia in Melanesia and Papua New Guinea are different from those of the mainland and are set in different α-globin gene haplotypes.[40] One feature of the distribution of α thalassemia in this region that, on the face of it, does not fit with the malaria hypothesis was that it is also found in Fiji in the west, Tahiti and beyond in the east, and in Micronesian atolls, populations in which malaria has never been recorded. It has been found that a single mutation, which has been previously defined in Vanuatu, accounts for virtually all the cases of α^+ thalassemia that have so far been described in Polynesia, indicating that the presence of α thalassemia in these nonmalarious areas has almost certainly resulted from population migration rather than selection.[41]

These population data were augmented by prospective case-control studies in northern Papua New Guinea, where it was found that compared with normal children, the risk of contracting strictly defined severe malaria was 0.4 for α^+ thalassemia homozygotes and 0.66 for α^+ thalassemia heterozygotes.[42] Similar findings have since been reported from studies conducted in two African populations.[43,44] Although some progress has been made toward an understanding of the mechanisms of malaria protection afforded by α thalassemia, the overall picture is still far from clear. Paradoxically, early studies in Papua New Guinea suggested that very young children with α^+ thalassemia might be slightly more prone to uncomplicated malaria than normal children.[45] Later studies conducted in Vanuatu appear to support this conclusion, showing that the incidence of uncomplicated malaria and the prevalence of splenomegaly, an index of malaria infection, were both significantly higher in children with α thalassemia than in normal children. Moreover, the effect was most marked in the youngest children and in those affected by the nonlethal parasite, *P. vivax*.[46] It was suggested that the early susceptibility to *P. vivax*, which may reflect the more rapidly turning over red cells of α thalassemic infants,[47] could be acting as a natural vaccine by inducing cross-species protection against *P. falciparum*. These intriguing observations require further study in other populations.

There has also been some progress toward determining how protection might be mediated at a cellular level. Overall, there is no evidence for a reduced rate of invasion or growth of *P. falciparum* in red cells of the genotype -α/αα or -α/-α, the mild forms of α thalassemia that have been shown to be protective by case-control studies. It has been found that these cells consistently bind more malaria-immune globulin than normal red cells.[48,49] When infected with parasites, α thalassemic red cells are less able than normal red cells to form rosettes, an in vitro phenomenon whereby uninfected red cells bind to infected cells. It has been demonstrated that complement receptor 1 expression, which is required for rosette formation, is reduced on α thalassemia red cells,[50] offering a convincing potential mechanism for reduced rosetting.[51,52] In addition, infected α thalassemic red cells are less able than normal red cells to adhere to human umbilical vein endothelial cells.[51] Because rosetting and cytoadherence are mechanisms that underlie sequestration of infected red blood cells and are associated with virulence of infection, these observations suggest that malaria protection by α thalassemia might be determined by specific red cell membrane abnormalities that are associated with this condition. In an extensive series of studies to define other membrane components involved, it was suggested that altered red cell membrane band 3 could also be a target for enhanced antibody binding to α thalassemic cells infected with parasites.[49]

Thus, although there are a number of tantalizing clues as to possible mechanisms of protection against malaria by the milder forms of α thalassemia, a coherent picture of how they fit together remains to be produced.

β Thalassemia (Chapters 16 and 17)

In their now classic studies conducted in the 1960s, Siniscalco and colleagues[53] found that the population

frequencies of thalassemia carriers in Sardinia, a considerable number of whom must have been β thalassemia carriers, correlated with altitude. Although malaria was no longer endemic in Sardinia at that time, historically, its incidence had been correlated closely with altitude. Similar correlations were found later in Melanesia.[54] In addition, a relatively small case-control study in Northern Liberia suggested that the β thalassemia trait is protective against severe malaria.[55] Thus, although a number of other population studies, mostly analyzing parasite rates or densities, failed to show any correlations between β thalassemia and malaria (see ref. 4), such epidemiological data that are available certainly point to a protective effect of the β thalassemia trait (see also Chapters 16 and 17).

Another finding in favor of the concept that β thalassemia is a protective polymorphism is the observation that in every country in which this disease is common there is a different set of mutations. Studies of β-globin gene haplotypes (Chapter 27) and their relationship to β thalassemia mutations have been particularly interesting in this respect. Unlike the α-globin gene haplotypes there is a "hot-spot" for recombination between the 5′ and 3′ ends of the β gene haplotypes (Chapter 27). Over time there seems to have been admixture between the 5′ and 3′ haplotypes among human populations but this has not occurred in the case of thalassemia; the thalassemia mutations, which occur in the 3′ haplotype, are almost invariably associated with the same 5′ haplotype, indicating that in evolutionary terms they are much more recent and that there has not been time for mixing the 5′ and 3′ ends of haplotypes that carry these mutations (see ref. 4). This suggests a fairly recent selective pressure, possibly approximately 5,000 years, which is in agreement with current estimations of the time that human populations have been exposed to pathogenic forms of *Plasmodium* (see later).

Very little is known about the potential mechanisms of protection against malaria in the case of β thalassemia. In vitro studies have shown that β thalassemic red cells are invaded at the same rate as normal red cells and that the rate of parasite growth is also indistinguishable from normal. One potential explanation is that protection is related to levels of fetal hemoglobin (HbF) that are associated with this condition. There is clear evidence that the rate of decline of HbF levels after birth is delayed in β thalassemia heterozygotes (see ref. 4) and studies conducted in both humans[56] and in transgenic mice[57] have found defective development of *P. falciparum* or *P. yoelii*, respectively, in red cells that contain human HbF. This could provide a mechanism for protection by β thalassemia during the first year of life, but not thereafter (see later section).

A more general hypothesis for why β thalassemia heterozygotes might be protected against malaria has also been proposed.[58] In short, it is known that these cells are under increased oxidative stress due to globin chain imbalance; it is suggested therefore that the further stress imposed by the parasite might render these cells prone to damage and rapid removal from the circulation, a mechanism reminiscent of that outlined earlier for the protective effect of HbAS.

Epistatic Interactions Between Protective Polymorphisms

Because different hemoglobin disorders that offer protection against malaria frequently occur together in the same population it is becoming increasingly important to determine whether they interact with one another and, in particular, the effect that this might have on changing the pattern of susceptibility to malarial infection.

The term epistasis is used to describe nonadditive interactions between two or more different genetic loci. A study in East Africa has provided intriguing information that suggests that there is negative epistasis between the HbS and α thalassemia genes with respect to protection against *P. falciparum* malaria. Although those with HbAS or heterozygous or homozygous for α^+ thalassemia alone have been found to have a highly significant protection against *P. falciparum* malaria (see previous sections) this effect was completely nullified in individuals who had HbAS and were homozygous or heterozygous for α^+ thalassemia.[59] Although the numbers involved in this study were relatively small, results from a recent case-control study conducted in Ghana were compatible with the same conclusion.[60] Considering current uncertainty about the precise mechanism of protection mediated by either of these variants alone, it is difficult to explain this remarkable epistatic interaction. Phenotypically, the major difference between HbAS individuals and those who, in addition to HbS, carry α thalassemia is that the doubly affected persons have significantly lower levels of HbS in their red cells (see ref. 4). It is possible therefore that protection in HbAS persons may require a critical level of HbS. In this context it should be noted that these doubly affected individuals have reduced mean corpuscular hemoglobin (MCH) and mean corpuscular volume (MCV) values associated with the particular α thalassemia genotype (Chapter 22). In uncomplicated sickle cell trait HbS accounts for approximately 40% of total red cell hemoglobin and the MCH is 30 pg, giving an absolute amount of HbS per cell of approximately 12 pg. On the other hand, in those with the HbAS who are also homozygous for α^+ thalassemia, the level of HbS is reduced to approximately 25% and the MCH to only 20 pg, giving an absolute level of HbS of only 5 pg per cell; a more than 50% reduction in the absolute amount of HbS per cell could, therefore, have an important effect on the degree of protection enjoyed by individuals of different genetic combinations.

It seems very likely that other interactions of this type occur. Apart from their intrinsic interest in the population genetics of these conditions their further study may provide valuable information about the protective mechanisms of some of the hemoglobinopathies.

Summary

From the data summarized in the previous sections, it is clear that, at least at the population level, there is reasonably convincing evidence that the five major groups of hemoglobin disorders that occur at very high frequencies in different populations are all associated with protection against *P. falciparum* malaria in the heterozygous, and, in some cases, homozygous states. The clinical and parasitological evidence for protection varies widely; in some cases there appears to be a genuine reduction in parasite densities, whereas in others the effects seem to be mediated almost entirely by protection against the severe complications of malaria.

Perhaps it is not surprising that progress has been much slower in trying to determine the protective mechanisms involved. The studies that have been conducted are asking questions of an enormously complex biological system; transmission rates of malaria vary widely, populations differ in whether one type of parasite predominates or whether there are several. There is a wide difference in antigenic strains of parasite and many of the in vitro techniques that have been used are extremely difficult to standardize between different laboratories. Added to this, the cellular pathophysiology of these different hemoglobinopathies, although there might be some features in common, is undoubtedly different. Against this complex background, however, certain generalizations are beginning to appear. For example, a reduction in rosette formation seems to be common to several different hemoglobinopathies, suggesting that changes in the red cell membrane associated with particular differences in antigen presentation may be at least one common pathophysiological mechanism. No doubt more will be found.

An even more difficult question, and one posed by the increasing evidence for an additional immune basis to protection, is how the primary protective mechanisms at the level of the red cell might be associated with enhanced immune response. Clearly this question requires a great deal more work.

It is beyond the scope of this chapter to discuss the increasing list of protective polymorphisms associated with malaria. They are the subject of several recent reviews.[13,17,18] As in the case of the hemoglobinopathies, in the majority of cases the protective mechanisms have not been fully worked out. There is one notable exception however. Epidemiological studies, first in Africa[61] and later in Papua New Guinea[62] showed a high frequency of the Duffy-negative phenotype in populations in which malaria is common. Further studies suggested that the Duffy blood group antigen might be the receptor for *P. vivax*. Later studies demonstrated that the Duffy antigen chemokine receptor (DARC) is not expressed on red cells when there is a promoter mutation that alters a GATA-1 binding site. In cells carrying this mutation DARC expression is abolished and therefore DARC-mediated entry of *P. vivax* is inhibited. This receptor is expressed predominantly on reticulocytes and young red cells and hence this observation is in keeping with the proposal discussed earlier in this chapter regarding the possible immune basis for protection against α thalassemia, at least in populations where *P. vivax* is common. The finding of increased susceptibility to both *P. vivax* and *P. falciparum* in babies with α thalassemia in Papua New Guinea, possibly because of the relative increase in young red cells in their blood, might allow early immunization against *P. vivax* and, because there is cross immune response between the two species, later protection against *P. falciparum*.[46]

Some other interesting similarities to observations in the hemoglobinopathies are also appearing in relationship to other protective polymorphisms. For example, evidence has been emerging for several years that individuals of blood group O are protected against *P. falciparum* malaria (reviewed in ref. 63). Interestingly, as in the case of some of the hemoglobinopathies, individuals of blood group O show significantly reduced rosette formation compared with nongroup O individuals. It appears therefore that there could be common pathways among the malaria-related protective polymorphisms, and further work of this kind might help to clarify some of the protective mechanisms involved in the hemoglobinopathies.

POPULATION AND EVOLUTIONARY IMPLICATIONS

The picture that is emerging is that the extremely common hemoglobin disorders occur at a high frequency in those parts of the world in which malaria was, or still is, a major cause of mortality. These protective polymorphisms are extremely patchy in their distribution; the HbS mutation occurs across Africa, the Middle East and the eastern side of India, but not further east; the HbE mutation occurs at an extremely high frequency in many of the populations stretching from the eastern part of the Indian subcontinent throughout the rest of Asia. Every high-frequency population for thalassemia has its own mutations and, at least in the case of HbS and HbE, there is evidence that they may have arisen de novo on more than one occasion.

These observations are best explained by the occurrence of local mutations with rapid selection; the lack of homogenization of some of these highly protective polymorphisms suggests that exposure of populations to malaria has been, at least in evolutionary terms, a fairly recent event. Although ancestral forms of the malaria species that infect humans arose many millions of years ago, it is likely that *P. falciparum* arose from its closest ancestor approximately 10 million years ago.[64] After approximately 10 million years of development in Africa, modern humans emigrated out of Africa 40,000–100,000 years ago, probably carrying at least some polymorphisms that evolved from selection against *P. falciparum*.[65] It is likely that death due to malaria increased very rapidly between 5,000 and 10,000 years ago with the development of agriculture and

settlements that would have greatly facilitated the transmission of the disease by mosquitoes.[66] These observations are all compatible with a fairly recent appearance of the malaria-resistant polymorphisms such as the hemoglobinopathies. This interpretation is certainly in keeping with recent studies of haplotype diversity and linkage disequilibrium at the human glucose-6-phosphate dehydrogenase locus.[67]

These concepts also go some way toward explaining the absence of common hemoglobinopathies in the indigenous populations of the new world. Presumably the selective factors leading to the high frequency of the thalassemias in Asian populations had not been present before their early migrations into the New World. Currently, it is not clear when malaria reached this region, although it has been suggested that it was as recently as the early Spanish conquests. Hence there might not have been time for selection to generate high frequencies of malaria-resistant polymorphisms in these populations.

Another interesting aspect of the population genetics of the hemoglobin disorders is how different polymorphic genes interact in the same population to produce present day frequencies.[4,21] Mutations like those for HbS and β thalassemia, which are alleles, interact to produce compound heterozygotes, HbS–β thalassemia, which can have clinically severe phenotypes. In this case, selection will not only act against those with sickle cell anemia and homozygous β thalassemia, but also to some extent against compound heterozygotes with HbS–β thalassemia. Early theoretical analyses of this type of situation[21] concluded that a stable equilibrium would be obtained provided that heterozygotes for both genes enjoyed a selective advantage. A consequence of selection acting in this way is that the more advantageous heterozygous state, in this case HbAS, would tend to come under much stronger selection and therefore the HbS and β thalassemia alleles would tend to be mutually exclusive in populations. Although this is not entirely the case, it mirrors broadly the pattern of distribution of these alleles in Africa. In the case of HbE and β thalassemia in many Asian populations, there is an inverse relationship between the frequency of β thalassemia and HbE, although because both are so common there still is a high frequency of compound heterozygotes.

POPULATION DYNAMICS AND IMPLICATIONS FOR THE CONTROL OF THE HEMOGLOBINOPATHIES

Population Dynamics

In the interests of public health planning a number of attempts have been made to predict the future burden of the inherited disorders of hemoglobin at local, regional, and global scales. As we will discuss later, such predictions suggest that we will be unlikely to see a significant decline in their current frequencies for the foreseeable future and the hemoglobinopathies will therefore assume increasing importance in many countries in development as they go through their demographic transition.

The population dynamics of the hemoglobinopathies are related to a number of issues including potential changes in the factors that result in selective advantage, the rates of epidemiological and demographic transitions in the developing countries, population migration, and the potential role of medical intervention. Predicting what might happen to the gene frequencies of the hemoglobinopathies in the face of a reduction in the incidence of malaria is complex and discussed in detail elsewhere.[68] In short, even if malaria were eradicated completely it would take many generations before the frequency of these diseases fell significantly. Furthermore, it is still not clear whether relative protection against malaria is the only factor that has maintained the hemoglobinopathies at their present high level. Studies conducted in Papua New Guinea suggested that the α thalassemias might offer protection against the infectious diseases of childhood,[42] although this effect has not been seen in other populations.

The Epidemiological Transition and the Frequency of Severe Forms of Hemoglobinopathy

During the last decade of the twentieth century, gross domestic product per head in the developing countries grew by 1.6% each year, and the proportion of people living on less than $1 a day fell from 29% to 23%. These statistics are reflected in improvements in the overall health of a number of populations in the developing world and in declines in childhood mortality, most notably in South America and the Caribbean, east Asia and the Pacific, the Mediterranean region, the Middle East and parts of North Africa.[6]

The consequences of such epidemiological transition for the recognition of the importance of genetic disease in developing countries were shown graphically in Cyprus after World War II. Thalassemia was not known to occur on the island until 1944, at which time the clinical findings in 20 patients were reported.[69] This study highlights the difficulty in identifying diseases of this type against the background of chronic malaria and other infections; it was published at the end of an extremely successful program to control mosquito breeding and other improvements in public health. Hence, during this remarkably short period it became clear that there was a high frequency of genetic anemia. By the early 1970s it was estimated that, if no steps were taken to control the disease, in approximately 40 years the blood required to treat all the children with thalassemia would amount to 78,000 U/year, 40% of the population would need to be donors, and the total cost to the health services would equal or exceed the island's health budget.[4] A similar trend is occurring at present throughout many Asian countries and will undoubtedly be repeated in subsaharan Africa as social conditions improve. A more detailed analysis of the effects

of both demographic and epidemiological transitions has been summarized recently.[70]

The potential effects of improvements in the medical management of the hemoglobinopathies on the size of their gene pools is also complex and difficult to predict. In the short term, such improvements have been shown to result in treatment-seeking migration of affected individuals from high-frequency regions to countries with stronger medical services, potentially widening the geographic range of these diseases. Although improved treatments for the more serious forms that allow patients to survive to reproductive age might have a modest effect on their overall population frequencies, the most contentious issue is the so-called dysgenic effect of programs for the control of these disorders by prenatal diagnosis and termination of affected pregnancies. This important issue is discussed in detail elsewhere[4,11,68,71] and will only be outlined here. The dysgenic effect of prenatal diagnosis is based on the premise that if most pregnancies that carry severely affected infants were aborted, the gene frequency for the particular disorder will steadily increase in the population. This is because homozygotes are replaced by healthy individuals, two thirds of whom are heterozygous and hence will pass on their genes. This assumes, of course, that couples undergoing prenatal diagnosis will attain the population norm for their final family size. But such evidence as there is suggests that this might not be the case; studies in Cyprus, for example, have shown that approximately 25% of the decrease in thalassemic births is due to limited reproduction.[71] Indeed, as elegantly summarized by Bodmer and Cavalli-Sforza, the changes in the size of the thalassemic gene pool that might follow interventions of this kind are likely to be extremely small: "It would seem therefore that the dysgenic effect of medicine is not a real threat. By the time that it may have a clearly perceptive global effect, 200 or 300 years from now – when the incidence of severe genetic disease may have doubled on average – our descendants almost certainly will have discovered simple methods of therapy."[68]

There have been few efforts to convert the health burden of the hemoglobin disorders into disability-adjusted life years, the only measure that the international public health community will accept as an approach to assessing the comparative health burden of different diseases. Recent and very preliminary analyses of this kind[70] have shown that the thalassemias pose a health burden comparable to some common communicable diseases in Asia; however, they encountered major difficulties because of lack of information about the gene frequency of some of the hemoglobin disorders in particular developing countries. In the future, it will be essential to improve these data and to obtain the help of health economists to assess the true health burden of the hemoglobinopathies.

In short therefore, in planning for the future public health measures required for the control and management of the hemoglobinopathies it can be assumed that as the developing countries continue to pass through the epidemiological transition they will impose an ever increasing burden on health services.

Control and Management Issues

The main approaches to the control and clinical management of the hemoglobinopathies are discussed in other chapters. Here, some of the particular problems relating to the control of the hemoglobinopathies are discussed in the light of their global distribution and peculiarities in their population genetics. The development of approaches to the global control and management of genetic disease in general,[72] and of the hemoglobin disorders in particular[4,73–75] have been discussed in detail recently.

The particular problems relating to the control of the hemoglobinopathies reflect their widespread heterogeneity and extremely uneven distribution even over relatively short geographical distances, their high frequency in rural populations of the developing countries, and inadequacies of education and medical services in these populations. These issues raise problems in bioethics, counseling, education, and the provision of medical care that are not encountered in the developed countries.

Ethical and Counseling Issues. Ethical issues in genetic research, screening, and testing in developing countries are discussed in detail in a report by the WHO[73] and in reports by the Nuffield Council on Bioethics.[76,77] They are also considered in a recent review.[72] There are major ethnic differences in how the nature of disease is interpreted. In many societies in which the level of education is limited it is viewed as being the action of evil spirits or other external forces, a belief that might be encouraged by visits to local healers. In these circumstances, even the simplest explanations of the nature of genetic disease might be extremely difficult to communicate. In many patriarchal societies, genetic disease raises particular problems for women who are carriers or who have affected children. Despite careful explanation of the mechanisms of inheritance, husbands frequently blame their wives for having a child with a genetic disease, often leading to the break up of the family and to a high rate of suicide. Genetic information may be used to discriminate or stigmatize in the context of social practices, particularly in countries in which arranged marriages are still common. In short, a screening program that has demonstrated that a woman is a carrier for a genetic disease can make her unmarriageable. Children with genetic diseases in developing countries can be severely stigmatized and even ostracized by their communities. Informed consent for any procedure is extremely difficult to establish and in many developing countries there are no regulatory or ethical bodies.

All these issues, and many others, need to be taken into account when developing genetic services of any kind in the developing countries. Although the principles of genetic

counseling are the same as in the developed countries, their application is quite different and must be developed hand in hand with those who have a full knowledge of the local scene. Indeed, a great deal more research is required about the appreciation of disease in different ethnic groups and how this may be best approached by sensitive counseling.

Genetic Services in Developing Countries. There have been several reviews of the problems of developing services for the control of genetic and congenital disorders in the developing countries.[6,73,74] Establishing programs for the hemoglobinopathies presents particular problems because this field has never come under the auspices of clinical genetics and usually requires special training in centers with experience of the field for appropriate pediatricians, hematologists, and technical staff. Once these personnel are in place, training of appropriate counselors and the development of public education programs can proceed. Next, based on local social and religious beliefs, decisions need to be made about whether community control will be achieved by prenatal diagnosis or community education alone. At a later stage, prenatal screening programs can be developed. Each country requires one or more centers with expertise in both the laboratory diagnosis and clinical management of the hemoglobinopathies, depending on its size.

In the current climate it is extremely difficult to achieve any of these developments in developing countries. Their governments are unwilling or unable to give priority to these conditions because of the many other more pressing problems of communicable disease, often associated with a concomitant increase in their health burdens by a rapidly rising rate of noncommunicable disease. Currently, very few governments in Asia or subsaharan Africa are able to support any form of hemoglobinopathy program and hence without some form of external international help it will be a long time before these diseases come under control in many parts of the world.

In a report published by the WHO[73] and in a follow-up article,[78] suggestions were made about how the international medical and scientific community could help the developing countries in establishing programs for the control of hemoglobinopathies. These concepts were based in part on the success of the hemoglobin field over the past 30 years in evolving programs for the control of the thalassemias in several developing countries by the development of north/south partnerships, that is a partnership between experts in centers in the developed countries and those in whom the skills were lacking in the developing world. The natural evolution of north/south partnerships is the development of south/south partnerships in which those developing countries that have gained skills in the diagnosis and treatment of genetic disorders can form partnerships with countries in which these skills are lacking. Currently, several of the centers in developing countries that were established by north/south partnerships are taking forward the concept of helping neighboring countries.

None of these developments will move forward successfully without some form of external support from international health organizations. Like many of the developing country governments, to date these bodies have prioritized more immediate health problems such as those posed by communicable disease, malnutrition, and dysfunctional healthcare systems and, as a consequence, have shown little interest in the hemoglobinopathies. At the time of writing there does appear to be at least some recognition on their part of the increasing health burden posed by the common inherited disorders of hemoglobin. For example, the next phase of the Global Burden of Disease study will include the hemoglobinopathies in its assessment of the relative roles of different diseases in the overall economic burden of disease.[79]

Genetic Modulation of Sickle Cell Disease and Thalassemia

Martin H. Steinberg and Ronald L. Nagel

INTRODUCTION

Sickle cell anemia is a typical mendelian, single gene disease. Nevertheless, because of its characteristic phenotypic heterogeneity it resembles a multigenic trait. That is, the mutation in *HBB* is necessary, but alone insufficient to account for the phenotypic differences among patients, and other genes and the environment are likely to modulate its phenotype. In β thalassemia, and even in HbH disease, genotype–phenotype correlations are also often difficult to establish. Modulation of the phenotypes of these disorders by epistatic and other modifying genes has been a subject of increasing interest. Although studies based on candidate-modulating genes – genes chosen for study on the basis of their possible affects on a phenotype – have started to suggest genes and pathways that might modulate the phenotype of sickle cell anemia, a complete picture of genetic modulators should emerge as genome-wide association studies mature.

It is likely that fetal hemoglobin (HbF) concentration, and its distribution among erythrocytes is the major genetic modulator of both sickle cell disease and the β thalassemias. The coincidence of α thalassemia with sickle cell anemia or β thalassemia is another powerful modulatory influence. Individually, other genetic modulators are likely to have small effects, yet together the interactions of modulatory genes (and environmental factors) might have an important influence on morbidity and mortality.

In this chapter we will first discuss HbF and the genetic elements and genes that might modulate its levels and then the effects of α thalassemia in sickle cell disease and β thalassemia. Finally we will look at genetic association studies that have attempted to link polymorphisms in many genes with the phenotypes of sickle cell disease and thalassemia. As in other chapters, we will try to summarize and consolidate information available in the first edition of this book and concentrate on more recent data.

HbF

HbF ($\alpha_2\gamma_2$) is the best-known modulator of sickle cell anemia and β thalassemia. Its effect in sickle cell disease is mediated principally by its ability to inhibit HbS polymerization. In β thalassemia, HbF compensates for the reduced expression of the β-globin gene, with the resulting deficit of HbA and severe anemia.

HbF concentrations vary considerably among patients with sickle cell disease and β thalassemia, suggesting that there is genetic regulation of γ-globin gene (*HBG1, HBG2*) expression and HbF levels.[1–5]

Initially, only very high levels of HbF were considered capable of influencing the phenotype of sickle cell anemia. Further epidemiological studies suggested that any increment in HbF was clinically and perhaps therapeutically important.[6–8]

Haplotypes of the β-Globin (*HBB*) Genelike Cluster in Sickle Cell Anemia and β Thalassemia

An important event for understanding the genetic heterogeneity of sickle cell anemia was the discovery that the β^S-globin gene (*HBB* glu6val) was in linkage disequilibrium (LD) with a polymorphic site in its 3′ flanking region that was identifiable by a Hpa I restriction endonuclease cleavage site (Fig. 27.1). The complexity of this linkage was suggested by the finding that the Hpa I single nucleotide polymorphism (SNP), a recognition site for cleavage of DNA by this restriction endonuclease, was territorially segregated in Atlantic West Africa, Bantu-speaking central Africa and central west Africa, where this SNP was either negatively or positively linked to the HbS mutation (Fig. 27.1). A β-globin gene cluster haplotype was based on a series of restriction endonuclease–defined SNPs in and surrounding this gene cluster.[9,10]

The β^S-globin gene was present on three different haplotypes, and each haplotype was localized to one of three geographical regions of Africa.[11] This suggested that the β^S gene had at least three origins, with subsequent expansion of the frequency of the abnormal gene in each area of origin (Fig. 27.1). Other independent origins of the HbS mutation occurred in Cameroon (Cameroon haplotype) and in the Indian subcontinent (Arab–Indian haplotype). The origins of the HbS gene in Africa, its expansion within Africa, the role of *Plasmodium falciparum* in the selection of this gene, its spread throughout the world, and the genetic differences among HbS gene haplotypes have been extensively reviewed.[12–18]

A C-T polymorphism 158 bp 5′ to *HBG2* (rs7482144) in carriers of Senegal and Arab–Indian haplotypes is strongly associated with HbF levels. Nevertheless, there is considerable diversity of HbF levels in carriers of this SNP, suggesting that other modulatory elements could have an effect. One study suggested that the β-globin gene cluster

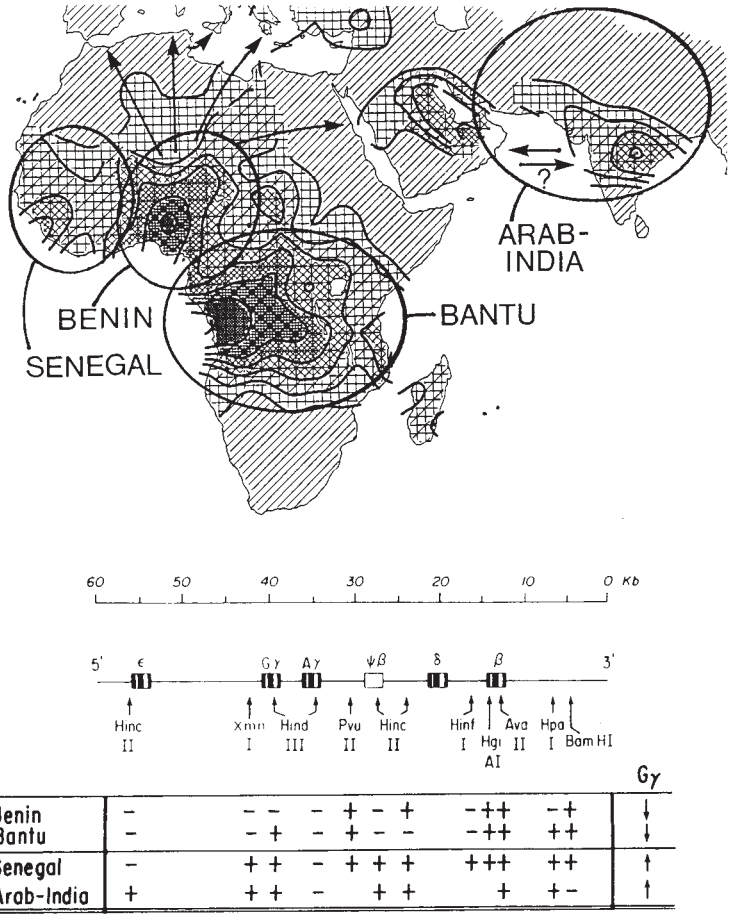

Figure 27.1. Haplotypes of the β-like globin gene cluster. (Above) Africa, the Mideast, and India showing regions of greatest frequency of their cognate haplotypes and the fall in this frequency moving outward from the center. Arrows depict possible routes of gene flow. (Below) This group of genes and their associated regulatory elements corresponds to a 60-kb stretch of DNA that contains the β-globin gene (*HBB*) and other highly homologous globin genes including the $^{G}\gamma$- and $^{A}\gamma$-globin genes (*HBG2*, *HBG1*, the δ-globin gene [*HBD*], the ε-globin gene [*HBE1*], and some pseudogenes). It is generally inherited en bloc but a "hot spot" of recombination has been located around the ψβ-δ region. Depicted by arrows are also the location of the sites that are polymorphic in human populations and cleaved by several restriction endonucleases. Haplotypes correspond to a set of SNPs identified by the presence or absence of selected restriction endonuclease cleavage sites. Although approximately 20 different haplotypes are found in different ethnic groups, only five–seven of them are frequent.

haplotype, independent of HbF level, is a correlate of survival in hydroxyurea-treated sickle cell anemia patients.[19] How this might occur is unclear; other modifying genes or elements might be linked to the β-globin like cluster, although to date, a haplotype-associated effect on HbF concentration is the sole known modulating factor.

Molecular Characteristics of the African and Indo–European β^s-linked Haplotypes. SNPs that define a haplotype are present in a 63-kb stretch of DNA subdivided into a 34-kb 5′, 19-kb 3′, and 9 kb central domain. Many other SNPs are present in these haplotype blocks and some could modulate the expression of the γ-globin genes and the accumulation of HbF; however, a mechanism for modulation of HbF gene expression is still lacking.

Atypical haplotypes in sickle cell anemia usually result from recombination between common and rare haplotypes. In African Americans, because of their genetic diversity, many atypical haplotypes are found.[20] In the central domain, 5′ to the δ-globin gene, is a "hot spot" for recombination.

When a 5′ subhaplotype, including the β-globinlike gene cluster locus control region (LCR, Chapter 5), becomes linked to a β^S-globin gene by recombination, polymorphisms in the LCR or any region 5′ to the site of recombination need not be the same as that linked to the β^S-globin gene in the original haplotype. For example, a 5′ Benin subhaplotype from a β^A chromosome might contain SNPs distinct from those of the 5′ Benin subhaplotype linked to the β^S-globin gene. This is a consequence of the relatively short time the β^S-globin gene has been linked to the 5′ Benin haplotype compared with the β^A-globin gene. This longer period of evolution allows for many more SNPs to be associated with the LCR. In some atypical haplotypes of African Americans, the 5′ subhaplotype is likely to be of Caucasian origin, further uncoupling the β^S-globin gene from the influence of genetic elements that could have coevolved to maintain high HbF levels.

LD between the β^S-globin gene and the Arab–Indian haplotype was discovered independently in sickle cell anemia patients inhabiting the eastern oasis of Saudi Arabia. This haplotype is also linked to the C-T SNP 5′ to *HBG2*. The Arab–Indian haplotype also has a unique $(AT)_9T_5$ repeat sequence 5′ to the β gene and an unusual sequence in HS-2 of the LCR. The $(AT)_9T_5$ motif lies within a negative regulatory region between nucleotides −610 and −490, and binds the protein BP-1, a putative repressor of gene expression, which was postulated to influence the fractional concentration of HbS in sickle cell trait (HbAS).[21,22] Nevertheless,

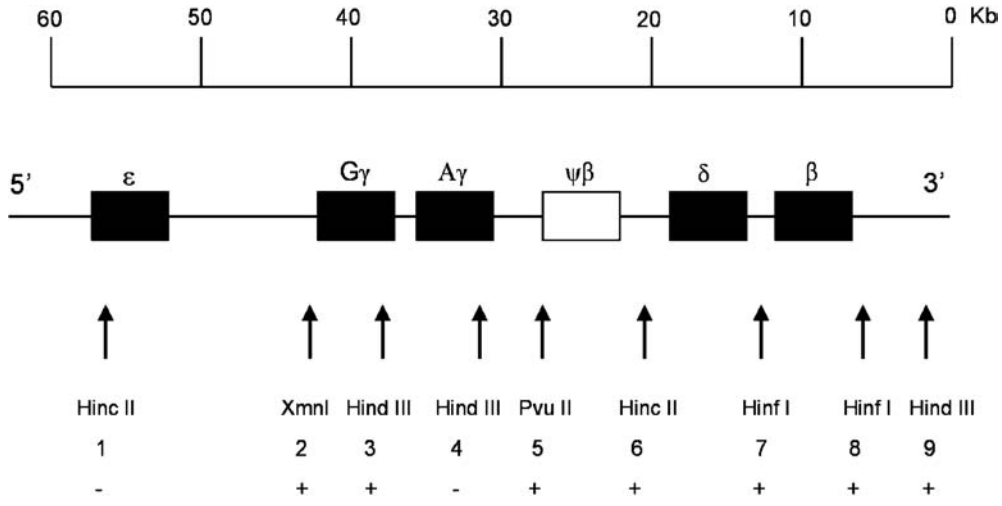

Figure 27.2. The β-like globin gene cluster and the 5′ $^{G}\gamma$-158 C-T SNP. The restriction endonuclease sites defining the β-like globin gene cluster are shown, including the 5′ $^{G}\gamma$-158 C-T SNP (rs7482144) (site number 2) that characterizes the Senegal and Arab–India haplotype. Sickle cell anemia patients who are compound heterozygotes for a Senegal and Benin chromosome typically have between 6% and 10% HbF, whereas homozygotes can have up to 20% HbF. These numbers are modulated by age, sex, hydroxyurea treatment, and likely, other genetic differences among patients.

although Indian subjects with HbAS have a lower percentage of HbS than subjects of African descent, this might be a result of α thalassemia or even iron deficiency (Chapter 23). In 5′ HS-2 of the Arab–Indian haplotype, the AT repeat region has the unique form $(AT)_{10}$ACACATATACGT$(AT)_{12}$. How and if these and other polymorphisms modulate HbF and $^{G}\gamma$-globin chain levels in the Arab–Indian and Senegal haplotypes is unclear.

In β thalassemia, different mutations were associated with each haplotype and more than one haplotype was linked to the same thalassemia mutation.

Effects of β-Globin Gene Cluster Haplotype on HbF

Sickle Cell Anemia. Any effect of the β-globin gene cluster haplotype on the phenotype of sickle cell anemia and β thalassemia appears to be dependent on the HbF level associated with a haplotype. This, in turn, is associated with the presence of the 5′ *HBG2* C-T SNP (rs7482144) and perhaps other *cis*-acting elements (Fig. 27.2). Other studies have suggested that regions 5′ to the γ-globin genes have regulatory importance. Multiple point mutations in the promoters of the γ-globin genes have been found to modulate γ-globin gene expression and cause the nondeletion HPFH phenotype (Chapter 7).

Erythroid colonies derived from precursor cells obtained from carriers of HbAS with the Arab–Indian haplotype and normal HbF concentration synthesize more HbF than colonies derived from controls.[23,24] Erythroid colony growth in vitro might mimic the perturbed erythropoiesis that occurs with hemolysis, suggesting that hematopoietic stress might be needed for the −158 *HBG2* C-T SNP to increase levels of HbF. In normal adults and neonates, the −158 C-T SNP is also associated with small but statistically significant increases in the synthesis of HbF and $^{G}\gamma$-globin chains.[25,26]

The Cameroon haplotype and Mediterranean haplotypes II and VI have in common a high $^{G}\gamma$:$^{A}\gamma$ ratio but lack the −158 C-T SNP. Haplotype II is linked to β thalassemia and to a 4-bp deletion (AGCA) in the region of a GCA repeat at −124 to −127 bp relative to the $^{A}\gamma$ CAP-site.[27] This 4-bp deletion has been reported in the promoters of the $^{A}\gamma$ alleles on both β^{A} and β^{S} chromosomes; no effect on the expression of the $^{A}\gamma$-globin gene was noted however.[28] It was suggested that the 4-bp deletion is a common polymorphism linked to the $^{A}\gamma$ gene (see later). Other polymorphisms that might be associated with HbF level have been called the pre-γ framework.[29]

β Thalassemia. Many different mutations cause β thalassemia, making an understanding of the molecular basis of HbF modulation in β thalassemia more difficult. Most studies suggest that the −158 C-T *HBG2* SNP is a major modulating factor.[28,30,31] One study of polymorphisms related to high HbF suggested that a haplotype of the $^{A}\gamma$-δ-globin intergenic region, the motif $(TA)_9N_{10}(TA)_{10}$ in HS-2, and the pre-$^{G}\gamma$ haplotype were sufficient but not necessary for high HbF expression. The genetic determinant(s) of high HbF without HPFH was linked to a specific $^{A}\gamma$-δ intergenic haplotype.[32]

In HbE–β thalassemia, the Senegal haplotype but not the (AT)(x)T(y) 5′ to the β-globin gene was linked to the high-HbF phenotype.[33]

More detailed studies of HbE–β^0 thalassemia examined 67 SNPs within the β-globin genelike cluster in two groups of unrelated patients, all of whom had a normal α-globin genotype. Approximately 200 patients had mild disease and 300 had severe disease when severity was graded by a clinical scoring system.[34] The SNPs associated with disease

severity and HbF comprised two distinct LD blocks, one containing the β-globin gene and the other extending from the LCR to the δ-globin gene, and they were separated by a recombination hotspot in the region of the β-globin gene promoter. Forty-five SNPs within the interval, including the LCR region and the δ-globin gene, showed strong association with disease severity. The strongest association was observed with the −158 C-T *HBG2* SNP, but this explained only approximately 5% and 8% of the HbF variation in the two groups. Carriers of the T allele were more likely to have a milder disease course and higher level HbF in both the mild and severe patient groups. The T allele was always in *cis* with the HbE allele. Although it seems likely that the association with disease severity is mediated through the effect on HbF level (severe cases, 32.7% ± 11.7%; mild cases, 39.2% ± 11.6%), these differences are small and a mechanistic explanation for the differences in HbF is still lacking.

Genetic Modulation of HbF

HbF expression is regulated by complex interactions among chromosome remodeling activities, transcription factors, genes modulating erythropoiesis, and elements linked to the β-globin gene cluster (Chapters 4 and 5). This complexity provides many sites for modulation of HbF level in sickle cell disease and thalassemia.

LCR and HbF. With rare exceptions, the only *cis*-acting SNP consistently associated with HbF levels in sickle cell anemia has been the aforementioned −158 C-T transversion 5′ to *HBG2*. Most studies of the influence of the LCR on HbF production have focused on 5′ HS-2, which appears to be the only 5′ hypersensitive site that is polymorphic among HbS-associated haplotypes. Because this region probably has some regulatory role in globin gene transcription, it was of interest to see if polymorphisms of this region were associated with phenotypic variation in sickle cell anemia and the results of these studies were previously summarized.[13] To date, SNPs in the LCR associated with HbF in sickle cell anemia have yet to be pinpointed. In a sickle cell anemia patient homozygous for the Benin haplotype with a HbF of 21% and with 65% $^{G}\gamma$-chains, the sequence of HS-2 was characteristic of the Senegal type but the −158 C-T SNP was absent, suggesting a crossover 5′ to the $^{G}\gamma$-globin gene. The Senegal HS-2 is distinguished by the presence of Sp1 and GATA-binding sites and a motif similar to that found 5′ to the BP-1–binding site; however, the functional significance of this association is not known. HbF levels in six Benin haplotype homozygotes with a Senegal haplotype HS-2 were between 2.6% and 8.5%, suggesting that this polymorphism alone did not lead to increased levels of HbF of the magnitude often seen in carriers of a Senegal haplotype.

Polymorphisms in a tandem repeat of the sequence $(TA)_xN_{10-12}(TA)_y$ that contains a Hox2-binding site were examined in 100 patients with sickle cell anemia aged 1–18 years.[35] Nearly 8% of chromosomes had a discordance in the HS-2 tandem repeat that was not characteristic of the haplotype.[36,37] A region between −1445 and −1225 5′ to the promoter of the $^{G}\gamma$-globin gene was found to vary among haplotypes. Senegal–Benin chromosomes associated with modest HbF levels had a likely breakpoint for recombination upstream of −1500 bp 5′ to $^{G}\gamma$-globin gene promoter. In contrast, when a high HbF was present with the Senegal–Benin chromosome recombination, the breakpoint was 3′ to position −369 to −309 in the $^{G}\gamma$-globin gene promoter. In HbAS with a Benin haplotype, when the normal chromosome had the HS-2 $(TA)_9$ $N_{12}(TA)_{10}$ structure, HbF (0.9%) and F cells (8.3%) were approximately twice as high as with the presence of other configurations for this region.[38] These data suggest that HbF is influenced by elements 3′ to HS-2 and 5′ to the γ-globin gene promoter.

F-cell numbers in Benin haplotype HbAS carriers were more strongly associated with the $(TA)_9N_{12}(TA)_{10}$ configuration of HS-2 of β^A chromosomes than the −158 C-T SNP.[39] These subjects did not have hemolytic anemia so the results are less likely to reflect differential F cell survival and more likely to estimate HbF production.

Although other *cis*-acting elements, for example, in additional phylogenetically conserved regions of the LCR outside the core sequences of its constituent hypersensitive sites, might partake in the regulation of γ-globin gene transcription; definitive associations have not yet been found.[13]

The activity of constructs containing variant HS-2 enhancers derived from HbS chromosomes was studied to examine the functional effects of these polymorphisms.[40] A relationship of reporter gene activity with HbF and the β-globin gene cluster haplotype was not found. In a multiplex assay permitting simultaneous analysis of three polymorphic *cis*-acting elements spanning 53 kb of the β-globin gene cluster, concordance between polymorphic alleles in γ- and β-globin gene promoters was identified. SNPs in HS-2 of the LCR were found juxtaposed to atypical *cis* alleles in the γ-globin gene promoter. Analysis of many such hybrid haplotype chromosomes suggested that polymorphisms in the γ-globin gene promoter exerted the dominant influence on HbF level in sickle cell disease.[5]

β-Globin Gene Silencer. Located −530 bp 5′ to the β-globin gene is an AT-rich region with the core structure $(AT)_x(T)_y$, which is polymorphic and linked to the β-globin gene cluster haplotype. This element has been proposed as a β-globin gene silencer that might influence the expression of the β-globin gene by variably binding a putative repressor protein, BP-1, depending on the $(AT)_x(T)_y$ composition.[41] BP-1 is a member of the homeobox gene family and the Distal-less subfamily, genes important in early development. BP-1 protein can repress the β-globin gene promoter and in the human erythroid cell line MB-02; its expression decreases upon induction of the β-globin gene.[21] By modulating erythropoiesis, BP-1 might also effect HbF production.[22]

The Arab–Indian motif has a higher affinity for BP-1 than the Bantu haplotype motif. This could be reflected

at the protein level by less HbS in Indian carriers of the β^S gene and a normal α-globin genotype, when compared with blacks with HbAS, however, this interpretation, as discussed in Chapter 22, is not clear-cut. $(AT)_9(T)_5$, along with the −158 C-T polymorphism, can be associated with high HbF in some homozygous β thalassemia patients. In these patients, the $(AT)_9(T)_5$ motif was associated with approximately 10 g/dL HbF, whereas $(AT)_7(T)_7$ was accompanied by approximately 5 g/dL of HbF.

Four–base pair Deletion Linked to the $^A\gamma$ Gene. Only the Cameroon haplotype β^S chromosome is associated with an AGCA deletion at nucleotides −222 to −225 5′ to the β-globin gene and is always linked to the $^A\gamma^T$ allele. The effects of this deletion on γ-globin gene expression are controversial and unlikely to affect carriers of other haplotypes. In a study of sickle cell anemia in which a Cameroon haplotype was *trans* to a typical HbS haplotype, HbF levels, packed cell volume (PCV) and mean corpuscular volume was similar whatever the haplotype in *trans*.[20] It was also suggested that the 4-bp deletion was associated with decreased expression of not only the $^A\gamma^T$-globin gene, but also of the $^G\gamma$-globin gene in cis. Studies in β thalassemia in which the 4-bp deletion was present also suggested decreased $^G\gamma$ gene expression in *cis* to the $^A\gamma^T$ allele. Together, these results implicate the region of the 4-bp deletion as a possible *cis*-acting element that augments the expression of both γ-globin genes when combined with a *trans*-acting factor.[42]

$^G\gamma$ Gene 5′ Regulatory Region. Approximately 1.65–1.15 kb 5′ to the $^G\gamma$ gene lies an area of 0.5 kb proposed to be another region that potentially has a regulatory role in γ-globin gene expression.[29] Designated the pre-$^G\gamma$ framework, this region was found to have four polymorphic variants that, like most other *cis*-acting sequences with possible regulatory roles, are linked to the β-gene cluster haplotype. This region contains four GATA-1–binding sites and Sp1 and CRE protein–binding domains. Strongest protein binding was associated with the Senegal pre-$^G\gamma$ framework and the Benin haplotype–linked pre-$^G\gamma$ enhancer activity was sevenfold lower than the Bantu and Senegal type pre-$^G\gamma$ framework. The physiological significance of these findings remains unclear.

A SNP, GATA→GAGA, in a GATA site that is in a putative silencing element at nucleotide −567 5′ of the $^G\gamma$-globin gene promoter was associated with increased HbF in two otherwise normal individuals. This mutation alters a GATA-1–binding motif to a GAGA sequence. DNA–protein binding assays showed that this GATA motif was capable of binding GATA-1 transcription factor in vitro and in vivo. Truncation analyses of $^G\gamma$-globin gene promoter linked to a luciferase reporter gene revealed a negative regulatory activity present between nucleotides −675 and −526. In addition, the T→G mutation at the GATA motif increased the promoter activity by two- to threefold in transiently transfected erythroid cell lines. The binding motif is uniquely conserved in simian primates with a fetal pattern of γ-globin gene expression. This GATA motif appears to have a functional role in silencing γ-globin gene expression in adults. The T→G mutation in this motif disrupts GATA-1 binding and the associated repressor complex, abolishing its silencing effect and resulting in the up regulation of γ-globin gene expression.[43]

The functional importance of this site was supported by studies in transgenic adult β-YAC mice, where it was shown that during definitive erythropoiesis, γ-globin gene expression is silenced, in part, by binding a protein complex containing GATA-1, FOG-1, and Mi2 at the −566/−567 GATA sites of both γ-globin gene promoters. Chromatin immunoprecipitation assays showed that GATA-1, FOG-1, and Mi2 were recruited to the −566 or the −567 GATA sites of the γ-globin gene promoters when γ-expression was low, but not when these genes were being expressed.[44]

A C-T SNP in 3′ HS1 was associated with increased HbF in 11 β thalassemia intermedia patients lacking other explanations for their mild phenotype.[45] This report is difficult to interpret because the β thalassemia mutations in these cases were diverse and two individuals had HbF levels less than 10%.

Polymorphisms in trans*-acting Regulatory Elements Regulating HbF Expression.* It has been estimated that the −158 SNP 5′ to *HBG2* and other postulated haplotype-associated effects on HbF account for less than 25% the variability of HbF in sickle cell anemia. This suggests that *trans*-acting regulatory elements exert control over HbF levels.

Putative *trans*-acting elements modulating HbF include four quantitative trait loci (QTLs). These are the F cell production locus, a QTL at Xp22 associated with F cell number;[4] a QTL at 6q22.3-23.2 associated with F cell numbers first described in an extended Asian–Indian family;[1,2,46] a QTL at chromosome 8q that appeared to interact with the −158 C → T SNP;[47] and a QTL at 2p16.1, identified in a genome-wide association study of healthy adults that mapped to *BCL11A*, a zinc-finger protein, which accounted for 15% of F cell variance.[48] These elements were first associated with F cells or HbF in individuals with β thalassemia trait or those who did not have a hemoglobinopathy. Further examination of some of these QTLs was undertaken to identify the genes and polymorphisms associated with modulation of HbF in sickle cell anemia and β thalassemia.

A candidate gene screening study in patients with sickle cell anemia showed associations with HbF and SNPs in phosphodiesterase 7 (*PDE7B*), microtubule-associated protein 7 (*MAP7*), mitogen-activated protein kinase kinase kinase 5 (*MAP3K5*), and peroxisomal biogenesis factor 7 (*PEX7*). These genes abut but were not within 6q 23.2.[3] It had been hypothesized that variable expression of a collection of linked genes of functional interdependence might be associated with certain phenotypes,[49] and long-range LD, as seen in this QTL, has been reported for other chromosomal regions.[50]

To refine further the functional importance of the 6q QTL direct sequencing of five protein-coding genes, *ALDH8A1*, *HBS1L*, *MYB*, *AHI1*, and *PDE7B*, within the

1.5-Mb candidate interval of 6q23 was done but failed to detect mutations that could be associated with HbF modulation.[51] The expression profile of these genes in cultured erythroid cells of healthy adults with non-gene deletion hereditary persistence of HbF (HPFH) found that two genes, *MYB* and *HBS1L*, were down regulated. Transfection of K562 cells with cDNA of *MYB* and *HBS1L* showed that overexpression of only *MYB* inhibited γ-globin gene expression. Low levels of *MYB* were associated with low cell expansion and accelerated erythroid differentiation, suggesting that differences in the intrinsic levels of *MYB* might account for some variation in adult HbF levels by its effect on the cell cycle.[52] In northern European families, polymorphisms within and 5′ to *HBS1L* were strongly associated with F cell levels, accounting for 17.6% of the F cell variance. Although mRNA levels of *HBS1L* and *MYB* in erythroid precursors are positively correlated, only *HBS1L* expression correlated with high F cells, suggesting that *HBS1L* variants modulate HbF.[53]

A QTL at chromosome 8q appeared to interact with the −158 C-T SNP to modulate HbF levels in the same Asian–Indian family in which the 6q QTL was first discovered.[2,47] In more than 870 dizygotic twins, effects of the 8q QTL on HbF were also conditional on the genotype of the −158 *HBG2* C-T SNP.[54]

Panels of haplotype tagging SNPs in the β-globin genelike cluster and in QTLs on chromosomes 8q and Xp were genotyped in two independent sickle cell anemia patient groups to study their association with baseline HbF levels. In one group of 327 individuals, three SNPs in *TOX* (thymus high mobility protein; 8q12.1) were associated with HbF. Three additional SNPs in *TOX* showed significant association in a second group of 987 individuals. Joint analysis of all SNPs and covariates confirmed the association with *TOX* and identified SNPs potentially associated with HbF in two genes in the Xp22.2-p22.3 QTL. SNPs in *TOX* and a few other genes were associated with the HbF response to hydroxyurea treatment in sickle cell anemia.[55] *TOX* belongs to a conserved high-mobility group box protein family that binds the minor groove of DNA.

Eight hundred and fifty SNPs in 320 candidate genes in the β-globin genelike cluster, QTL on chromosomes 6q, 8q, and Xp and other candidate genes were studied in a group of 1,518 adults and children with sickle cell anemia and validated in an independent group of 211 adults. HbF concentration was modeled as a continuous variable with values in a finite interval by using a novel Bayesian approach. In individuals aged 24 years or older, five SNPs in *TOX*, two SNPs in the β-globin genelike cluster, two SNPs in the Xp QTL, and one SNP in chromosome 15q22 were associated with HbF. Four SNPs in 15q22 were associated with HbF only in the larger patient sample. When patients younger than 24 years were examined, additional genes, including four with roles in nitric oxide (NO) metabolism, were associated with HbF level. These observations raise the possibility that different genes might modulate the rate of decline of HbF and the final HbF levels in sickle cell anemia.[56]

The results of this analysis confirmed work where more traditional analytical approaches showed associations of SNPs in *TOX*, *GPM6B*, and the β-globin genelike cluster with HbF levels. Included in the 15q22-21 interval are *MAP2K1*, *SMAD3*, and *AQP9*. None of these genes have a known connection to HbF synthesis or erythropoiesis, and this region is not a known QTL associated with HbF.

Genome-wide association studies focused on HbF concentration in normal individuals and patients with β thalassemia trait, β thalassemia intermedia, and sickle cell anemia, have been reported.[57] Six SNPs in *BCL11A* (2p16.1) were first found to be associated with F cells in 179 normal adults[58] with the highest and lowest 5% of F cell numbers. *BCL11A*, is a highly conserved zinc-finger protein, and codes for a transcription factor containing three C2H2-type zinc finger motifs, a proline rich region, and an acidic domain.[48] Similar associations of SNPs in *BCL11A* were found in Sardinian β thalassemia patients and by focused genotyping, in more than 1,200 patients with sickle cell anemia. In the β thalassemia patients the C allele of SNP rs1188686 was associated with higher HbF in the general population and in patients with thalassemia intermedia compared with thalassemia major.

With genome-wide association studies of 113 parents of Thai HbE-β thalassemia patients and 255 unrelated African Americans with sickle cell anemia, and by focused genotyping of 250 parents of β thalassemia major patients from Hong Kong, association of HbF and F cells were found with SNP rs766432, one of the same SNPs of *BCL11A* previously reported. In the patients with sickle cell anemia, homozygotes for the C allele of SNP rs766432 had an average of 7% HbF compared with 3% HbF in patients homozygous for the A allele. These findings in at least four different populations are consistent with an aboriginal *BCL11A* variant in Yorubans that is highly conserved among ancestral populations, even as the haplotype blocks containing this gene have diverged. Together, these observations suggest that possible functional motifs responsible for modulating HbF level or F cells might reside within or immediately adjacent to a 3-kb region bounded by rs1427407 and rs4671393 in intron 2 of *BCL11A*.

A small guanosine triphosphate (GTP)-binding protein, secretion-associated and RAS-related (*SAR1A*) protein is inducible by hydroxyurea and might play a pivotal role in induction of γ-globin gene expression via its role in erythroid maturation. Polymorphisms in the *SAR1A* promoter were associated with differences HbF levels or the HbF response to hydroxyurea in patients with sickle cell anemia. Three SNPs in the upstream 5′ untranslated region (−809 C-T, −502 G-T and −385 C-A) were significantly associated with the HbF response in sickle cell anemia patients treated with hydroxyurea and four SNPs (rs2310991, −809 C-T, −385 C-A and rs4282891) were significantly associated with the change in absolute HbF level after 2 years of treatment.[59,60]

Effects of β-Globin Gene Cluster Haplotype on the Phenotype of Sickle Cell Disease. Generally, a haplotype is

associated with characteristic hematological and clinical findings, although there is considerable heterogeneity within any haplotype. For example, carriers of the HbS gene on Senegal or Arab–Indian haplotype usually have the highest HbF level and PCV and the mildest clinical course. Individuals with Bantu haplotypes have the lowest HbF level and PCV and the most severe clinical course. Carriers of the Benin haplotype have intermediate features (reviewed in ref. 13).

Studies of small numbers of African patients with sickle cell anemia and different β-globin gene cluster haplotypes who had distinct hematological characteristics first suggested that haplotype could be a marker for the phenotypic heterogeneity of sickle cell anemia. In most of Africa, the environmental, nutritional, and infectious obstacles make it difficult to distinguish the role of haplotype in modulating the course of disease, but clinical differences have been noted. It appears that Africans with the Senegal haplotype fare better than those with other common haplotypes, but there are too few clinical data to permit dogmatism.[61]

Most of the detailed and larger studies of the clinical and hematological effects of haplotype in sickle cell anemia have been in regions where the HbS gene arrived by gene flow, and after many years of genetic admixture, patients in such regions are usually haplotype heterozygotes, which complicates interpretation of the association of haplotype with phenotype. Reports of the clinical and hematological effects of haplotype in sickle cell anemia should be interpreted carefully because often few patients were studied, the patient's ages differed among series, clinical events might not have been sharply defined, and distinctions between haplotype homozygotes and heterozygotes were often not clearly drawn.

In longitudinal studies from the United States, the Senegal haplotype was associated with fewer hospitalizations and painful episodes.[62,63] An effect of the Senegal haplotype on reducing episodes of acute chest syndrome was of marginal significance. The Bantu haplotype was associated with the highest incidence of organ damage, and renal failure was strongly associated with this haplotype.[64] Both sex and haplotype affect HbF levels in sickle cell anemia. PCV was higher in males with Benin and Bantu haplotypes. Among carriers with a Senegal haplotype, the PCV in males and females was equal and females had the highest HbF. Females with the Senegal haplotype and high HbF can have less hemolysis and therefore higher PCV.[65] Most work suggests that the Arab–Indian haplotype is also associated with milder disease although vasoocclusive events do occur.[66–69]

Lacking a reasonable hypothesis about how the haplotype of the β-globin gene cluster could modify disease severity, other than via an effect on HbF, it seems most reasonable to conclude that the effect of haplotype on the phenotype of disease is mediated through a *cis*-acting effect on HbF.

EFFECTS OF α THALASSEMIA IN SICKLE CELL DISEASE AND β THALASSEMIA

Sickle Cell Disease

Approximately a third of patients with sickle cell anemia have coincidental α thalassemia (Chapter 23). These individuals have less hemolysis, higher PCV, lower mean corpuscular volume, and lower reticulocyte counts (see Table 23.9, Chapter 23). Coincident α thalassemia results in longer erythrocyte lifespan because of the reduction of dense and rigid red cells (Table 23.8, Chapter 23).

α Thalassemia decreased the risk of organ failure in carriers of a Bantu haplotype. In Jamaicans, the absence of α thalassemia coupled with a high HbF presaged benign disease.[70] When phenotypes of sickle cell anemia were clustered into two or three phenotype groups, neither α thalassemia nor the β-globin gene cluster haplotype appeared to influence the clinical events defining the groups.[71]

The benefits and liabilities afforded by the presence or absence of α thalassemia in sickle cell anemia is very likely to be due to its effects on hemolysis. Recent work suggests that concurrent α thalassemia reduces the incidence of stroke, priapism, leg ulceration, and pulmonary hypertension but has little effect or increases the chances of developing osteonecrosis, acute chest syndrome, and painful episodes.[72–75] As discussed in Chapter 11, hemolysis is associated with a proliferative vasculopathy due to decreased bioavailable NO.

β Thalassemia

Concurrent α thalassemia or the presence of α-globin gene duplications modifies the phenotype of β thalassemia. As the pathophysiology of β thalassemia is largely determined by imbalance globin chain synthesis (Chapter 17), concurrent α thalassemia, by reducing the accumulation of α-globin chains, tends to balance the deficit in β-globin chains and causes a milder disease. A sufficient α-globin gene deficit can cause a thalassemia intermedia phenotype in homozygotes or compound heterozygote for severe β-thalassemia mutations where the expected phenotype would be thalassemia major.

Conversely, extra α-globin genes, as seen with chromosomes containing triplicated or quadruplicated α-globin loci, by increasing the imbalance in α:β synthesis, can convert a heterozygote for β thalassemia into a symptomatic thalassemia intermedia.[76,77] One might hypothesize that with an improvement in the α:β globin synthesis ratio and reduced hemolysis, hemolysis-related complications of β thalassemia, which also include pulmonary hypertension, leg ulcers, and perhaps priapism, might also be reduced; however, there are no data on this subject.

Role of α-Hemoglobin Stabilizing Protein. α-Hemoglobin stabilizing protein (*ERAF*, 16p11.2), by binding free α-globin chains, prevents their proteolysis and preserves their ability to form α:β dimers.[78] In β thalassemic mice that

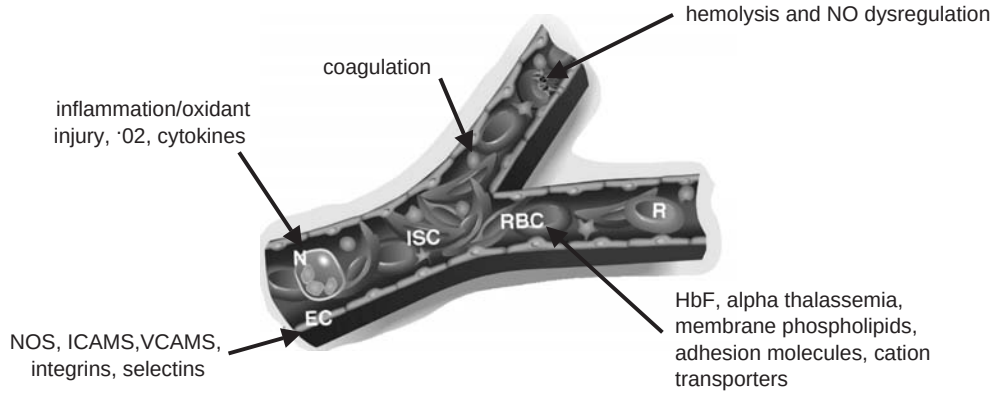

Figure 27.3. Some facets of sickle cell disease pathobiology that might be genetically modulated. (See color plate 27.3.)

are also deficient in α-hemoglobin–stabilizing protein, the phenotype of the β thalassemia was more severe.[79]

The role of α-hemoglobin–stabilizing protein as a modulator of β thalassemia is less conclusive, with no relationship found between haplotypes of α-hemoglobin–stabilizing protein and the severity of HbE–β thalassemia.[80,81] In a study of more than 100 healthy individuals, expression of α-hemoglobin–stabilizing protein was measured. Among six common variants of this protein, four were strongly associated with its expression. In nine anemic patients with heterozygous β thalassemia who also had a triplicated α-globin locus, one variant of α-hemoglobin–stabilizing protein was more common than expected, suggesting that variation in the protein could contribute to some heterogeneity in β thalassemia.[82]

HEMOGLOBIN A_2

HbA_2, a tetramer of α-and δ-globin chains (Chapter 7), impairs the polymerization of HbS to the same extent as the γ-globin chain of HbF. HbA_2 has the advantage of being evenly distributed in all red cells, whereas HbF is sequestered in F cells. The naturally low level of HbA_2 makes it an inconsequential contributor to the total hemoglobin concentration but there are instances when the level of HbA_2 is increased far beyond its usual values. Some exceptionally high HbA_2 levels are the result of deletions that remove the β-globin gene promoters. When HbA_2 and HbF levels are high, their combination might modulate sickle cell disease and cause a milder phenotype, but few patients with these genotypes are available to establish conclusively its phenotype (Chapter 23). With these rare exceptions, it is unlikely that variation in HbA_2 level affects the phenotype of sickle cell anemia.

MODULATION OF THE PHENOTYPE OF SICKLE CELL ANEMIA

Genetic Polymorphisms as Predictors of Disease Severity

The diversity of sickle cell anemia cannot be explained solely by HbF and α-globin gene–linked modulation. Modifying or epistatic genes that potentially affect the pathogenesis of sickle cell anemia and modulate the phenotype of disease include: mediators of hemolysis; vascular remodeling; inflammation; oxidant injury; NO biology; vasoregulation; cell–cell interaction; blood coagulation and hemostasis; growth factors; cytokines and receptors; and transcriptional regulators (Fig. 27.3). These genes have modifying affects independent of effecting HbS polymerization, the mechanism by which both HbF and α thalassemia impact the phenotype of disease (Fig. 27.4). Polymorphisms have been found in candidate genes that might affect the phenotype of sickle cell disease (Table 27.1).[83]

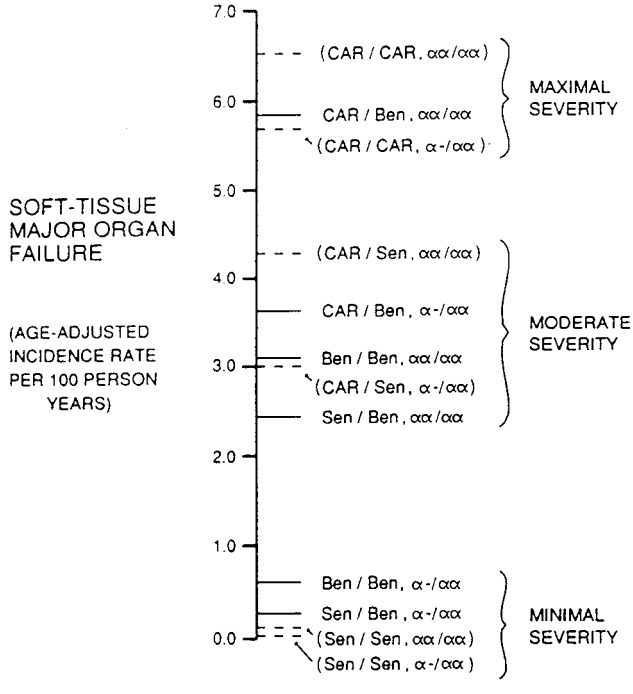

Figure 27.4. The relationships between β-like globin gene cluster haplotypes and clinical features of sickle cell anemia. PCV connotes packed cell volume. The clinical features include events such as osteonecrosis, acute chest syndrome, renal failure, and other common disease complications. These associations of haplotype and phenotype in sickle cell anemia are only generalities, and within each haplotype group there is considerable heterogeneity whose cause is unknown.[168]

Other genetic variants, some mentioned in the text, have been studied and have shown no associations.

A unifying theme emerging from these studies is that polymorphisms in genes of the transforming growth factor–β/bone morphogenetic protein (TGFβ/BMP) pathway appear involved in several subphenotypes of disease and could reflect the hitherto unappreciated role of this very large pathway in the pathobiology of disease.[84]

The first approaches to understanding how genetic polymorphism might modulate the phenotype of sickle cell anemia were based on the selection of candidate genetic modifiers. A candidate gene–based approach is limited by the imagination needed to define likely candidates and alone cannot provide a complete picture of the genetic heterogeneity that must account for the complex pathobiology of any disease. In some studies, picking the "wrong" SNP or choosing insufficient numbers of SNPs in large genes might have lead to false-negative results. Nonsynonymous coding region SNPs are an obvious first choice to examine, but they are the least common. Recent studies suggest that by affecting protein folding, even synonymous SNPs might modulate a genes' function,[85] and genome-wide association studies have yield surprising results in other diseases in which the strongest associations of genotype with phenotype have occurred in gene-poor regions.[86] SNPs that effect gene expression might be even more important, but it is difficult to identify all of these by in silico analysis.

Genome-wide association studies are just beginning and have the promise of unbiased interrogation of the entire genome for an association with a phenotype. Copy number variants can also be assessed with the available technology. Analytical methods for genetic association studies are evolving, and dealing with the problem of false-positive results can be vexing when more than 1 million SNPs can be genotyped across the genome of thousands of cases.[87] Other issues that must be considered in genome-wide association studies include: LD with causative polymorphisms; interpretation of associations with SNPs without an obvious function; gene–gene interaction; gene–environment interaction; and precise phenotype definition.

Painful Episodes. Acute painful episodes are the major clinical event in sickle cell disease. These episodes are one measure of disease severity, and a predictor of early death in adults.[6] The rate of painful episodes varies widely among patients; highest pain rates are found in patients with high PCV and low HbF. In addition to HbF concentration and a possible role of α thalassemia, a genetic basis for the heterogeneous distribution of painful episodes among patients has not been described. Case-control studies are problematic because nearly all patients will have pain, therefore, finding genes that modify the risk of pain will be difficult. SNPs modulating HbF levels in sickle cell anemia

were genotyped in the CSSCD patients and a smaller number of patients from Brazil. SNPs in *BCL11A*, *HBS1L-MYB* and the C-T polymorphism 158 bp 5′ to *HBG2* (rs7482144) were strongly associated with HbF and the rate of painful episodes.[88]

Patient response to opioid analgesics varies considerably, and the efficacy of these drugs is known to depend on genetic variability of their catabolic enzymes and receptors.[89] How this might affect the treatment of the sickle cell acute painful episode is unknown.

Stroke. Most genetic association studies in sickle cell anemia have examined the stroke phenotype (Chapter 19). A family predisposition to stroke in sickle cell disease suggested that inherited modulation of this phenotype was possible.[90] Among the genes associated with stroke in sickle cell anemia, two alleles of vascular adhesion molecule–1 (*VCAM1*), G1238C in the coding region of immunoglobulin domain 5, and, T-1594C, an intronic SNP, had an association with stroke. The coding region SNP was protective, whereas the intronic SNP predisposed to small-vessel stroke.[91,92] Preliminary studies also suggested that the*VCAM1* G1238C SNP was protective for developing high transcranial Doppler flow velocity, which is a strong predictor of stroke in children (Chapter 19).[93] VCAM1 is approximately 19,000 bp long and has nine exons and at least 200 SNPs. Clearly, choosing the "right" SNP is not trivial and an association is likely to identify LD.

Six SNPs in the intercellular adhesion molecule–1 and CD 36 genes (*ICAM1*; *CD36*) were not associated with stroke.[91] When stroke was subdivided into large- and small-vessel disease based on imaging studies, SNPs in the interleukin-4 receptor gene (*IL4R;* nonsynonymous coding region, S503P) predisposed to large vessel stroke, whereas TNFα gene (*TNFA;* noncoding G308A) and β-adrenergic receptor 2 (*ADRB2;* nonsynonymous coding region, Q27E) SNPs were protective. In the small-vessel stroke group, a low-density lipoprotein receptor (*LDLR;* untranslated region) SNP was protective. Homozygosity for the combination of *TNFA* -308 GG and the *IL4R* 503P heterozygosity was associated with a strong predisposition to large-vessel stroke.[92] The endothelium and vascular response to regulators might distinguish small from large blood vessels but a continuum must exist, making the pathophysiological basis of these observations enigmatic.

Human leukocyte antigen (HLA) genes might be risk factors for vascular disease. In sickle cell anemia patients with cerebral infarction, the HLA DRB1*0301 and *0302 alleles increased the risk of stroke and the DRB1*1501 protected from stroke. DQB1*0201, in LD with DRB1*0301, was associated with stroke and DQB1*0602, in LD with DRB1*1501, was protective. HLA genotyping was performed in patients with large-vessel stroke and with small-vessel stroke.[94,95] In the small-vessel stroke group, HLA DPB1*0401 was associated with stroke, whereas DPB1*1701 was protective. In the large-vessel stroke patients, DPB1*0401 was associated with susceptibility, and DPB1*1701 was associated with a trend toward protection. Also, HLA-A*0102 and A∗2612 caused susceptibility to stroke and A∗3301 was protective.

Other genes have been studied in the stroke phenotype. These include the C1565T mutant of the platelet glycoprotein IIIa (*ITPG3*) gene, angiotensinogen (*AGT*), cystathionine B synthase (*CBS*; 278thr 68-bp insertion), cholesterol ester transfer protein (*CETP*; −628A), apolipoprotein C III (*APOC3*; −641A) the C677T polymorphism in 5,10-methylenetetrahydrofolate reductase (*MTHFR*) the plasminogen activator inhibitor–1 gene (*PAI1*), TGFβ receptor 3 (*TGFBR3*), and adenine cyclase 9 (*ADCY9*).[96–99] These studies were all equivocal or negative; however, the sample size was usually insufficient for a definitive result.

It seems unlikely that a still undiscovered gene polymorphisms in any single gene will have a dominant effect on a phenotype of disease. To examine the interactions among genes and their SNPs and to develop a prognostic model for stroke in sickle cell anemia, a bayesian network was developed to analyze SNPs in candidate genes in 1,398 unrelated patients with sickle cell anemia (Fig. 27.5).[72] SNPs in 11 genes and four clinical variables, including α thalassemia and HbF, interacted in a complex network of dependency to modulate the risk of stroke. This network of interactions included three genes, *BMP6*, *TGFBR2*, and *TGFBR3* with a functional role in the TGFβ/BMP pathway and P-selectin (*SELP*). The model was validated in a different population by predicting the occurrence of stroke in unrelated individuals with 98.2% accuracy, predicting the correct outcome for all stroke patients, and for 98% of the nonstroke patients. This gave a 100% true positive rate, a 98.14% true negative rate, and a predictive accuracy of 98.2%. As traditional analytical methods are often inadequate for the discovery of the genetic basis of complex traits in large association studies, bayesian networks are a promising approach. The predictive accuracy of this stroke model is a step toward the development of prognostic tests that are better able to identify patients at risk for stroke. The association in the general population of genes like *SELP* and genes in the TGFβ pathway with stroke suggest that predisposition to stroke might be shared by both sickle cell anemia patients and stroke victims overall.

Gene expression studies have also contributed to understanding predisposition to stroke.[100] When individuals at risk for stroke, estimated based on the presence of circle of Willis disease or history of stroke, were compared with controls, transcripts in genes of inflammation-related pathways expressed in blood-outgrowth endothelial cells were most strongly associated with stroke or predisposition to stroke.

Priapism. SNPs in 44 candidate genes were examined for their association with priapism in 148 patients with sickle cell anemia with priapism and controls who had not developed priapism. Polymorphisms in Klotho (*KL*) showed an association with priapism by genotypic and haplotype analyses.[101] *KL* has a role in NO biochemistry and directly or indirectly promotes endothelial NO production.

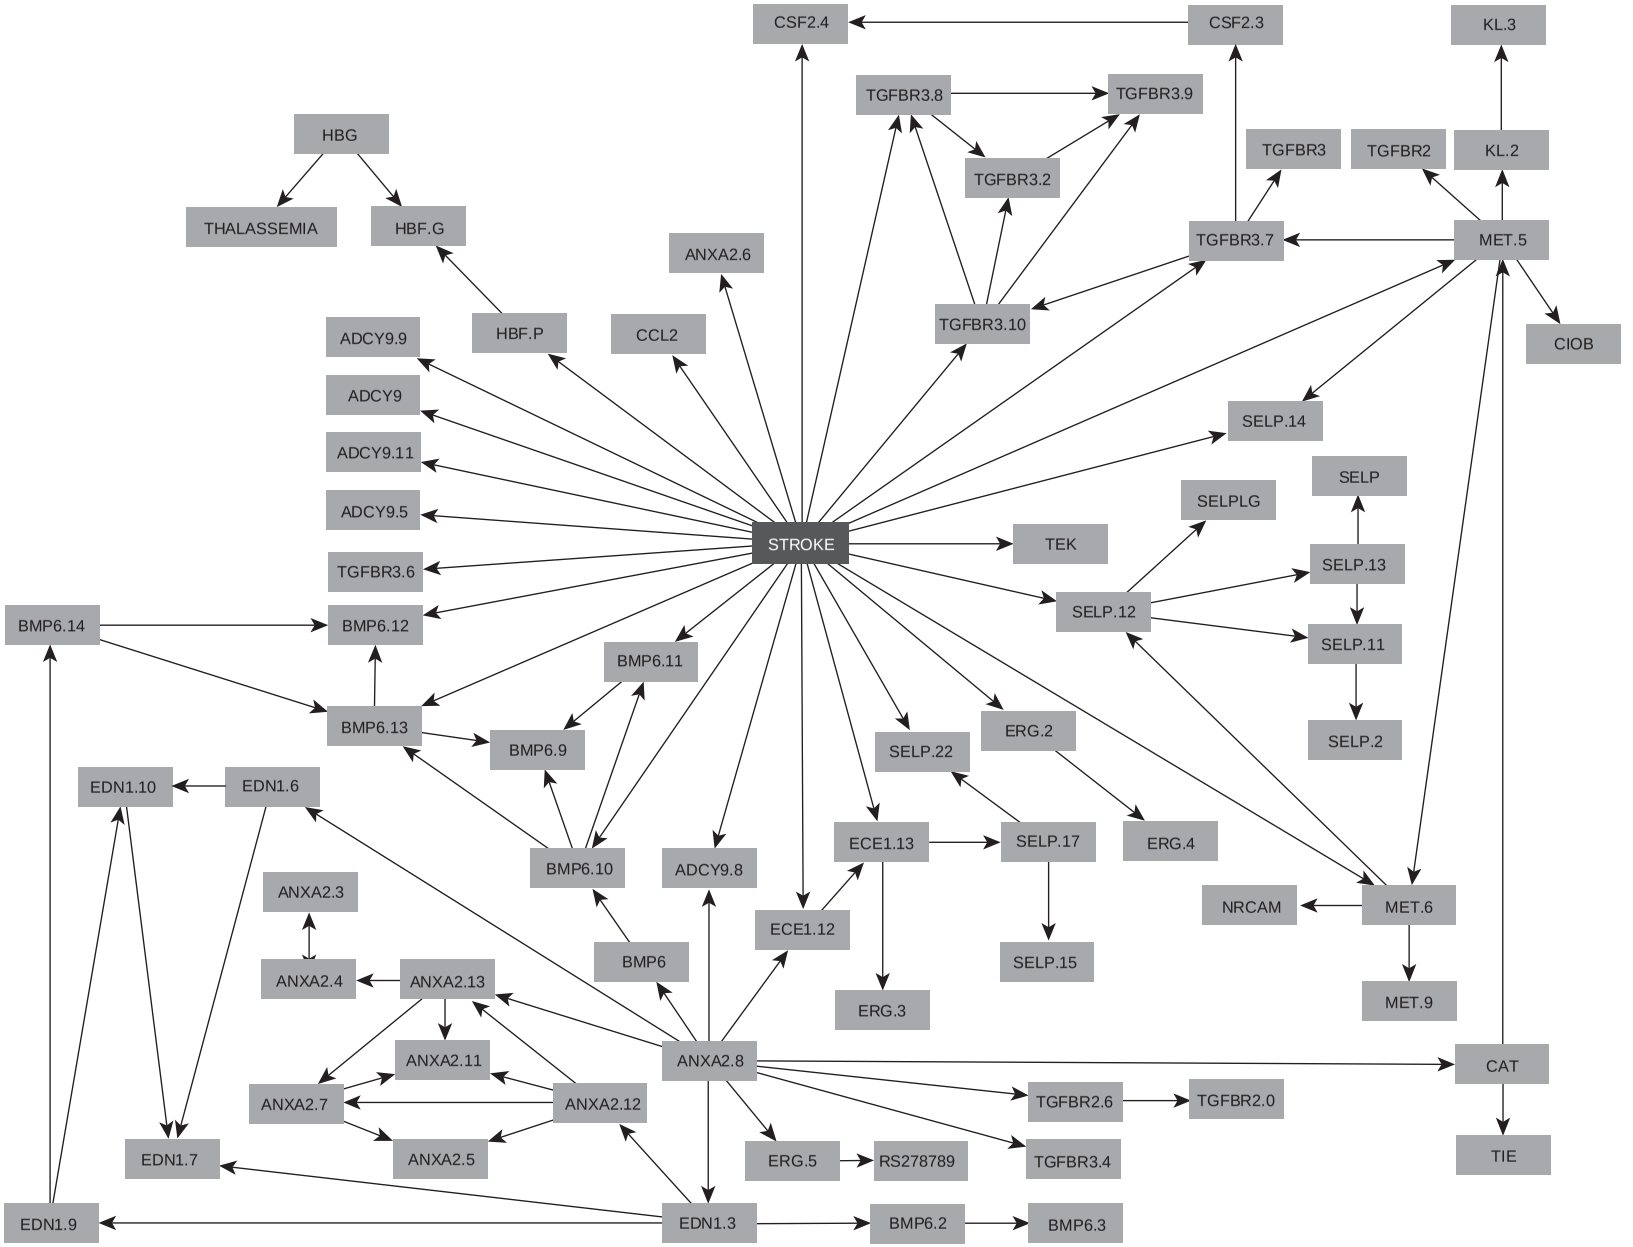

Figure 27.5. A bayesian network describing the associations of SNPs in candidate genes with the likelihood of developing nonhemorrhagic stroke in sickle cell anemia.[72] (See color plate 27.5.)

A strong association was also found between the prevalence of priapism, the severity of hemolysis, and the presence of α thalassemia.[73] Of approximately 200 men older than 18 years, 83 had a history of priapism. A candidate gene study in this population failed to show an association of priapism with SNPs in *KL*, nevertheless, there were associations with SNPs in *TGFBR3, AQP1* and the adhesion molecule, *ITGAV*.[102] Further study of this population, which included 186 men with a mean age of 32.4 years, found that a single coding SNP in *F13A1*, the Factor XIII gene was associated with priapism with an odds ratio of 2.43 for individuals with C/C compared with the C/G genotype.[103]

Osteonecrosis. Osteonecrosis is found in nearly half of all adults with sickle cell anemia. It is one of the so-called vasoocclusive/viscosity-associated phenotypes and it appears to be increased by concurrent α thalassemia (Chapter 19). The C677T polymorphism in *MTHFR* was found in 36% of adults with sickle cell disease and osteonecrosis but only 13% of controls.[94] Nevertheless, other reports failed to confirm this association (reviewed in ref. 78). The C1565T SNP in *ITPB3* and a polymorphism in *PAI1* were not associated with sickle osteonecrosis.[105] These studies all examined small numbers of patients and few SNPs.

When sickle cell anemia patients with osteonecrosis were compared with controls, individuals with osteonecrosis had a higher prevalence of coincident α thalassemia, and there were no differences in PCV or HbF levels. Significant associations were observed with SNPS in seven genes (*BMP6*, *TGFBR2*, *TGFBR3*, *EDN1*, *ERG*, *KL*, and *ECE1*). Additional SNPs, equally distributed within the gene, were typed in all seven genes and a significant association with many SNPs in *KL* and *BMP6* was found.[106] Of the 18 SNPs typed in *KL*, 10 were significantly associated with osteonecrosis. Most of these SNPs were located in the 20-kb region, representing the first half of the first *KL* intron and were in LD with each other. SNPs in *BMP6* (5/14) and *ANXA2* (6/13) were also associated with osteonecrosis; however, these SNPS were distributed throughout the intronic and 3′ untranslated regions of the genes, and disease-associated SNPs tended to be in LD. The distribution of haplotypes of all three genes was significantly different among cases and controls.

These genes might play a role in bone metabolism. Among its many functions, *KL* is a glycosyl hydrolase that participates in a negative regulatory network of the vitamin D endocrine system. BMPs, including *BMP6*, are secreted proteins structurally related to TGFβ and activins and are involved in bone formation and development. *ANXA2*, a member of the calcium-dependent phospholipid-binding protein family, is involved in osteoblast mineralization. Lipid rafts containing annexin-2 seem important for alkaline phosphatase activity in bone. The actual mechanisms by which variants of these genes predispose sickle cell patients to vascular complications are unknown.

Leg Ulcers. Sickle cell leg ulcers are related to hemolysis and associated with SNPs in genes that could affect sickle vasoocclusion. Leg ulcer patients had lower PCV and higher levels of lactate dehydrogenase, bilirubin, aspartate aminotransferase, and reticulocytes than controls. Age-adjusted comparisons showed that sickle cell anemia–α thalassemia was more frequent among controls than cases, suggesting that the likelihood of having leg ulcers was related to the intensity of hemolysis, which is modulated by α thalassemia. In candidate gene association studies, associations were found with SNPs in *KL*, *TEK*, and several genes in the TGFβ/BMP signaling pathway. The *TEK* receptor tyrosine kinase is involved in angiogenesis, whereas the TGFβ/BMP signaling pathway modulates wound healing and angiogenesis, among its other functions.[74]

Bacteremia. Infection, bacteremia, and sepsis are common events in sickle cell anemia. SNPs in candidate genes have been associated with an increased risk of sepsis in other diseases. In a case-control study, bacteremia in sickle cell anemia was associated with SNPs and haplotypes of genes of the TGFβ/BMP pathway such as *BMP6*, *TGFBR3*, *BMPR1A*, *SMAD6*, and *SMAD3*. The TGFβ/BMP pathway might play an important role in immune function.[107]

Renal Disease. Patients with sickle cell anemia associated with a Bantu haplotype are more likely to develop renal failure and other vasoocclusive complications, perhaps because these individuals have the lowest levels of HbF.[64,108]

SNPs in selected candidate genes are also associated with glomerular filtration rate. When the estimated glomerular filtration rate was used as a phenotype of sickle nephropathy, and tagging SNPs in approximately 70 genes of the TGFβ/BMP pathway were studied, four SNPs and three haplotypes in *BMPR1B*, a BMP receptor gene, yielded statistically significant associations. The TGFβ/BMP pathway has been associated with the development of diabetic nephropathy, which has some features in common with sickle cell nephropathy.[109]

Pulmonary Disease. Pulmonary hypertension or pulmonary vascular disease has emerged as an important risk factor for premature death in patients with sickle cell anemia, but its genetic basis has only recently started to be studied.[110,111] Pulmonary hypertension is likely to be modulated by the effects of genes that control NO and oxidant radical metabolism, cell–cell interaction, vasculogenesis, and vasoreactivity. For example, mutations in BMP receptor 2 (*BMPR2*) and other genes have been associated with both familial and idiopathic pulmonary hypertension.[112–114] A study of patients with sickle cell pulmonary hypertension compared with controls found that SNPs in *BMPR2* and *ADCY6* were associated with this phenotype, and follow-up studies suggested that SNPs in *TGFBR3* were associated with this phenotype.[115] Further work by this group involved the study of 297 SNPs in 49 candidate genes in 111 patients screened for pulmonary hypertension, and evidence of an association was primarily identified for genes in the TGFβ/BMP superfamily, including *ACVRL1*, *BMPR2*, and *BMP6*.[116] *BMP6* SNP 449853, associated with pulmonary hypertension, was also associated with stroke

and bacteremia in studies of totally different patients, supporting these associations.[72,107]

Acute chest syndrome is a common vasoocclusive complication with, significant morbidity and mortality rates.[111] Both an increased and decreased risk of having acute chest syndrome were associated with a T786C SNP in the endothelial NO synthase gene (*NOS3*); one small study did not replicate either of these observations.[117–119] Exhaled NO levels were reduced in patients with acute chest syndrome compared with controls, and this was associated with the number of AAT repeats in intron 20 of *NOS1*.[120] In follow-up studies, the ATT repeat polymorphism in *NOS1* was associated with acute chest syndrome only in patients without asthma (itself, a risk factor for acute chest syndrome).[119] In this study of 134 children, 64% had at least one acute chest syndrome, and 36% had asthma. This study examined a small number of patients. Also, the relationship between the number of *NOS1* ATT repeats and risk of acute chest syndrome was an unusual curvilinear one. The association was modest, at best, and a plausible reason why this polymorphism should be important only in acute chest syndrome patients without asthma is not obvious. A T8002C SNP in the endothelin-1 gene (*EDN1*) was associated with an increased risk of acute chest syndrome in 173 children in whom sickle cell anemia was detected at birth and patients followed longitudinally.[118] All of these studies examined small numbers of cases and controls; most were limited to children, and few SNPs were examined.

To deal with these issues, a candidate gene association study of acute chest syndrome was performed using data from 1,422 individuals with sickle cell anemia. Because the etiology and clinical course of acute chest syndrome in patients younger than 4 years is different from that in older individuals, the population was dichotomized into pediatric (aged $\leq$ 5 years) and older children and adults (aged $>$ 5 years).[121] There were 170 acute chest syndrome cases and 884 controls in the group younger than 5 years and 388 cases and 819 controls in older group. Using time to first event in an age-, sex-, leukocyte-, reticulocyte-, and platelet count–adjusted analysis, and controlling for the false discovery rate, two SNPs were found to be significantly associated with acute chest syndrome in both patient groups. These SNPs were in *TGFBR3* and in an unknown gene in LD with *SMAD7*, which is also in the TGFβ pathway. Additional SNPs significantly associated with acute chest syndrome in younger cases were in *PIK3CG*, a member of the PI3/PI4 kinase family involved in cell–cell adhesion. Six additional SNPs were associated with acute chest syndrome in older patients were found in *SMAD1*, *KL*, *NRCAM*, and *SMAD3*. The *NOS1* ATT repeat polymorphism, *EDN1*, and *NOS3* SNPs discussed previously were not examined in this study.

Hyperbilirubinemia and Gallstones. Promoter polymorphisms in the uridine diphosphate–glucuronosyltransferase 1A (*UGT1A*) gene are associated with unconjugated hyperbilirubinemia and Gilbert syndrome. Children with sickle cell disease had a significantly higher mean bilirubin level if they carried the 7/7 *UGT1A* genotype compared with the wild-type 6/6 or 6/7 genotypes; patients with the 7/7 genotype were more likely to have had a cholecystectomy. This suggested that symptomatic cholelithiasis is more common in carriers of this genotype.[122,123] Steady-state bilirubin levels are also influenced by the presence of α thalassemia and the HbF level.[124,125] The 7/7 and 7/8 genotype were risk factors for symptomatic gallstones only in older patients with sickle cell disease, and although coincident α thalassemia was associated with less hemolysis, it did not compensate for the *UGT1A* promoter polymorphism.[126,127] α Thalassemia, regardless of the *UGT1A* genotype, was associated with reduced serum bilirubin levels.[125]

Erythrocyte Glucose-6-Phosphate Dehydrogenase (G6PD) Deficiency and the Endothelium. G6PD deficiency is common in sickle cell anemia. Studies of the phenotype of combined G6PD deficiency and sickle cell anemia have given disparate results. In a multiinstitutional study, however, G6PD deficiency was not associated with differential survival, reduced hemoglobin levels, increased hemolysis, more pain crises, septic episodes, or a higher incidence of acute anemic episodes.[128] Using DNA-based methods to detect unequivocally the GdA- allele of *G6PD*, it was reported that the frequencies of GdA^- and of the normal GdB and GdA^+ genes were identical in patients with sickle cell anemia and controls.[129] Blood counts were similar in patients with and without G6PD deficiency, although the hemoglobin concentration was lower in sickle cell anemia with the GdA^- gene. The prevalence of GdA^- did not change with age.

Although there is clearly little, if any, modulation of the phenotype of sickle cell anemia by coincident G6PD deficiency, perhaps the "right" phenotype has not been studied. Patients with sickle cell anemia have impaired flow-dependent and independent vasodilation.[130] This might be a consequence of intravascular hemolysis, heme scavenging of NO with decreased NO bioavailability, and oxidant stress (Chapter 11). Adequate availability of G6PD is needed to maintain both NO levels and preserve the proper redox milieu. It has been proposed that a G6PD-deficient phenotype could be present in critical vascular tissues in G6PD-deficient individuals and perhaps even in sickle cell disease patients with a normal G6PD genotype.[131] In sickle cell disease, flux through the pentose phosphate pathway is reduced.[132] G6PD activity in sickle cell disease might be inadequate to maintain intracellular GSH levels, producing in effect, a functional G6PD-deficient state.[133] This same relative deficiency might also occur in endothelium and play a role in the endothelium-related pathophysiology of disease. It has been hypothesized that the hyperaldosteronism of sickle cell anemia might impair vascular reactivity by decreasing endothelial G6PD activity.[134]

Sickle erythrocyte adherence to endothelium is likely to be an important component of the pathophysiology of

disease (Chapter 8). One determinant of this interaction is red cell adhesion to laminin, which increases in response to adrenaline stimulation of β_2-adrenergic receptors and adenylate cyclase. Polymorphisms of the β_2-adrenergic receptor (*ADRB2*) and adenylate cyclase (*ADCY6*) genes were associated with increased adhesion, suggesting that this and other features of the interaction of sickle erythrocytes with endothelial cells could be genetically modulated.[135]

Compound Phenotypes and Integrated Measure of Disease Severity. Few studies have combined disease complications and laboratory variables to seek associations with polymorphisms in candidate genes. One small study of patients with histories of stroke, acute chest syndrome, osteonecrosis, and priapism showed that patients with complications had a significantly higher frequency of the HPA-5b allele compared with controls.[136] In this small study, an individual needed only a single complication to be included. Most events were osteonecrosis, and only four individuals had more than a single phenotype.

To produce an integrated disease phenotype, a Bayesian network model was developed that described the complex associations of 25 clinical and laboratory variables, deriving a score to define disease severity as the risk of death within 5 years[137] (Chapter 19). The genetic basis of severity was examined using this score as a phenotype and studying the association of 795 SNPs in 320 candidate genes by using a Bayesian test that compared the genotype distribution among cases with mild and severe disease and calculated the probability that the two distributions were different in 741 HbS homozygotes older than 18 years of age.[138] Positive associations were validated in a smaller independent patient sample. Among the SNPs in genes associated with disease severity, some associations, like *TGFBR3*, confirmed previous findings in stroke and pulmonary hypertension in patients with sickle cell anemia, and support the speculation that dysregulation of the TGFβ/BMP signaling pathway might play a major role in the modulation of disease severity. Other genes in which SNPs were associated with severity, such as *ECE1* and *KL,* are expressed in endothelium or modulate endothelial function. Some associated genes play a less obvious role in the pathobiology of disease, such as *HAO2* and *TOX*, but were strongly associated with sickle cell disease severity and with normal aging. It seems likely that increased oxidative stress and the relentless progression of vasculopathy in sickle cell anemia cause accelerated tissue damage, and this might be modulated by a set of genes similar to those involved in the normal aging process.

As the results of unbiased genome-wide association studies are added to capture polymorphisms not included in candidate gene studies, a predictive network with even greater reliability than one using only clinical and laboratory variables might be developed. To begin this process, 684 mild and severe sickle cell anemia patients, based their severity score, were compared with 877 centenarians and 1,850 younger controls and each SNP was tested for association with the traits of severe or less severe sickle cell anemia and exceptional longevity. The analysis identified 140 SNPs in more than 50 genes and some intergenic regions that showed robust and consistent associations, a number more than twice than expected by chance. Among the most "significant" associations were genes with putative roles in blood circulation, coronary artery disease, type 2 diabetes, triglyceride, and glucose metabolism and sudden death. SNPs in *HAO2* and *MAP2K,* associated with both sickle cell disease severity and exceptional longevity in candidate gene studies, were also associated in the genome-wide association studies. These data further suggest that common metabolic pathways are likely to influence the chance of developing complications of mendelian and multigenic diseases and the likelihood of achieving exceptional longevity.[139] This might explain the commonality of genes whose SNPs are associated with the vascular complications of sickle cell anemia, arteriosclerosis and diabetes. A new paradigm suggests that hitherto unexpected genetic differences modulate a limited number of pathways that form a common route toward determining good health and disease.

Duffy red cell glycoproteins (Fy^a and Fy^b) have been implicated in the clearance of inflammatory cytokines. Duffy negative individuals that include approximately 70% of African Americans might clear these cytokines less efficiently. In adults with sickle cell anemia, end-organ damage and overall disease severity, assessed by a composite score reflecting the presence or absence of injury to a group of organs, were compared between Duffy-positive and -negative patients, as assessed by a SNP (rs2814778) in the promoter of the *DARC* gene. Sixty-five percent of Duffy-negative patients had chronic organ damage and 32% had proteinuria, statistically significant differences from Duffy-positive cases.[140]

GENETIC MODULATION OF THE PHENOTYPIC DIVERSITY OF β THALASSEMIA

Genetic Polymorphisms as Predictors of Disease Severity

Very little is known about the modifiers of the phenotype in β thalassemia other than the roles played by HbF level and α thalassemia.[30]

Hyperbilirubinemia and Gallstones. As with sickle cell anemia, bilirubin levels are modified by promoter polymorphisms of *UGT1A*.[141–146]

Iron Loading. Part of the phenotype of β thalassemia is the tendency for iron loading as a result of chronic hemolytic anemia, increased iron absorption, and blood transfusion. Hereditary hemochromatosis – most often a result of a C282Y mutation in *HFE*, a gene regulating iron metabolism – can also be found in rare cases of β thalassemia and might increase iron loading and its consequences.[147] However, in a larger study of patients with β thalassemia, there was no association of the C282Y *HFE*

SNP with iron overload.[148,149] Concurrent β-thalassemia trait can increase iron loading in classic hereditary hemochromatosis.[150]

Homozygosity for the H63D SNP in *HFE* has been associated with increased serum ferritin in Italian carriers of β thalassemia trait. In northern Indian β thalassemia carriers, this SNP was not associated with iron loading.[151–153]

In the Chinese, classic *HFE* mutations are even less common than in Italians; thus it is unlikely that polymorphisms of this gene would influence iron loading in β thalassemia. Mutations in the transferrin receptor gene (*TFR2*) can cause hemochromatosis. Two polymorphisms of *TFR2* were not associated with ferritin level or transferrin saturation in Chinese patients with transfusion-dependent β thalassemia or in nontransfusion-dependent β-thalassemia intermedia.[154]

Bone Disease. Bone disease and osteoporosis are causes of morbidity in severe β thalassemia, and bone mass is regulated by many genes.[155] In severe β thalassemia, a G-T SNP in the collagen type α1 gene (*COL1A1*) was associated with osteoporosis and in patients with β-thalassemia major and intermedia, an intronic SNP in *VDR*, the vitamin D (1,25-dihydroxyvitamin D3) receptor gene, was associated with a reduction in lower spine bone mineral density.[156–159] SNPs in *TGFB1* were not associated with osteoporosis.[158] Both studies examined a small number of cases and controls and very few SNPs, so these results must be replicated in larger patient samples.

Cardiovascular Disease. Heart failure, a result of iron loading, is the common cause of death in severe β thalassemia. Decreased antioxidant activity of the apolipoprotein E (*APOE*) 4 allele was postulated as a genetic risk factor for the development of left ventricular failure in homozygous β thalassemia. Greek patients with β thalassemia were grouped into 1) patients without heart disease, 2) patients with left ventricular failure, and 3) patients with left ventricular dilation and normal systolic function. Patients with normal hearts had an *APOE* 4 allele frequency similar to that of normal controls. Patients with left ventricular failure had a significantly higher frequency of *APOE* 4 than the controls, suggesting that this allele can represent a genetic risk factor for the development of heart failure.[160]

Two SNPs in the estrogen receptor gene (*ESR1*) were examined in pre- and postpubertal, well-treated, homozygous β thalassemia patients. Individuals lacking an Xba I restriction site polymorphism had higher body mass index, triglycerides, and blood pressure. The authors suggested that this SNP might influence nutrition and could be considered an additional risk factors for later cardiac disease.[161]

GENETIC MODULATION OF THE PHENOTYPIC DIVERSITY OF HbH DISEASE

Heterogeneity of α-globin gene mutations leads to phenotypic diversity of HbH disease.[162] If little is known about the modulation of phenotype in β thalassemia, even less is known about the other modulators of phenotype in HbH disease or Hb Bart's hydrops fetalis caused by identical α-globin gene mutations. As might be expected, polymorphism of the *UGT1A* promoter affects the bilirubin concentration and the likelihood of cholelithiasis.[163]

Iron overload is a cause of disability in HbH disease even in the absence of regular blood transfusion. When polymorphisms of *TFR2* and *HFE* were tested for their association with iron overload in HbH disease, iron loading was similar in patients with and without these mutations. It was concluded that excess iron in HbH disease is most likely a result of increased absorption.[164]

Laboratory Methods for Diagnosis and Evaluation of Hemoglobin Disorders

Mary Fabry and John M. Old

INTRODUCTION

Hemoglobinopathy detection is often a part of the evaluation of anemia, hemolysis, microcytosis, cyanosis, or erythrocytosis. For this purpose, protein (hemoglobin)-, cellular-, and DNA-based approaches to the detection of variant hemoglobins and thalassemias are available. Diagnostic details can be found in each disease-specific chapter, whereas in the following pages we focus on the available methods and their strengths and weaknesses.

Characterization of mutant hemoglobins and thalassemias described throughout this book takes place in different contexts: large newborn screening laboratories that need to identify positively the most common mutants; general hematology laboratories that most often encounter common hemoglobinopathies and thalassemias; and reference or research laboratories that can detect rare mutant globin genes. Approaches that are necessary in one setting might not be practical in others.

Normal adult blood contains predominantly HbA ($\alpha_2\beta_2$) and small amounts of HbF ($\alpha_2\gamma_2$) and HbA_2 ($\alpha_2\delta_2$). After synthesis, monomeric globin chains form α/non-α dimers that do not dissociate under physiological conditions. In the presence of oxygen, hemoglobin tetramers rapidly dissociate into very low concentrations of dimers that can then form new tetramers.[1,2] This implies that when more than one α- or non-α-chain is present, the predominant form in the red cell will be the heterotetramer (for example, in red cells of HbSC disease, the dominant species will be $\alpha_2\beta^S\beta^C$, and $\alpha_2\beta^S\gamma$ heterotetramers form when HbS is present with high levels of HbF (Fig. 28.1). Most hemoglobin separation techniques detect only the homotetramer because the migratory properties of the individual dimers are similar to those of the homotetramers (identical αβ subunits); hence, following dissociation of the heterotetramer into dimers, the two dimers will move apart toward the region where the respective homotetramers are found and recombine. This process will continue until all heterotetramers have dissociated. Heterotetramers can be detected by conventional separation techniques if oxygen is rigorously excluded because exchange is greatly slowed in deoxyhemoglobin.[1]

PROTEIN- AND CELLULAR-BASED METHODS USED TO IDENTIFY AND STUDY HEMOGLOBIN DISORDERS

Sample Preservation, Preparation, and Laboratory Safety

Analytical techniques depend on the starting materials, which include hemoglobin in dried filter paper blots. Anticoagulated whole blood should be refrigerated and processed within 48 hours. Hemoglobin is best stored as red cells in plasma because the red cell contains methemoglobin reductase, which will convert methemoglobin to deoxyhemoglobin. Plasma glucose and albumin stabilize the red cell and its membrane and ensure that enzyme activity will be maintained. With prolonged storage, methemoglobin will be generated and less stable mutant hemoglobins might be selectively lost.

Hemoglobin for analysis is usually prepared by hypotonic lysis with shaking. Care must be taken that all cells undergo lysis. In sickle cell disease, red cells are heterogeneous in their properties with different hemoglobin compositions (Chapter 7) and can be particularly resistant to lysis. Long-term storage of hemoglobin samples requires first washing the cells in isotonic saline to remove plasma proteins and then immersing them in liquid nitrogen or a freezer at −135°C or below. Hemoglobin stored at higher temperatures gradually loses heme, becomes insoluble, and can form degradation products that complicate analysis.

Safety of personnel working in hematology laboratories is a major consideration with the primary risks of hepatitis and human immunodeficiency virus. All human samples should be regarded as a potential source of infection. The first line of defense is care in sample handling: avoiding aerosol formation; wearing gloves; and observing precautions to avoid transferring material from gloves to other surfaces that may be touched by exposed skin. For more detailed discussion of laboratory safety, see the Occupational Safety and Health Agency web site (www.osha.gov).

Electrophoresis

Electrophoresis was once the most widely used method for initial detection of variant hemoglobins but has been supplanted by high-performance liquid chromatography (HPLC) as the most useful screening approach.

Proteins are composed of amino acids that bear side chains that can ionize. The pH at which a side chain is half ionized is its pK. Proteins are amphoteric; that is, they bear both positively and negatively charged side chains, and the net charge will depend on the pH of the solution and the pKs of its amino acids. Because proteins are charged

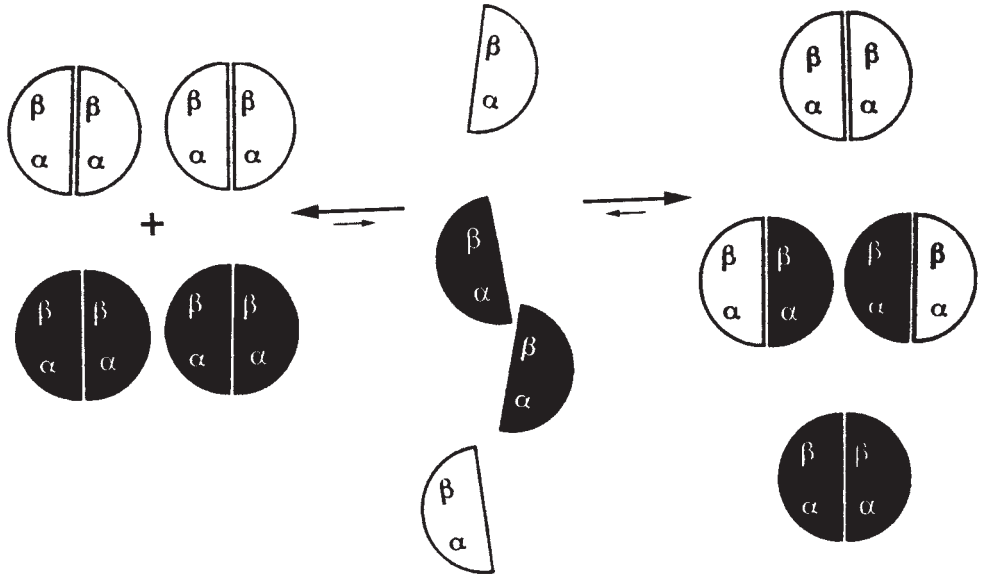

Figure 28.1. Hemoglobin is a tetramer of two $\alpha\beta$ dimers that do not dissociate under physiological conditions; however, the tetramers rapidly dissociate and reassociate, generating very low concentrations of dimers under physiological conditions. Mixing two hemoglobins, represented by black and white, rapidly leads to an equilibrium mixture in which the original homotetramers and the heterotetramer exist in a ratio of 1:2:1.

molecules, they will migrate in an electrical field and the relative speed and direction will depend on the sign and magnitude of the net charge.

At pH 8.6, all human hemoglobins will have a net negative charge and will migrate in an electrical field toward the positive pole or anode. Mutations that do not alter the charge may be "silent" and not detectable by electrophoresis; however, interaction with the matrix (such as cellulose acetate or agar) can also affect the rate of migration. Most electrophoretic methods separate hemoglobin tetramers, but only tetramers composed of two identical α-non-α dimers, or homotetramers, are seen at the end of the separation process.

Because many different hemoglobins migrate similarly under a given set of conditions, electrophoresis is usually performed at two different pHs and on two different supporting mediums, but this method is insensitive to many rare variants. The usual choice is cellulose acetate electrophoresis at pH 8.4 and citrate agar electrophoresis at pH 6.0.[3] On citrate agar, in addition to the net charge, there is some selective interaction with the substrate, which further aids in resolution of some hemoglobins. This is based on the interaction of the central cavity of the hemoglobin with agaropectin in agar.[4] In all cases, a set of reference hemoglobins, usually HbA, A_2, F, S, and C should be included with each run. Electrophoresis can also be performed on separated globin chains if denaturing conditions are used.[5–7] Another approach that sometimes allows separation of overlapping hemoglobins, one of which contains cysteine, is treatment of the sample with cystamine.[8]

Most laboratories use commercially prepared kits that contain the hemolyzing agent, buffers, support media, a means for applying multiple samples, and a stain. The sample is lysed and applied to the cathodic or negative side and an electrical field is applied. Gels can be stained with protein- or hemoglobin-specific stains, or the color of the hemoglobin itself can be used for visualization. Quantification of hemoglobin fractions by densitometry is possible but inaccurate when a hemoglobin fraction is present at less than 5%.

Isoelectric Focusing, Capillary Isoelectric Focusing, and Capillary Electrophoresis

Isoelectric focusing (IEF) is capable of much higher resolution than the electrophoretic techniques. If a molecule has two or more ionizable groups, at least one of which has a pK in the acidic range and another in the basic range, then there will be a pH at which the net charge is zero. Proteins and amino acids all have a pH at which the net charge is zero, which is called the isoelectric point (pI) where there is no net movement in the presence of an externally applied electrical field. To separate proteins based on their pIs, a stable pH gradient must be created. This is achieved by applying a set of ampholytes with pIs that cover the range of pIs of the proteins that are to be separated on a support matrix. During the initial period after the current is applied, both the ampholytes and the proteins to be separated move as the pH gradient is formed. If a protein molecule finds itself on the acidic side of its pI it will migrate to the cathode, and if it finds itself on the basic side of its pI, it will migrate toward the anode (hence the term isoelectric focusing). Sharp bands of individual proteins are thus formed. With optimization, methods using free ampholytes can resolve two proteins with a pI difference of approximately 0.01 pH unit (Fig. 28.2).[9] Even higher resolution can

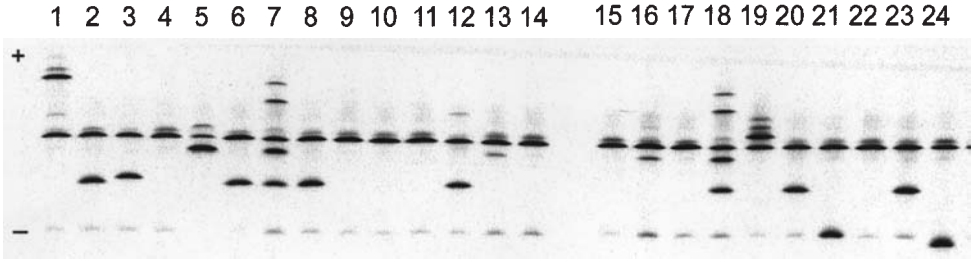

Figure 28.2. Separation of various mutant hemoglobins by IEF. A precast agarose gel (Resolve Systems, Wallac Inc., Akron, OH) was used at 75 mA, 1,200 V, 14°C, for 90 minutes. Present on the gel are: lane 1, HbA–HbN Baltimore; lanes 2, 6, 8, 12, 20, 23, HbAS; lane 3 HbA–HbD Punjab; lane 5 normal newborn; lanes 7, 18 controls (HbA_2, HbS, HbF, HbA, HbJ Baltimore, HbI Texas); lane 16 β thalassemia trait; lane 19 HbA–Hb Hope; lane 21 HbE trait; lane 24 HbC trait. (Gel contributed by H. Wajcman, Director of Research INSERM, Hopital Henri Mondor, Paris, France.)

be attained if the ampholytes are covalently bound to the matrix and the pH gradient is preformed by casting the gel with a two-vessel gradient mixer, thus preforming a stable pH gradient before the protein is applied. This type of gel is capable of resolution of proteins with pIs differing by approximately 0.001 pH units.[10,11] The most commonly used IEF technique is application of multiple samples to a commercially prepared thin-layer gel, which precludes automated technology.

Capillary IEF is performed by using pH gradients in fine capillary tubes. Available commercial systems require small sample size, have good resolving power, are rapid and sensitive, allow automated data analysis, and provide quantitative information. Capillary zone electrophoresis is another alternative in which hemoglobin molecules migrate through a capillary filled with a salt buffer near physiological conditions. There are no matrix interactions to introduce complexities or alter reproducibility, and the system has the potential for automation.[12,13]

Capillary electrophoresis combined with mass spectrometry has been applied to analysis of proteins present in single cells.[14,15] A wide variety of detection systems have been used, including conventional UV/visible detection similar to that used by HPLC instruments,[16] absorption imaging,[17] and mass spectrometry.[18]

High-performance Liquid Chromatography

The techniques described so far depend primarily on the ionization (pKs) of the amino acid side chains of intact hemoglobin molecules and their migration in an electrical field. In HPLC, ionic and hydrophobic interactions of the sample with the supporting matrix are the basis of separation. The sample is applied to the top of the column under conditions wherein it interacts strongly with the matrix. The proteins are then eluted with a developing solution (buffer) of gradually increasing strength, until all of the proteins are eluted. In cation and anion exchange chromatography, the properties of the developing solution that are varied are pH and ionic strength (salt concentration) and in reverse phase chromatography, the hydrophobicity (organic solvent) content is also varied. Hemoglobin may be separated as the intact tetramer or, under denaturing conditions, the individual globin chains can be separated. Human hemoglobins usually have a relatively small number of possible homotetramers and analysis of the intact tetramer generally yields readily interpretable results.

HPLC is currently the standard for the initial evaluation of hemoglobin variants and thalassemia. It is rapid, automated, capable of resolving most of the common and many uncommon variants, and provides reliable measurement of hemoglobin fractions such as HbA_2 and HbF (see later). Dedicated clinical systems based on HPLC separation of tetrameric hemoglobin with very rapid-automated sampling are in widespread use and allow preprogramed detection of hemoglobin variants (see Fig. 23.7, Chapter 23). Hemoglobin from transgenic mice – because of the possible formation of human – mouse chimeric dimers and hence a wide variety of homotetramers – and less common human variants yield a more readily interpretable chromatogram when denaturing conditions are used and the isolated globin chains are detected (Fig. 28.3). In most systems the pumps and the detector are computer controlled and the area under each detectable peak is automatically calculated. Very small internal diameters increase column resolution and decrease the amount of sample required at the cost of increased time per sample.[19]

Under the appropriate conditions HPLC readily separates hemoglobin variants that cannot be resolved by other means. The equipment used for HPLC is expensive, sophisticated, and difficult to maintain compared with that used for electrophoresis or IEF. HPLC screening techniques have been developed in which individual samples can be run in approximately 3 minutes with very high reproducibility.

Mass Spectrometry

Mass spectrometry is rarely used for clinical purposes and DNA-based studies have largely supplanted its use for definitive detection of rare variants. This method can start with a hemolysate and return the molecular weights of individual globin chains to within 1 atomic mass unit (amu). This level of accuracy allows detection of posttranslational

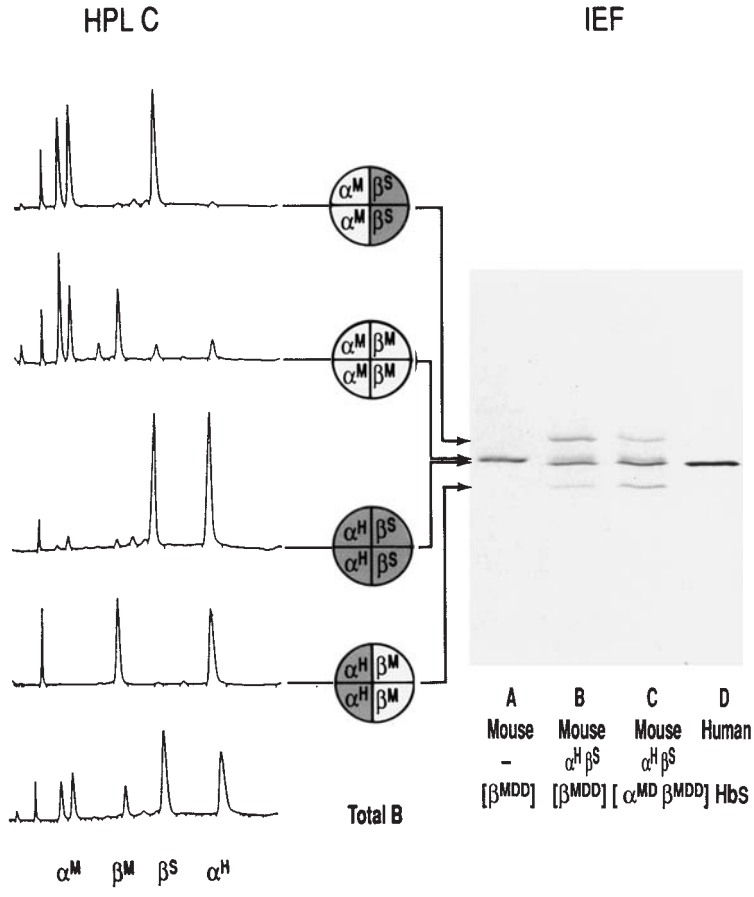

Figure 28.3. IEF and HPLC of hemoglobins from several transgenic mice expressing human HbS and mouse globins. The bands representing homotetramers composed of dimers of mouse α and human β^S chains, mouse α and mouse β chains, human α and human β^S chains, and human α and mouse β chains were separated by IEF, isolated from the gel, and separated by denaturing HPLC to allow identification of the tetramers present in the IEF gel. (From Fabry et al., 1992 Proc Natl Acad Sci, USA 89;1250–1254, with permission.)

modification[20] and verification of mutant and recombinant hemoglobins, and in contrast to electrophoretic techniques, mass spectrometry can separate similarly charged samples. Individual bands or peaks from IEF or HPLC can also serve as the starting sample. Requiring a few picomoles of protein, hemoglobin is an ideal molecule for mass spectrometry because it has a favorable size, an adequate number of protonation sites, distinct mass differences between mutants, and few posttranslational modifications.[21] Mass spectrometry combined with capillary electrophoresis has been applied to analysis of proteins present in single or small numbers of red cells.[15]

This method is based on the principle that charged particles moving through a magnetic field will undergo deflection proportional to the charge/mass ratio. Particles with the smallest charge/mass ratio are the least affected. The sample is first converted to gaseous ions and an accelerating voltage is applied. The particles are focused through a slit into a highly evacuated area, where they are subjected to the magnetic field that causes them to separate. The most important methods of ionization are electrospray ionization (ESI),[22] and matrix-assisted laser desorption (MALDI). ESI is most suitable for intact globin chain analysis and MALDI is the method of choice for peptide identification. ESI allows mass spectrometers to be interfaced with HPLC and capillary IEF devices, which frequently allows immediate positive identification of the separated species and is also useful for identification of small peaks that could represent derivatives or degradation products.[23,24]

Mass spectrometry can be used for complete sequencing of proteins based on identification of fragments that can be produced classically by proteolytic digestion and then exposed to MALDI. The abnormal fragments can be identified, and in many cases, the mutation deduced. With a few exceptions, whole blood hemolysates can be subjected to digestion without further separation. Separation is necessary when the variant is present at a low level, a mass difference of 1 D is suspected, or high levels of HbF are present. In these cases the sample can be purified by IEF or HPLC prior to digestion.[26] Alternatively, the protein can be fragmented in the spectrometer itself without resorting to wet chemistry and the fragments produced in the spectrometer can be used to identify the portion bearing the mutant animo acid.[23–28]

Hemoglobin F

HbF (Chapter 7) in adult blood is normally is less than 1%–2% of total hemoglobin. It is unevenly distributed among red cells. Cells with high levels of HbF are called F cells and, in sickle cell disease, F cells are seldom found among the most dense cells. This implies that when either HbF or F cells are measured, care must be taken to avoid biasing the sample. Careful mixing into the suspension of any cells that

have settled at the bottom of the tube is sufficient; however, automated systems for resuspending normal red cells might not be sufficient for blood from patients with any of the sickle hemoglobinopathies.

Several methods may be used for quantitation of HbF, including alkaline denaturation, electrophoresis, or IEF followed by densitometry, disposable minicolumns, and HPLC. HbF is more resistant to denaturation by alkaline conditions than is HbA. In the alkaline denaturation method, potassium hydroxide is added to a known concentration of hemoglobin and, after a predetermined time interval, the reaction is stopped by adding a known volume of ammonium sulfate, which lowers the pH and precipitates the denatured hemoglobin that is removed by filtration. The concentration of hemoglobin remaining in solution is then determined. Two versions of the alkaline denaturation protocol exist: that of Betke et al.,[29] which is reliable for HbF less than 10%–15%, and thereafter systematically underestimates the percentage of HbF, and that of Jonxis and Visser,[30] which is only accurate when HbF is greater than 10%. HPLC allows accurate quantitation of HbF and is currently the most widely used method.[31,32] It is accurate for samples with levels of HbF down to approximately 0.5% and has no upper limit of detection. Some hemoglobin components that are present at low concentrations elute in the position of HbF under some HPLC conditions (Chapter 7). Electrophoresis or IEF followed by densitometry are less reliable than HPLC for HbF quantification. For detection of very low levels of HbF radioimmunoassay,[33,34] and enzyme-linked immunosorbent assay (ELISA)[35] are alternative techniques.

Because HbF is almost always unevenly distributed among erythrocytes – an exception is some types of hereditary persistence of HbF (HPFH) – immunological techniques using flow cytometry that allow the determination of F cells are also useful and can provide a reasonable surrogate for whole blood HbF levels.[36] Measuring F cells is discussed later.

Hemoglobin A_2

HPLC systems that detect many hemoglobin variants are the current standard for measuring HbA_2 levels. Electrophoresis can separate HbA_2 from HbA and HbF, enabling accurate measurement of this minor hemoglobin component but this requires elution from gels or membranes because densitometric scanning is inaccurate.[45,46] Acid agar gel electrophoresis does not resolve HbA_2 from HbA. Refrigeration and freezing may reduce the percentage of HbA_2 in stored hemolysates. The differential elution of HbA_2 in minicolumns is reliable, rapid, and inexpensive.[37]

HbA_2 cannot be separated from hemoglobin variants with similar positive charges, such as HbC and HbE, by electrophoresis or many column-chromatographic methods. In the company of abnormal globins that contain only a single additional positive charge, such as HbS, the HbA_2 level has been reported to be higher than normal but appropriate separation methods can circumvent this overestimation of HbA_2.

Recent improvement allows reasonably accurate measurement of HbA_2 by HPLC even in the presence of HbS as in sickle cell trait (HbAS) or sickle cell anemia, although the level of HbA_2 reported is slightly higher than normal because of the coelution of minor HbS fractions (Chapter 7). HbE, and Hb Lepore have very similar retention time to HbA_2, and these hemoglobins cannot be positively separated. HbC and Hb O-Arab also cannot be definitively distinguished by cation HPLC that affords excellent resolution of HbA_2 from HbS and HbC.

HbA_2 can be measured immunologically[33,38] with high specificity. The levels obtained correlate well with the more traditional methods of measurement.

Capillary IEF has been used to measure HbA_2 in normal subjects and in those with β thalassemia trait, HbAS, and sickle cell anemia.[39,40] Accurate measurements are possible, although in one study HbA_2 levels in HbAS and sickle cell anemia were slightly elevated compared with normal. Nevertheless, they were clearly separated from β thalassemia trait. Glycosylated forms of HbA_2, analogous to the minor components of HbA, are present and can be quantified by HPLC and IEF. Like HbA_{1c}, these glycohemoglobins are elevated in poorly controlled diabetics (Chapter 7).

Functional Properties of Hemoglobin

P_{50} and Other Measurements of Oxygen Saturation

The partial pressure, at which hemoglobin is half saturated with oxygen, or P_{50}, is an important property of hemoglobin in solution and in the red cell. P_{50} is extremely sensitive to the presence of 2,3-bisphosphoglycerate (2,3-BPG), inorganic phosphate or other phosphates, pH (Bohr effect), CO_2, anions, and, in the case of HbS, polymer formation. In dilute solutions, the P_{50} of HbA and HbS are equal. In the red cell and in plasma, HbA has a P_{50} of 25 ± 2 mm Hg when equilibrated with gases containing 5% CO_2. The increase in P_{50} (or decrease in oxygen affinity) is primarily due to the effect of 2,3-BPG on the oxygen affinity of hemoglobin. P_{50} of HbS in the red cell is higher, ranging from 25 to 45 mm Hg. HbS polymerization increases P_{50} in proportion to the amount of polymer formed because polymer has a lower P_{50}.[41] With HbA, the association curve ($Hb \rightarrow HbO_2$) is identical to the dissociation curve ($HbO_2 \rightarrow Hb$); there is no hysteresis. The P_{50} in blood samples with HbS depends on whether equilibrium with polymer has been reached, that is, whether polymer formation or polymer melting is complete before the next level of oxygenation is tested. The delay time for polymer formation is dependent to the 30th power of the deoxyhemoglobin concentration.[42] In the absence of equilibrium there is hysteresis and the P_{50} for the association and dissociation curves will differ. Changing the pO_2 at a slower rate will bring the two curves closer together.

The most common measurements of P_{50} are based on measurement of oxygen association curves. Two parameters are simultaneously measured: pO_2, which is continuously varied, and the percentage of hemoglobin, which is saturated with oxygen. In these measurements, the hemoglobin is first fully deoxygenated and then oxygen is gradually reintroduced, whereas the pO_2 is measured with an oxygen electrode. At the same time, hemoglobin saturation with oxygen is measured optically. The Hemoscan (no longer manufactured) used equilibrated hemoglobin or whole blood samples between layers of gas-permeable membranes and allowed measurement of whole blood P_{50} in plasma. The Hemox-Analyzer (TCS Medical Products) measures percentage of oxyhemoglobin with a dual-wavelength spectrophotometer at 560 nm, which is sensitive to the transition between deoxyhemoglobin and oxyhemoglobin, and at 570 nm, at which the absorption is sensitive to the hemoglobin concentration but insensitive to the oxygenation state. Dual-wavelength systems cannot discriminate between oxyHb and several other forms of hemoglobin such as CO, NO, metHb, or sulfHb, which can lead to systematic errors (Chapter 25).

Blood gas analyzers measure the pH, pO_2, and pCO_2 for samples of whole blood and then calculate hemoglobin saturation with oxygen and a number of other parameters, based on the normal P_{50}. This will systematically overestimate the percentage of oxyhemoglobin present in the blood of sickle cell disease patients and any other hemoglobinopathies that result in elevated P_{50}. Similarly, a low P_{50} such as is found for HbF will result in systematic underestimation of the percentage of oxyhemoglobin. The presence of met- and carbonmonoxy hemoglobin (CO-Hb) are not accounted for in these measurements.

A CO-Oximeter (Instrumentation Laboratories, Lexington, MA) uses multiple wavelengths to measure the hemoglobin concentration, percentage oxyhemoglobin, hemoglobin, percentage metHb, and percentage CO-Hb and can be used in conjunction with blood gas analyzers to give a more accurate, but still incomplete, picture of hemoglobin saturation.

The 2,3-BPG content of the red cell is needed to evaluate the significance of P_{50} measurements because altered P_{50} might be the result of a hemoglobin abnormality or altered 2,3-BPG content.

If a hemoglobin with a P_{50} different from that of HbA is present (such as HbS or HbF), the hemoglobin saturation cannot be obtained from a blood gas analyzer, which uses the P_{50} of HbA to calculate hemoglobin saturation from the measured pO_2.

A useful test for patient monitoring is measurement of the arterial hemoglobin saturation with oxygen that can be measured in vivo by use of a pulse oximeter. The pulse oximeter estimates arterial hemoglobin saturation by measuring the light absorbance of pulsating vascular tissue at two wavelengths. The relationship between measured light absorbance and saturation was developed empirically and is built into the oximeter software. The presence of methemoglobin and CO-Hb will lead to systematic overestimation of oxygen saturation by pulse oximetry (Chapter 25).

Detection and Estimation of Polymer Formation in Red Cells and Solutions Containing HbS

Solubility

The insolubility of deoxyHbS in high-phosphate solutions is the basis of a rapid nonquantitative test that when combined with the results of HPLC provides a positive identification of sickling hemoglobin variants. Solubility tests should never be used for definitive diagnosis. If they are performed correctly, they can identify the presence of a sickling hemoglobin variant (Chapter 23). This could be clinically important when rapidly knowing if HbS is present is imperative, but the need for this knowledge is uncommon.

C_{SAT}

The solubility of a substance is the concentration of that substance in equilibrium with a condensed phase that may be crystalline, polymer, or particulate. In the case of HbS, the solubility is important because it allows estimation of the percentage of the HbS content of the red cell that will be converted to polymer under fully deoxygenated conditions. The concentration of deoxyHbS in equilibrium with the polymer phase (C_{SAT}) is useful for characterizing sickle hemoglobins that contain a second mutation and for characterizing mixtures of HbS with other hemoglobins.

Several methods are used. One method uses quasiphysiological conditions and the other relies on high phosphate to precipitate sickle hemoglobins. Formation of protein crystals and polymers is extremely sensitive to the nature and concentration of the counter ions present. Either the crystal structure itself or the rate of nucleation can be affected. In the low-phosphate method,[43] hemoglobin is concentrated versus 0.1 M potassium phosphate buffer and deoxygenated, first by alternating vacuum and nitrogen, and then by adding enough sodium dithionite solution to give a final concentration equal to three times the heme concentration. The samples are transferred anaerobically to C_{SAT} tubes filled with paraffin oil, incubated overnight in a nitrogen atmosphere, and centrifuged for 2 hours at 35,000 rpm with purified HbS used as a control. The supernatants are removed anaerobically, and concentrations and deoxy pHs are determined; solubility is expressed in grams per deciliter of HbS in equilibrium with the polymer. This is regarded as the reference method.

Another method is based on the turbidity of a microparticulate suspension that is formed when HbS is introduced into a solution at pH 7.0 and 27°C with a high-phosphate concentration that has been deoxygenated with dithionite.[44] A third alternate approach uses 50 mM

phosphate in the presence of 70 kD dextran to decrease polymer solubility.[45] Because solubility is determined by the residues in the contact area between the tetramers, this method offers an advantage over the high-phosphate method, in which the insoluble phase does not have a fiber structure. Finally, a method that takes advantage of the observation that polymerization of HbS shifts the P_{50} to the right and that this shift is proportional to the amount of polymer formed is available. Correlation of the C_{SAT} determined by P_{50} with that determined by the centrifugation method has been shown to be good for a wide range of samples[46] and has been applied to suspensions of red cells.[47]

In the high-phosphate method, the pH dependence of solubility is opposite to that found in the minimum gelling concentration method.[48]

Plasma Hemoglobin

The importance of cell free or plasma hemoglobin in sickle cell disease and other hemolytic anemias has recently been emphasized[49,50] (Chapter 11). In plasma, due to the low hemoglobin concentration, all hemoglobin will be dissociated into less stable dimers, and oxidation will result in conversion to methemoglobin with potential loss of heme. The first consideration for measurement of plasma hemoglobin is avoiding artifacts due to technique in blood draws or sample preparation. This is particularly so in sickle cell disease because of the greater fragility of sickle erythrocytes. Small bore needles, rapid flow, and vortexing should be avoided. Red cells and plasma should be separated promptly. In recent studies,[50] blood was collected from artery or vein by using large-bore catheters (18 gauge). The first 3 mL of blood was discarded, and the blood then slowly drawn into heparinized syringes. Blood was spun at 750 G at 4°C for 10 minutes without braking, and the plasma was removed. Plasma was then spun at 14,000 G at 4°C for 10 minutes to eliminate residual erythrocytes and platelets.

Several techniques can be applied to measure cell-free hemoglobin: For relatively high concentrations, plasma can be diluted 1:1 with Drabkin reagent. A more sensitive technique is use of tetramethylbenzidine.[51] Tetramethylbenzidine is noncarcinogenic and more sensitive than benzidine. Samples can be read at 600 nm, at room temperature, and concentrations can be calculated using the slope of the sample and the slope of a calibrator. This method is sensitive to heme in all forms: heme in hemoglobin, bound to albumin, and heme in haptoglobin and hemopexin. An ELISA can also be used.[52]

Both Drabkin reagent and tetramethylbenzidine are inexpensive and do not require complex instrumentation and they are sensitive to heme in all forms. This can lead to overestimation of plasma hemoglobin, but because heme or heme proteins bound to albumin, haptoglobin, or hemopexin are usually present at a relatively low concentration, this might not be a major drawback. The ELISA method is more expensive and is sensitive to all forms of human hemoglobin, including HbF.

Lactate dehydrogenase (LDH) is released from the red cell on hemolysis. There are five isoforms of LDH that come from red cell, heart, kidney, lymphoid cells, platelets, liver, and skeletal muscle. If only LDH isoforms 1 and 2 are measured, the sources are narrowed to red cell, heart, and kidney. A high correlation between serum LDH and plasma heme measured by ELISA exists in sickle cell anemia.[52] Absence of an accepted standard of LDH measurement makes it difficult to compare values between different laboratories, making agreement problematic on a single upper limit of LDH that would identify all cases of high plasma hemoglobin.

CHARACTERIZING THE RED CELL

Complete Blood Count

Blood for a complete blood count (CBC) should be slowly drawn into an anticoagulant, usually EDTA. Prompt but gentle mixing is needed to avoid clotting. This is particularly important for patients with low packed cell volume (PCV) because the amount of anticoagulant may be only marginally sufficient. Red cells from patients with hemoglobinopathies can be fragile, and narrow gauge needles, rapid flow, or violent mixing should be avoided. Whole blood can be stored refrigerated or on wet ice and used within 24 hours and shipped overnight on wet ice. To avoid hemolysis, freezer packs should not be used and should never be placed in direct contact with tubes containing whole blood. Special care may be needed to resuspend whole blood from patients with sickle cell disease because these cells may adhere to each other and resist resuspension.

Manual Methods

Although red cell indices are determined by automated methods in most laboratories, manual methods are still used sometimes. The ratio of hemoglobin to PCV can be used to calculate a mean corpuscular hemoglobin concentration (MCHC) that might be more reliable than that determined by automated measurements. The most accurate way to measure hemoglobin concentration is by the cyanmethemoglobin method, which is insensitive to oxygenation and pH. Hemoglobin is oxidized to methemoglobin by ferricyanide and then interacts with cyanide to form cyanomethemoglobin and its absorbance at 540 nm is read in a spectrophotometer. A dedicated microhematocrit centrifuge that generates a force of 12,000 G and microhematocrit tubes with or without heparin are used to estimate PCV. For samples from patients with high PCV, and those with sickle cell anemia or hereditary spherocytosis, an additional centrifugation might be required. If MCHC is to be calculated from hemoglobin and hematocrit, multiple measurements should be made.

Automated Methods

Current automated CBC methods measure properties of single cells flowing through a detector.[53,54] Two general types of detection are currently used: Coulter-type detectors based on impedance and high-frequency conductivity, and detectors based on optical properties of the cell. Most instruments measure several variables for a large number of cells and present results as an average value; the averaging of samples with red cell heterogeneity, therefore, such as those from sickle cell anemia or hereditary spherocytosis, might yield values that seem normal. All instruments count particles, estimate their size, and hemolyze the cells and measure hemoglobin. The results of the direct measurements (hemoglobin, red blood cell count, white blood cell count, and platelet count) are the most accurate values, but failure to hemolyze all cells can lead to error in hemoglobin concentration in hemoglobinopathies such as sickle cell disease. Failure to resuspend completely all cells in samples of blood that have been stored for several hours can also lead to errors in hemoglobin and PCV. Because identification of erythrocytes and platelets is based on their size, fragmentation might lead to misclassification. Most systems measure hemoglobin by the cyanmethemoglobin method. Coulter detectors are based on the observation that the electrical conductivity of cells is lower than that of saline solutions and measurement of the impedance across a small orifice with cells flowing through allows cell size (mean corpuscular volume [MCV]) to be estimated. Factors that lead to deviations are cellular asymmetry and loss of an intact cell membrane, both of which may be features in samples with abnormal red cells.

Cell volume measurements using light scattering (Mie principle) are based on the observation that the intensity of light scattered at small angles in the forward direction is proportional to cell size. Two major factors lead to deviations: cell shape and variation in refractive index, which is related to hemoglobin concentration. The first problem has been approached by sphering the cells at constant volume, and the second problem has been addressed directly by measuring at two wavelengths, which allows intracellular hemoglobin concentration and refractive index to be estimated. Incomplete sphering is a problem for some samples such as those from sickle cell disease patients. PCV, mean corpuscular hemoglobin (MCH), MCHC, and red cell distribution width (RDW) and other functions that provide information on dense cells are calculated from measured variation in red cell size. For most instruments, the least reliable measurement is the MCHC, which is calculated from the whole blood hemoglobin concentration divided by the mean cell volume times the number of cells. Because the calculation requires three measurements in most instruments, the error from all of them enters into the calculation; the exception to this is the Bayer Advia machine, which measures intracellular hemoglobin concentration directly as cell hemoglobin concentration mean (CHCM).

The major advantages of automated methods are speed, low manpower requirements, and high precision. Comparisons of available instruments have been made.[53–57] Automated systems have high reproducibility; however, the accuracy is sensitive to errors in calibration that systematically affect the results so that absolute values may vary between instruments. All systems generate flags to call attention to unusual values, which may be taken either as indications of pathology or a need to examine the sample more closely. In general all instruments performed all tests satisfactorily with the exception of estimation of MCHC, which was the least reliable. Analyzers using the Mie principle, by measuring density of individual red cells, are able to generate histograms of variation in cell density (cell hemoglobin distribution) of individual red cells in a given blood sample (see later). This is useful for following changes in the distribution of dense red cells in sickle cell anemia.

Reticulocyte Count

Reticulocyte counts, along with PCV, are useful for evaluating hematopoiesis and hemolysis. Reticulocytes contain remnants of mRNA; they continue to synthesize hemoglobin for 1–2 days in the marrow and for another day after release into the circulation. The reticulocyte count may be elevated even in cases where hemoglobin levels are normal, and, in these cases, can serve as a more sensitive indicator of errors in either production or destruction of red cells. The peripheral blood of normal adults has less than 2% reticulocytes, but the count varies with the method. If the individual is under hematopoietic stress, the peripheral blood can contain stress reticulocytes, cells prematurely released from the bone marrow, or even nucleated erythrocytes. All reticulocyte counts are based on the presence of mRNA in the cell. In the manual method, the cells are stained with new methylene blue, which precipitates RNA, rendering it visible. The amount and distribution of the precipitate allow the degree of immaturity of the reticulocyte to be estimated, and stress reticulocytes have a characteristic appearance. After staining, the cells are spread on a microscope slide and reticulocytes are counted as a percentage of all red cells.

Automated reticulocyte counts use fluorescence-stained cells that are read in a flow cytometer, which may be either dedicated to reticulocyte counting or part of a larger automated system. Red cells are usually discriminated from white cells and platelets by size, and a maximum fluorescence gate is usually set that may exclude nucleated red cells. The relative age of reticulocytes can be estimated by the degree of fluorescence. One drawback of these methods is that staining with the most frequently used reagent, thiazole orange, requires approximately 30 minutes incubation and variation in the chosen time of incubation can affect the final reticulocyte count. Based on the intensity of the reaction between the dye Oxazine 750 and reticulocyte mRNA, reticulocytes can be classified as low-, medium-, or high-staining intensity

reticulocytes. An increase in the number of high-staining intensity reticulocytes indicates the presence of stress reticulocytes. Reticulocytes can also be stained with a labeled antibody to the transferrin receptor.[58] Bayer Advia counters can also measure reticulocyte volume (MCVr), reticulocyte hemoglobin concentration (CHCMr), and total reticulocyte hemoglobin (retHb), ratio of total hemoglobin to retHb (Hb/retHb), absolute reticulocyte count, mature red cell hemoglobin (rbcHb), rbcHb/retHb ratio, and numbers of erythrocytes with MCHC more than a chosen value. From the absolute reticulocyte count and the CHr, the retHb is calculated, which is expressed in grams per liter, the hemoglobin content of all reticulocytes.[59] The ratio of rbcHb to retHb defines the ratio between the hemoglobin contained in mature red cells and in the reticulocytes. Under steady-state conditions, erythrocyte survival can be estimated indirectly from the ratio of hemoglobin contained in mature red cells and in reticulocytes. A reduction in retHb and a concomitant increase in rbcHb/retHb ratio provide indirect evidence for prolonged red cell survival. Changes in MCVr can provide a much more rapid indication of response of patients to folate or vitamin B12 deficiency.[60]

Measures of Cell Heterogeneity

Most automated counters produce an indication of red cell heterogeneity called the RDW, which is calculated from the measured variation in red cell size by a nonlinear formula that magnifies heterogeneity. Increased reticulocyte count will increase RDW and a correlation between the RDW and percentage of cells in the densest part of density gradient separations has also been shown.[61] Bayer Advia counters also compute a hemoglobin distribution width that is based on the variation of the CHCM, which is directly determined for each cell. Typically hemoglobin distribution width is a much smaller number than RDW.

MCHC has distinct characteristics in many hemoglobinopathies. Small increases in MCHC occur when normal erythrocytes are deoxygenated and this can be visually demonstrated on continuous density gradients.[62,63] Hemoglobin concentration is directly proportional to cell density, but is not necessarily correlated with cell volume unless cells from the same source are compared at different osmolarities. For example, the red cells of patients with HbE are microcytic but have a narrow range of densities identical to that of individuals with HbA.[64] Red cells from normal adults have an MCHC of 33 ± 1.5 g/dL by conventional measurements; however, more sensitive measurements show that there are consistent differences between males and females and between African Americans and Caucasians. Several hemoglobinopathies have altered MCHC with a narrow range of densities. For example, in δβ thalassemia trait the cells are uniformly less dense by approximately 2 g/dL and in homozygous HbC disease, the cells are uniformly denser by approximately 4 g/dL. In other diseases, such as sickle cell disease, hereditary spherocytosis, and some of the thalassemias, there is a broad but characteristic distribution of red cells that include both high- and low-density red cells.

MCHC is the least reliable of all automated measurements and is frequently considered uninformative, so alternative methods are used to analyze and isolate red cells according to density. These can be broken into three broad classes: methods using microhematocrit tubes filled with materials of different densities, methods that rely on discontinuous or layered density of supporting media for separation, and techniques that rely on continuous density gradients. All methods take advantage of the fact that cells will move under the influence of centrifugal force until they find a region of density the same as that of the cell – continuous gradients – or stop when they encounter a region of higher density – at the boundaries in discontinuous gradients.

Discontinuous gradients based on a number of substances have been used in density-based separation. The most successful of these methods are based on substances that are nontoxic to the cell, have a low osmolarity, neutral pH, and low viscosity. Phthalate esters, Percoll®, Hypaque®, Stractan®, (Larex®), and others have all been used for red cell separations. Danon and coworkers[65] devised a simple method of generating density profiles and isolating cells of defined density by using mixtures of phthalate esters that cover the density range of red cells. A disadvantage of this method is that the separated cells are not viable for physiological studies.

Stractan (arabinopolygalactan, now marketed as Larex) is a high-molecular-weight product made from the bark of the larch tree. It is physiologically benign and has a low osmotic contribution, which allows the ionic content of solutions to be adjusted freely.[66] A disadvantage of discontinuous gradients is that they usually have four or fewer densities that can either mask relatively large changes in density of cells at the upper boundary between density levels, or exaggerate small changes in cells at the lower boundary.

Percoll is a commercially available product that spontaneously generates a continuous density gradient when centrifuged. It is composed of silica particles coated with polyvinyl pyrrolidone with range of sizes whose rate of sedimentation by centrifugation force is determined by size. The density at any depth in the tube is determined by the number and size of the particles. For this reason the density profile of Percoll gradients depends on the duration of centrifugation, viscosity (which is temperature dependent), and G force applied. The density range of Percoll is suitable for separation of white cells and needs to be increased before it can be applied to red cells. Renografin® and Percoll can be combined to produce a continuous density gradient capable of separation of red cells by their density.[67] A disadvantage of Renografin is its high osmolarity, which results in a final osmolarity of the mixture of more than

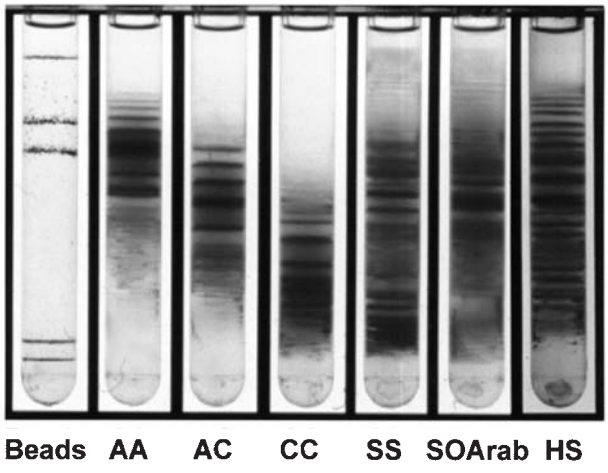

Figure 28.4. Percoll–Larex continuous density gradient. Red cell density is directly proportional to the MCHC. The least dense (lowest MCHC) cells are at the top of the gradient and the highest density cells are at the bottom. This technique provides a method for directly visualizing the distribution of red cell density in a sample of whole blood. The example shows a continuous density gradient with density marker beads and red cells from patients with normal hemoglobin (AA), HbC trait (AC), HbC disease (CC), sickle cell anemia (SS), HbS-O Arab, and hereditary spherocytosis (HS). (See color plate 28.4.)

360 mOsm. Stractan and Percoll can produce continuous density gradients with physiological pH, osmolarity, and ionic composition.[68] These gradients are sensitive to very small changes in red cell density and can be used both preparatively and analytically. Assignment of density is based on position relative to density marker beads and on measured MCHC of cells isolated from defined positions in the gradient. An example of the power of separation of Percoll–Larex gradients is given in Figure 28.4, in which the red cell density distributions of several common hemoglobinopathies are compared.

All separations based on red cell density are sensitive to the pH and osmolarity of the solutions because these variables will change the MCHC of the cells. Sedimentation through the interface may depend on red cell deformability,[69] leading to systematic underestimation of the density of poorly deformable cells. Stractan (Larex) is tedious to prepare, but cells isolated from these gradients are suitable for transport measurements and other protocols requiring physiologically intact cells.

F Cells

With the exception of some forms of HPFH (Chapter 16), HbF is not uniformly distributed among red cell. Erythrocytes with detectable amounts of HbF are called F cells (Chapter 7), and these can be detected by the acid elution method and flow cytometry. The Kleihauer and Betke method relies on resistance of precipitated HbF to acid elution. Cells are spread on a slide, fixed, and then incubated with citric acid–phosphate buffer. HbF remains precipitated while all other hemoglobins are eluted from the cell. When stained with hematoxylin–eosin F cells are stained; in gene deletion HPFH all erythrocytes are uniformly stained.

Development of monoclonal antibodies to HbF in several laboratories allowed a more quantitative detection of HbF. Cells are first lightly fixed and the membrane permeabilized with detergents and/or organic solvents. After fixation and permeabilization, the cells are stained with antibody and may be observed either by microscopy or by flow cytometry[70–72] (Fig. 28.5). Early measurements used immunodiffusion to create a ring of precipitated HbF antibody around the positive cells. Fluorescent labels can be attached directly to the antibodies and cells observed by fluorescence microscopy.[70] Monoclonal antibodies against several hemoglobins including HbF are commercially available. These antibodies can be used for immunofluorescent labeling of F cells in fixed smears on slides, including archival samples.[70]

Globin Chain Synthesis

Incorporation of labeled amino acids into intact cells was first reported more than 50 years ago. Imbalance of synthesis of α- versus non-α-globin chains is the fundamental definition of thalassemia. Globin-chain synthesis can be measured in blood reticulocytes and marrow erythroid precursors, although the results are not always equivalent. The most convenient means of chain separation is

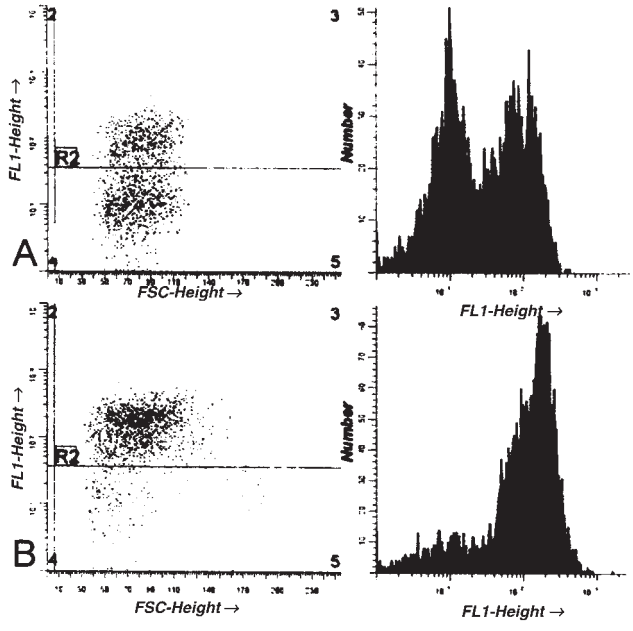

Figure 28.5. Comparison of distribution of γ-globin chains in red cells by fluorescence-activated cell sorting analysis using fluorescein isothiocyanate–labeled antibody specific for human γ-globin chains (supplied by Thomas Campbell of EG&G Wallac). In this case, the examples are two different types of transgenic mice expressing exclusively human hemoglobin and either a low level of γ globin (panel **A**) or a high level of γ globin (panel **B**). Left panels: fluorescence intensity versus cell size; right panels: number of cells versus fluorescence intensity. Note the presence of two populations of red cells that represent non-F cells and F cells (high fluorescence intensity).

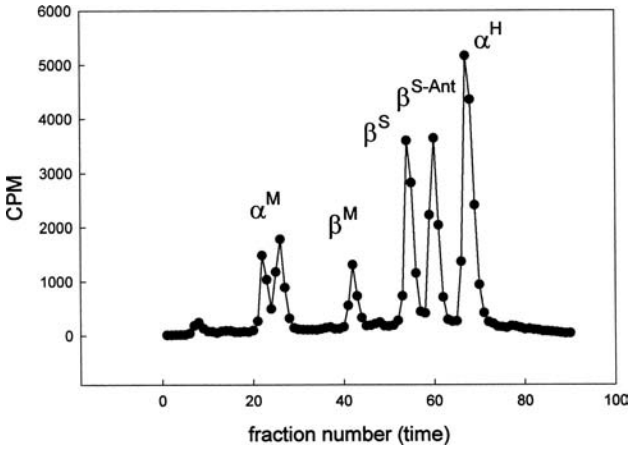

Figure 28.6. Chain synthesis as measured by incorporation of radioactive leucine followed by separation of globin chains by denaturing reverse-phase HPLC. In this case the sample studied was from a transgenic mouse expressing human α, β^S, and $\beta^{S\text{-Antilles}}$ as well as mouse α- and β-globins.

reverse-phase HPLC.[73] Fractions containing globin chains are collected, and the radioactivity incorporated is counted (Fig. 28.6). The efficiency of labeling can be greatly improved if the percentage reticulocytes is enriched by a process such as layering whole blood on a discontinuous Stractan gradient and collecting the lightest fraction that contains the most reticulocytes. Chain synthesis is still the gold standard when trying to elucidate the mechanism(s) by which synthesis of γ-globin is enhanced by butyrate in sickle cell disease.[74,75]

Hemoglobin S Polymerization, Rate of Sickling, and Percentage of HbS Polymer

When the concentration of deoxyHbS exceeds the C_{SAT}, polymer is formed. Polymer formation does not occur immediately because, prior to polymer formation, nucleation must occur, and because the nucleus consists of several hemoglobin molecules, there is a very high concentration dependence (Chapter 6). The time between deoxygenation and the onset of polymer formation is called the delay time[76] that has one of the highest concentration dependencies in biology[77] and may range from values of less than a microsecond at high hemoglobin concentrations to several minutes at low concentrations.

The distortion of the red cell known as sickling is the result of intracellular polymer formation and can be used as an indirect endpoint for polymer formation. Two methods have been used to measure the rate of sickling: manual mixing and continuous flow. In the manual and continuous flow methods, oxygenated red cells are mixed with buffered sodium dithionite, which reacts with the oxygen and, at predetermined intervals, cells are fixed with isotonic formalin; the number of cells that have sickled are counted, and the results plotted as a function of time. The earliest recorded time point for continuous mixing was at 25 msec. Because samples of blood from sickle cell disease patients can contain appreciable numbers of cells with unusual shapes, the number of deformed cells can be counted in a control sample and subtracted from the total of sickled cells. This method is capable of showing that cells from patients with HbSC disease have a stronger response to reduced osmolarity than cells from sickle cell anemia patients and can detect retardation of polymer formation by antisickling agents. Polymer formation can occur much more rapidly than the mixing time in these methods and methods capable of directly studying polymerization in solutions and intact cells have been devised.

These more quantitative methods consist of two parts: 1) rapid generation of high concentrations of nonpolymerized deoxyHbS, and 2) a sensitive, rapid readout. Two methods have been used to generate high concentrations of deoxyhemoglobin: temperature jump and laser photolysis. Readout methods have included optical birefringence, turbidity, light scattering, water proton line width and relaxation time, and differential interference contrast. The temperature jump method makes use of the negative temperature dependence of HbS solubility and is very simple, but requires a minimum of approximately 10 seconds to reach thermal equilibrium and has a resolution of approximately 1 second. In addition, the highest hemoglobin concentration that can be attained at 0°C without polymer is approximately 30 g/dL. The majority of sickle cells have a MCHC exceeding this value.

Because of these limitations a laser photolysis method was developed that allows direct measurement of polymer formation with very high time resolution both in solutions and in red cells. Using laser photolysis of CO-Hb, deoxyHb is produced followed by detection of polymer formation by light scattering. The principle of this measurement is the observation that CO can be completely dissociated from hemoglobin by exposure to a focused laser beam at 514.5 nm, yielding deoxyhemoglobin and that this deoxyhemoglobin can be maintained with continuous photolysis with minimal heating. Polymerization can then be monitored by the method of choice such as light scattering.

New insights into nucleation, fiber growth, and factors affecting red cell shape have been obtained using differential interference contrast and birefringence.[78,79]

Clinical Evaluation of Hemoglobinopathies and Thalassemias using Protein-based and Cellular Diagnostics

When clinical evaluation, family history, or the results of a screening or routine blood count raise the possibility of a hemoglobinopathy or thalassemia, the first approach to diagnosis lies in the further evaluation of the erythrocyte indices, such as MCV or MCH, followed by expert examination of a peripheral blood film. The reticulocyte count, when persistently elevated is highly suggestive of

hemolysis. As discussed in individual disease-specific chapters, peripheral blood smear morphology can provide clues to the diagnosis of most of the common hemoglobinopathies and thalassemia.

No single hemoglobin analytical procedure available in most clinical laboratories can distinguish definitively all common and clinically important variant hemoglobins, and rare variants can be especially difficult to resolve. The highest levels of hemoglobin-based diagnostics are limited to reference laboratories. The β thalassemias rely on quantitation of HbA_2 levels to detect heterozygotes, and some α thalassemias are characterized by HbH inclusion bodies. Quantitation of HbF is important for the diagnosis of thalassemia syndromes and HPFH.

If a hemoglobin variant is detected, the major clinical questions to be resolved are, what is the nature and abundance of the variant, and is it relevant to the clinical condition? In general, mutations of the β-globin gene usually cause only a single abnormal hemoglobin fraction, and if stable (Chapter 24), forms half of the total hemoglobin. In contrast, α-globin chain variants cause alterations in all hemoglobins, as all hemoglobins contain an α-globin chain. Usually, mutation of one α-globin gene creates variants forming 20%–25% of the total HbA, and proportionally similar fractions of the total HbA_2 and HbF. γ-Globin variants will alter a single major hemoglobin during fetal and neonatal life, but after the first year of life will alter only the small residual amount of HbF, and as a result, are rarely detected. Mutants of the δ-globin gene will alter only the HbA_2 band. The actual amounts of different hemoglobin types that accumulate in vivo depend on the expression of each globin gene, the stability of the monomer, dimer and tetramer, and on the posttranslational assembly of αβ dimers (Chapter 7).

Not all variant hemoglobins are resolvable using the commonly available protein-based means of detection, and a definitive diagnosis of rare variants is usually not possible with these methods. Therefore, rather than attempt the questionable, when definitive diagnosis is called for, it is best to move to DNA-based diagnostics.

DNA-BASED DIAGNOSIS OF THE HEMOGLOBIN DISORDERS

Hemoglobinopathies were the first genetic diseases to be characterized at the molecular level and consequently have been used as a prototype for the development of new techniques of mutation detection. Many different PCR-based techniques can be used to detect the known globin gene mutations, including dot blot analysis, reverse dot blot analysis, the amplification refractory mutation system (ARMS), denaturing gradient gel electrophoresis (DGGE), mutagenically separated polymerase chain reaction (MS-PCR), gap-PCR, and restriction endonuclease (RE) analysis. Each method has its advantages and disadvantages and the particular one chosen by a laboratory for the diagnosis of point mutations depends not only on the technical expertise available in the diagnostic laboratory but also on the type and variety of the mutations likely to be encountered in the individuals being screened.

The spectrum of α- and β-globin gene mutations is different for each population, and many mutations are regionally specific. Although more than 1,200 different globin gene alleles have been identified, mutation analysis is simplified by the fact that each country has only a few common alleles. Thus, a strategy is required for mutation diagnosis that involves knowledge of the ethnic group of the patient under study, the gene frequencies of the mutations in the ethnic group of the patient, and the appropriate method of mutation detection for those mutations. The following is an overview of the diagnostic methods currently being used worldwide for DNA-based diagnosis, including their use in antenatal diagnosis, and we describe strategies and the methods used in one large national laboratory for the diagnosis of mutations in an ethnically heterogeneous population. The approach used in ethnically homogeneous populations will be different and more focused.

SOURCES OF DNA

Blood

DNA is normally prepared from 5 to 10 mL of peripheral blood that is anticoagulated with heparin or preferably EDTA. The DNA can be isolated by the standard method of phenol–chloroform extraction and ethanol precipitation or by using one of several commercial kits based on salt extraction, protein precipitation etc. Sufficient DNA is obtained for both molecular analysis and subsequent storage in a DNA bank at −20°C.[80] If DNA banking is not required, a much smaller quantity of blood may be used for just PCR techniques. Mutation analysis may be performed by simply adding 1 μL of boiled whole blood to the PCR mixture.[81]

Amniotic Fluid

DNA can be prepared from amniotic fluid cells directly or after culturing. It is prudent to split an amniotic fluid sample into a sample to be sent for culturing and a sample for direct DNA analysis. It takes 2–3 weeks to grow amniocytes to confluence in a 25-mL flask, but culturing has the advantage that a large amount of DNA is obtained (the yield from such a flask has varied from 15 to 45 μg, enough DNA for all types of analyses). This provides a backup for failure with a direct analysis or material for confirmation in case of maternal contamination problems. A diagnosis can be made using DNA from the noncultivated cell sample in most cases. Approximately 2 μg of DNA is obtained from 7 mL of amniotic fluid and this is sufficient for all PCR-based methods of analysis. The method of DNA preparation

for both cultured and noncultivated cells is essentially the same as that for chorionic villi.[80]

Chorionic Villi

The two main approaches to chorionic villus sampling, ultrasound-guided transcervical aspiration and ultrasound guided transabdominal sampling, provide good-quality samples of chorionic villi for fetal DNA diagnosis. Sufficient DNA is normally obtained for both PCR and Southern blot analysis of the globin genes. In 200 chorionic villus sampling DNA diagnoses, the average yield of DNA was 46 μg and only in one instance was less than 5 μg obtained.[80]

The main technical problem with this source of fetal DNA is the risk of contamination with maternal DNA, which arises from the maternal decidua that is sometimes obtained along with the chorionic villi. Careful dissection and removal of the maternal decidua with the aid of a phase-contrast microscope, yields pure fetal DNA samples, as shown by a report of 457 first trimester diagnoses for β thalassemia in Italians, without any misdiagnoses.[82] Maternal contamination can be ruled out in most cases by the presence of one maternal and one paternal allele following the amplification of highly polymorphic repeat markers. Originally, variable number tandem repeat (VNTR) polymorphic markers were amplified and analyzed by gel electrophoresis and ethidium bromide staining,[83] but now most laboratories have switched to using short tandem repeat markers or microsatellite polymorphic markers analyzed on a DNA sequencing machine.[84] The risk of misdiagnosis from maternal DNA contamination might be further reduced by the preparation and analysis of DNA from a cleaned single villus frond;[85] however, following a case in which a single frond appeared to give a different sickle cell genotype compared with the remaining chorionic villus sampling material, this techniques was abandoned.

Fetal Cells in Maternal Blood

Fetal cells have long been known to be present in the maternal circulation and they provide an attractive noninvasive approach to prenatal diagnosis, but attempts to isolate the fetal cells as a source of fetal DNA by using immunological methods and cell sorting have had only moderate success in providing a population of cells pure enough for fetal DNA analysis. Until recently, analysis of fetal cells in maternal blood could only be applied for the prenatal diagnosis of β thalassemia in women whose partners carried a different mutation, as reported for the diagnosis of Hb Lepore.[86] The development of the technique of isolation of single nucleated fetal erythrocytes by micromanipulation under microscopic observation[87] has permitted the analysis of both fetal genes in single cells from maternal blood. This approach has now been used successfully for prenatal diagnosis in two pregnancies at risk for sickle cell anemia and β thalassemia.[88] The approach has proved subject to technical difficulties and is costly and time consuming and so is not widely applicable.

Fetal DNA in Maternal Plasma

The analysis of fetal DNA in maternal plasma is a simpler and more robust procedure than the analysis of DNA in fetal nucleated red cells in maternal blood as no enrichment process is involved.[89] Cells are removed from the plasma by simple centrifugation and then the DNA in the plasma can be purified by standard methods.[90] Fetal DNA has been detected in as little as 10 mL of maternal plasma at 11–17 weeks gestation and is cleared very rapidly from the maternal plasma postpartum.[91] The technique is being used for the prenatal diagnosis of sex-linked disease and fetal RhD blood group type. The approach can only be used to detect the paternally inherited mutation and thus for β thalassemia it is limited in that it is only potentially applicable to couples in whom the paternal mutation is different than the maternal mutation. It has been used for the prenatal exclusion of β thalassemia major in eight fetuses at risk, using allele-specific primers for the detection of the CD 41/42 (-CTTT) mutation by real-time PCR[92] and the detection of homozygous α^0 thalassemia.[93] Further development of the method to detect both maternal and paternal linked polymorphisms might allow the technique to exclude maternal β thalassemia mutations.[94]

Preimplantation Diagnosis

Preimplantation genetic diagnosis represents a state-of-the-art procedure that allows at risk couples to have disease-free children without the need to terminate affected pregnancies. PCR-based diagnostic methods can be potentially applied for preimplantation genetic diagnosis using three types of cells: polar bodies from the oocyte/zygote stage, blastomeres from cleavage stage embryos, and trophectoderm cells from blastocysts.[95] Although the technique requires a combined expertise in both reproductive medicine and molecular genetics, a small number of centers around the world can now perform this procedure for hemoglobin disorders, resulting in the birth of more than 50 healthy children. Preimplantation diagnosis has been used successfully for both α[96,97] and β thalassemia.[98,99] The approach is especially useful for couples for whom religious or ethical beliefs will not permit the termination of pregnancy, and for couples who have already had one or more therapeutic abortions.

Nevertheless, preimplantation genetic diagnosis is technically challenging, multistep, and expensive. The PCR protocol must be able to detect accurately the required genotype in single cells, be optimized to minimize PCR failure and avoid the problem of allele drop out, which could lead to misdiagnosis. Protocols designed to monitor the

occurrence of allele drop out include multiplex PCR to detect both alleles that contribute to the genotype, such as DGGE, single-strand conformation analysis and real time PCR.[100] The birth of a healthy unaffected baby depends not only on an accurate diagnosis, but also on the success of each of the multiple stages of the assisted reproduction procedure. Overall, the success rate of the procedure is only 20%–30% and thus this approach is not likely to be used routinely for the monitoring of pregnancies at risk for hemoglobin disorders. One specific use of this approach is to allow the birth of a normal child who is HLA identical to an affected sibling, thus permitting a possible cure by stem cell transplantation.[20]

DNA DIAGNOSIS OF α THALASSEMIA

α Thalassemia is almost always a result of mutations affecting either one α-globin gene (α^+ thalassemia) or both α-globin genes on the same chromosome (α^0 thalassemia) (Chapter 13). The majority of the mutations are gene deletions but some point mutations in one of the two α-globin genes resulting in α^+ thalassemia have been described. The deletion breakpoints of the seven most common deletion alleles have been determined, and these deletions can be diagnosed quickly by the technique known as gap-PCR (Table 28.1). The remainder of the deletion alleles used to be diagnosed by Southern blot analysis,[101] but now are diagnosed by the technique called multiplex ligation–dependent probe amplification (MLPA).[102]

Diagnostic Strategy

α^0 Thalassemia is found in mainly patients of Mediterranean or Southeast Asian in origin. Although α^0 thalassemia has been described in patients of Asian Indian or African origin, it is extremely uncommon, and patients with the phenotype of α^0 thalassemia trait usually have the genotype of homozygous α^+ thalassemia. α^+ Thalassemia can reach high gene frequencies in parts of Africa and Asia, with the $-\alpha^{3.7}$ deletion being the predominant mutation in African, Mediterranean, and Asian individuals and the $-\alpha^{4.2}$ being more common in Southeast Asian and the Pacific islands populations. The strategy for screening is based on ethnic origin of the individual, although PCR now makes it easy to screen for all the common deletion mutations in any individual.

In multiethnic countries like the United Kingdom and United States the ethnic origin of carriers of α thalassemia include individuals of African, Indian, Pakistani, Chinese, Southeast Asian, Greek Cypriot, and Turkish Cypriot descent and occasionally members of the indigenous population. In this environment, screening is first done for the $-\alpha^{3.7}$-kb and $-\alpha^{4.2}$-kb α^+ thalassemia deletions by multiplex gap-PCR. If indicated by the MCH, MCV, or suspected HbH disease, screening is next done for α^0 thalassemia deletions by multiplex gap-PCR for either the Mediterranean or Southeast Asian deletions according to an individuals' ethnic origin. If negative results are still obtained, screening for nondeletion mutations by selective DNA sequencing of both α-globin genes for suspected α^+ thalassemia carriers and screening, for other deletions by MLPA analysis in suspected α^0 thalassemia carriers can also be done. All prenatal diagnoses for α^0 thalassemia are carried out by both gap-PCR and MLPA.

Table 28.1. Globin gene disorder deletions diagnosable by gap-PCR

Disorder	Deletion mutation	Distribution
α^0 Thalassemia	$--^{SEA}$	Southeast Asia
	$--^{MED}$	Mediterranean
	$-(\alpha)^{20.5}$	Mediterranean
	$--^{FIL}$	Philippines
	$--^{THAI}$	Thailand
α^+ Thalassemia	$-\alpha^{3.7}$	Worldwide
	$-\alpha^{4.2}$	Worldwide
β^0 Thalassemia	290-bp deletion	Turkey, Bulgaria
$(\delta\beta)^0$ Thalassemia	532-bp deletion	Africa
	619-bp deletion	India, Pakistan
	1393-bp deletion	Africa
	1605-bp deletion	Croatia
	3.5-kb deletion	Thailand
	10.3-kb deletion	India
	45-kb deletion	Philippines, Malaysia
	Hb Lepore	Mediterranean, Brazil
$(^A\gamma\delta\beta)^0$ Thalassemia	Spanish	Spain
	Sicilian	Mediterranean
	Vietnamese	Vietnam
	Macedonian/Turkish	Macedonia, Turkey
	Indian	India, Bangladesh
	Chinese	Southern China
HPFH	HPFH1	Africa
	HPFH2	Ghana
	HPFH3	India
	Hb Kenya	Africa

Diagnosis of Deletion Mutations by PCR

The two most common α^+ thalassemia gene deletions, the $-\alpha^{3.7}$ and $-\alpha^{4.2}$ alleles, together with 5 α^0 thalassemia deletion genes, the $--^{FIL}$, $--^{THAI}$, $--^{MED}$, $-(\alpha)^{20.5}$, and the $--^{SEA}$ alleles can be diagnosed by gap-PCR[81,103–106] (Table 28.1). Gap-PCR is the simplest of amplification techniques, using two primers complimentary to the sense and antisense strand of the DNA regions that flank the deletion. Amplified product is only obtained from the α thalassemia deletion allele as the primers are located too far apart on the normal DNA sequence for successful amplification. Therefore, the normal allele (αα) is detected by amplifying across

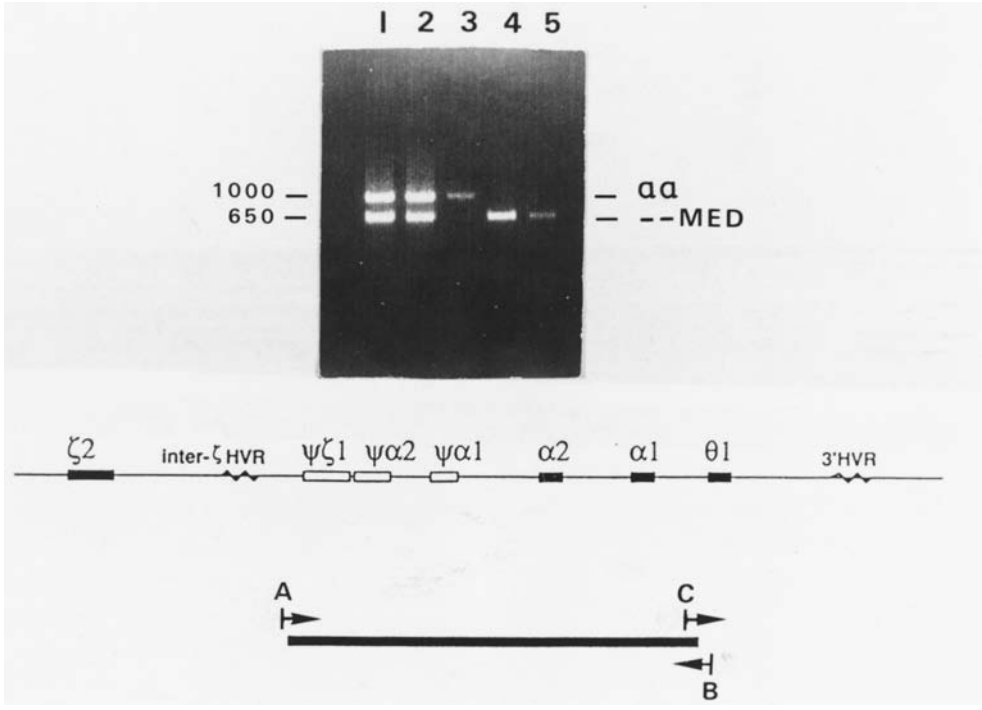

Figure 28.7. Prenatal diagnosis of the --^{MED} α^0 thalassemia allele by using gap-PCR. The amplification products after agarose gel electrophoresis and ethidium bromide staining are shown as follows: track 1, maternal DNA; track 2, paternal DNA; track 3, normal DNA; and tracks 4 and 5, different concentrations of chorionic villi DNA. The diagram below shows the location of the --^{MED} deletion with respect to the α-globin gene cluster. Primers A and B span the deletion and amplify --^{MED} allele to give a 650-bp product; primers B and C span one breakpoint and amplify the normal allele to give a 1000-bp product.

one of the breakpoints, using one primer complimentary to the deleted sequence and one to the normal sequence. An example of the use of gap-PCR for the prenatal diagnosis of the Mediterranean α^0 thalassemia mutation --^{MED} is illustrated in Figure 28.7.

Gap-PCR provides a quick diagnostic test for α^0 thalassemia trait but requires careful application for prenatal diagnosis. Prenatal diagnosis results by gap-PCR should be confirmed by MLPA analysis. Amplification of sequences in the α-globin gene cluster is technically more difficult than that of the β-globin gene cluster, requiring more stringent conditions for success due to the higher GC content of the α-globin gene cluster.[107] For a more reliable diagnosis of the carrier state by gap-PCR, amplification of the GC-rich α-globin locus can be improved by using betaine and dimethyl sulfoxide in the PCR reaction. These agents enhance the reaction by disrupting the base pairing of the GC-rich region and lead to the destabilization of the secondary structure by making the GC and AT base pairs equally stable in the DNA duplex. The application of these agents with redesigned primers has lead to the development of multiplex assays to detect heterozygosity and homozygosity of the seven deletion mutations.[81,108] Experience has shown that great care is still needed in interpreting the results, as some tests still result occasionally in unpredictable reaction failure and allele drop out. Testing several different dilutions of a DNA sample can help resolve this problem, as the inhibition causing allele drop out can be diluted out.

Other approaches have been developed to provide quick, simple, rapid, accurate, and cost effective methods of screening for the deletion mutations. These include the use of real-time quantitative PCR analysis for the Southeast Asian α^0 thalassemia deletion in Taiwan,[109] the use of denaturing HPLC to diagnose the 4.2-kb α^+ thalassemia deletion gene in Chinese individuals,[110] real-time quantitative PCR to detect the Southeast Asian α^0 thalassemia deletion,[93] and the use of an oligonucleotide microarray to detect the Southeast Asian α^0 thalassemia deletion and the -$\alpha^{3.7}$-kb and -$\alpha^{4.2}$ -kb α^+ thalassemia deletions.[111,112] The most useful recent development for the diagnosis of deletion mutations is MLPA.[102] In this method, two sets of 35 probes have been developed to detect all known deletions located in the α-globin gene cluster on chromosome 16p13.3. This method will detect rare and novel forms of deletional α thalassemia that cannot be diagnosed by gap-PCR and provides an excellent back-up screening method for the common deletion mutations. In some cases, MLPA can replace Southern blotting for the routine diagnosis of α^0 thalassemia deletions.

Diagnosis of Point Mutations by PCR

The nondeletion α^+ thalassemia mutations can be identified by PCR techniques following the selective amplification of the α-globin genes.[113] This technique allows the amplified product from each α-globin gene to be analyzed for the expected known mutation according to the ethnic

origin of the patient or for the gene to be sequenced to identify new mutations. Selective amplification followed by DNA sequence analysis is a reasonable approach for the diagnosis of all nondeletion α^+ thalassemia mutations.

Several of the nondeletion α^+ thalassemia mutations create or destroy a restriction enzyme site and can be analyzed for by restriction enzyme digestion of the amplified product. For example, Hb Constant Spring mutation can be diagnosed by *Mse* I digestion.[114] In theory, any technique for the direct detection of point mutations such as allele specific oligonucleotide hybridization or allele specific priming can be used for the diagnosis of nondeletion α^+ thalassemia mutations. No simple strategy to diagnose all the known mutations has been developed however. The only published approach to date is a complex strategy involving the combined application of the indirect detection methods of DGGE and single-strand conformation analysis, followed by direct DNA sequencing.[115]

DNA DIAGNOSIS OF β THALASSEMIA

Although more than 200 different β-globin gene mutations have been associated with the phenotype of thalassemia, only approximately 30 mutations are found in at risk groups at a frequency of 1% or greater (as listed in Table 28.2), and thus just a small number account for the majority of the mutations worldwide.[116] All of the mutations are regionally specific and the spectrum of mutations has now been determined for most at risk populations.[117] Each population has been found to have just a few of the common mutations together with a larger and more variable number of rare mutations. This makes it easy to screen for β thalassemia mutations in most cases if the ethnic origin of the patient is known.

Diagnostic Strategy

The strategy for identifying β thalassemia mutations in most diagnostic laboratories is to screen for the common ones first using a PCR-based technique that allows the detection of multiple mutations simultaneously. This approach will identify the mutation in more than 90% of cases. Further screening for the possible rare mutation will identify the defect in most of the remaining cases. Mutations remaining unknown after this second screening are characterized by direct DNA sequence analysis. The β-globin gene can be amplified simultaneously in three sections of approximately 500 bp in length for direct DNA sequence analysis using an automatic DNA sequencer. Alternatively, the site of the mutation can be localized first by the application of a nonspecific detection method such as DGGE and then the mutation identified using just one sequencing reaction. Although a bewildering variety of PCR techniques have been described for the molecular diagnosis of point mutations, most diagnostic laboratories are using one or more of the techniques described herein.

Panels of primers for the detection of the common mutations in each ethnic group can be developed by the primer-specific amplification method known as ARMS. Panels for the common Mediterranean, Asian Indian, Chinese, and African mutations are available along with a panel for the most common silent or normal HbA_2 β thalassemia mutations. Rare or novel mutations are then diagnosed by DNA sequence analysis. Prenatal diagnosis results for β thalassemia are confirmed by a second method, either by restriction enzyme analysis of amplified product (RE-PCR), or more usually, by DNA sequence analysis.

Allele-specific Oligonucleotide PCR

The hybridization of allele-specific oligonucleotide (ASOs) probes to amplified genomic DNA bound to a nylon membrane in the form of dots was the first PCR method to be developed. This method, known as dot blotting, is based on the use of two oligonucleotide probes for each mutation, one complimentary to the mutant DNA sequence and the other complimentary to the normal β-globin gene sequence at the same position. The probes are usually 5′ end-labeled with ^{32}P-labeled deoxynucleoside triphosphates, biotin, or horseradish peroxidase. The genotype of the DNA sample is diagnosed by observing the presence or absence of a hybridization signal from the mutation specific and normal probes. The technique has been applied in many laboratories with great success, especially for populations with just one common and a small number of rare mutations, as in the example of Sardinia.[118] When screening for a large number of different mutations, this method becomes limited by the need for separate hybridization and washing step for the detection of each mutation.

To overcome this problem of screening for multiple mutations, the technique of reverse dot blotting has been developed in which the roles of the oligonucleotide probe and the amplified genomic DNA are reversed.[119] Unlabeled oligonucleotide probes complementary to the mutant and normal DNA sequences are fixed to a nylon membrane strip in the form of dots or slots. Amplified genomic DNA, labeled by either the use of end-labeled primers or the internal incorporation of biotinylated deoxyuridine triphosphate, is then hybridized to the filter. This allows multiple mutations to be tested in one hybridization reaction. It has been applied to the diagnosis of β thalassemia mutations in Mediterranean individuals,[120] African Americans,[121] and Thais,[122] using a two-step procedure with one nylon strip for the common and another for the less common mutations.

Reverse hybridization screening is the only technique for the diagnosis of β thalassemia mutations to have been developed commercially with some success and there are currently there are two competing systems on the market. One uses a strip with oligonucleotide probes for eight common Mediterranean mutations affixed together with probes to detect HbS and HbC mutations in amplified DNA. Another uses nucleotides complementary to mutant and

normal sequences immobilized in the wells of a microplate and thus is more complex, requiring a dedicated microplate incubator, washer, and reader. Two kits, one for eight common Mediterranean mutations and one for the eight most common Southeast Asian β-thalassemia mutations, including HbE, are available.

Oligonucleotide Microarrays

The principle of reverse dot blotting has been brought up to date by the development of microarrays for the simultaneous detection of multiple β thalassemia mutations. Several groups have now published details of a DNA chip platform that has been used to genotype β thalassemia carriers and patients.[112,123] The approach of tagged single-based extension and hybridization to glass or flow-through arrays has been developed for the detection of 17 β-globin gene mutations[124] and a similar approach of arrayed primer extension has been used to detect 23 mutations.[125] It is not clear whether these state-of-the-art methods will be economically viable and replace conventional techniques in the future. This will depend on the market for thalassemia mutation chips, especially for the diagnosis of mutations in populations with just one or two very common mutations that can be easily screened for by rapid low-technology methods and for which the additional screening capacity on the chip would be redundant.

Primer-specific Amplification

Different diagnostic methods have been developed based on the principle of primer-specific amplification, where

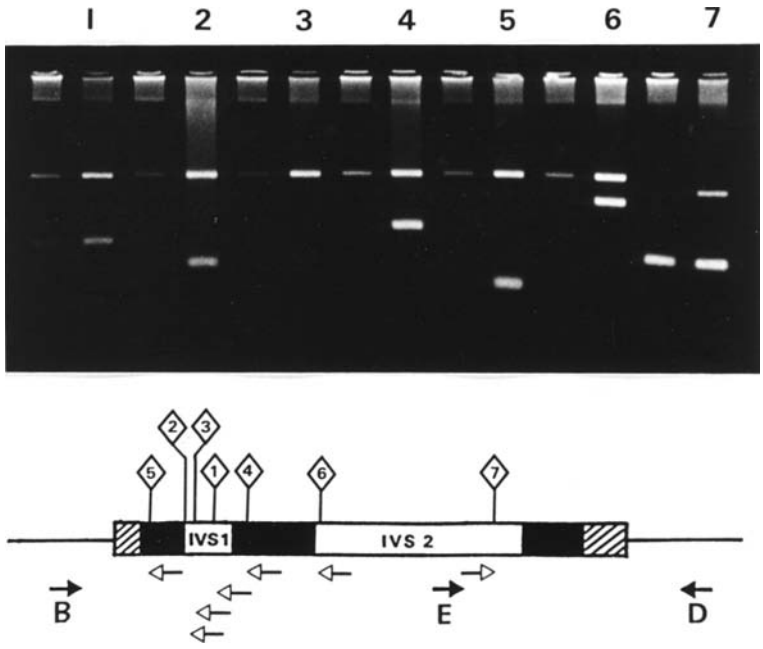

Figure 28.8. ARMS-PCR screening of a DNA sample for seven common Mediterranean mutations. The gel shows alternating tracks containing the amplification products from DNA of a patient with β thalassemia trait and those from control DNA for each of the seven mutations (labeled 1–7). The mutations screened for are: 1, IVSI-110 (G→A); 2, IVSI-1 (G→A); 3, IVSI-6 (T→C); 4, codon 39 (C→T); 5, codon 6 (-A); 6, IVSII-1 (G→A); 7, IVSII-745 (C→G); as shown in the diagram of the β gene. In the first 12 tracks, the control primers D and E (Table 28.4) were used (producing an 861-bp fragment), and in the last 2 tracks, the $^{G}\gamma$-*Hin*d III RFLP control primers were used (producing a 323-bp fragment).

a perfectly matched PCR primer is much more efficient in annealing and directing primer extension than a mismatched primer. The most widely used method is ARMS, in which a primer will only permit amplification to take place when it perfectly matches the target DNA sequence at the 3′ terminal nucleotide.[126] The target DNA is amplified using a common primer and either of two allele specific primers, two complimentary to the mutation to be detected (the β thalassemia primer) and the other complimentary to normal DNA sequence at the same position. The method provides a quick screening assay that does not require any form of labelling as the amplified products are visualized by agarose gel electrophoresis and ethidium bromide staining. ARMS primers were first developed for the screening and prenatal diagnosis of β thalassemia mutations in the Asian Indian and Cypriot populations in the United Kingdom.[127] Subsequently, ARMS primers have been designed to screen for the common mutations of all ethnic groups.[128] Figure 28.8 shows the results of a screening a Cypriot individual with β thalassemia trait for seven common mutations by ARMS-PCR. Details of the mutation-specific and normal sequence-specific primers used to diagnose the common β thalassemia mutations are presented in Tables 28.3 and 28.4. ARMS-PCR is currently the main approach for mutation detection and prenatal diagnosis for β thalassemia, HbE–thalassemia, and the sickling disorders in the United Kingdom. The technique has been established in nations such as India because of its rapidity and economy, making realistic for the first time the development of a prenatal diagnostic service in developing countries.[129]

Other variations on the primer-specific amplification theme are multiplex ARMS, competitive oligonucleotide priming (COP)–PCR and mutagenetically separated (MS)-PCR. More than one mutation can be screened for at the same time in a single PCR reaction by multiplexing the ARMS primers provided that they are coupled with the same common primer.[130] Fluorescent labeling of the common primer allows the sizing of the amplification products on an automated DNA fragment analyzer.[131] If the normal and mutant ARMS primers for a specific mutation are coamplified in the same reaction they compete with each other to amplify the target sequence. This technique is called COP and requires the two ARMS primers to be labeled differently. Fluorescent labels permit a diagnosis to be made by means of a color complementation assay.[132] A variation of this method is to use ARMS primers that differ in length instead of the label. The primers compete with each other to produce fragments that can be distinguished simply by agarose gel electrophoresis. Normal, heterozygous and homozygous DNAs are diagnosed by simple analysis of the presence or absence of the two products. This technique, called MS-PCR, has been applied to the prenatal diagnosis of β thalassemia in Taiwan.[133]

Restriction Enzyme PCR

This is a useful but limited technique because very few β thalassemia mutations create or abolish a restriction endonuclease site and generate diagnosable products (Table 28.5). The presence or absence of the enzyme recognition site is determined from the pattern of fragments of digested fragments after agarose or polyacrylamide gel electrophoresis. Mutations that do not naturally create or abolish restriction sites may be diagnosed by the technique of amplification created restriction sites. This method uses primers that are designed to insert new bases into the amplified product to create a restriction enzyme recognition site adjacent to the mutation sequence. This technique

has been applied to the detection of Mediterranean β thalassemia mutations.[134]

Other Methods for Point Mutations

Many other techniques for the diagnosis of known β-globin gene point mutations have been published, including the use of denaturing high-performance liquid chromatography (DHPLC), the DNA ligase reaction, minisequencing, real-time PCR and multiplex primer extension technology. For example, DHPLC has been used for the analysis of polymorphic duplexes created by allele-specific priming,[135] the analysis of five common Southeast Asian mutations by multiplex minisequencing,[136] multiplex primer extension analysis for 10 Taiwanese mutations[137] and the most common Chinese mutations,[138] and the screening for 11 most common Greek mutations.[139] Real-time PCR quantification and melting curve analysis using LightCycler technology have been used to provide rapid genotyping for a panel of the 10 most frequent Greek mutations[100] and six Lebanese mutations.[140] The DNA ligase method has been updated by the development of a novel piezoelectrical method for detection of a single base mutation in codon 17 of the β-globin gene using nano-gold-amplified DNA probes.[141] All provide rapid and accurate genotyping of the common mutations and are worth considering as alternative diagnostic approaches for point mutations.

Gap-PCR and MLPA

Deletions in the β-globin gene cluster are detected by gap-PCR and/or MLPA analysis. Table 28.1 lists the deletions detectable by gap-PCR. Small deletion mutations in the β-globin gene sequence may be detected by PCR using two primers complimentary to the sense and antisense strand in the DNA regions that flank the deletion.[142–149] For large deletions, amplified product using flanking primers is obtained only from the deletion allele because the distance between the two primers is too great to amplify normal DNA. As is the case with the α thalassemia deletions, the normal allele may be detected by amplifying sequences spanning one of the breakpoints, using a primer complimentary to the deleted sequence and one complimentary to flanking DNA.

PCR Methods for Unknown Mutations

A number of techniques have been applied for the characterization of β-thalassemia mutations without prior knowledge of the molecular defect. The most widely used

of these methods is DGGE, which allows the separation of DNA fragments differing by a single base change according to their melting properties.[150] The technique involves the electrophoresis of double-stranded DNA fragments through a linearly increasing denaturing gradient until the lowest melting temperature domain of the fragment denatures, creating a branched molecule that effectively becomes stationary in the gel matrix. DNA fragments differing by 1 bp in the low melting temperature domain have different melting temperatures and can be separated in most but not all cases. The β-globin gene is amplified in segments using five–seven pairs of primers, one of each pair having a GC-rich sequence added to it to create a high melting domain. Heterozygous DNA creates four bands, two heteroduplexes of normal and mutant sequence and two homoduplexes, one of normal sequence and the other of mutant sequence. DGGE has been used for prenatal diagnosis of β thalassemia in India[151] and also for the analysis of point mutations resulting in δ thalassemia and nondeletion HPFH.[152,153]

Another approach by heteroduplex analysis is using nondenaturing gel electrophoresis. Unique heteroduplex patterns can be generated for each mutation by annealing an amplified target DNA fragment with an amplified heteroduplex generator molecule, a synthetic oligonucleotide of approximately 130 bases in length containing deliberate sequence changes or identifiers at known mutation positions.[154] Other methods such as mismatch cleavage, single-strand conformation polymorphism, and protein truncation test have been used to detect unknown mutations but they have not been applied specifically to the diagnosis of hemoglobinopathies or thalassemias. These techniques simply pinpoint the presence of a mutation or DNA polymorphism in the amplified target sequence. Sequencing of the amplified product can then be performed manually or automatically to identify the localized mutation. This can now be done very efficiently with an automated DNA sequencing machine and fluorescence detection technology.

Although it is clear that many novel detection methods have been developed and used, many large laboratories prefer direct DNA sequencing of amplified product as the primary method of identifying rare or unknown β thalassemia mutations. Once a rare or novel mutation has been identified through DNA sequencing, the DNA sample can be used as a control for the development of ARMS primers to provide a more rapid and cheaper screening of further cases.[155]

β-Globin Gene Haplotype Analysis

At least 18 restriction fragment length polymorphisms (RFLPs) have been characterized within the β-globin gene cluster.[156] Conveniently, most of these RFLP sites are nonrandomly associated with each other and they combine to

produce just a handful of haplotypes[157] (Chapter 27). In particular, they form a 5′ cluster from the ε-globin gene to the δ-globin gene and a 3′ cluster around the β-globin gene, with a relative hot spot for meiotic recombination in between.[158] Each β thalassemia mutation is strongly associated with just one or two common haplotypes, and haplotype analysis has been used extensively to study the origin of globin gene mutations found in different ethnic groups[159] (Chapter 27).

The β-globin gene cluster haplotype normally consists of five RFLPs located in the 5′ cluster (*Hin*d II/ε-gene; *Hin*d III/$^{G}\gamma$-gene; *Hin*d III/$^{A}\gamma$-gene; *Hin*d II/3′ψβ; and *Hin*d II/5′ψβ) and two RFLPs in the 3′ cluster (*Ava* II/β-gene; *Bam*H I/β-gene). All the RFLPs can be easily analyzed by RE-PCR except the *Bam*H I polymorphism, for which a *Hin*f I RFLP located just 3′ to the β-globin gene is used instead, because these two RFLPs have been found to exist in linkage disequilibrium.[160] The primer sequences together with the sizes of the fragments generated are listed in Table 28.6. Primers for three other useful RFLPs are also listed: an *Ava* II RFLP in the ψβ-gene; a *Rsa* I RFLP located just 5′ to the β-globin gene; and the $^{G}\gamma$-*Xmn* I RFLP C→T polymorphism at position −158 5′ to the $^{G}\gamma$-globin gene that acts as a nondeletion HPFH allele under conditions of erythropoietic stress, raising the HbF level in patients with β thalassemia or sickle cell anemia (Chapters 27 and 30).

DNA DIAGNOSIS OF δβ THALASSEMIA, Hb LEPORE, AND HPFH

The δβ thalassemia, Hb Lepore, and HPFH deletion mutations were characterized originally by restriction endonuclease mapping and Southern blotting, but gap-PCR is now used for the diagnosis of the common mutations (Table 28.1). This technique is useful for the diagnosis of Hb Lepore,[86] six δβ-thalassemia alleles, and three HPFH deletion mutations[161] and has also been used for the diagnosis of Hb Kenya. It provides a useful and simple screening method for distinguishing HPFH from δβ thalassemia in Asian Indian, African and Mediterranean individuals. Those testing negative and carrying novel or rare δβ thalassemia, εγδβ thalassemia, and HPFH deletion mutations can now be examined by MLPA analysis.[102] Fifty probes have been developed to cover a region of 500 kb of the β-globin gene cluster, including the locus control region. This enables all large deletions to be identified, including the εγδβ thalassemias, that leave the β-globin genes intact and are not easily detected by conventional techniques.

DNA DIAGNOSIS OF ABNORMAL HEMOGLOBINS

More than 1,000 hemoglobin variants have been described to date, although only a few are clinically important and require routine diagnosis by DNA-based methods. These variants are HbS, HbC, HbE, HbD-Punjab, and HbO-Arab. The mutations for these five abnormal hemoglobins can be diagnosed by a variety of methods.

Sickle Hemoglobin

The HbS mutation destroys the recognition site for three restriction enzymes, *MnI* I, *Dde* I, and *Mst* II. *Mst* II was used for detection of the β^{S} allele by Southern blot analysis because it cuts infrequently around the β-globin gene producing large DNA fragments. For PCR, the enzyme *Dde* I is the enzyme of choice (Fig. 28.9). The primer sequences are listed in Table 28.7. The β^{S} mutation can also be detected by a variety of other PCR-based techniques such as ASO/dot blotting or ARMS. Prenatal diagnosis of sickle cell disease should always be done using two methods, ARMS-PCR and *Dde* I PCR, with careful attention being paid to the intensity of the stained bands on electrophoresis. The ratio of intensity between the mutant band and the control or normal bands must be identical to those of all the control samples. Fainter bands indicate possible maternal DNA contamination; stronger bands may indicate PCR product contamination.

Hemoglobin C

The HbC mutation does not abolish the recognition site for *Dde* I or *Mst* II because the mutation occurs at a nonspecific nucleotide in the enzyme recognition sequences. Thus another method such as ASO/dot blotting or the ARMS technique must be used. The primer sequences used for the ARMS method are included in Table 28.3.

Hemoglobin D-Punjab and Hemoglobin O-Arab

The mutations giving rise to the abnormal variants HbD Punjab (*HBB* glu121gln) and HbO-Arab (*HBB* glu121lys) both abolish an *Eco*R I site at codon 121. Mutation detection is conducted very simply by RE-PCR using *Eco*R I. The primer sequences used for this approach are listed in Table 28.7. This assay does not distinguish the two variants, so this test must be combined with hemoglobin HPLC. HbD-Punjab can be detected by ARMS (Table 28.3).

Hemoglobin E

The HbE mutation abolishes a *Mnl* I site and may be diagnosed by amplification of exon 1 and restriction enzyme analysis. The primer sequences used for this approach are listed in Table 28.7. The HbE mutation may also be diagnosed easily using ASO probes or ARMS primers (Tables 28.3 and 28.4).

Other Variants

A definitive identification of the other abnormal variants requires either DNA sequencing or analysis of the amino

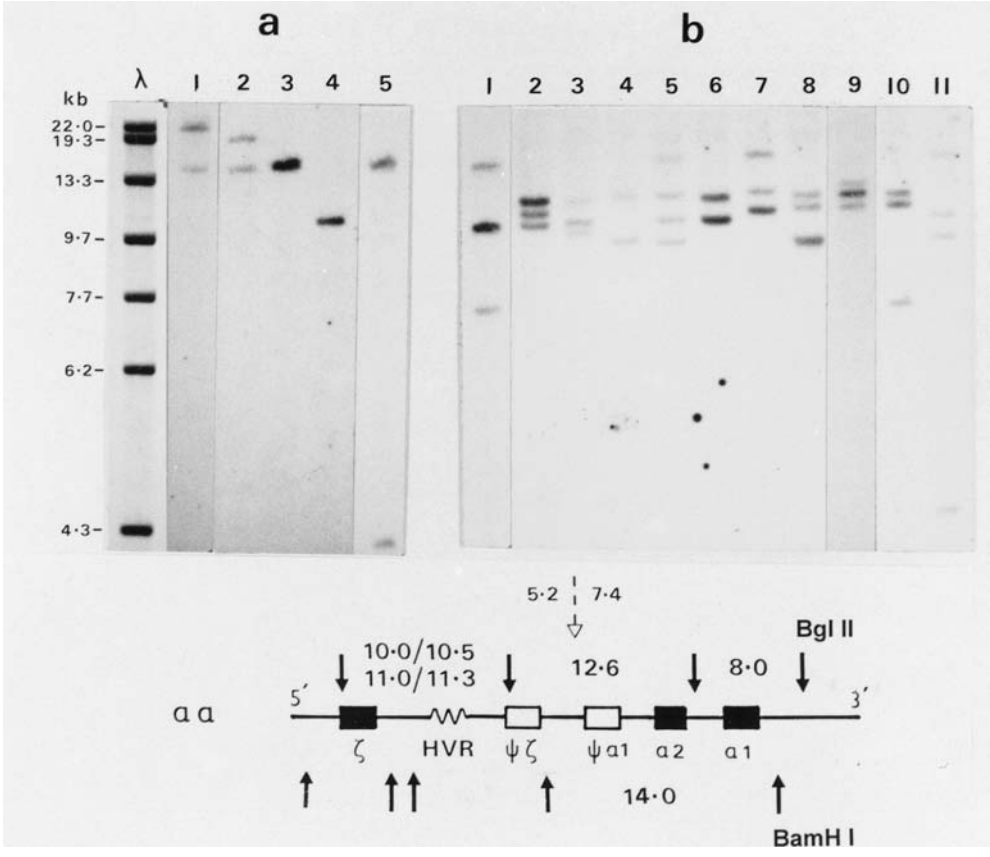

Figure 28.9. The diagnosis of the HbS gene mutation by *Dde* I digestion of amplified DNA. The gel shows *Dde* I–digested fragments of: HbAS individuals (tracks 2, 3, and 5); normal HbA individual (track 6); and sickle cell anemia (track 4). Track 1 contains ϕX174 – *Hae* III DNA markers. The primers used are listed in Table 28.7. The *Dde* I site 5′ to the one at codon 6 (marked by the dotted arrow) is a rare polymorphic site caused by the sequence change G→A at position −83 to the β-globin gene. When present the fragment of 175 bp is cleaved to give 153-bp and 27-bp fragments as shown in track 2.

acid change by mass spectrometry, although a few have had other quick diagnostic tests developed, such as the ARMS technique for the α-chain variant HbQ-India[162] and HbD-Iran (Table 28.3). DNA sequence analysis can be performed in the same manner as that described for the identification of α-chain and α thalassemia point mutations, or more simply through the use of just one sequencing reaction, by sequencing cDNA produced by the reverse transcription of globin mRNA.[84] For the future, the ultimate goal of the identification of all known and unknown hemoglobin variants, by a DNA chip containing every possible codon mutation is within technological reach, but again, this attractive "one stop" method of total variant identification might never find a market as most variants have no clinical significance and identification is often of academic interest only.

ANTENATAL DIAGNOSIS

An antenatal screening program for detection of at risk couples should be able to identify by hematological and DNA testing the majority of carrier states for α thalassemia, β thalassemia, δβ thalassemia, and common variant hemoglobins such as HbS, HbC, HbD-Punjab, HbO-Arab, and Hb Lepore.[163] Strategies for antenatal screening depend on the programs' context. In multiethnic countries such as the United Kingdom or United States, two strategies are applied; one based on universal screening in high prevalence areas for thalassemia or a hemoglobinopathy and one based on ethnic origin of the woman and her partner in low prevalence areas. For example, in the United States, neonatal screening for the HbS gene is universal. The screening algorithms and guidelines for referral of patients for DNA analysis in the United Kingdom can be found on the NHS Sickle Cell and Thalassaemia Screening Programme web site (http://www.kcl-phs.org.uk/haemscreening).

PCR-based techniques provide a quick and relatively simple method for the prenatal diagnosis of homozygous α^0 thalassemia, β thalassemia, and sickle cell disease. The techniques have proven to be reliable and accurate as long as careful attention is given to all potential diagnostic pitfalls and best-practice guidelines are followed.[164,165] These include using two different mutation detection methods whenever possible and excluding maternal DNA contamination by the analysis of VNTR or STR polymorphisms. Kits for profiling 12 or more STR markers simultaneously by

using an ABI or Beckman DNA sequencer are now available and recommended for checking maternal contamination of fetal DNA.[84]

WHICH TECHNIQUES TO USE?

The variety of techniques for the DNA-based diagnosis of hemoglobinopathies and thalassemia creates a problem for laboratories wishing to start molecular analysis of globin gene mutations: What is the best method to adopt? It is clear that ASO hybridization and the ARMS currently form the linchpins for the diagnosis of β thalassemia. Both offer a rapid, cheap, and convenient method to test for multiple mutations simultaneously. Whether one chooses the dot blot method or the reverse dot blot approach will depend on a number factors, including the range of mutations to be diagnosed, the ability to use radioactivity, or the need to use a nonisotopic approach (and thus to consider the use of one of the kits on the market). The laboratory also needs to become proficient in a number of other techniques such as gap-PCR and be able to sequence a β-globin gene for the rare cases in which no common mutations can be identified in individuals with clear-cut phenotypic evidence of β thalassemia. In addition, when these techniques are used for prenatal diagnosis a number of precautionary measures have to be implemented, such as the analysis of fetal DNA samples for maternal DNA contamination when necessary and the confirmation of a diagnosis by a different approach. Therefore, the answer to the question is that each laboratory must carry out preliminary studies using a number of these approaches and work out for itself which techniques are best suited to its needs and the mutations found in the population.

SECTION EIGHT

NEW APPROACHES TO THE TREATMENT OF HEMOGLOBINOPATHIES AND THALASSEMIA

Martin H. Steinberg

The treatment of hemoglobin disorders is evolving and clinical trials of many new agents are underway. Hydroxyurea is used to increase fetal hemoglobin (HbF) levels, stem cell transplantation has the potential for cure, and a larger repertory of iron chelators might make long-term transfusion more feasible. In this section of five chapters, three cover clinically available treatments, discussing in detail aspects of HbF induction, blood transfusion with iron chelation, and stem cell transplantation. One chapter focuses on innovative treatment approaches that remain, at the time of writing, investigative. Treatments include antioxidants, statins, antiinflammatory agents, transport channel inhibitors, antiadhesive agents, and therapeutic methods of increasing nitric oxide bioavailability. The first patients have been treated in a gene therapy trial in which lentiviral vectors containing therapeutic β-like globin genes are used to counter the results of the sickle or β thalassemia mutation, and a final chapter brings this field up to date.

Transfusions are not innocuous and are complicated by alloimmunization, the transmission of unsuspected viral diseases, and iron overload. Controlled, randomized trials of the utility of transfusions for specific complications are sparse. When transfusion is contemplated, expert opinion, with its pitfalls, is relied on in most instances. Usually, it is unclear if simple transfusion or exchange transfusion yields superior results for sickle cell disease complications such as stroke in children or the acute chest syndrome. Strong personal feelings among clinicians regarding the method of transfusion make the chance of definitive clinical trials dim. Since our last edition, efficacious new oral iron chelators have been approved in many countries. Deferiprone might have special benefit for the iron-overloaded heart, but it is not approved for use in the United States. Deferasirox, an oral agent, has efficacy similar to desferrioxamine, the standard for chelating agents. If long-term experience shows that the toxicities of deferiprone and deferasirox are manageable, they will be major adjuncts in dealing with transfusion-induced iron overload.

Stem cell transplantation has been used successfully in sickle cell anemia and β thalassemia. Pioneers in the development of transplantation for sickle cell disease and β thalassemia discuss criteria for patient selection, conditioning regimens, complications and their management, and the most recent results of transplantation. Transplantation is a dynamic field and its future includes the use of cord blood stem cells, inducing stable mixed chimerism, and new possibilities for immunosuppression. Stem cell transplantation, if successful, provides the sole cure for β thalassemia and sickle cell disease, but with the risk, albeit small, of transplant-related death.

The efficacy of hydroxyurea has been proven in a randomized controlled trial in which its use was associated with a nearly 50% reduction in the incidence of pain crisis, acute chest syndrome, frequency of hospitalization, and the use of blood transfusion. Moreover, during a 10-year follow-up period that was no longer randomized or controlled, mortality appeared to be reduced by 40% and toxicity was minor. This cytotoxic agent could have other therapeutic mechanisms in addition to inducing HbF with effects on erythrocytes and vasculature. Studies of hydroxyurea in very young children, in whom therapeutic benefits should be greatest, are nearing completion and the results awaited eagerly. In children, the HbF response is greater than seen in adults with levels near 20% achieved after 6 months–1 year of treatment and with minimal short-term toxicity. Early interruption of the vasoocclusive and hemolytic processes in young patients might also prevent damage to the central nervous system, lungs, kidneys, and bones that end in neurocognitive damage, pulmonary hypertension, disability, and premature death.

We do not yet know the long-term negative effects of hydroxyurea – is it mutagenic, carcinogenic, or leukemogenic? Whether or not the incidence of neoplasia is increased is not known, but in seriously ill patients, small risks are likely to be dominated by the benefits of treatment. In the very young, in whom this agent is likely to be used for decades one must consider longer-term toxicities. In HbSC disease, hydroxyurea appeared to reduce hemolysis but a clinical a trial of this agent in HbSC has not been done.

Studies of butyrate given by short-term pulses have shown remarkable increases in HbF that could be synergistic with those of hydroxyurea. Butyrate was the first agent whose effects could be mediated by epigenetic mechanisms, and work on orally available agents of this general class of drug is continuing. Finally, decitabine, a less toxic analog of 5-azacytidine, the drug that began the effort to induce HbF synthesis, has shown promising results in sickle cell anemia, and development of an oral form is progressing.

The principles of gene therapy approaches to sickle cell disease and β thalassemia are discussed along with the current problems of this approach, foremost among them, how to achieve safe, stable and robust transgene expression.

Until cures of disease by stem cell transplantation or gene therapy become feasible and widely applicable, drug treatment will remain in the forefront. A single agent that will prevent or reverse the disease pathophysiology seems an unlikely possibility, except for the still unachievable goal of an agent that will increase HbF to sufficient concentrations in each sickle erythrocyte to totally prevent HbS polymerization and its consequences. Any other class of drug used alone is unlikely to be sufficient. Trials of combined treatments should be undertaken and include one or more HbF-inducing agent and drugs that target facets of pathophysiology other than HbS polymerization. One can imagine clinical trials that combine agents that increase nitric oxide bioavailability, reduce intercellular interactions, reduce hemolytic anemia, and are antiinflammatory used along with HbF-inducing drugs.

Transfusion and Iron Chelation Therapy in Thalassemia and Sickle Cell Disease

Janet L. Kwiatkowski and John B. Porter

TRANSFUSION

Thalassemia Major (Cooley Anemia)

Eighty years ago, Dr. Thomas Cooley and his colleagues at the Children's Hospital of Michigan administered blood transfusions to children with a newly recognized clinical entity whose features included severe anemia, splenomegaly, and peculiar facies.[1] Five years later, Cooley's name had become indelibly associated with the disease, and transfusions were administered along with ferrous carbonate, ultraviolet rays, and extract of pituitary gland.[2] Not surprisingly, given the state of crossmatching at the time, the response to transfusion was poor. Another 30 years elapsed before improvements in blood banking and recognition of the benefits of a higher hemoglobin level came together to initiate the era of modern transfusion therapy for thalassemia major.

Transfusion Programs

In 1963, the results of an evaluation of 35 children with thalassemia major, aged 12 years or younger, whose pretransfusion hemoglobin levels fell into three categories – 4.0–5.9 g/dL, 6.0–7.9 g/dL, or 8.0–9.9 g/dL – were described.[3] Children in the highest hemoglobin group had better linear growth, less enlargement of the liver and spleen, less facial and skull bony abnormalities, fewer fractures, and less cardiomegaly than children in the two lowest hemoglobin groups. Two patients who received regular red cell transfusions to maintain their hemoglobin level above 10 g/dL at all times were also reported.[4] More than 40 years later, this regimen – hypertransfusion – remains the standard of care for the treatment of thalassemia major. General guidelines for hypertransfusion therapy are presented in Tables 29.1 and 2.

By 1968, several reports confirmed the benefits of hypertransfusion[5–7] and that patients were leading normal, active lives. Their satisfaction with the benefits of hypertransfusion therapy was tempered by a growing appreciation of the problem of transfusional iron overload and the need for iron chelation therapy.

Hemoglobin Level and Physiological Parameters

The target pretransfusion hemoglobin level varies among thalassemia centers, but usually falls between 9.0 and 10.5 g/dL. The goal is to select a hemoglobin level that achieves the important physiological benefits while minimizing the rate of iron accumulation. In regard to the first issue, no significant difference in appearance, cardiac size, occurrence of splenomegaly, or feeling of well-being has been identified with higher or lower hemoglobin levels in a hypertransfusion regimen. Because some of the complications of thalassemia might be related to erythroid hyperplasia in the bone marrow, the level of bone marrow suppression achieved by different target hemoglobin levels could have clinical significance. Both ferrokinetic studies and measurements of soluble serum transferrin receptor levels have demonstrated an inverse relationship between mean pretransfusion hemoglobin level and marrow erythroid activity.[8–10] When anemia is severe – hemoglobin levels 4–7 g/dL – the marrow erythroid activity increases to 10 times normal. One important clinical consequence is impaired bone metabolism with osteoporosis;[11] however, when the selected mean pretransfusion hemoglobin level is 9 g/dL rather than 10.5 g/dL, erythroid activity increases only threefold,[9] and this level of erythroid expansion is associated with little or no impairment of bone metabolism.[11] Thus, no significant physiological difference between target pretransfusion hemoglobin levels of 9 and 10.5 g/dL is known at this time.

Hemoglobin Level and Blood Requirements

The relationship between target hemoglobin level, blood requirements and rate of iron accumulation in patients with thalassemia major is controversial. In 166 splenectomized and nonsplenectomized patients, transfusion requirements remained constant at mean transfusion hemoglobin levels of 10–14 g/dL (equivalent to pretransfusion hemoglobin levels of ~8–12 g/dL).[12] A subsequent expansion of this study to include 392 patients confirmed the earlier findings and concluded that the maintenance of higher hemoglobin levels in transfusion programs for thalassemia major did not necessitate a higher blood requirement.[13] Additional supportive evidence came from a study of "supertransfusion," in which maintenance of pretransfusion hematocrits of 27% and 35% required similar amounts of blood.[14]

Nevertheless, several studies found that maintenance of higher hemoglobin levels requires more blood. Transfusion requirements in 14 patients were directly proportional to the mean hemoglobin levels and nearly doubled

Table 29.1. General guidelines for transfusion. Therapy for thalassemia major

Variable	Range
Pretransfusion Hb level	9–10.5 g/dL
Blood product	Leukoctye-depleted red cells
Amount of blood	1–3 units
Interval between transfusions	2–4 wk

between 9.6 and 13.4 g/dL.[15] Among 3,468 patients, transfusion requirements in 1,985 were proportional to mean hemoglobin level in both splenectomized and nonsplenectomized individuals.[16] Only one large study is reported in which the annual transfusion requirement has been measured repeatedly in the same patients under two different transfusion regimens.[17] From 1982 to 1986, when the mean pretransfusion hemoglobin level of 32 patients was 11.3 g/dL, the mean annual transfusion requirement was 137 mL/kg[17] (Table 29.3). Following modification of the transfusion regimen in 1987–1992, the mean transfusion hemoglobin level fell to 9.4 g/dL, and the mean blood requirement decreased to 104 mL/kg. Of note, the change in target hemoglobin level from 11.3 to 9.4 g/dL was associated with a reduction in serum ferritin levels from a mean level of 2,448 to 1,187 μg/L. The improvement in overall iron status at the lower hemoglobin level might have been a combined effect of decreased transfusional iron loading, enhanced desferrioxamine-induced iron excretion, and maintenance of an acceptable level of gastrointestinal iron absorption.

Beginning Transfusion Therapy

The decision to begin chronic transfusion therapy in an infant or young child with homozygous β thalassemia is based on a combination of laboratory and clinical data. The specific molecular defect may provide general, albeit imperfect, prognostic clues, and the course of an affected sibling might also be helpful. Steady-state hemoglobin levels that remain below 7 g/dL on at least two measurements are one indication for transfusion, particularly in children, but this is not the only consideration. Clinical factors and other laboratory findings in addition to the hemoglobin level will determine whether a chronic hemolytic anemia or a chronic transfusion program better serves the interests of the patient. For example, the development of Cooley facies, growth retardation, pathological fractures, or persistent fatigue is a strong indication for transfusion, even when the hemoglobin level is 8 g/dL. On the other hand, for a patient with none of these problems despite a lower hemoglobin level, the marginal benefits of transfusions might be outweighed by the associated risks. Clinicians should regularly assess growth, and in conjunction with the family, the overall well-being of the child. In addition, the nucleated red cell count and/or other laboratory indicators of the degree of erythropoiesis such as soluble transferrin receptor levels should be monitored because the consequences of excessive bone marrow expansion could be as important as those of anemia in prompting regular transfusions. Later initiation of transfusion therapy might delay the need for iron chelation therapy until an age at which side effects are less common. Earlier initiation of transfusion therapy might prevent irreversible facial changes and lower the risk of alloimmunization. When the indications for transfusion therapy are equivocal but a decision is made to proceed, the treatment should be reevaluated if the patient later undergoes splenectomy. Sometimes, removal of the spleen makes the difference between transfusion dependency and nondependency.

Table 29.2. Estimation of blood requirements according to hematocrit of donor unit

Hematocrit of packed red cell units (%)	Amount of packed red cells to raise Hb by 1 g/dL (mL/kg)
60	3.7
65	3.5
70	3.2
75	3.0

Table 29.3. Effect of target hemoglobin level on transfusion requirements in thalassemia

Years	Mean pretransfusion Hb level (g/dL)	Mean transfusion requirement (mL/kg/y)	Median serum ferritin (μg/L)
1981–1986	11.31 ± 0.5	137 ± 26	2,280
1987–1992	9.4 ± 0.4	104 ± 23	1,004

From ref. 17.

Choice of Blood Product

Patients with thalassemia should receive leukocyte-reduced red blood cells to decrease or eliminate febrile reactions. The reduction of white cells to less than 5×10^6 per unit of red cells could carry the additional benefit of delaying sensitization to human leukocyte antigens in patients who might later be candidates for bone marrow transplantation. Filtration of the blood product, before storage, or at the time of administration, is the method most commonly used for leukocyte reduction. Prestorage leukocyte reduction is usually more efficient than bedside filtration.[18] Prestorage leukocyte reduction might also decrease cytokine accumulation in the blood during storage, further diminishing the chance of a febrile reaction. One study has suggested that prestorage leukocyte reduction has the additional advantage of reducing the proliferation of *Yersinia enterocolitica* in blood products

inoculated with the organism.[19] Because infection with *Y. enterocolitica* can be a serious event in patients with iron overload on chelation therapy, decreasing the likelihood of its transmission from asymptomatic donors might reduce the risk of one of the more serious infectious complications of thalassemia. Whether leukocyte reduction removes prions from potentially infected units remains under investigation.[20]

Even after 42 days of storage, red cell recovery 24 hours after transfusion is 75% or greater.[21] Little information is available, however, regarding the survival of these red cells after this time. Earlier studies showed that the survival of red cells stored in acid-citrate-dextrose for 28 days was reduced in comparison with red cells stored for 14 days.[22] Although this difference is not important for patients with acute or one-time indications for transfusions, it might have a marked effect on the overall blood requirements of patients receiving long-term transfusion. Until more is known about the effect of storage time on posttransfusion red cell survival, it seems prudent to use red cells less than 14–21 days old for patients with thalassemia major.

Frequency and Amount of Transfusion

When using donor units with a hematocrit of 75%, transfusion of 10–15 mL of red cells per kilogram body weight at 3- or 4-week intervals usually maintains a minimum hemoglobin level of 9.0–10.5 g/dL. New additive solutions have reduced the hematocrit of packed red cells from 75%–80% to 55%–65%, and larger volumes of the blood product are therefore necessary to achieve the same target hemoglobin level. This can pose problems for small children or for older patients with heart disease, and in these instances, hemoconcentration of the donor units can be used. Although intervals between transfusions of 3–4 weeks accommodate the school or work schedule of most patients with thalassemia major, shorter intervals would more closely mimic the physiological situation by reducing fluctuations in hemoglobin level. Moreover, mathematical modeling suggests that maintenance of a pretransfusion hemoglobin level of 9 g/dL with transfusions every 2 weeks rather than every 4 weeks would reduce overall blood requirements by 20%.[23] In a large group of splenectomized patients, however, a shorter interval of 2 weeks between transfusions had no measurable effect on transfusion requirements in comparison with an interval of 3 or 4 weeks.[24]

Other conditions might increase the frequency of transfusion or the amount of blood needed to maintain the target hemoglobin level. For example, transfusion requirements rise during pregnancy in women with β thalassemia major.[25,26] Patients undergoing treatment of hepatitis C infection with ribavirin need additional blood due to drug-induced hemolysis; transfusion requirements rise by a median of approximately 40% (range 25%–136%), compared with pretreatment transfusion requirements.[27,28] Transfusion requirements also appear to show seasonal variation. In patients from four thalassemia centers, pretransfusion hemoglobin levels were significantly lower in the summer months in all centers except the one where monthly temperatures varied the least.[29] Possible explanations include hemodilution from expanded plasma volume in the patients and lower hemoglobin levels in donor blood in the summer months.

Young Red Cells

Several groups have evaluated the effect of young red cell (neocyte) transfusions on overall blood requirements, and therefore on the rate of iron loading. The theoretical benefit of this modified blood product lies in the assumption that although all red cells contribute the same amount of iron upon senescence, younger red cells from the donor will circulate longer in the recipient before their iron is released. Thus, enhancement of the blood product for younger donor red cells should reduce the transfusion requirements and the rate of iron loading. Studies in animals have confirmed that age-dependent separation of red cells by density gradient centrifugation has a marked effect on red cell survival.[30] Both simple centrifugation of single donor units and neocyte enhancement during continuous centrifugation apheresis of the donor have yielded red cells with younger estimated mean ages, and in labeled erythrocyte survival studies, longer half-lives than conventional units.[10,31–34] Several factors have impeded the clinical application of young red cell transfusions. In particular, preparation of neocytes by continuous flow centrifugation is costly, and trials using neocytes prepared from single donor units have been disappointing. In three studies, the reduction in the rate of iron loading was only 13%–20%, and both the preparation costs and donor exposures were significantly higher in transfusion regimens in which neocytes were used.[35–38]

Partial Exchange Transfusion

Partial exchange transfusion, whether performed manually or by erythrocytapheresis, decreases the net blood requirement by combining the administration of donor red cells with the removal of red cells from the patient. The rationale for the use of partial exchange transfusion to prevent complications of sickle cell disease is straightforward. Donor HbA-containing cells directly replace endogenous HbS-containing cells, and because the goal of lowering the HbS level is largely independent of the total hemoglobin level, little or no net gain of red cells occurs. The goal of transfusion therapy for thalassemia major differs from that for sickle cell disease. The critical outcome in thalassemia is maintaining a particular hemoglobin level. Although the rationale for the use of partial exchange transfusion for this purpose is less obvious, some studies support this approach in thalassemia major.[39] Seventeen patients

Table 29.4. Comparison of simple transfusion and red cell exchange transfusion in thalassemia

	Mean pretransfusion Hb level (g/dL)	Mean posttransfusion Hb level (g/dL)	Mean transfusion interval (d)	Transfusion requirement level (mL/kg/d)
Simple transfusion	9.7	14.2	35.7	0.41
Red cell exchange transfusion	9.6	14.5	50.8	0.29

From ref. 39.

with thalassemia, and one each with sickle cell disease and Diamond–Blackfan anemia, underwent regular partial exchange transfusion for 6–7 months. Continuous flow centrifugation was used, and returned blood was enriched for younger red cells. In comparison with simple transfusion, the net rate of iron loading fell by 29% (Table 29.4).[39] The mean interval between transfusions increased from 36 to 51 days. Serum ferritin levels decreased by 20% during partial exchange transfusion therapy in contrast with an increase of 12% during a comparable period of conventional transfusion therapy. The authors noted the disadvantages of a 40%–60% increase in exposure to donor units and a 1.5–2.0-fold increase in transfusion-associated costs. Subsequently, the investigators reported the successful extension of this program without neocyte enrichment.[40]

A preliminary report describing a prospective clinical trial that utilized a crossover design to compare simple transfusion to partial exchange transfusion confirmed these findings. In 16 patients with thalassemia major, automated partial exchange transfusion decreased net red cell requirements, and therefore, transfusional iron loading, by a mean of 29% in comparison with simple transfusion, although with considerable interpatient variability in response.[41] Overall, donor blood exposure increased 2.1–3.7-fold. Age-dependent separation of pretransfusion blood samples by density gradient analysis showed an increase in younger red cells during partial exchange transfusion compared with simple transfusion. This suggests that the benefit of partial exchange transfusion in thalassemia might be derived primarily from the replacement of previously administered donor red cells with new donor red cells that have a younger mean age. By reducing the rate of new iron accumulation, this method of transfusion could enhance the overall management of transfusional iron overload in some patients with β thalassemia.

Sickle Cell Disease

Transfusions are used for both the acute management of complications of sickle cell disease and for chronic therapy to prevent the development or progression of complications. One goal of transfusion in sickle cell disease is to raise the hemoglobin level to improve oxygen carrying capacity. A second goal involves lowering the proportion of HbS-containing erythrocytes to reduce complications related to vasoocclusion and hemolysis. In some situations, such as an acute anemic event related to parvovirus B19 infection (Chapter 19), the former goal predominates; in other situations, such as severe acute chest syndrome, the two goals transfusion therapy overlap. Still for other indications, such as preparation for surgery while receiving general anesthetic, the benefits of transfusion therapy cannot be attributed with certainty to one goal or the other.

Choice of Blood Product

The same considerations of used in selecting a blood product in thalassemia also apply to sickle cell disease and leukocyte reduction is important. Selection of blood with a shorter storage time is as important for chronically transfused patients with sickle cell disease as it is for patients with thalassemia.

Extended red cell antigen typing prior to the first transfusion is particularly important in sickle cell disease because, as discussed later, alloimmunization is common. The use of the original antigen profile to determine accurately the specificity of new antibodies and to eliminate the possibility of an autoantibody helps to guide the choice of an appropriate blood product for future transfusions. In chronically transfused patients, in whom the presence of donor red cells can interfere with serological testing, DNA typing of blood groups can aid in accurate determination of the patient's true red cell antigen genotype.[42]

The choice of the best blood product to use for patients with sickle cell disease has been controversial.[43] Generally, most investigators and clinicians agree that at a minimum, in addition to matching ABO and D, partial antigen matching for C, E, and Kell – the antigens most frequently associated with alloimmunization and delayed hemolytic transfusion reactions in sickle cell disease – should be used when selecting red cell units.[43–45] When this transfusion approach was used in a multicenter primary stroke prevention trial, 8% of children receiving chronic transfusions developed a clinically significant alloantibody.[46] The rate of new red cell alloantibodies or autoantibodies was only 0.5% per unit, compared with a rate of approximately 3% per unit in prior studies.[46–49] Several investigators have advocated the use of blood matched for multiple red cell antigens for patients with sickle cell disease.[49,50] This approach can be particularly useful when the racial composition of

the donor and recipient pool differ as they do in the United States and elsewhere where certain blood group antigens are common in donors but rare in recipients. A prospective study showed that the initiation of complete matching of donor blood for the Rh, Kell, Kidd, and Duffy systems with less stringent matching for other minor groups resulted in a 10-fold reduction in the rate of new alloantibody formation per unit.[50] Because of the high cost associated with extended antigen matching, other investigators have proposed using this approach only after patients have developed one or two alloantibodies.[51,52]

Units donated by African Americans have an eightfold greater likelihood of antigen identity than units from predominantly Caucasian donor pools.[53] Programs to increase blood donations by African Americans have been introduced to increase the availability of phenotypically matched blood products for chronically transfused patients with sickle cell disease.[54,55] Such a program has been successful in providing racially matched (as well as C, E, and Kell antigen matched) red cell units for the majority of transfusions to children with sickle cell disease in a large urban sickle cell disease program.[54] Another strategy to reduce alloimmunization is to recruit a limited number of dedicated donors to provide the majority of red cell units used for chronically transfused patients with sickle cell disease, thereby limiting donor exposure.[55] The long-term effect of such programs on alloimmunization rates remains to be seen.

Patients with sickle cell disease in chronic transfusion programs generally should not be given blood from donors with sickle cell trait. As discussed later, the target of chronic transfusion programs is a reduction in the percentage of endogenous HbS-containing cells to a particular level, and this is measured in the laboratory by the relative amounts of HbA (from the donor) and HbS (from the recipient). Although not harmful to the patient, the administration of sickle cell trait blood obscures the laboratory assessment of the proportion of the patient's HbS-containing cells that remain in the circulation.

Transfusion Methods

Simple Transfusion

In the acute setting, red cells often are administered as a simple transfusion, although exchange transfusion also is used emergently for complications such as stroke and severe acute chest syndrome. When administering red cells to relieve anemia, the physician must first determine whether there is accompanying hypovolemia. If the blood volume is reduced, as with acute splenic sequestration, sufficient red cells to raise the hemoglobin concentration to the desired level can be given without concern about circulatory overload. In contrast, in a more slowly developing anemia such as an aplastic episode or with advancing renal disease, the patient's blood volume is maintained, and the volume of administered red cells must be calculated to limit the risk of congestive heart failure. One simple approach is to use the hemoglobin level to determine the volume of the transfusion product. For example, if the hemoglobin level is 3 g/dL, the volume of packed red cells is 3 mL/kg of body weight. In most clinical situations, even a small rise in the hemoglobin level is sufficient to address the immediate problem. As noted, however, the use of newer additive solutions has reduced the hematocrit of donor red cell units, complicating the balance between raising the hemoglobin concentration and preventing volume overload; a diuretic might be helpful in this situation. A further consideration when utilizing simple transfusions in the acute setting is that the posttransfusion hemoglobin level should not exceed 10 g/dL because higher levels can lead to hyperviscosity.[56,57]

Simple transfusion also is frequently used in chronic transfusion programs. In general, the administration of 10–15 mL/kg of red cells every 3 or 4 weeks will maintain the pretransfusion HbS level at less than 30%–50%. The target pretransfusion HbS level is variable, but generally a value of less than 30% is used for primary stroke prevention and for secondary stroke prevention at least for the first few years after the event.[58,59] A switch from a target HbS of 30%–50% after 3 or 4 years of more aggressive transfusion for secondary stroke prevention is used in some centers (see later).[60] A target HbS level of 50% often is used for the prevention of severe chronic pain and acute chest syndrome, although studies to determine the optimal HbS level to manage these complications are lacking. The main benefit of targeting a higher HbS level is the reduction in red cell transfusion requirements, which limits iron loading.[60]

Exchange Transfusion

Exchange transfusion can be performed either manually or by an automated process, erythrocytapheresis. A single partial exchange transfusion is useful for the rapid reduction of HbS levels in the patient with sickle cell disease who has an acute complication such as stroke. Partial exchange transfusion can decrease the HbS level below 30% in less than 2 hours without volume overload or hyperviscosity that would accompany repeated simple transfusions for this purpose.[61,62] In comparison with simple transfusion, manual or automated partial exchange transfusion decreases the net amount of blood needed to lower HbS levels by combining the administration of donor red cells with the removal of the patient's red cells.[60,63–65] This has proven to be a valuable tool in the management of iron overload in patients with sickle cell disease in long-term transfusion programs for prevention of stroke or other complications. New iron accumulation is stopped or greatly reduced. Limitations to exchange transfusion include greater donor exposure, higher cost, less widespread availability due to the need for special expertise, and the need for large intravenous access.[63,64]

Table 29.5. Indications for transfusion in sickle cell disease

	Generally Accepted	Controversial
Episodic transfusion	Stroke	Priapism
	Aplastic episode	Prior to surgery with general anesthesia – low risk procedure*
	Splenic sequestration	
	Acute chest syndrome	
	Acute multiorgan failure	
	Retinal artery occlusion	
	Prior to surgery with general anesthesia – moderate- to high-risk procedure*	
Chronic transfusion	Stroke	Recurrent priapism
	Abnormal transcranial Doppler ultrasound	Pregnancy
	Recurrent acute chest syndrome	Silent cerebral infarcts*
	Recurrent severe vasoocclusive pain	Recurrent splenic sequestration
	Pulmonary hypertension	Leg ulcers

* Currently under study.

Clinical Application of Transfusion Therapy in Sickle Cell Disease

Specific complications of sickle cell disease and their treatment are discussed in Chapter 19. The following focuses on the data for and against transfusion therapy for selected disease complications. Particular attention is devoted to randomized, prospective studies of transfusion therapy, but few such studies are available. The specific clinical indications for transfusion therapy are divided into episodic and chronic therapy and evidence-based recommendations are made when possible (Table 29.5).

Indications for Episodic Transfusions

Transient Aplastic Episode

Patients with sickle cell disease can develop profound anemia in association with transient red cell aplasia caused by infection with parvovirus B19. Furthermore, cerebrovascular events, acute chest syndrome, splenic sequestration, and vasoocclusive pain episodes can occur in association with parvovirus B19 infection.[66,67] Transfusion of red cells is indicated to relieve the severe anemia and to prevent or treat organ complications. When the anemia is milder and the need for a transfusion is uncertain, evidence of imminent bone marrow recovery such as nucleated red cells in the peripheral blood or the reappearance of reticulocytes might favor waiting. The *HBB* genotype of the patient might help predict the eventual need for transfusion: Individuals with sickle cell anemia and HbS–β^0 thalassemia generally maintain a lower baseline hemoglobin level and, thus, often develop more severe anemia with an aplastic episode. Nonetheless, patients with HbSC disease or HbS–S β^+ thalassemia also can require transfusion, so knowledge of the genotype cannot substitute for close clinical and laboratory monitoring. For example, in a retrospective study of 84 patients with aplastic episodes, 72% received transfusion therapy, including 85% of those with sickle cell anemia, 57% with HbSC disease, and 14% with other genotypes.[66] If red cells transfusion is necessary, the slow administration of one or two transfusions of small volume, raising the hemoglobin by 2–3 g/dL over 4–8 hours, is usually sufficient to improve the clinical condition until spontaneous recovery occurs.

Acute Splenic Sequestration

Sudden, massive enlargement of the spleen with pooling of large amounts of blood within the organ can cause profound anemia and hypovolemia. Transfusion therapy carries two benefits: restoration of intravascular volume and improvement in oxygen carrying capacity. Acute splenic sequestration is one of the few complications of sickle cell disease in which rapid administration of red cells is not only safe but can also be lifesaving. Occasionally, transfusion with Rh- and ABO-specific, non-crossmatched blood might be necessary to prevent death from shock and severe anemia. Hypovolemia makes consideration of the volume of the transfused red cells less important; however, small amounts of blood are usually sufficient to reverse the process of sequestration, with subsequent release of trapped blood back into the circulation, which further improves the intravascular volume and the hemoglobin level.

Acute Stroke

Red cell transfusion to lessen the anemia, reduce tissue hypoxia, and reduce the percentage of HbS is the mainstay of treatment for acute infarctive stroke, and red cells should be administered as quickly as possible to patients who develop this complication. Manual or automated exchange

transfusion, when available, often is used initially. The goal is to reduce the percentage of HbS to less than 30% of the total hemoglobin and to raise the hemoglobin level to approximately 10 g/dL. No prospective studies have been undertaken to compare simple with exchange transfusion. A multicenter, retrospective study found a fivefold higher incidence of stroke recurrence in children who were treated acutely with simple transfusion compared with those treated with exchange transfusion.[68] Nonetheless, a simple transfusion to raise the hemoglobin level to no higher than 10 g/dL should be given if exchange transfusion cannot be performed within a few hours of presentation.

Acute Chest Syndrome

The use of red cell transfusions in the management of acute chest syndrome can cause a rapid improvement in oxygenation.[69] Both simple and exchange transfusion have been used for this indication. In one multicenter study, no significant difference between simple and exchange transfusion in improvement in oxygen levels in patients with acute chest syndrome was seen, although transfusion method was at the treating physician's discretion and, thus, subject to bias.[69] Given the lack of randomized, controlled trials comparing these two transfusion methods, management usually is based on the patient's clinical condition and physician preference. Simple transfusions often are used as first-line treatment with the administration of 1–2 U to raise the hemoglobin level to no greater than 10 g/dL. In more severe cases, such as patients requiring mechanical ventilation or those developing a worsening clinical condition despite simple transfusion, or for patients with a high baseline hemoglobin level that precludes simple transfusion, exchange transfusion should be considered. Case reports and uncontrolled series describe rapid clinical and radiological improvement and higher paO_2 levels after exchange transfusion.[70–73] In the largest series to date, 35 patients with acute chest syndrome and clinical deterioration underwent exchange transfusion.[74] Thirty-two of the 35 patients, including five of seven on assisted ventilation, had a rapid and dramatic improvement in oxygenation and other clinical parameters, leading the investigators to recommend that exchange transfusion be considered for patients with diffuse pulmonary involvement.

Almost half of all acute chest syndromes follow hospitalization, usually for acute painful episodes.[69] Early transfusion might prevent the development of acute chest syndrome in high-risk patients. Such an approach is preferable because it could help prevent lung injury and associated long-term complications. Elevated secretory phospholipase A_2 levels, particularly in association with fever, predict an increased risk of acute chest syndrome in patients admitted with vasoocclusive pain[75]. In a pilot study, patients with sickle cell disease admitted with pain who developed fever and elevated phospholipase A_2 levels (>100 ng/mL) with a negative chest radiograph were randomized to receive a single transfusion of approximately 10 mL/kg or to standard care.[76] Five of eight (63%) patients randomized to standard care developed acute chest syndrome compared with none of seven patients randomized to receive transfusions. A multicenter study currently is under design to study further the benefit of red cell transfusions in preventing acute chest syndrome.

Table 29.6. Effect of goal of perioperative transfusions on outcome

Complications	Group 1 (HbS < 30%, Hb = 10 g/dL)	Group 2 (Hb = 10 g/dL)
Serious or life-threatening postoperative complications	21%	22%
Acute chest syndrome	10%	10%
Fever or infection	7%	5%
Painful crisis	4%	7%
Neurological event	1%	< 1%
Death	1%	0%
Transfusion-related complications	14%	7%
New antibody	10%	5%
Hemolysis	6%	1%

From ref. 93.

Perioperative Management

The use of transfusions to prevent complications of general anesthetics and surgery is particularly controversial. To reduce the high risk of perioperative complications, some have favored simple transfusions to correct the anemia, whereas others have favored exchange transfusion to decrease the HbS level. Uncontrolled studies of these approaches yielded perioperative complication rates of 0%–20%, and a very low death rate.[58,77–88] Other investigators argued that careful attention to hydration and oxygenation rather than administration of red cells produced an equally successful outcome, at least in minor surgical procedures.[82,89–92] Partial resolution of the role of perioperative transfusion therapy came from a large, multiinstitutional, randomized study of two approaches.[93] Patients in group 1 received simple or exchange transfusions to reduce the HbS level below 30% and to raise the total hemoglobin level to 10 g/dL; patients in group 2 received simple transfusions to raise the total hemoglobin level to 10 g/dL, irrespective of the HbS level. The type of transfusion therapy did not affect the rate of minor or major perioperative complications other than those related to transfusion itself (Table 29.6).[93] Acute chest syndrome occurred in 11% of patients in group 1 and 10% of patients in group 2. Both deaths occurred in group 1. The reduction in HbS level in group 1 required twice as much donor blood as the increase

in hemoglobin level in group 2. As a result, patients in group 1 had a significantly higher rate of alloimmunization.

Although this study randomly assigned patients only to one of two transfusion arms, the investigators concurrently followed a group of patients who, for different reasons, did not undergo transfusion.[93] In a subanalysis of patients undergoing cholecystectomy, the most common surgical procedure, the rate of sickling-related complications was higher in the patients who did not undergo transfusion than in those receiving either of the two transfusion protocols.[94] Acute chest syndrome occurred in 19% of the 37 nontransfused patients, and two patients died. In other series of patients who did not routinely receive transfusions preoperatively, retrospective analyses have demonstrated complication rates of 13%–26%.[82,85,95] Adverse events generally were more common in patients undergoing major surgery or emergency surgery.

Questions and controversies remain regarding optimal transfusion practices for patients undergoing surgery. Given the lack of randomization to a no-transfusion treatment arm, it remains unclear if transfusion truly is superior or if meticulous supportive care without transfusion could be equally effective, at least for some surgical procedures. For example, success has been reported using a regimen without preoperative transfusion, but with supportive care measures including continuous positive airway pressure postoperatively in patients with sickle cell disease undergoing cholecystectomy.[92] The benefit of routine preoperative transfusion in those undergoing low-risk surgical procedures also is unclear. In one retrospective study of 34 minor surgical procedures, such as myringotomy, strabismus repair, and dental procedures, performed in children without preoperative transfusion, minor complications were seen in 15% of cases and neither acute chest syndrome nor severe complications developed.[89]

The value and goal of preoperative transfusions in patients with HbSC disease is not established. One multicenter study in which transfusions were administered at the physicians' discretion showed a 20% incidence of sickle cell complications with moderate-risk procedures in patients with HbSC disease who did not receive preoperative transfusion compared with none in transfused cases;[96] no difference was seen between the two groups for low-risk procedures. Currently available data also do not address some issues such as the management of a patient with sickle cell disease who maintains a steady-state hemoglobin level of 10 g/dL or a patient receiving hydroxyurea with good hematological response, and transfusion strategies in these instances vary among sickle cell centers.

Given the lack of a robust randomized clinical trial comparing transfusion to no transfusion in the preoperative period, considerable variability in clinical practice exists. In a recent prospective study involving 31 hospitals in Great Britain, among 114 patients with sickle cell disease who underwent surgery, 43% were not treated with preoperative transfusion, whereas 39% received simple transfusion, and 23% underwent exchange transfusion.[97] Although for hip surgery and otorhinolaryngological procedures, exchange transfusion and simple transfusion, respectively, were used in most cases, for other surgical procedures such as cholecystectomy, preoperative transfusion practices varied widely. In multivariate analysis, moderate/high-risk surgery was the only variable associated with postoperative complications and transfusion was not associated with a lower risk of complications. A randomized, multicenter study has been designed to compare surgical complication rates between groups randomized to receive or not to receive preoperative transfusions, which might provide better guidance for optimal management of the patient with sickle cell disease who needs surgery.

Based on current data, preoperative transfusion to raise the hemoglobin level to 10 g/dL generally appears to be equally as effective as a transfusion program to reduce the HbS below 30%. With either approach, acute chest syndrome remains a substantial risk, especially in patients with a history of lung disease who are undergoing a high-risk operation. Transfusions before minor, elective procedures with short anesthesia times might convey no advantage in patients without chronic lung disease or other significant complications.

Vasoocclusive Pain Episode

The value of transfusion therapy in the management of acute painful episode is uncertain. Partial exchange transfusion to reduce the HbS below 50% improved the clinical condition and reduced the duration of hospitalization in eight patients.[98] No subsequent study has confirmed or disproved these old but intriguing findings. In general, the use of red cell transfusion for the management of acute painful episodes is not indicated; however, acute painful episodes occasionally may progress to catastrophic multiorgan failure associated with a falling hemoglobin level. In 17 such episodes, transfusion therapy rapidly and dramatically improved the encephalopathy, urine output, oxygenation. and general clinical condition.[99]

Priapism

Transfusion therapy for the treatment of acute, prolonged episodes of priapism is also controversial. No randomized, controlled studies exploring the use of this therapeutic modality exist and several small, uncontrolled studies of simple and exchange transfusion in the treatment of priapism have yielded inconsistent results.[100–109] In one recent case series, among six patients treated with exchange transfusion the procedure was "very" effective in five and partially effective in one patient,[109] whereas in another report of seven patients treated with red cell exchange, only one patient improved partially.[103] Overall, no difference between the results with simple and exchange transfusion is readily discernible, aside from descriptions of

individual patients who had immediate detumescence or relief of pain during erythrocytapheresis. Importantly, neurological events, including headache, seizures, and strokes, have occurred in a small but worrisome number of patients within 1–14 days of simple or exchange transfusion for priapism (ASPEN syndrome).[104,110–112] Whether the risk of such events is greater after transfusion therapy for priapism than other complications of sickle cell disease is uncertain. The limited benefit of transfusion therapy for priapism and the possible risk of neurological sequelae should be carefully considered in managing this acute problem.

Indications for Chronic Transfusion Therapy

Stroke

Although transfusion therapy has not been studied in a randomized controlled clinical trial for prevention of recurrent stroke, data from several case series[113–115] and two multicenter retrospective studies[59,116] support its beneficial effect. Regular red cell transfusions to maintain the HbS level below 30% reduce the risk of recurrent infarctive stroke from approximately 70%[117] to 10%–20%.[59,116] This finding has led to the recommendation to initiate chronic transfusion therapy after a first stroke in children with sickle cell disease.

Although the value of transfusion in preventing recurrent stroke is clear, the optimal duration of therapy is uncertain. Most recurrences in nontransfused patients are in the first 3 years after the initial event,[117] suggesting that lowering the HbS level is particularly important during this period. This view is supported by the recurrence of stroke in seven of 10 patients who stopped transfusion therapy after 1 or 2 years[118] and in four of 10 patients who stopped after 1–4 years.[119] The benefits of longer transfusion therapy are debatable. In one study, stopping transfusions after periods of 5–12 years resulted in a 50% recurrence rate within 1 year,[120] whereas in another study, stopping transfusions in nine patients after a mean duration of 6 years resulted in no recurrences during the next 3–18 years.[121] Six of the nine patients began hydroxyurea therapy at a median of 4 years after discontinuing transfusions, which might have affected stroke risk. At present, most pediatric sickle cell centers continue transfusion therapy indefinitely for the prevention of recurrent stroke. This therapy, however, frequently ends when patients transfer to adult centers. The determination of the optimal duration of transfusion therapy for prevention of recurrent stroke awaits a prospective, randomized trial that avoids the pitfall of selection bias and that accounts for the potential impact of transfusions administered for other purposes.

Given that the major reason for discontinuing transfusions is the concern about iron overload, an alternative to stopping therapy is to modify the transfusion program to reduce the rate of iron accumulation. In a study of nine patients with no recurrence of stroke and no progressive neurological deterioration during at least 4 years of simple transfusion therapy, a subsequent increase in the pretransfusion HbS level from 30% to 50% reduced blood requirements, and thus the rate of iron loading by approximately 30% without raising the risk of recurrent infarctive stroke.[60] A second study supported the safety and benefits of this modified simple transfusion program.[122] Even greater reductions in net blood requirements have been achieved with manual or automated exchange transfusions (Table 29.7).[60,63,64] Novel transfusion programs that prevent recurrent stroke and reduce the risk of iron overload and new oral chelation treatment options could increase the clinician's level of comfort with long-term therapy.

Table 29.7. Effect of transfusion therapy on prevention of first stroke in children with sickle cell disease and abnormal transcranial doppler ultrasonograph

	Patient-months	Cerebral infarctions	Intracerebral hematoma
Transfusion (n = 63)	1,321	1	0
No Transfusion (n = 67)	1,229	10	1

From ref. 123.

Abnormal Transcranial Doppler Ultrasonography

The screening technique of transcranial Doppler ultrasonography (TCD) now allows the identification of children who are at high risk of developing a first stroke, creating the potential for intervention before overt neurological injury occurs (Chapter 19). In the Stroke Prevention Trial in Sickle Cell Anemia (STOP) 63 children with abnormal TCD studies were randomly assigned to receive regular transfusions to maintain the percentage of HbS less than 30%, and 67 to receive standard care without transfusions.[58] Transfusions were associated with a significantly lower risk of stroke (Table 29.7),[123] which led to early termination of the trial. In the years following the publication of the STOP results, the rate of first stroke in children in California with sickle cell disease fell from a baseline of 0.88 per 100 patient-years to 0.17 per 100 patient-years, suggesting a tremendous impact of TCD screening and transfusion therapy on preventing this devastating complication.[124]

A follow-up study, Optimizing Primary Stroke Prevention in Sickle Cell Anemia (STOP II), was designed to assess whether transfusions could be discontinued in children with a history of abnormal TCD whose TCD studies normalized while receiving transfusions, suggesting a reversion to low-risk of stroke.[125] Children considered to have more severe vasculopathy as demonstrated by moderate to severe vessel stenosis detected by brain magnetic resonance angiography were excluded. Among the 41 children

who discontinued transfusions, 14 had a reversion to abnormal TCD studies and an additional two children developed stroke; no TCD reversions or strokes occurred in the 38 children who continued transfusions. This highly significant finding led to the current recommendation to continue transfusion therapy indefinitely for primary stroke prevention. Modified transfusion programs that allow the HbS level to rise to 50% or higher have not been studied in this clinical setting and thus the target pretransfusion HbS level is usually kept at less than 30%.

Silent Cerebral Infarcts

Given that silent infarcts occur commonly in sickle cell anemia, often progress over time, and are associated with neurocognitive abnormalities and a higher risk of overt stroke[126–129] effective treatments are needed. Transfusion therapy has been suggested as a treatment option for patients with silent infarcts who demonstrate neurocognitive abnormalities,[46] but the benefit of such therapy is currently unknown. In the STOP study, among the 37% of randomized subjects who had silent infarcts, those receiving transfusions had a significantly lower risk of progression of silent infarcts than those receiving standard care.[130] Whether transfusions will prevent silent infarct progression and neurological complications in children without abnormal TCD remains to be determined. A pilot study showed that transfusion therapy for children with silent infarcts is feasible[131] and a larger, randomized, controlled trial assessing the effect of transfusions on the prevention of neurological complications in children with silent infarcts is currently underway.[132]

Pregnancy

Transfusions are commonly used in the management of acute complications such as toxemia, severe acute chest syndrome, exacerbation of anemia, stroke, acute renal failure, or when emergency surgery is needed in pregnant women with sickle cell disease.[133] Greater controversy surrounds the use of prophylactic transfusion therapy during pregnancy.[134–142] Assessment of the effectiveness of this approach is hindered by differing transfusion protocols and by retrospective analyses. Even if one limits the additional confounding effect of general improvements in obstetrical care by considering only those studies reported in the past three decades, conclusions differ widely. For example, in a retrospective review of 101 women with sickling disorders treated between 1981 and 1990 at a single institution, the investigators concluded that the early (mean 19 weeks) introduction of partial exchange transfusions to maintain the HbS below 50% resulted in fewer episodes of pain, a lower incidence of pneumonia, a reduction in preterm deliveries, a lower perinatal death rate, and fewer low-birth-weight infants.[138] In contrast, two retrospective British studies covering similar periods found no beneficial effect of prophylactic transfusions on either maternal or fetal outcome.[136,143] One study used partial exchange transfusions from the first or second trimester but no consistent target hemoglobin level or HbS percentage,[136] whereas the other used simple transfusion to reduce the HbS level below 25% and raise the hemoglobin to 11 g/dL.[143]

The most informative data regarding the role of prophylactic transfusions during pregnancy in women with sickle cell disease come from a multicenter, prospective, randomized, controlled study.[137] Thirty-six women received prophylactic simple or partial exchange transfusions beginning before 28 weeks of gestation to maintain the hemoglobin level between 10 and 11 g/dL and to reduce the HbS level to less than 35%. An equal number of women received transfusions only for medical or obstetrical emergencies. Although women receiving prophylactic transfusions had fewer painful episodes and a lower cumulative incidence of sickle cell disease–related complications, the two treatment groups did not differ in obstetrical complications or perinatal outcome, which was high at 10%. Even without a clear benefit of transfusions on perinatal outcome, the lower rate of sickle cell complications could be enough to prompt some physicians to treat pregnant patients with transfusions.

Recurrent Acute Chest Syndrome and Pulmonary Hypertension

The role of transfusion therapy for acute chest syndrome might extend to the prevention of recurrences in patients with severe or repeated episodes. This long-term application is predicated on the finding that recurrent acute chest syndrome might be immediately life threatening or contribute to chronic pulmonary failure, pulmonary hypertension, and cor pulmonale.[144,145] In a retrospective study of 17 children receiving chronic transfusion therapy, 13 for stroke and four for recurrent pain, the rate of hospitalizations for acute chest syndrome was reduced significantly from 0.7 per year before treatment to 0.04 per year on transfusion therapy.[146] These findings were confirmed in an analysis of children participating in the STOP trial: The hospitalization rate for acute chest syndrome was significantly lower in the transfusion group compared with the standard care group (4.8 vs. 15.3 per 100 patient-years).[128] A single retrospective study evaluated the effect of chronic transfusions in children treated for the primary indication of recurrent or severe acute chest syndrome.[147] In that study, transfusions were effective in preventing recurrences of acute chest syndrome. The incidence of acute chest syndrome fell significantly from 1.3 per year before transfusions to 0.1 per year during treatment. Chronic transfusions did not reduce the severity of acute chest syndrome in those who developed recurrent episodes.

The effect of transfusion therapy on late pulmonary outcomes remains unknown. Although studies of red cell transfusions for the management of pulmonary hypertension are lacking, this treatment might be beneficial for some patients who develop this complication. Potential benefits

of transfusion include improved oxygen carrying capacity and reduction in the amount of HbS. Maintaining a low HbS level should reduce hemolysis, a factor thought to be central to the pathogenesis of pulmonary hypertension in sickle cell disease.[148,149] In addition, transfusions might prevent other complications of sickle cell disease such as acute chest syndrome and pain, which can exacerbate pulmonary hypertension. Further studies are needed to determine the role of transfusions in the management of pulmonary hypertension.

Recurrent Splenic Sequestration

Short-term chronic transfusion therapy might be beneficial in some infants with recurrent acute splenic sequestration to reduce the risk of recurrence and delay the need for splenectomy until the age of 1–2 years. Given, however, that functional asplenia develops in children with sickle cell anemia and HbS–β^0 thalassemia when they are 6–12 months old,[150] it is unclear if deferring surgical asplenia adds much benefit in the protection against invasive infection. One study of 130 Jamaican patients with sickle cell disease who underwent splenectomy showed no increased risk of bacteremia or death compared with nonsplenectomized control subjects.[151] The study group included 46 young children who underwent splenectomy at a median age of 2.3 years for recurrent splenic sequestration. With the routine use of penicillin prophylaxis and the availability of the pneumococcal conjugate 7-valent vaccine, the benefit of postponing splenectomy in young children is even less clear. Furthermore, recurrences of splenic sequestration occur even while receiving regular transfusions to maintain the HbS below 30% and recurrences are frequent when the transfusion program is interrupted or completed.[152] Thus, the role of a short course of prophylactic transfusions for the prevention of recurrent splenic sequestration remains unproven.

Recurrent Painful Episodes

Five percent of patients with sickle cell disease have three–10 episodes of intense pain resulting in hospitalization each year.[153] No study to date has directly addressed the value of transfusion therapy in reducing the physical and social consequences severe pain; however, the experience gained from transfusion therapy for prevention of primary or recurrent stroke demonstrates that reduction of the HbS level to 30% reduces the rate of vasoocclusive pain episodes seven–10-fold, suggesting that such an approach could be beneficial.[146,154] Randomized, controlled clinical trials are needed to address the effect of transfusion therapy on recurrent or unusually severe pain.

Other Proposed Indications

Long-term transfusion therapy might help prevent recurrent episodes of priapism.[104] Case reports and uncontrolled series also have suggested a possible therapeutic role for red cell transfusions in the management of other complications of sickle cell disease such as leg ulcers, avascular necrosis, and persistent hematuria. In some of these descriptions the benefit of transfusion has appeared to be very dramatic, but specific recommendations must await more extensive clinical trials.

Other Approaches

New approaches to the management of sickle cell disease might redefine the role of transfusion therapy. For example, hydroxyurea therapy is an alternative to transfusions for the treatment of recurrent painful episodes and acute chest syndrome. In addition, a strategy of switching from transfusion therapy to hydroxyurea treatment for secondary stroke prevention showed promising results in a pilot study of 35 children,[155] and a larger, multicenter study is currently underway. Bone marrow transplantation is being offered with increasing frequency as an alternative to transfusion therapy for patients with stroke or other severe or recurrent complications. These advances, as well as progress in the general management of pregnancy, general anesthetics, and other medical and surgical conditions, will require regular reevaluation of the effectiveness and safety of transfusions.

Other Hemoglobinopathies

Patients with unstable hemoglobins might need occasional red cell transfusions during exacerbations of anemia. If the unstable hemoglobin has an increased oxygen affinity, the decision to transfuse reaches a higher level of complexity.[156] In this situation, the chronic hemolysis due to the unstable hemoglobin blocks the usual compensatory erythrocytosis in response to the hemoglobin's abnormally increased oxygen affinity. The resultant "normal" hemoglobin level may have only one-half of the normal oxygen delivery capacity. Simple transfusions to achieve normal oxygen delivery at the time of surgery or acute illnesses might raise the hemoglobin to unacceptably high levels. Alternatively, exchange transfusion carries the dual benefits of improving oxygen delivery while maintaining a normal total hemoglobin level, and replacing the unstable hemoglobin variant with HbA.

COMPLICATIONS OF TRANSFUSION THERAPY

Most adverse consequences of transfusion therapy for thalassemia, sickle cell disease, and other hemoglobinopathies are independent of the underlying blood disorder, although they might occur with differing frequency in each of these diseases because of environmental or other reasons. The following sections focus on complications that are particularly problematic for patients with hemoglobinopathies receiving long-term transfusions. A detailed discussion of other complications such as febrile or allergic reactions and

acute hemolytic transfusion reactions can be found in textbooks of transfusion medicine. Iron overload, the leading and most complex clinical problem of long-term transfusion therapy, is discussed in full in the second major section of this chapter.

Alloimmunization

Thalassemia

Alloantibodies have been detected in 3%–37% of patients with thalassemia.[24,157–163] Variations among the protocols practiced at different centers are likely due to several factors. Alloimmunization rates are generally higher when there is a greater discordance of red cell antigen frequencies between donors and recipients. For example, the prevalence of alloimmunization was 20.8% among thalassemia patients of Asian descent treated at a northern California center where donors are primarily Caucasian,[158] whereas lower rates of 5%–10% were reported in more homogeneous populations.[157,159] The degree of antigen matching of blood products also affects alloimmunization rates. Antibodies are most commonly directed against antigens of the Rh and Kell systems.[159–161] In the northern Californian thalassemia population, the alloimmunization rate was only 3% among patients receiving Rh- and Kell-matched blood, compared with 33% in those treated with nonphenotypically matched blood.[158] Extension of antigen matching beyond the Rh and Kell systems might not be helpful.[165] Immune factors, related to both the recipient and to the blood product preparation, could also impact alloimmunization rate. For example, splenectomy might increase the risk of alloimmunization, whereas prestorage leukocyte depletion can lower the rate because leukocytes release potentially immunomodulatory cytokines during storage.[158,161]

The age at which transfusion therapy is initiated in thalassemia major has a consistent effect on the rate of alloimmunization. In two studies from Greece, alloimmunization occurred more than twice as often in children beginning transfusion therapy after age 3 years[160] and four times as often in children beginning transfusion therapy after 1 year of age.[164] In 110 alloimmunized patients in Greece and Italy, alloantibodies developed in fewer than 3% of children who began transfusion therapy in the first year of life, but did occur in more than 15% of children who received their first transfusion after age 4 years.[24] Because alloimmunization by itself is rarely a significant clinical problem in thalassemia, these findings of the influence of age might not have a substantial impact on the decision to initiate or delay transfusion therapy. In some children, however, receiving regular transfusions, alloantibodies are accompanied by red cell autoantibodies, presenting additional and often serious clinical problems. This unusual but severe complication is worthy of consideration in deciding at what age to initiate transfusion therapy in the child with a marginal hemoglobin level or clinical status.

Sickle Cell Disease

Red cell alloimmunization occurs in 3%–76% of patients with sickle cell disease who have been transfused.[46,47,49,50,157,165–169] In the Cooperative Study of Sickle Cell Disease, the overall rate of alloimmunization in 1,814 patients transfused before or after study entry was 18.6%.[167] In a subanalysis of 604 patients who had no alloantibodies at study entry and subsequently underwent transfusion, the investigators found a significantly higher incidence of alloimmunization in patients with sickle cell anemia in comparison with patients with other sickling disorders. A relationship between age and risk of alloimmunization exists in sickle cell disease as it does in thalassemia. Patients with sickle cell disease who received their first transfusion at age 10 years or older had a 20.7% rate of alloimmunization compared with 9.6% in individuals first transfused when aged younger than 10 years. Alloimmunization rose continuously with an increasing number of transfusions. Patients first transfused at a young age consistently required more transfusions to become alloimmunized than those first transfused at older ages.

Red cell antigens causing alloimmunization in patients with sickle cell disease most commonly belong to the Rh, Kell, Duffy, and Kidd systems. Antibodies to E, C, K, Jk^b, and Fy^a account for approximately 80% of clinically significant alloantibodies, reflecting the differences in red cell phenotype between blood donors who are predominantly Caucasian and patients with sickle cell disease who are predominantly of African ancestry.[49,167] The red cell alloimmunization rate was 76% among patients with sickle cell disease who underwent transfusion in the United Kingdom compared with a rate of only 2.6% in patients transfused in Jamaica, where donors and recipients are more genetically similar.[166] Similarly, the rate of alloimmunization among previously transfused Caucasians with sickle cell disease in Italy is only 5.4%.[170]

Red cell autoantibodies also can develop in patients with thalassemia or sickle cell disease, often in association with alloantibodies.[171–173] The mechanism underlying the formation of autoantibodies is unclear, but possible causes include antigenic changes in the erythrocyte membrane or more generalized immune dysregulation. Erythrocyte autoantibodies occur in 5%–8% of multiply transfused children with sickle cell disease but cause hemolysis in only approximately 2%.[46,169,171]

Alloimmunization has consequences that range from additional work and expense in the blood bank to severe hemolysis. Delayed hemolytic transfusion reactions pose a particularly important problem for patients with sickle cell disease.[47,52,174–176] In two prospective studies, delayed hemolytic transfusion reactions occurred in 38% and 44% of newly alloimmunized patients with sickle cell disease.[49,93] Delayed hemolytic transfusion reactions arise when an alloantibody is not present in sufficient quantity to be detected by direct or indirect antiglobulin testing or

when the antibody is directed against a low-frequency antigen that is not present on the screening cells used for the indirect antiglobulin test.[177] On reexposure to the offending antigen, an anamnestic response occurs, and hemolysis begins in 3–10 days. Fever, and back, leg, or abdominal pain can accompany the delayed hemolysis, mimicking a vasoocclusive episode.[176,178] In addition to destruction of the transfused cells, the patient's HbS-containing cells also can be destroyed, leading to profound anemia.[173,176,179] Reticulocytopenia might occur and the direct antiglobulin test also can be negative, further complicating the diagnosis. Treatment with steroids, intravenous immunoglobulin, and erythropoietin might be helpful; further transfusions, even using apparently compatible blood, should be carefully considered in light of the risk of life-threatening hemolysis.[176,179]

Transfusion-transmitted Infections

Because patients with thalassemia major and regularly transfused patients with sickle cell disease usually receive 12–50 U of red cells each year, they are at higher risk than most blood recipients for transfusion-transmitted infections such as hepatitis and human immunodeficiency virus (HIV). Rates of seropositivity for hepatitis C have varied from 12% in patients with thalassemia who received treatment in the United Kingdom to 91% in those who were treated in Italy.[180,181] Serological testing of donated blood for hepatitis C, which became available in developed countries in the early 1990s, has reduced the risk of acquiring this infection from transfusion. In a 2004 report from the Thalassemia Clinical Research Network, 35% of 334 North American patients with thalassemia had evidence of hepatitis C exposure.[182] Among children aged younger than 5 years, only 5% had evidence of hepatitis C exposure compared with 70% of patients aged 25 years and older. Antibodies to hepatitis C have been detected in 23%–30% of repeatedly transfused patients with sickle cell disease.[183,184] Nucleic acid testing for hepatitis C, implemented in most developed countries by 2000, is expected to reduce greatly the risk of transfusion-transmitted hepatitis C virus. Viral hepatitis might have particularly grave clinical consequences in regularly transfused patients with hemoglobinopathies because iron overload aggravates the liver damage and can diminish the response to antiviral therapy.[185,186] New cases of transfusion-transmitted hepatitis B are rare in the United States as a result of vaccination programs and blood screening. High rates of hepatitis B infection continue to occur in thalassemia patients in some parts of the world,[187,188] mostly attributable to late or no vaccination. A recent study of children with thalassemia in India infected with hepatitis B found a number of mutations in viral DNA regions involved in reactivity to antihepatitis B surface antibody, raising concern that such mutations might contribute to vaccine failures.[189] This intriguing finding deserves further study.

The risk of transfusion-transmitted HIV infection in patients with thalassemia and sickle cell disease has varied with time and geographical location. In 1984, when donor testing was still unavailable, 12% of patients with thalassemia at one center in New York were seropositive for HIV.[190] In contrast, in a 1987 study of 3,633 patients with thalassemia in Europe, only 1.56% were seropositive for HIV.[191] Following the introduction of routine donor screening programs and serological testing for HIV by enzyme-linked immunosorbent assay, new seroconversions became extremely rare in many countries.[192,193] In a more report from the Thalassemia Clinical Research Network, 2% of North American patients with thalassemia major were positive for HIV.[182] The current risk of acquiring HIV from transfusion is less than 1 in 2 million.[194] In countries with a high prevalence of HIV coupled with inadequate blood safety programs, the risk of HIV infection in repeatedly transfused children with sickle cell disease remains high.[195]

Iron overload, as assessed by serum ferritin level, might contribute to the progression of HIV infection in patients with thalassemia.[196] The iron chelator desferrioxamine, on the other hand, might have a dose-dependent inhibitory effect on disease progression.[197] This observation is supported by in vitro studies of the effect of chelators on HIV infectivity. Both desferrioxamine and deferiprone have an inhibitory effect on HIV-1 replication[198] and more recently, the newer oral chelator, deferasirox has been shown to inhibit HIV-1 transcription.[199]

Red cell transfusions infrequently transmit bacterial infections.[200] *Yersinia enterocolitica*, the organism responsible for seven of the eight fatal red cell–transmitted bacterial infections reported to the Food and Drug Administration between 1986 and 1991, deserves special attention. This contaminant represents a particular problem for chronically transfused patients because iron overload and the iron chelator desferrioxamine enhance its pathogenicity. *Y. enterocolitica* enters the blood supply when blood donation coincides with asymptomatic bacteremia, making efforts at prevention difficult. Evaluating febrile transfusion reactions or persistent unexplained fevers in regularly transfused patients with hemoglobinopathies should include careful consideration of systemic or localized *Y. enterocolitica* infection.

Hypersplenism and Increased Transfusion Requirements

A sustained increase in transfusion requirements is an indication for splenectomy in patients with thalassemia major.[201] When the annual blood requirement exceeds 200 mL of packed red cells (hematocrit 75%) per kilogram body weight, a minimum reduction of at least 20% usually follows removal of the spleen. The role of splenectomy in reducing transfusion requirements might be less important in patients in whom chelation therapy is working well, and should be weighed against potential complications such as postsplenectomy sepsis and thrombosis. Moreover, other

causes of increased blood requirements, such as alloimmunization or different preparation of donor units, should be sought before removing the spleen for this purpose. Regular red cell transfusions can have the unintended consequence of reversing partial splenic atrophy in children and adults with sickle cell disease. As the newly restored spleen enlarges, transfusion requirements sometimes increase substantially.[202,203] In such cases, removal of the spleen reduces the need for donor blood and therefore the accumulation of iron by 39%–51%. Careful monitoring of spleen size and annual transfusion requirements assists in identifying patients with hypersplenism who might benefit from surgical intervention.

Hypertension and Encephalopathy

Hypertension, accompanied or followed shortly by headache, or changes in mental status and seizures, is an unusual but potentially devastating complication of transfusion therapy in thalassemia, especially when the hemoglobin is raised from very low levels to normal or high levels.[204,205] This constellation of findings also has been reported after transfusion in sickle cell disease.[111,206] The cause is unknown. Autopsy findings in six cases showed brain edema and congestion, gross or microscopic hemorrhage, and microdissecting aneurysms.[207] No underlying vascular disease distinguished these patients from those without encephalopathy. Similar symptoms of hypertension, seizures, and mental status changes accompanied by reversible T2 hyperintensities on brain magnetic resonance imaging (MRI), constitutes a syndrome known as reversible posterior leukoencephalopathy. This has also have been reported in children with sickle cell disease and severe acute chest syndrome treated with erythrocytapheresis.[208] Complaints of headache or weakness after transfusion should prompt careful evaluation for neurological abnormalities including cerebral hemorrhage; hypertension, if present, should be treated aggressively.

IRON OVERLOAD AND CHELATION THERAPY

Pathophysiology of Iron Overload

Rates of Iron Loading

The average iron content of a healthy human is 40–50 mg/kg of body weight, with 30 mg/kg present in hemoglobin. Approximately 4 mg/kg is found in muscle myoglobin and 2 mg/kg in iron-containing enzymes. The remaining body iron is in the storage form of ferritin or hemosiderin, predominantly in liver, spleen and bone marrow. Mean iron stores are 769 mg in men and 323 mg in women.[209,210] A healthy individual absorbs approximately 10% of the dietary iron, or 1–2 mg daily. This intake is matched by insensible losses through exfoliation of skin, urinary tract, and gut mucosal cells together with gastrointestinal and menstrual loss of red blood cells. Humans have a limited capacity to modulate iron absorption and no physiological mechanism for excreting excess iron.

Iron can accumulate as a consequence of increased gastrointestinal absorption or from repeated red cell transfusions. In thalassemia major, iron loading predominantly derives from blood transfusion but excess iron absorption might also contribute. A unit of red cells, processed from 420 mL of donor blood, contains approximately 200 mg of iron (0.47 mg iron/mL of whole donor blood or 1.16 mg iron/mL of pure red cells). Splenectomized patients with thalassemia major received the red cells derived from approximately 300 mL/kg/year of whole blood per (range 200–400 mL whole blood/kg)[211] to maintain a mean hemoglobin level of 12 g/dL. This volume of transfused blood is equivalent to 0.4 mg/kg of transfused iron daily or 28 mg of iron in an adult weighing 70 kg. Iron loading varies greatly both within a given diagnosis and among diagnoses.[212,213] In thalassemia major with a mean loading rate of 0.4 mg/kg/day[212] there is considerably variability with approximately 20% of patients receiving less than 0.3 mg/kg/day, approximately 60% receiving 0.3–0.5 mg/kg/day, and a further 20% more than 0.5 mg/kg/day. The transfusion requirements in nonsplenectomized patients are generally higher than splenectomized patients and might contribute to an increased rate of iron loading. In one study of patients on hypertransfusion regimens who required more than 250 mL/kg/year of packed red cells, splenectomy decreased the annual iron loading by an average of 39%.[214] Average transfusion requirements in nonspelenectomized thalassemia major patients are 0.43 mg/kg/day compared with 0.33 mg/kg/day in splenectomized patients.[212] In general, hypertransfusion decreases the rate of splenic enlargement,[215] and the early introduction of a hypertransfusion regimen might diminish the extent to which the spleen contributes to an increased blood transfusion requirement.[211]

The contribution of increased iron absorption to iron loading in hemoglobin disorders is variable depending on the underlying condition. In thalassemia major, gastrointestinal iron absorption accounted for a further 1–4 mg daily of net iron loading[216] in a splenectomized adult patient who weighed 70 kg. In thalassemia intermedia, blood transfusion is intermittent or absent, and the increased iron loading is mainly a consequence of excess iron absorption. The amount of excess iron absorption depends on the degree of ineffective erythropoiesis, the extent of erythroid expansion, and the severity of the anemia, all of which are highly variable in thalassemia intermedia. In one study, patients with thalassemia intermedia absorbed 26%–73% of food iron.[217] Patients with this form of thalassemia absorbed 60% (range 17%–90%) of a 5-mg dose of ferrous sulfate, whereas healthy controls absorbed 10% (5%–15%).[217] In another study, absorption varied from 20% to 75% in HbE–β thalassemia and correlated

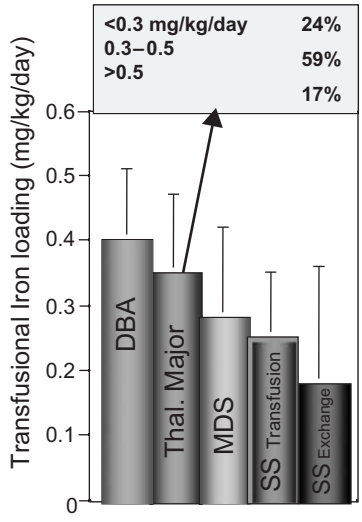

Figure 29.1. Rates of transfusional iron loading by diagnosis. (Original figure derived from data in refs. 212, 225, 246, 453.)

with plasma iron turnover, transferrin saturation, and liver iron concentration.[218] Iron absorption in thalassemia intermedia can thus be as much as five–10 times normal, or 0.1 mg/kg/day.[219]

In sickle cell disease, iron overload does not occur in the absence of blood transfusion.[220] Indeed, a variable proportion of untransfused patients might be iron deficient.[221–223] Repeated simple blood transfusions will inevitably lead to iron overload, but can mitigate iron deficiency.[60,224] The average rate of transfusional iron loading was less in sickle cell disease (0.22 mg/kg/day)[225] than in thalassemia major.[212] Figure 29.1 shows the relative rates of iron accumulation from transfusion measured in clinical trials involving desferrioxamine and deferasirox. Various exchange transfusion rates were highest in Diamond–Blackfan anemia (DBA) and lowest in sickle cell disease. These rates affect the chelation doses that are typically required for each condition.[212,213]

Distribution of Excess Iron

The tissue distribution and clinical manifestations of transfused iron are influenced by the mode and rate of iron loading and by the absolute levels of tissue iron within the body. Increased iron absorption leading to a predominantly parenchymal distribution of iron loading is a feature of genetic hemochromatosis and is also found in many conditions associated with ineffective erythropoiesis.[218,226–228] Postmortem examination of patients with thalassemia major showed a striking variability in iron concentrations among different tissues.[229] In thalassemia major in the pre–chelation era, iron was found at high concentrations in liver, heart, and endocrine glands with very little present in striated muscle[229] and none in the brain and nervous tissue. In the absence of chelation therapy, siderosis in liver macrophages and hepatocytes correlates with the number of units of blood transfused, with age, and with liver iron concentration.[230] With more advanced iron overload or in splenectomized patients, hepatocyte deposition predominates.[230]

Recent evidence in iron-loaded mice suggests that uptake of nontransferrin-bound iron (NTBI) into tissue expressing L-type calcium channels can account for this uneven distribution of iron overload and in particular the uptake into heart and endocrine tissues.[231] Another factor that could influence iron distribution in transfusional iron overload is hepcidin synthesis by the liver. Under relatively normal levels of iron loading, hepcidin is upregulated by increments in iron loading causing decreased iron absorption from the gut and decreased iron release from macrophages by secondary down regulation of ferroportin.[232] This process could occur through increments in transferrin saturation with progressive iron loading.[233] There is evidence, however, that hepcidin synthesis is downregulated by ineffective erythropoiesis as seen in thalassemia[234–236] and at very high levels of iron loading in the liver,[237] possibly through production of reactive oxygen species. This would lead to an increased propensity to distribute iron to the heart and endocrine tissues in conditions associated with high levels of ineffective erythropoiesis and also when liver iron levels reach a point at which increased damage through reactive oxygen species production is seen. Increased alanine aminotransferase values[238] and progression of fibrosis[239] are associated with liver iron concentrations above approximately 15–20 mg/g dry weight. These levels of liver iron loading are also associated with an increased likelihood of myocardial iron deposition in patients who have not undergone intensive chelation treatment.[240,241] In transfusional iron overload, cardiac iron is preferentially distributed to the ventricular compared with atrial myocardium or conducting tissue.[240] In nonthalassemic patients in the pre–chelation era, increased myocardial iron was found at postmortem in approximately 30% of patients after 50–75 U of blood, in 60% of patients who received 65–200 U of blood and in all patients who had received 200–300 U of blood.[240] Ventricular myocardial iron distribution is uneven, being maximal in the subepicardium, intermediate in the subendocardial region and papillary muscles, and least in the middle third of the ventricular myocardium. Focal areas of fibrosis can also be seen in papillary muscles or ventricles.[240] The uneven distribution of iron makes endocardial biopsy an unreliable tool for assessing cardiac iron concentration and iron-mediated cardiac damage.[242,243] The use of cardiac MRI to estimate myocardial iron has added to the understanding of factors affecting myocardial iron uptake and removal with chelation therapy. In adult patients with myelodysplastic syndrome who have not undergone chelation therapy, increased myocardial iron was demonstrated by MRI using signal intensity ratios to skeletal muscle, after 75 U of blood or when the liver iron concentration exceeded 400 μmol/g (~ 23 mg/g dry wt.).[241] Correlations between

liver iron concentration and myocardial iron and between serum ferritin and myocardial iron were seen prior to initiation of chelation in these patients: After 6 months of chelation therapy with desferrioxamine, these correlations were still present but less strong in the case of serum ferritin and myocardial iron. With chronic chelation therapy in thalassemia major, a clear relationship between liver iron and cardiac iron is no longer seen,[244] most likely because the rate of iron removal from the liver by chelation therapy exceeds that from the heart.[245] With modern chelation regimes, as many as 45% of thalassemia major patients still show evidence of myocardial iron loading on MRI.[246] Iron loading in the heart can occur after multiple transfusions in a variety of other conditions such as Diamond–Blackfan anemia and sideroblastic anemia.[246] In sickle cell disease, multiple transfusions are less likely to result in myocardial iron deposition,[246,247] perhaps as a result of lower levels of plasma NTBI compared with thalassemia patients matched for body iron load.[248]

Mechanisms of Iron Overload Toxicity

In the absence of iron overload, iron is unavailable to participate in the generation of harmful free radicals by its binding to physiological ligands such as transferrin. When iron overload develops, these protective mechanisms become saturated, and NTBI[249] and increased quantities of redox-active low-molecular-weight intracellular iron[250] are available to participate in the generation of harmful free radicals. NTBI species are likely to be heterogeneous, consisting of iron citrate monomers, oligomers and polymers and protein-bound forms.[251,252] In experimental models, NTBI is rapidly taken up by hepatocytes[253] and by myocytes.[254] Although the most important effects of NTBI result from its pattern of uptake and subsequent iron accumulation in tissues expressing appropriate receptors,[231] plasma NTBI (or subtractions of it) can generate lipid peroxidation through free radical formation,[255] and depletion of plasma antioxidants is associated with increased NTBI levels.[256] In cultured heart cells, species of NTBI are taken up at 200 times the rate of transferrin iron and generate free radicals, lipid peroxidation, organelle dysfunction, and abnormal rhythmicity.[254,257]

A free radical is defined as any species capable of independent existence that contains one or more unpaired electrons. The products formed sequentially during the reduction of molecular oxygen (O_2) to water are superoxide (O_2-), hydrogen peroxide (H_2O_2) and the hydroxyl radical (·OH), the reduction of the latter resulting in the formation of water. The hydroxyl radical has a great affinity for electrons and will oxidize all substances within its immediate vicinity diffusion radius of 2.3 nm.[258] H_2O_2 is relatively stable and nontoxic by itself. It is, however, an important precursor of ·OH requiring the availability of catalytic trace elements such as iron, copper, or cobalt. Iron is particularly important because it is present at sufficient concentrations in tissues and because of the favorable redox potential of the Fe^{2+}/Fe^{3+} couple (between +0.35 and -0.5 V). The oxidation of Fe^{2+} to Fe^{3+}, with the concomitant generation of the ·OH from water, is referred to as the Fenton reaction.

$$H_2O_2 + Fe^{2+} \rightarrow OH^- + HO' + Fe^{3+} \text{ (Fenton reaction)\#}$$

Within cells are a number of physiological scavengers of toxic oxygen products such as superoxide dismutase, which dismutates O_2- to H_2O_2, and catalase, which scavenges H_2O_2. Tissue damage depends on the relative rates of formation and scavenging of toxic free radicals. ·OH can damage proteins, DNA, and membrane lipids by peroxidation. Particularly important is the initiation of peroxidation of lipid (Lp) by hydrogen abstraction:[259]

$$LpH + HO' \rightarrow Lp' + H2O.$$

Because iron is concentrated in hepatocyte lysosomes in both primary and secondary iron overload, these organelles are particularly susceptible to lipid peroxidation.[260,261] The resulting lysosomal fragility[262] is directly proportional to the degree of iron overload.[263] In cultured heart cells, iron increased lysosomal instability and caused direct damage to mitochondria.[257,264] Lipid peroxidation and damage to organelles and lysosomal fragility might lead to apoptotic cell death[265–267] but might also encourage fibrogenesis. Iron-induced aldehyde lipid peroxidation products such as malondialdehyde[268] and others[269] have been shown to promote collagen gene expression and fibrogenesis in cultured fibroblasts and perisinusoidal stellate (Ito) cells. Fibrogenesis is also associated with autocrine production of transforming growth factor–β (TGFβ) in stellate cells[270] and increased mRNA levels of TGFβ and procollagen al(I) have been observed in a model of iron and alcohol induced fibrogenesis.[271] Increased TGFβ expression and malondialdehyde protein adducts have also been reported in hepatocytes and sinusoidal cells of patients with genetic hemochromatosis,[272] suggesting that iron overload increases both lipid peroxidation and *TGF-β* gene expression, which together might promote hepatic injury and fibrogenesis. In other tissues, similar mechanisms are likely to be involved, although the concentration and distribution of intracellular iron clearly differs among tissues: Tissues that have a high mitochondrial activity could be particularly susceptible to iron toxicity.[273] A scheme for iron-induced cell injury is shown in Figure 29.2.

Clinical Consequences of Transfusional Iron Overload

The consequences of transfusional iron overload and the effects of chelation treatment on these consequences are best described in thalassemia major, in which transfusion typically begins in the first few years of life and transfusional iron loading occurs at a rapid rate. In other forms of transfusional iron overload, the pathological effects of transfusional iron overload are less well documented.

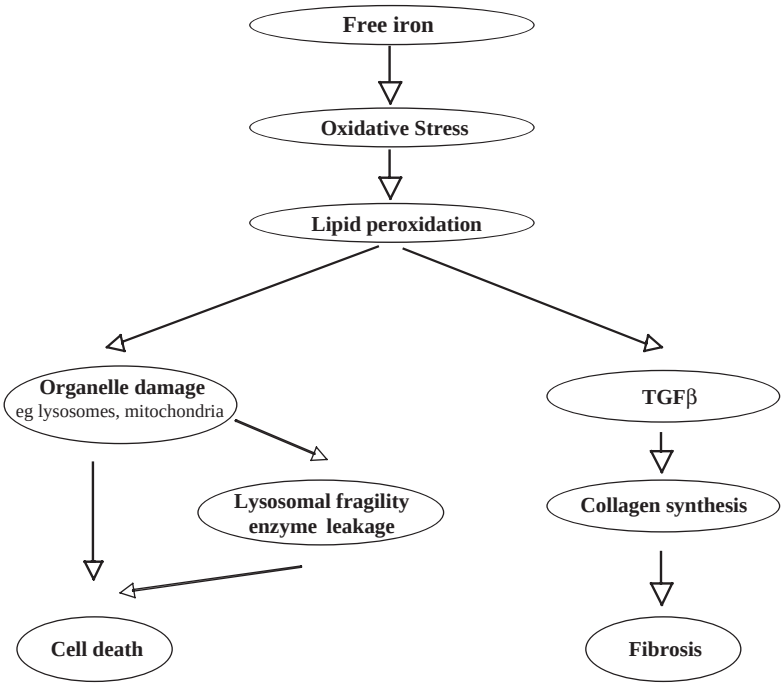

Figure 29.2. Mechanisms of liver damage in iron overload.[277]

Thalassemia Major

In thalassemia major, if chelation treatment is withheld, death from iron-induced cardiac failure is common from the second decade on.[274–276] By contrast, in conditions such as genetic hemochromatosis in which iron loading is slower, cirrhosis is a common presenting feature, usually in the fourth and fifth decades, and commonly leads to death from liver failure or hepatocellular cancer. Cirrhosis is also a common feature in thalassemia major, being present in 50% of patients at postmortem examination, particularly if chronic infective hepatitis (e.g., hepatitis C) is also present. Although cirrhosis was a relatively uncommon cause of death in thalassemia major[275] as patients live longer with improved chelation, cirrhosis and hepatocellular carcinoma[277] are likely to become increasingly common problems. Liver fibrosis can develop early in the course of thalassemia major, even in the absence of infective hepatitis. For example, fibrosis has been observed as early as 3 years after starting transfusion.[278] Fibrosis correlates with age, the number of units of blood transfused, and with liver iron concentration.[230] In these studies there was an exponential increase in hepatic fibrosis with increasing liver iron concentrations. The concentration of liver iron at which fibrosis progresses was examined in ex-thalassemic patients who had received a successful bone marrow transplant.[239] In the absence of active hepatitis C, fibrosis only progressed when liver iron concentrations exceeded 16-mg/g dry weight.

The most common cause of death in thalassemia major remains iron-induced cardiomyopathy but this has been reduced since the introduction of subcutaneous desferrioxamine infusions in the late 1970s[277] (Fig. 29.3). Risk factors for the development of fatal cardiomyopathy include late commencement of chelation therapy,[276,279] failure to maintain serum ferritin below 2,500 μg/L over a period of a decade or more,[277,279–283] failure to control iron concentration below 15 mg/g dry weight,[276,282] poor compliance with chelation therapy,[276,279,281] and a fall in ejection fraction below reference ranges.[279] Development of left ventricular dysfunction is increasingly likely when a myocardial T2* values fall below 20 m sec[244] and especially if T2* values are less than 8 msec.[284]

Hypogonadism commonly occurred in 55% of patients aged more than 12 years[285] and led to disturbances of growth and sexual maturation. The frequency of this complication is falling in progressive birth cohorts treated from an early age with desferrioxamine, so that at age 20 years, 65% of patients born between 1970 and 1974 had evidence of hypogonadism, and this fell to 14% in 1980–1984 birth cohorts[277] (Table 29.8). Hypogonadism is typically secondary to anterior pituitary dysfunction (hypogonadotrophic hypogonadism), and hence in many female thalassemics with secondary amenorrhea,[286] induction of ovulation and successful pregnancy are often achievable.[287] The effects of iron damage to the anterior pituitary with consequent hypogonadotrophic hypogonadism will clearly be more devastating if transfusion begins early in life and damage occurs before growth has ceased and full sexual maturity has been achieved.

Other complications such as diabetes, hypothyroidism,[288] and hypoparathyroidism are seen in a variable proportion of patients, and the frequency of these complications is also falling with improved chelation.

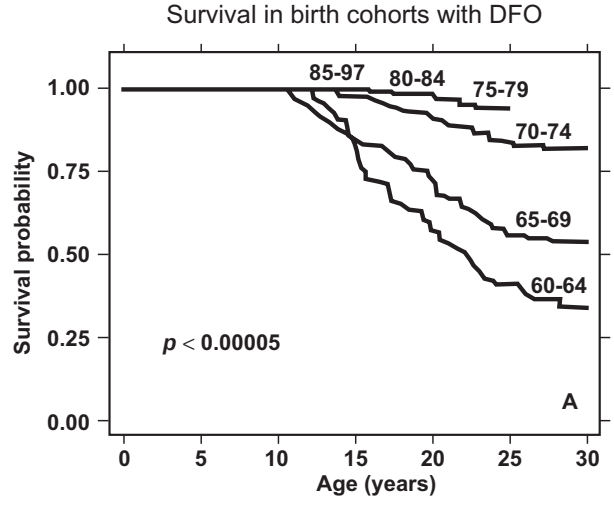

Figure 29.3. Survival by birth cohort in desferrioxamine-treated thalassemia major patients.[277]

Table 29.8. Falling complications since the introduction of DFO chelation therapy patients with thalassemia major born after 1960, n = 977

	Birth 1970–1974*	Birth 1980–1984†
Death at 20 y	5%	1%
Hypogonadism	64.5%	14.3%
Diabetes	15.5%	0.8%
Hypothyroidism	17.7%	4.9%

* DFO intramuscularly, 1975
† DFO subcutaneously, 1980.
In 1995, 121 patients switched to DFP (censored at this time).

The frequency of diabetes at age 20 years has fallen from 16% to 0.8% between birth cohorts from 1970–1974 to 1980–1984[277] (Table 29.8). In optimally treated patients who receive more than 260 infusions of desferrioxamine each year, these complications are absent at 15 years of follow-up.[281] Low levels of adrenal androgen secretion with normal glucocorticoid reserve have also been reported.[289] Other features of iron overload include skin pigmentation, arthropathy, ascorbic acid deficiency and osteoporosis.[219]

Infections are the second most frequent cause of death in thalassemia, occurring particularly commonly in younger age groups.[275] Postsplenectomy sepsis due to encapsulated organisms is an important contributor,[290] but iron overload also appears to play a central role in increasing susceptibility to infection. Reports of infection with *Y. enterocolitica*, *Vibrio vulnificus*, *Listeria monocytogenes*, *Escherichia coli, Candida* sp. and *Klebsiella* can be found.[291–294] The increased infective risk partly results from the saturation of transferrin with iron, depriving the body of an important mechanism to withhold this nutrient from bacteria. Defective neutrophil and macrophage function,[295–297] presumably secondary to the effects of excess iron, might also be important. Some bacteria such as *Yersinia* are able to utilize iron from iron complexes of chelators.[298] This is particularly likely if the chelator is a naturally occurring siderophore such as desferrioxamine.

The relevance of the rate of iron loading to the clinical manifestations of iron overload is further illustrated by the contrasting complications of excessive iron in thalassemia major and thalassemia intermedia. Thalassemia intermedia patients have different transfusion requirements.[218] Because of the slower buildup of iron, damaging levels of iron loading typically develop later than in thalassemia major and might not affect pituitary function until the third or fourth decade or beyond. Therefore, in thalassemia intermedia, growth and sexual development are typically unaffected by iron overload per se, and, when present, are more likely to be the consequences of ineffective erythropoiesis and anemia.

Sickle Cell Disease

In sickle cell disease, in which regular blood transfusions to correct anemia are usually not needed, iron overload only develops in individuals who receive repeated blood transfusions to prevent certain complications. In the minority of patients who receive repeated transfusions sufficient to cause significant iron overload, clinical consequences begin later than in thalassemia major, and thus effects on growth and sexual development are relatively uncommon. The use of the serum ferritin to estimate iron loading is problematic in sickle cell disease. The ferritin level is disproportionately increased in relation to iron loading for several weeks after a painful sickle episode[299] and often correlates poorly with hepatic iron concentration,[300] although under carefully controlled conditions a correlation is seen.[301] Transfusion-induced iron loading in the liver[301] with fibrosis and cirrhosis are seen.[302–304] Portal fibrosis develops quickly: after 21 months of transfusion without chelation, fibrosis was found in the livers of approximately a third of patients; after 4 years of transfusion, with variable chelation, fibrosis was still present in a third of patients with cirrhosis and in one of 29 patients in the absence of hepatitis C infection.[304] The fibrosis score correlates with liver iron concentration[303] but develops at widely varying hepatic iron concentrations of 9–38 mg/g dry weight in the absence of hepatitis C infection.[305]

Postmortem studies have found that cirrhosis was present in nearly half of patients who died with severe liver siderosis.[306] Postmortem studies also show clear evidence of iron deposition in the heart in heavily transfused patients;[240,306] however, MRI evidence suggests that the propensity for myocardial iron deposition[246,247,307] is less than in other forms of transfusional iron overload. A variety of endocrine disturbances have been reported in sickle cell disease,[308,309] including hypothyroidism[310] and increased pancreatic deposition of iron.[311] If sickle cell disease and thalassemia major patients matched for liver iron are compared, the incidence of heart disease, gonadal failure, and endocrine disturbances appears to be less in sickle cell disease patients aged younger than 20 years compared with thalassemia major.[308] Sickle cell disease patients typically begin transfusion later than those with thalassemia, and the rate of transfusion is on average lower, so that without carefully controlled studies the significance of these differences is unclear. At similar levels of iron loading, plasma NTBI values are lower in sickle cell disease than in thalassemia,[248,312] and this could account for decreased iron distribution to organs such as the heart.[247,248,307] Lower plasma NTBI values could result from the existence of a chronic inflammatory state in sickle cell disease[312] that would depress NTBI though increased hepcidin synthesis.

Other Transfusion-dependent Anemias

In multitransfused patients with myelodysplastic disease and a mean transfusional load of 120 U, there was evidence for multiple endocrine disorders including impaired glucose tolerance, decreased gonadotrophins, and impaired ACTH reserve.[313] A functional impact of myocardial iron deposition was suggested by one study in which heart

failure was the cause of death in 51% of patients.[314] Among 705 patients followed for 2 years or until death, cardiac comorbidities were seen in 79% of chronically transfused patients, in only 54% of nontransfused patients, and in 42% of a control population.[315] Furthermore overall survival was significantly worse in iron overloaded myelodysplastic disease patients compared with untransfused patients;[316,317] an independent effect of iron loading on survival is uncertain without prospective studies.

Monitoring of Iron Overload

Liver Iron Concentration

Liver iron concentration (LIC) is a key measure of iron overload because its value relates to body iron stores in a well-defined mathematical relationship: body iron stores in mg/kg = 10.6 x the LIC (in mg/g dry weight).[318]

Normal LIC values are up to 1.8-mg/g dry weight and levels up to 7 mg/g dry weight are seen in some nonthalassemic populations without apparent adverse effects.[319] In principle, iron balance with a given chelation regime can be calculated from the change in LIC over time, provided the iron input from transfusion is known. Change in LIC over a given time can also be used to calculate the efficiency of a chelator (i.e. the proportion of administered drug that is excreted in an iron bound form). Thus the change in LIC over a period of time period (6 months–1 year) is useful way to assess the efficiency and effectiveness of an iron chelator regime.

Measurement of LIC also has prognostic and pathophysiological significance. Sustained LIC values more than approximately 15–20 mg/g dry weight over a period of time predict an increased risk of liver fibrosis progression[239] and liver function abnormalities.[238] In patients not receiving chelation therapy, similar LIC values predict an increased risk of myocardial iron deposition[240,241] and iron-induced cardiomyopathy.[276,282] Intensive chelation therapy reduces liver iron faster than cardiac iron so that a simple relationship between LIC and estimated heart iron values is often not seen once long-term or intensive chelation therapy has been used.[245] Patients might develop heart failure after iron has been removed from the liver because excess iron remains in the heart.[320] Although low LIC in previously highly iron overloaded patients does not necessarily guarantee low heart iron concentrations, sustained high levels of LIC has clearly poor prognostic significance.

The use of LIC to follow the progress of transfusional iron overoad is becoming easier because noninvasive approaches to measurement are now more widely available. Liver biopsy to measure iron overload has the obvious disadvantage that it is invasive and carries a small risk of bleeding but in expert hands, using ultrasound guidance, no mortality was seen in more than 1,000 biopsies, with an overall complication rate of 0.5%.[321] Although liver iron is somewhat uneven in distribution,[322] this is not a serious problem provided a sample of 1 mg dry weight (4 mg wet or $\sim$ 2.5 cm in length) is obtained.[318,323] The presence of cirrhosis could increase the unevenness of iron distribution and hence the accuracy of LIC measurement.[323] In expert hands, with established methodology,[324] and with samples of adequate size, and in the absence of cirrhosis the coefficient of variation on duplicate specimens is only 6.6%.[325]

A problem in comparing values between studies is that the measurement of wet and dry weights of samples varies considerably among laboratories. Paraffin-embedded biopsy material can be used to measure LIC[324] but a recent multicenter study has shown that the ratio of wet/dry weight differs using this approach when compared with using fixed nonembedded tissue, being higher in paraffin-embedded tissue (5.9) than vacuum-dried fresh samples (3.8).[326] In many clinics worldwide, the regular measurement of LIC by biopsy is organizationally difficult. Furthermore, many patients who have been monitored successfully for many years by using the serum ferritin level are reluctant to undergo yearly liver biopsies. On the other hand, liver biopsy yields additional information about inflammation and fibrosis that might be particularly important in monitoring the activity of hepatitis C or evaluating experimental chelation regimens. Because of the increased use of LIC to monitor treatment, there is a need to harmonize both the techniques used to measure LIC and the units in which it is expressed. For example, some laboratories weigh the wet samples but use a conversion factor from wet to dry weight and express results in the latter units. A variety of conversion factors from wet to dry weight have been used by different centers. The implementation of an internationally agreed on standard and methodology would be helpful to the interpretation of studies on outcome of chelation treatment.

For these reasons, a noninvasive method to measure LIC that is reliable, standardized, and widely available would be highly desirable. Noninvasive measurement of LIC has been possible for many years by using superconducting quantum interface devices (SQUIDs) but these are expensive and only available in four centers worldwide (west and east coast of the United States, Germany, and Italy) and have been calibrated using different approaches. Excellent correlations with LIC values measured by biopsy were reported in hemochromatosis patients ($r = 0.98$)[327] but less impressive correlations were obtained in thalassemia,[328] possibly because of the diverse methodology for LIC biopsy measurements. Standardization between these devices has been problematic.[329] In recent multicenter trials using SQUID, significant differences in SQUID measurements were obtained from different centers.[213]

The current development of room temperature handheld susceptometric devices would have wider applications. Several MRI techniques for measuring LIC are now available,[330,331] relying on the general principle that tissue iron exerts a paramagnetic effect on surrounding tissues that affects the relaxation time of molecules excited by the application of a magnetic field. There is now a standardized and validated MRI method (FerriScan®) in which there

is a linear relationship between the measured value (R2) and LIC by biopsy over a clinically useful range.[330] Further advantages of this method are that it uses standard MRI equipment that is available in most hospitals, can be used with little extra training of local staff, and analysis of data acquired locally is performed at a central facility.

Use and Limitations of Serum Ferritin

Although LIC predicts body iron and this can now be measured noninvasively, the practical advantages of having a blood test for monitoring iron overload that can be repeated with each clinic visit are obvious. Serum ferritin fits many of the requirements as it broadly correlates with iron loading and can be performed frequently and inexpensively. There are limitations to its use and interpretation: Serum ferritin is increased not only by increased body iron stores but also as a result of tissue damage and inflammation; levels are depressed by ascorbate deficiency. Unlike tissue ferritin, serum ferritin is predominantly iron free, being secreted in glycosylated form by macrophages proportional to their iron content, up to values of approximately 3,000 μg/L.[332] Above this value, iron-rich ferritin tends to leak from hepatocytes so that responses to treatment at levels more than 3,000 μg/L might occur at a different rate compared with values below 3,000 μg/L.[333] The relationship between serum ferritin and body iron stores can vary with the chelator being used, and it is important to define such a relationship for each chelation regime so that informed dose adjustments can be made.[334] Serum ferritin is usually measured by immunoassay with reference to an agreed international standard; however, 'kits' for measuring serum ferritin have been optimized for identifying iron deficiency so care must be taken at high ferritin values to ensure that dilutions allow measurements within the linear range of the assay.

In normal subjects[335] and in genetic hemochromatosis[336] a good correlation exists between iron mobilizable stores by quantitative phlebotomy and serum ferritin. With transfusional iron overload in the pre–chelation era, a correlation of serum ferritin with the number of units transfused in thalassemic children was present,[337] but this correlation was reduced in adults.[332] Serum ferritin also correlates with the LIC; in children with thalassemia major, this correlation was present both in those receiving and not receiving chelation therapy ($r = 0.75$).[337] In patients with HbE–β thalassemia and HbH disease, a correlation of $r = 0.82$ was noted between the log of serum ferritin and liver iron measure by SQUID.[218] A very weak correlation between serum ferritin and LIC was seen in a diverse group of patients, many of whom had liver disease ($r = 0.11$). When the serum ferritin was corrected for liver inflammation, by dividing by the aspartate aminotransferase, the correlation was much closer ($r = 0.92$).[338] More recent studies, although confirming the general relationship between serum ferritin and LIC, have emphasized that this is not close enough in multiply transfused thalassemia patients, many of whom have hepatitis C, to give a clinically reliable prediction of LIC.[339,340] In one study, variation in body iron stores accounted for only 57% of the variability in plasma ferritin.[301] The relationship between serum ferritin and iron stores is similar in thalassemia major and sickle cell disease[301] provided serum values are taken several weeks away from a vasoocclusive episode,[224] but in thalassemia intermedia, serum ferritin tends to underestimate the amount of iron overloading.[234]

Depression of serum ferritin occurs in ascorbate deficiency. Subclinical but biochemically demonstrable ascorbate deficiency is common in iron-overloaded patients[256,341] due to the rapid oxidation of ascorbic acid in the presence of redox active iron.[342] In ascorbate-deficient patients, the correlation between serum ferritin and LIC was 0.39, whereas in ascorbate-replete patients it was 0.77[341]. Repletion of ascorbate status increased transferrin saturation and serum ferritin rose in approximately half the treated patients.

In an individual patient with iron overload, long-term control of serum ferritin, at least with desferrioxamine therapy, has prognostic significance. If the ferritin is maintained below 2,500 μg/L on a long-term basis, this is associated with a significantly lower risk of iron-mediated cardiac disease and death.[277,280–282,343] Maintenance of a serum ferritin of 1,000 μg/L might be associated with additional advantages.[277] Serum ferritin has also been used as means of modifying the dose of chelation treatment, based on experience with desferrioxamine therapy in which toxicity due to this agent is more likely in the context of low serum ferritin levels. Dose modification algorithms have been constructed for desferrioxamine under circumstances of falling ferritin values;[340,344] however, the basis for dose modification with other chelation regimens has yet to be established.

Monitoring of the Heart

Iron-mediated cardiomyopathy remains the most common cause of death in thalassemia major;[277] therefore, the identification of patients at the greatest risk is of paramount importance, so that effective intensification of therapy can be introduced.

Long-term quantitative sequential measurement of left ventricular ejection fraction in thalassemia major has shown that a fall below reference values indicated a 35-fold increased risk of cardiac failure and death with a median interval to progression of 3.5 years.[343] Longitudinal monitoring of heart function is best achieved using a method that can be standardized and is not operator dependent. In the hands of an expert, echocardiography is a useful tool for visualizing heart function but it is difficult to quantify left ventricular ejection fraction reproducibly over time. Mulitgated acquisition scanning is well suited to this purpose as it has excellent reproducibility and less operator dependence, but MRI techniques are now widely available and measurement of left ventricular ejection fraction

function can now be combined with measurement of heart iron in a single visit.

Little or no role exists for measuring cardiac iron by biopsy because of the uneven distribution of cardiac iron.[240,242,243] MRI can be used to estimate tissue iron because iron overload results in shortening of the T1 and T2 tissue relaxation times on which MRI is based and thus leads to a reduction in signal intensity. The decrease in the intensity of spin echo images with iron overload derives from decrements in the T2 relaxation times.[345,346] This shortening is due mainly to the paramagnetic properties of ferritin iron.[346,347] The problem in measuring heart iron was that levels were considerably lower than in the liver and the heart is rapidly moving. Early approaches lacked sensitivity over a wide enough linear range but several MRI methods have now been developed that are applicable to the heart.[241,244]

Myocardial T2* is a gradient echo method that is now the most widely used to estimate myocardial iron and has been found to be highly reproducible.[348] The T2* gradient echo sequence was first used in imaging of iron deposits in the brain[349] but is particularly applicable to myocardial imaging because a short acquisition time is possible, which is advantageous when measuring a moving tissue. T2 is related to T2* by the formula $1/T2^* = 1/T2 + 1/T'$, where T2 is the tissue relaxation and T' is the magnetic inhomogeneity of the tissue being analyzed. As the T2* becomes shorter implying higher tissue iron concentrations, there is an increased chance of left ventricular function being adversely affected.[244] In one study, the left ventricular ejection fraction was decreased in 10% of patients with T2* less than 20 msec, 18% of patients with T2* values between 8 and 10 msec, 38% of those with T2* of 6 msec, and 70% at 4 msec.[284] Myocardial iron deposition has been found by using this technique in as many as half of adult patients with thalassemia major and in a variety of other forms of transfusional iron overload.[246] Myocardial T2* can be used to identify patients most at risk of myocardial decompensation, which can occur suddenly over a period of a few days, and allow consideration of intensification of chelation therapy in those most at risk prior to decompensation.

Monitoring for the Clinical Effects Iron Overload

The earliest consequence of iron overload in transfused children is hypogonadotrophic hypogonadism, which although not fatal, has severe consequences for growth, sexual development, fertility, and bone health.[286] Close monitoring of growth and sexual development in children is therefore vital so that chelation can be intensified before irreversible effects ensue. In older patients, regular monitoring for the cardiological, endocrinological, and growth and developmental effects of iron overload is an essential part of management of iron overload. For example, monitoring for impaired glucose tolerance might identify patients at most risk of developing diabetes. Monitoring for hypothyroidism and hypoparathyroidism is also advisable, particularly in adults. As there is no clear evidence that damage to these tissues can be reversed, prevention of these complications by adequate control of body iron at all times is the optimal strategy. A scheme for such monitoring is outlined in Table 29.9 showing that monitoring will tend to be predicated by the availability of local resources.

Table 29.9. Monitoring for iron toxicity from transfusion

Observation	Frequency	Expense
Iron intake rate	Each transfusion	Chelation dose and frequency	3 monthly	
Growth and sexual development	6 monthly children	
Liver function	3 monthly	
Sequential ferritin	3 monthly	
GTT, thyroid, Ca metab.	Yearly in adults	
Liver iron	Yearly	
Heart function	Yearly	
Heart iron (T2*)	Yearly	

Monitoring Tissue Iron in Other Organs

MRI can be used to visualize iron in other organs affected by iron loading such as the anterior pituitary and pancreas. MRI of the pituitary shows a correlation between anterior pituitary size and biochemical markers of anterior pituitary function.[350] More recently T2* MRI has been used to assess iron in the anterior pituitary,[351,352] but prospective studies are required to determine how changes in pituitary T2* relate to biochemical evidence of disturbed gonadotrophin production. Attempts have been made to use MRI to relate changes in pancreatic function to iron deposition and a possible correlation between MRI signal and pancreatic exocrine but not endocrine function was found.[353,354]

Urine Iron Excretion

Measurement of urinary iron has been used with desferrioxamine monotherapy, with deferiprone monotherapy, and with combinations of the two drugs. Because all iron is excreted by the fecal route with deferasirox, urinary iron measurement has not been used with this chelator. A relationship between 24-hour urinary iron excretion following intramuscular desferrioxamine and iron stores was recognized soon after the introduction of the chelator.[355] Later it was suggested that 24-hour urinary iron excretion could be used to titrate an individual's therapy with desferrioxamine by "tailoring the dose"[356] as the dose at which the urinary iron excretion plateaus varies considerably.[356] Several limitations to this approach exist. First, there are practical difficulties for many families in obtaining reliable sequential 24-hour urine collections outside of a hospital setting. Second, there is considerable day-to-day variability in urinary iron excretion when taking desferrioxamine, even under controlled conditions of collection, and this might be compounded by variable daily ascorbate

intake.[356] Finally, the proportion of urinary iron excretion relative to fecal iron excretion is not constant. The urinary iron excretion decreases following blood transfusion and suppression of erythropoiesis and is proportionately less at higher doses of desferrioxamine.[357] Whereas fecal iron excretion contributes to at least half of desferrioxamine-induced iron excretion there is little fecal excretion with deferiprone, making urine iron determination a potentially useful tool. When the two drugs are used in combination, however, changes in urinary iron excretion without reference to total iron removal or the fecal excretion are uninterpretable.

Other Markers of Iron Overload

Plasma transferrin saturation increases with increasing iron loading but is also affected by inflammation,[358] hepcidin synthesis,[359] and degree of erythropoiesis,[360] making its use in the management of transfusional iron overload of limited value. NTBI is present when transferrin becomes saturated in iron overload[249] and sometimes before.[361,362] Plasma NTBI negatively correlates with evidence of antioxidant depletion.[256] NTBI is highly labile, being only partially removed with chelation therapy and returning rapidly after elimination of the chelator.[363] NTBI is also affected by factors other than iron overload. For example, fewer iron-loaded thalassemia intermedia patients appear to have higher NTBI levels, which rebound faster after cessation of iron chelation than thalassemia major patients with higher levels of iron loading. This suggests that ineffective erythropoiesis may influence plasma NTBI.[364] Plasma NTBI is heterogeneous, consisting of iron citrate of varying molecular weights and loosely protein bound iron species.[252] Total plasma NTBI can be measured by a number of methods.[365,366] An assay has been developed for a redox active subfraction that has been termed labile plasma iron.[367] Assays for NTBI have variable reference ranges but generally correlate.[365] An assay measuring a labile subfraction, the component capable of accelerating oxidation of a fluorophore, termed labile plasma iron,[367] is convenient for measuring in the presence of chelators. Progressive removal of this subfraction has been seen with deferasirox,[368] consistent with the notion that continuous chelation minimizes exposure to NTBI species.[364] The application of NTBI or labile plasma iron as a way of tailoring chelation therapy on an individual patient basis has yet to be determined. How hepcidin levels can be used to guide chelation management is also unclear.[233,369]

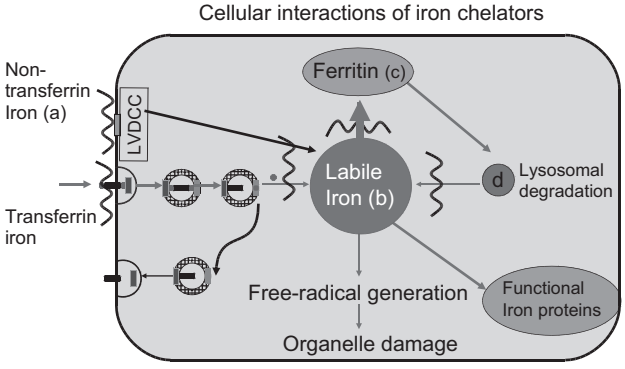
Objectives of Chelation Therapy

Iron Balance

The primary objective of chelation therapy is to balance iron excretion with intake so that tissue iron never reaches damaging levels. If this strategy is successfully applied, iron-mediated tissue damage is prevented. Unfortunately many patients either start treatment too late or fail to maintain effective exposure to iron chelation so that rescue chelation therapy is needed. Rescue therapy has two objectives: to detoxify iron pools promoting acute tissue damage and to remove excess storage iron from affected tissues. The first objective can be achieved rapidly in some circumstances, for example by inducing rapid reversal of heart failure before much storage iron has been removed. The second goal of removing storage iron can take months or years especially in tissue not designed to store iron such as the heart.[245] Because of the difficulty in removing established storage iron overload from heart, pituitary, thyroid, and pancreas, a long-term strategy to prevent primary iron loading is preferable. At lower levels of iron loading, chelation therapy might lead to removal of essential metals required for physiological functions. In this instance, over chelation too early in the iron loading process could lead to unwanted toxicities.[370] Iron chelation requires that iron loading and excretion be balanced and that the intensity of chelation is matched to the level and rate of iron loading.

Maintenance of Safe Tissue Iron Concentrations

How the age iron loading begins, its rate, and how the absolute levels of iron loading contribute to tissue damage or determine the distribution of iron overload are incompletely understood. Thus there is debate about what constitutes “safe” levels of body iron burden. Good evidence supports the notion that control of serum ferritin (mainly iron free), liver iron (iron-rich ferritin and hemosiderin), and myocardial T2* visible iron (iron-rich storage iron) has prognostic significance. This does not mean that these forms of iron are the direct cause of tissue damage however, but rather that these are valuable markers for potential iron-mediated problems. Both biopsy and MRI techniques measure storage iron rather than the small fraction of labile iron that is directly toxic to cells.[264,371,372] The slow accumulation of iron in heterozygotes for hereditary hemochromatosis is typically not associated with liver damage, even though LIC values can approach 7 mg/g dry weight.[319] Conversely, liver fibrosis might develop in transfused and nontransfused,[373] iron-overloaded patients at or around these levels.[303,304] Progressive liver damage and abnormal liver tests in the absence of viral hepatitis are associated with LIC values of more than 16 mg/g dry weight[239] and similar sustained values over a decade or more are associated with an increased risk of cardiomyopathy in thalassemia major.[276] Yet we do not yet understand the relationship between myocardial iron load and LIC, particularly in patients undergoing chelation therapy. In the pre–chelation era, or in patients undergoing only light chelation therapy, there appears to be a relationship between myocardial iron loading and LIC, with myocardial iron appearing after approximately 75 U of blood in



LVDCC = L-type voltage-dependent calcium channel.

Figure 29.4. Mechanism of chelator action at cellular level.[246]

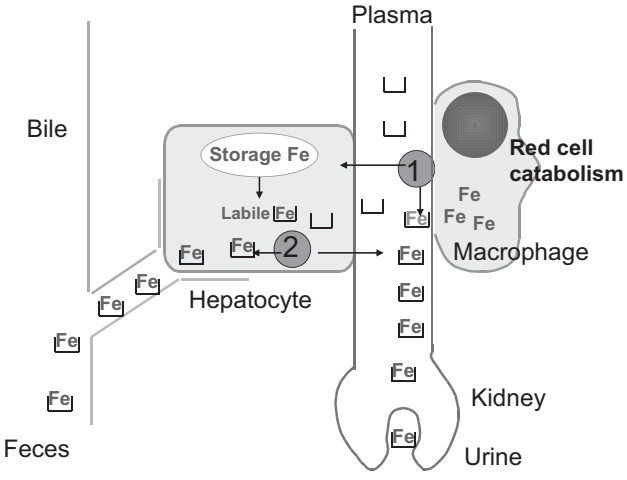


Figure 29.5. Major chelatable iron pools and excretion pathways.[249]

adults (15–20 mg/g dry weight with LIC). Together, the data suggest that it would seem wise to commence chelation therapy before LIC values approach 15 mg/g dry weight, probably at a time when LIC values exceed approximately 7 mg/g dry weight, and to aim to maintain LIC values lower than 7 mg/g dry weight. Whether the maintenance of LIC values lower than 7 mg/g dry weight at all times will prevent myocardial iron loading requires prospective evaluation for which studies are currently ongoing.

Detoxification of Harmful Iron Species

Although it can take months or years to remove all the excess iron from iron-loaded subjects, a well-designed chelator should ideally decrease the iron-mediated damage rapidly and until all the excess storage iron has been removed. To do this, potentially harmful labile iron pools must be removed rapidly and rendered harmless[246] (Fig. 29.4). As iron pools are constantly being turned over, continuous exposure to chelation is theoretically desirable, both in terms of maximizing the efficiency of chelation therapy and minimizing the exposure to harmful free radicals generated by labile iron species. Clinical data supporting the concept of detoxification of iron before storage iron has been changed significantly are seen in studies with intravenous desferrioxamine in which improvement in liver tests is rapid and precedes changes in T2* reflecting storage iron.[246]

Iron Pools Available for Chelation

Labeling of iron pools both in experimental animals[374,375] and in humans[376] suggest that only a small proportion of total body iron is available for chelation at any moment. This is broadly related to two iron turnover pools: red cell catabolism in macrophages (1 in Fig. 29.5): hemosiderin and ferritin catabolism in hepatocytes (2 in Fig. 29.5). This has a fundamental bearing on the strategies adopted for chelation therapy because it follows that escalation of chelation doses will have a finite impact on increasing iron excretion. The reason for this can be appreciated from consideration of both extracellular and intracellular iron turnover.

Extracellular Iron

The major turnover of body iron, amounting to some 20–30 mg/day in healthy individuals, is through the plasma compartment from the breakdown of effete red cells in the reticuloendothelial system. Iron is released onto transferrin for subsequent delivery to erythroid precursors in the bone marrow.[377] This can increase up to sevenfold when hemolysis and ineffective erythropoiesis are pronounced, as in thalassemia intermedia. Considerable evidence both in animal studies[375] and in humans[376] indicates that iron derived from the breakdown of hemoglobin in macrophages is chelated directly by desferrioxamine and other compounds such as DTPA before binding to transferrin[378] (Fig. 29.4). Whether this interception occurs extracellularly or within the macrophages is uncertain, but in vitro studies suggest the former is more likely with desferrioxamine.[379] This will presumably vary depending on rates of access of the chelator in question to intracellular iron pools in macrophages. Studies using selective ^{59}Fe cell–labeling techniques in iron-overloaded rats[374,375,380] and ferrokinetic data in humans[376] suggest that most urinary iron excretion with desferrioxamine is derived from catabolized red cells (1 in Fig. 29.5). Although other chelators used for the treatment of iron overload are excreted though different pathways than desferrioxamine the sources of chelatable iron are essentially the same. Thus with deferasirox, animal studies show that although nearly all iron bound to the chelator is excreted in feces, much of this is derived from red cell breakdown.[381] Deferiprone-bound iron is excreted almost entirely in urine but there is evidence for chelation of iron both from red cell breakdown and from parenchymal stores.[382]

Table 29.10. Characteristics of approved chelating agents

	Deferiprone	Desferrioxamine	Deferasirox
Denticity	Bidentate	Hexadentate	Tridentate
Molecular weight	175	560	373
Iron (III) binding (pM)	19.9	26.6	22.5
Lipid solubility	High	Low	High
Charge free ligand	Neutral	Positive	Negative (1-)
Charge iron complex	Neutral	Positive	Negative (3-)
Absorption route	Oral	Parenteral	Oral
Max. plasma levels	90–450 μM	7 μM (total)	20 μM
Elimination	Rapid	Very rapid	Slow
Route of iron excretion	Urine	Urine + Feces	Feces
Metabolism	Inactive glucuronide	Active metabolites	Active glucuronide

Another potential source of chelatable iron outside cells is transferrin-bound iron (Fig. 29.4). Although this is quantitatively very small (~ 4 mg) at any moment, approximately 20–30 mg pass through this pool every day after iron is released from reticuloendothelial cells. In principle, iron chelators are in competition with transferrin for iron released by reticuloendothelial cells. Because the concentration of transferrin in plasma exceeds that of desferrioxamine, deferasirox, or deferiprone, except at transient peak concentrations, and because the stability constant of transferrin for iron is comparable to that of these chelators, iron binds effectively to transferrin even when chelators are being used. Furthermore, once plasma iron has bound to transferrin it is virtually unavailable for chelation by desferrioxamine.[380] Hydroxypyridinones can remove iron from transferrin but the concentrations required to do so at a significant rate make this an unlikely mode of action in vivo. For example, at 100 μM concentrations of deferiprone, approximately a quarter of the iron is removed from 90% saturated transferrin (50 μM) and only 12% for 30% saturated transferrin after 24 hours.[383] It must also be remembered that iron can be donated to transferrin by bidentate hydroxypyridin-4-ones but not by desferrioxamine at clinically relevant concentrations of transferrin and chelator.[383] This is because the iron complexes of bidentate chelators are inherently less stable than those of hexadentate ligands such as desferrioxamine. Thus, because the plasma concentrations following orally administered chelators such as deferiprone are only transiently above 100 μM[384] (Table 29.10), donation of iron to transferrin might be as likely as iron removal, particularly when transferrin is not saturated in the steady state.

Another important potentially chelatable extracellular iron pool is NTBI (Fig. 29.4). Total NTBI values do not usually exceed approximately 10 μM[364] but the speciation is heterogeneous. These forms are not all equally available for rapid chelation.[252] Iron citrate polymers are more slowly accessed by chelators than monomers and dimers.[252] In plasma of iron-overloaded patients at clinically relevant concentrations, not all NTBI is removed by desferrioxamine.[363] The component of NTBI that is rapidly accessed by desferrioxamine has been termed desferrioxamine-chelatable iron.[385] Only the subfraction of NTBI capable of redox cycling, so-called labile plasma iron, is rapidly available for chelation.[386] The contribution of chelation of NTBI to iron balance has not been determined, but removal of NTBI by chelation therapy is potentially important for iron detoxification. NTBI is only partly removed by chelation with desferrioxamine and rebounds rapidly after cessation of an intravenous infusion[364] or subcutaneous infusion of chelator.[363] Thus, with conventional nightly subcutaneous desferrioxamine infusion, NTBI can enter tissues during the day.[363] Using the labile plasma iron assay, it was found that there is also rapid rebound of labile plasma iron at night with daytime use of deferiprone, but that when deferiprone is given three times a day with desferrioxamine at night, 24-hour coverage can be achieved.[367] A similar degree of 24-hour coverage from labile plasma iron can be achieved with once daily deferasirox because of its longer plasma half-life.[368]

Intracellular Iron

The major source of chelatable intracellular iron derives from the continuous turnover of intracellular ferritin and to a lesser extent hemosiderin (source b in Fig. 29.4 and source 2 in Fig. 29.5). Iron chelators can be considered as interacting potentially with three intracellular iron pools. These are the labile "transit" iron pool or (pool a), which is generally of low molecular weight, finite, and rapidly chelatable; the storage iron pool of hemosiderin and ferritin (pool b), which is relatively slowly chelatable but larger at any moment than pool a; and the functional iron pools (pool c), which are iron-containing molecules essential for normal cellular function (e.g., hemoglobin, myoglobin, enzymes such as lipoxygenase and ribonucleotide reductase). Pool a is in dynamic exchange with the other two pools. The goal of chelation therapy is to chelate pool a without affecting the important functions of iron in pool c (Fig. 29.4). Although some of pool b may be depleted directly, this is relatively slow because chelators cannot remove iron from ferritin cores at a clinically useful rate.

Transit iron can theoretically be chelated at any point during its uptake into cells by receptor-mediated endocytosis of transferrin, liberation from transferrin in the acidic endosome, or egress from the endosome via divalent metal ion transporter 1 (*SLC11A2*).[387] Labile chelatable intracellular iron has been demonstrated in a variety of cells including reticulocytes, marrow cells, intestinal epithelial cells, blood leukocytes, alveolar macrophages, and hepatocytes, although evidence has been largely indirect and the nature of the pool is uncertain.[371,388–391] It is clear that iron entering the cell, either from transferrin or by other mechanisms, becomes transiently chelatable before incorporation into ferritin.[392] Early studies in Chang cells showed approximately 20% of cellular iron was present as a nonheme, nonferritin soluble form after 24-hour incubation[393] and was rapidly chelatable with EDTA, desferrioxamine, or transferrin.[394] Quantification of this pool from tissue homogenate iron extracted by desferrioxamine showed a correlation with an ultrafilterable fraction bound to low-molecular-weight ligand(s).[395] Studies using the fluorescent probe calcein in K562 cells suggested that the labile intracellular iron pool is present at 0.4 μM with an estimated transit time of 24 hours.[390] Similar values have been obtained with rat hepatocytes labeled with $^{59}FeCl_3$ and analyzed for desferrioxamine-chelatable ^{59}Fe[396] and using electron paramagnetic resonance in K562 cells.[397] The magnitude of the labile iron pool is assumed to be sensed by a cytosolic iron-responsive protein so that increments in labile plasma iron increase ferritin mRNA translation and decrease transferrin receptor mRNA stability,[398] thereby having homeostatic effects on labile plasma iron concentrations. When cells become heavily iron loaded or the rate of uptake of NTBI into cells exceeds an as-yet undetermined rate, the sequestrating capacity of cellular ferritin is exceeded,[390] leading to an expanded labile plasma iron that is an obvious target of intracellular iron chelation therapy by drugs that are able to cross the cytoplasmic membrane. The same properties of chelators that favor mobilization of intracellular iron[399] such as lipid solubility, also favor chelation of the labile intracellular pool[400–402]. Thus hydroxpyridinones access labile iron pools more rapidly than desferrioxamine[372,397,400,403] the latter taking approximately 4 hours, whereas hydroxpyridinones may take only a few minutes. Deferasirox appears to access labile intracellular iron rapidly and have access to iron pools within organelles.[372,402]

With respect to pool b, iron can be mobilized from ferritin by desferrioxamine in vitro but the rate is less than 0.5%/hour, even when desferrioxamine is present in 15-fold molar excess.[404] Furthermore, acidic pH values, such as those present in the lysosome, do not appear to enhance this rate.[405] Bidentate hydroxypyridinones can gain access to the ferritin core directly by virtue of their smaller size.[406] At neutral pH values, iron mobilization from rat ferritin is still only 1%/hour even in the presence of 15-fold chelator excess.[405] Thus access by chelators to ferritin iron will occur at useful rates in vivo only when this protein is being degraded by proteolysis with the subsequent release of iron to the labile intracellular transit pool. It has been estimated that ferritin is turned over intracellularly with a half-life of approximately 72 hours[407] and that proteolysis is predominantly lysosomal rather than cytosolic.[408]

With respect to pool c, it is clear that the physicochemical properties of chelators have a major influence on their rate of access to iron. Desferrioxamine, by virtue of its hexadentate structure, relatively high molecular weight (Table 29.10), and its hydrophilicity compared with the clinically studied hydroxypyridinones, accesses intracellular iron and iron within organelles more slowly than hydroxypyridinones.[400,409] Furthermore, interaction with key enzymes in pool c such as lipoxygenase[410] and ribonucleotide reductase[411] is significantly slower for desferrioxamine than hydroxypyridinones. Because of the pivotal role of ribonucleotide reductase in DNA synthesis and cell proliferation, its rapid inhibition by hydroxypyridinones is a putative mechanism for the leukopenia and marrow hypoplasia associated with these agents.[411–413]

Constraints of Chelator Design

To be unavailable to participate in the generation of free radicals, iron must be fully coordinated at each of its six ligand-binding sites. If any of these remain partially coordinated, iron may participate in the Fenton reaction, resulting in lipid peroxidation with organelle and cell damage. The design of a chelator is crucial to preventing these events. In general, hexadentate ligands, which have six coordination sites and hence bind iron in a 1:1 ratio, scavenge iron at low chelator concentrations more efficiently and are more stable in their iron complexed forms than bidentate or tridentate chelators (Fig. 29.6). The latter chelator classes have two or three iron-coordinating sites per ligand, respectively, and therefore require three or two chelating molecules, respectively, to coordinate iron (III) completely. EDTA, which only coordinates one free electron, does not diminish the reactivity of iron salts in the Fenton reaction and indeed might catalyze such reactions.[259] By contrast the hexadentate desferrioxamine and physiological ligands such as lactoferrin and transferrin that surround the iron more completely are powerful inhibitors of lipid peroxidation in several systems.[414] The iron–chelate complexes of bidentate hydroxypyridinones, being less stable than the hexadentate desferrioxamine, can generate free radicals and damage cell membranes with increased lipid peroxidation and loss of cell viability, particularly if the chelators have high lipid solubility.[406] The effect can be "designed out" by synthesizing hydroxypyridinones with high pM (-log of the uncoordinated metal [iron] concentration calculated at pH 7.4, 10-μM ligand concentration and 1-μM iron[III] values).[415] Deferasirox, a tridentate chelator, is inherently less stable than ferrioxamine but is unlikely to participate in redox cycling of iron because Fe deferasirox

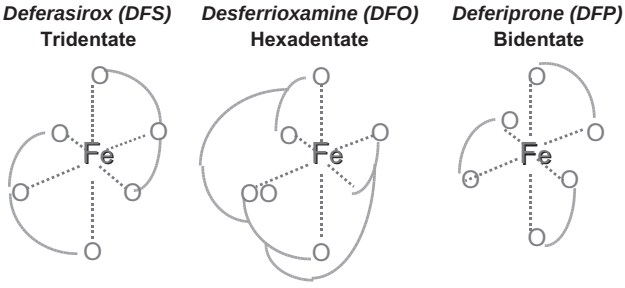

Figure 29.6. Denticity of iron chelation.[213]

is a very weak oxidizing agent, making its reduction under physiological conditions unlikely.[416]

Hexadentate chelators tend to have the advantage over bidentate and tridentate ligands of a greater ability to scavenge iron at low concentrations, a lesser potential to redistribute iron and a slower access to iron in pool c. Conversely, lower molecular weight bidentate and tridentate ligands have a potential to be absorbed from the gut and to access intracellular iron pools more rapidly. It is difficult to design hexadentate molecules with molecular weights less than 400, thus severely limiting their absorption from the gastrointestinal tract.[417] Consequently no hexadentate chelators have yet been identified with sufficient oral bioavailability for clinical use. Many bidentate and tridentate chelators have sufficiently low molecular weights for acceptable oral bioavailability. To minimize the inherent disadvantages of their lower denticity, novel chelators with greater stability of the iron–chelate complex are being sought.

Clinically useful iron chelators should possess a sufficiently high iron binding (stability) constant[409,417] and have specificity of iron binding over other essential metals like zinc and copper. A more clinically relevant expression of iron binding than the stability constant is the pM (Table 29.10). This measure takes into account the tendency of bidentate chelators to dissociate at low concentrations and is a more useful indicator of the ability of a chelator to scavenge iron at low chelator concentrations. Chelators with high pM values are therefore desirable.

The distribution of chelators to different tissues and subcellular compartments will also inevitably affect their toxicity. Ideally a compound should have low penetration of the central nervous system, where adverse effects have been observed with desferrioxamine (see later) and should have a high extraction of iron from liver cells where iron is present in high concentrations.[417,418] The rate at which chelators gain access to intracellular iron pools is determined by their lipid solubility, charge, shape, and molecular weight.[401,409,419] Once within cells, the structure of iron chelators also determines the rate of interaction with key iron-containing enzymes in pool 3. Larger and less lipophilic molecules tend to interact with intracellular metalloenzymes more slowly than small lipid soluble molecules.[403,411,420]

Finally, the pharmacokinetics and metabolism of an iron chelator are critical to its success. The metabolism of chelators has been shown to have a key bearing on their efficacy and toxicity.[421–424] As the majority of body iron is not directly chelatable, increasing the chelator dose might not have a proportionately increased effect on iron excretion while increasing the risk of toxicity disproportionately due to an excess of free chelator. This relative unavailability limits the efficiency of chelation therapy, where chelation efficiency refers to the proportion of the drug that ends up being excreted in the iron-bound form. In iron-overloaded humans, the efficiency of desferrioxamine is approximately 13%, deferiprone is approximately 4%, and deferasirox is approximately 27%.[425,426] The relatively low efficiency of deferiprone is likely to be explained not only by the rapid metabolism to forms that do not bind iron but also by its rapid elimination.[427] Conversely, the long plasma half-life of deferasirox contributes to the higher efficiency of this drug.[428] Thus iron excretion with deferasirox[429] as with desferrioxamine[363,430] is directly proportional to the area under the curve of the drugs. A further advantage of slow chelator elimination is that 24-hour protection from labile iron species in plasma or within cells can be achieved.[364,367]

CHELATION THERAPY WITH DESFERRIOXAMINE

Historical Perspective

Desferrioxamine, a naturally occurring hexadentate siderophore derived from *Streptomyces pilosus*, was discovered by chance in 1960 during work on isolation of the iron-containing antibiotic ferrimycin from *Streptomyces griseoflavus*. Following its isolation, the iron-bound form, ferrioxamine B, was initially investigated as a potential iron donor for iron-deficient subjects, but it was excreted intact in the urine without losing or exchanging its iron. The notion that an iron-free ferrioxamine, desferrioxamine, might be used to chelate excess iron was supported by clinical studies.[431]

Desferrioxamine when first given to thalassemia major patients as single intramuscular injections increased urinary iron excretion in a dose-dependent manner, proportional to iron stores.[432] Once daily intramuscular injections of 500 mg, 6 days a week in thalassemia major children over a period of 7 years, stabilized liver iron at approximately 3% dry weight and also stabilized liver fibrosis compared with untreated comparators.[325] Twenty-four-hour intravenous infusions produced more urinary iron than the same dose given as an intramuscular bolus.[433] The same group and others subsequently showed that 24-hour subcutaneous desferrioxamine infusions resulted in urinary iron excretion nearly equivalent to that achieved with intravenous infusions.[433,434] Urinary iron excretion was similar giving the same dose over 12 rather than 24 hours, and this was generally achieved iron balance.[356,435] Metabolic iron balance studies revealed that between 30% and 50% of total

iron excretion with desferrioxamine was in the feces[357] and that the proportion increased with ascending desferrioxamine doses and following suppression of erythropoiesis by blood transfusion.[357] Nightly 8–12-hour subcutaneous infusions of desferrioxamine gradually became standard practice. The use of ascorbate, 2–3 mg/kg daily, on the same day as desferrioxamine administration increased urinary iron excretion,[357] but doses in excess of this were possibly associated with cardiac toxicity.[436] In the 1980s progressively larger doses of desferrioxamine were tried, often by the intravenous route, in attempts to reverse massive iron overload or to reverse cardiac failure.[437–439]

Although some of these objectives were achieved, significant toxicity from desferrioxamine began to be reported, most noticeably retinal[440] and auditory toxicity.[441] Later, effects on bone and growth were reported in children.[442,443] From these and other studies, a "standard" dosing regimen for desferrioxamine has emerged, aimed at balancing the beneficial effects of chelation with unwanted effects of excessive dosing. It must be made clear however that some aspects of "standard therapy" recommendations, such a when to begin and the dose recommended to maximize growth potential, have been arrived at by empirical retrospective analysis rather than prospective randomized trials.

Chemistry and Pharmacology of Desferrioxamine

The hexadentate structure of desferrioxamine necessitates a relatively high-molecular-weight structure of 560 (or when administered clinically as the mesylate, 657) that limits its absorption from the gut, and therefore only parenteral routes of administration are realistic. Its hexadentate structure helps desferrioxamine to scavenge Fe^{3+} particularly at low concentrations of iron, as evidenced by the high pM (Table 29.10). A hexadentate structure and high pM also contribute to stabilization of the iron complex, and iron redistribution or partial iron complexation is insignificant. Other metals are bound with a much lower affinity; only the chelation of aluminum has clinical significance. Desferrioxamine has been successfully used to treat aluminum overload in renal dialysis patients at doses of 5–10 mg/kg/week.[444] Entry of desferrioxamine into most cell types and into subcellular compartments is retarded by two mechanisms, its relatively high molecular weight and its highly hydrophilic nature.[400,411] in hepatocytes, however, there appears to be a facilitated uptake mechanism.[363] The free drug is positively charged, as is the iron complex. This latter property accounts for the slow egress of the iron complex from cells.[411]

Elimination of desferrioxamine from plasma is fast, with an initial half-life of 0.3 hours and a terminal half-life of 3 hours.[445] With an intravenous infusion of 50 mg/kg/day, mean steady-state concentrations of 7.4 μM are achieved[445] (Table 29.10). Desferrioxamine and its major metabolites are cleared by the liver and the kidney in their iron-free forms. Once iron is bound to form ferrioxamine in the plasma, clearance is almost exclusively renal because ferrioxamine is not cleared by the liver. In renal disease, levels of ferrioxamine may therefore accumulate; however, ferrioxamine is highly stable and does not redistribute iron significantly within the body. With 24-hour infusion, the duration of protection from NTBI and labile plasma iron is continuous, but plasma levels still rarely exceed 10 μM at conventional doses.[364] Metabolism of the iron-free drug but not the iron complex occurs within hepatocytes, so that an increase in metabolites indicates a decrease in the availability of chelatable iron.[363,446]

Fecal iron excretion as ferrioxamine is almost entirely due to intrahepatic iron chelation, whereas urinary iron is mainly derived from plasma iron turnover[380] (Fig. 29.5). Uptake of desferrioxamine into hepatocytes results in chelation of cytosolic and possibly lysosomal iron to form ferrioxamine that is then excreted in the bile.[374] At conventional doses approximately a third of the iron is excreted through this route into the feces, and this amount increases with higher desferrioxamine doses,[447] reflecting a greater proportion of intrahepatic chelation.

Evidence of Efficacy of Desferrioxamine

Effects on Iron Balance and Liver Iron

Iron balance can be estimated from metabolic balance studies with measurement of iron excretion in urine and feces and iron input in the diet[357] or by measuring the change in LIC over time and relating this change to the Angelucci formula, which relates LIC to total body iron stores.[318] Early studies suggested that iron balance, based on urine iron alone, could be achieved at a dose of approximately 30 mg/kg/day when given as a 12-hour infusion.[356] In patients not previously receiving chelation therapy, the quantity of urine iron excreted correlated with transferrin saturation,[448] the number of transfusions,[448] and the dose of desferrioxamine[356,432,448] Fecal excretion contributes a further 30%–50% to total desferrioxamine-induced iron output.[357] Formal metabolic iron balance studies suggested that daily 12-hour infusions at 30 mg/kg could achieve iron balance in thalassemia major, particularly if oral ascorbic acid was supplemented at the equivalent of 2–3 mg/kg/day.[357]

Intramuscular desferrioxamine was more effective at stabilizing liver iron at 6 years follow-up in thalassemia major.[325] Using subcutaneous infusions of 40 mg/kg, more maintained liver iron at safe levels.[449–452] Intensification of therapy by combining subcutaneous and intravenous therapy can normalize liver iron levels.[438] Surprisingly, detailed studies of the dose effect of desferrioxamine on LIC and hence on iron balance have only become available recently as a byproduct of prospective 1-year comparisons with deferasirox, in which changes in LIC over a 1-year period were measured in 290 patients receiving sliding scale doses of desferrioxamine between 25 mg/kg/day

and 60 mg/kg/day 5 nights a week.[453] These studies have revealed the critical importance of dose and transfusion rate on iron balance.[212] Importantly at doses of desferrioxamine used in many recent studies, and at average transfusional iron loading rates of 0.3–0.5 mg/kg/day, negative iron balance was achieved in only half of patients prescribed 40 mg/kg/day 5 days per week. When doses of 50 mg/kg or higher were given, 86% of patients were in negative iron balance, even at high transfusional rates of 0.5 mg/kg/day or higher.[212] The proportions of patients in iron balance might be even less during routine clinical where compliance is likely to be poorer.

Effects on Serum Ferritin

Dose-dependent reductions of serum ferritin with desferrioxamine have been recognized for several decades, and the value of maintaining serum ferritin at less than 2,500 μg/L has been linked to protection from heart disease and with survival.[280] Formal trials relating changes in serum ferritin to dosage have been scarce. Recent studies comparing desferrioxamine with other chelators have added some important information about its effects on ferritin. In interpreting these findings it is critical to know what treatment patients received prior to the formal study as a change in ferritin is unlikely if patients simply continue the same dosage of drug.

In a prospective study of 290 patients with thalassemia major mainly treated with desferrioxamine prior to the trial and followed for 1 year, those receiving a daily dose of 40 mg/kg five times per week had mean decreased serum ferritin of approximately 360 μg/L, whereas a dose of 50 mg/kg decreased serum ferritin by approximately 1,000 μg/L.[453] These are average effects, and dose should be increased if the transfusional iron intake exceeds the average.

Long-term Effects on Survival

Because no other chelation treatment was available when desferrioxamine was introduced, the pattern of survival in progressive birth cohorts gives a clear indication of its impact on survival as well as its cardioprotective effects. The impact of desferrioxamine on overall survival began to emerge in the 1980s[454] but the full impact was clearly documented only later.[275–277,280,281] Only 70% of patients born before 1970, and hence prior to the modern era of iron chelation, survived to age 20 years compared with 89% of patients born after 1970 who received effective chelation treatment from an early age.[455] In nearly 1,000 Italian patients born between 1970 and 1974, mortality was 5% by age 20 years and this fell to 1% in cohorts born between 1980 and 1984 when desferrioxamine was widely used.[277] The age of starting treatment has been shown to be a key factor in outcome,[276,277,343] although the optimal age has not been assessed in prospective studies. Compliance with nightly infusions is key to long-term survival. Life table analysis shows that patients who comply well with treatment can have a 100% survival rate to age 25 years, whereas survival for patients who comply poorly is only 32%.[276] For patients who administer subcutaneous infusions of desferrioxamine more than 250 times a year, survival to age 30 years is 95%. If the frequency of infusion falls below 250 times a year, or approximately five times a week, survival to age 30 years is only 12%.[281] The environment in which patients are treated has an important effect on compliance and survival. In thalassemic patients treated at a single thalassemia center, 83% of patients survived to age 40 years, and all compliant patients born after 1975 survived to age 25 years.[320] The effect of compliance on survival has not been reported with other chelators. The provision of comprehensive care that delivers the necessary practical and psychological lifelong support to patients on chronic transfusion is therefore vital.

Effects on the Heart

Because iron-induced cardiomyopathy remains the most common cause of death in thalassemia major, the effects of desferrioxamine on heart disease and survival will be considered together. Perhaps the most persuasive evidence for the cardioprotective effects of desferrioxamine is the ability to reverse preexisting cardiomyopathy. Improvement in left ventricular function after 1 year of treatment was first noted in a small group of thalassemia patients with subclinical heart disease in response to intensive subcutaneous desferrioxamine[456] and was sustained with long-term follow-up.[439] This effect was confirmed in other studies.[457] Evidence for reversal of clinically overt heart failure in thalassemia major was first shown in three of five patients treated with intravenous doses of desferrioxamine of up to 200 mg/kg/day.[437] Later work using a discontinuous, high-dose regimen of 6–12 g of desferrioxamine over 12 hours daily[458] showed improvement in symptoms and echocardiographic parameters in one patient with congestive cardiac failure and another with a severe ventricular arrhythmia. Other experience with discontinuous therapy has been variable. No improvement in the cardiac status of two patients was seen at 100 mg/kg over 8–12 hours[459] but improvements were observed in eight thalassemic patients followed-up for 6.5 years while using high-dose administration via an indwelling central venous line for 8–10 hours daily.[460]

Experience with continuous 24-hour therapy has been more consistent, having the theoretical advantages of continuous removal of NTBI[364] and of reestablishing good compliance.[333,461] In one study, four patients were treated with continuous 24-hour therapy with improvement in left ventricular ejection fraction in two and reversal in atrial fibrillation in a third.[457] In nine other patients, not only did continuous 24-hour infusions produce superior urinary iron excretion compared with an equivalent subcutaneous 12-hour regimen, but the intravenous regimen encouraged

excellent compliance.[461] Longer-term studies have established that continuous intravenous therapy is a safe, life-saving therapeutic option in the management of high-risk thalassemia: 25 intravenous devices were inserted into 17 patients over a 16-year period, and desferrioxamine, usually at 50 mg/kg/day, was infused continuously over 24 hours, 6–7 days a week.[333] Resting ejection fraction improved significantly from 36%–49% in seven of nine patients with previously documented deterioration in left ventricular function. This occurred in some cases within a few days of starting treatment and therefore cannot be attributed to normalization of iron stores but to the depletion of a limited toxic labile iron pool. Atrial fibrillation was reversed in all six patients in whom this was present within 12 months; in one patient, cardioversion occurred within 5 days without the need for conventional antiarrhythmic drugs. Drug toxicity was limited to a single early case of reversible retinopathy in a patient with preexisting diabetes mellitus who had been on an initial dose of 80 mg/kg/day. Long-term follow-up showed 62% survival at 13 years in those with demonstrable cardiac disease. Deaths occurred in patients whose compliance was not maintained. Large doses such as those initially used to reverse heart failure and that were associated with severe retinal problems[437,440] might not be necessary and doses of 50–60 mg/kg/day could be sufficient.[333] The risk of overdosing can be minimized by adjusting the dose as the ferritin falls, maintaining the therapeutic index of desferrioxamine to serum ferritin ratio of 0.025 as recommended for conventional subcutaneous desferrioxamine treatment.[333]

Reversal of left ventricular dysfunction similar to that achieved with continuous intravenous therapy has also been shown with 24-hour subcutaneous therapy,[343] although this is demanding and only suitable for some patients. With the increasing use of T2* to estimate myocardial iron, there is now evidence that desferrioxamine, when given at sufficient doses and with sufficient frequency and duration can improve myocardial T2*. Patients with severe myocardial iron overload and a mean T2* less than 6 msec, with advanced myocardial dysfunction, when given continuous desferrioxamine infusions at 50 mg/kg/day or more showed improved T2* values of 3 msec over 1 year.[245] During this same observation period, liver iron levels were nearly normalized and left ventricular function normalized within 3 months of treatment, suggesting that heart function can be improved by continuous desferrioxamine even when heart storage iron remains high. It might take several years, however, to normalize heart iron when T2* values begin less than 10 msec.[320] It might not be necessary to use intravenous treatment to improve myocardial T2* values if myocardial iron loading is only mild: improvement in cardiac T2* even at low, intermittent doses has been confirmed in two prospective randomized studies,[462,463] even in people on a previous similar treatment regime. Using subcutaneous treatment at relatively low doses of 35 mg/kg patients with baseline T2* values between 8 and 20 msec showed improvement in T2* of 1.8 msec over 1 year;[462] doses of 40–50 mg/kg 5 days a week lead to an improvement of 3 msec over 1 year.[464]

Other Long-term Effects on Morbidity

Other effects of desferrioxamine therapy include: improvement in liver fibrosis,[325] decreased severity of hypogonadism,[465] improved glucose tolerance,[466] and decreased incidence of diabetes,[276] and hyperparathyroidism.[277] The onset of glucose intolerance is delayed and glucose intolerance can be improved[466] by the timely use of desferrioxamine. Hypothyroidism might also be reversed.[469] Introduction of subcutaneous infusions of desferrioxamine before age 10 years significantly reduces gonadal dysfunction, with improvement in pubertal status and growth.[465] Concomitant improvement in fertility has also been seen, although secondary amenorrhea is still common.[286]

Unlike heart failure,[467,468] once advanced endocrine dysfunction has developed, reversal has not been documented. Intramuscular desferrioxamine at relatively modest doses stabilizes hepatic fibrosis and there is no progression over an 8-year period in patients receiving subcutaneous infusions of desferrioxamine in the absence of histological evidence of active hepatitis.[451]

Tolerability of Desferrioxamine

General

Most of the toxic effects of desferrioxamine are dose related; effects on growth, skeletal changes, audiometric, and retinopathic effects are more likely at higher doses of the drug. Toxicity from desferrioxamine in thalassemia major is very unlikely at doses up to 40 mg/kg/day. The risk of toxicity at any given dose is greater in patients with low levels of iron loading than in those with high levels of iron loading so that as serum ferritin falls, particularly below 1000 μg/L, it is wise to consider reducing the dose.[344,470] It is clear that some unwanted effects such a those on growth and bone development are mostly applicable to children in whom special care must be taken to avoid doses of greater than 40 mg/kg/day. These patients should be monitored particularly carefully with the consideration of dose lowering as iron levels fall.

Injection Site Reactions

Local mild reactions can occur with skin reddening and soreness at the site of subcutaneous infusions. These are often caused by desferrioxamine being reconstituted above the recommended concentration of 10%. Increasing the volume of water used to dilute the desferrioxamine can substantially decrease reactions. On occasions when local reactions remain a problem, the addition of 5–10 mg hydrocortisone to the desferrioxamine solution can help.

Effects on Growth and Bone

Although desferrioxamine usually improves growth in thalassemia major by decreasing iron overload, excessive amounts might cause growth retardation. The risk factors are, age younger than 3 years at commencement of treatment, higher doses of desferrioxamine,[442] and lower levels of iron overload. It is advisable to monitor height velocity as well as sitting and standing height twice yearly and adjust dosing as necessary. A quick resumption in growth follows reduction in desferrioxamine dosing without the need to stop treatment.[443] Rickets-like bone abnormalities have been described in association with decreased growth[442] and radiographic abnormalities of the distal ulnar, radial, and tibial metaphases appear to be associated features. Vertebral growth retardation or milder changes involving vertebral demineralization and flatness of vertebral bodies have also been noted in patients receiving chelation therapy.[281] It might be advisable to undertake regular surveillance for the toxic effects of desferrioxamine on bone[471] with annual radiological assessment of the thoracolumbar–sacral spine and the forearm and knees and to reduce the dose of the chelator if significant changes are noted.

Renal and Auditory Toxicity

Retinal and optic nerve disturbances, sometimes associated with pigmentary retinal changes, were originally described in patients receiving 125 mg/kg/day[440] and are rare at currently recommended doses. Other abnormalities that have been linked to excessive use of desferrioxamine include blurred vision, loss of central vision, night blindness, and optic neuropathy.[441] The risk might be higher in patients with diabetes or other factors affecting the blood–retinal barrier,[472] so these groups should be monitored more carefully by using electroretinographic techniques. Desferrioxamine therapy should be withdrawn until symptoms partially or fully resolved and then resumed at a reduced dose with close monitoring by electroretinography.

High-frequency sensorineural hearing loss was initially described in approximately 25% of patients on high-dose desferrioxamine regimens.[441] This complication might be reversible if diagnosed early.[344] The risk is greatest in patients with low degrees of iron overload receiving high doses of desferrioxamine. By keeping the therapeutic index[344] below 0.025 and by monitoring audiometry regularly, the risks can be minimized. It is advisable to perform audiometry before starting treatment and approximately once a year during treatment.

Infections

There is an increased risk of *Yersinia* infection in iron overload, and this risk increases further with desferrioxamine treatment as *Yersinia* does not make a natural siderophore and uses iron from ferrioxamine to facilitate its growth.[473,474] Patients who present with diarrhea, abdominal pain, or fever should stop taking desferrioxamine until *Yersinia* infection can reasonably be excluded by appropriate stool samples, blood cultures, and serological testing. If *Yersinia* infection is proven or seriously suspected, desferrioxamine should be withheld until the infection has been eliminated by antibiotic treatment. Prolonged treatment with an antibiotic such a ciprofloxacin is occasionally necessary to prevent recurrence, but it is rarely necessary to withhold desferrioxamine after the initial infection has been treated. Very rarely, other infections such as *Pneumocystis carinii*[475] and *mucormycosis*[476] have been associated with desferrioxamine. In any patient with undiagnosed fever it is wise to consider stopping the desferrioxamine until the cause is identified.

Miscellaneous Effects

Generalized reactions such as fever, muscle aches, and arthralgia occur rarely. True systemic allergic reactions are uncommon but can include anaphylaxis. Some patients can be successfully desensitized using published procedures,[477,478] Renal impairment, characterized by a reduction in the glomerular filtration rate, has been reported in occasional patients given high doses[479] and a clinically significant decrease in glomerular filtration rate occurred in 40% of patients receiving subcutaneous desferrioxamine that was reversible on its discontinuation.[480] A fatal acute respiratory distress syndrome–like syndrome has been described in patients with acute iron poisoning given 15 mg/kg/hour desferrioxamine infusions for periods in excess of 24 hours; lower doses and shorter infusions are recommended for acute iron poisoning.[481] Pulmonary injury with fibrosis has also been reported in patients with chronic iron overload receiving doses of 10–22 mg/kg/hour.[482]

In noniron-overloaded patients, the use of desferrioxamine potentiated the action of prochlorperazine, a phenothiazine derivative, leading to reversible coma in two patients.[483] Lens opacities, observed rarely in patients receiving high doses of desferrioxamine, improved when the chelator was withdrawn.[437] In a recent randomized study comparing desferrioxamine with deferasirox, five of 290 patients randomized to desferrioxamine without lens opacities at baseline appeared to develop them over a 1-year period. In the context of the knowledge that clinically significant lens opacities are uncommon in patients on long-term desferrioxamine, these findings need interpreting with caution. Thrombocytopenia has been observed with desferrioxamine in two patients on renal dialysis.[484] It is important to avoid a sudden bolus infusion of desferrioxamine in patients receiving intravenous treatment through an indwelling catheter or during blood transfusions because this can lead to nausea, vomiting, hypotension with acute collapse,[485] or even transient aphasia.[486]

General Treatment Recommendations for Thalassemia Major

Standard Therapy

Guidelines aim to achieve a balance between the unwanted effects of under or over chelation, and advise what is most practical for the patient. Standard current practice for commencing desferrioxamine in β thalassemia major is to begin at the age of 3 years or when the ferritin reaches 1,000 μg/L, whichever is sooner, and not to exceed 30 mg/kg until response to this regimen can be assessed. Although it is clear that the introduction of desferrioxamine at excessive doses or too early increase the risks of toxicity, the optimal dosing and timing have not been the subjects of prospective, randomized trials, and recommendations are therefore to some extent empirically based. Delay in treatment until after age 3 years has been recommended because of observations of poor growth and metaphyseal dysplasia when started earlier.[442,471,487–489] Conversely, delay in starting treatment increases the risk of iron-mediated toxicity as hepatic fibrosis associated with liver iron loading has been reported in children as young as age 3 years.[278,490] It is possible that very low doses given from an earlier age could prevent accumulation of liver iron without concomitant desferrioxamine toxicity, but there are presently no data that address this directly. Furthermore, failure to start treatment sufficiently early increases the risk of growth retardation due to the well-established effects of iron overload on growth and sexual development.

Downward dose adjustment is advisable with young age and low levels of iron loading. In patients younger than age 5 years, doses in excess of 35 mg/kg/day might be inadvisable. Ferritin can be used as an approximate indicator of falling iron levels, and doses of desferrioxamine should be reduced accordingly keeping the therapeutic index less than 0.025 (mean daily dose in mg/kg, divided by the serum ferritin in μg/L).[344,370] If liver iron quantitation is available, a scheme for dose adjustment has been suggested.[340] Liver iron determinations are unlikely to be available more frequently than yearly, even in centers performing these measurement routinely, therefore, ferritin measurements will still be useful in dose adjustment.

Upward dose adjustment should be considered in patients with rates of transfusional iron intake greater than 0.5 mg/kg/day. Doses of 50–60 mg/kg/day will be necessary for negative iron balance in approximately half of these patients.[212] Even at intermediate transfusion rates between 0.3 and 0.5 mg/kg/day, approximately a quarter of all patients will require doses higher than 50 mg/kg/day to achieve negative iron balance. Doses less than 35 mg/kg/day result in positive iron balance even in patients with a transfusional iron loading rate of less than 0.3 mg/kg/day.[212] Therefore, in adults, doses above 40 mg/kg/day and typically 50–60 mg/kg/day are often necessary. Ascorbate supplementation of 2–3 mg/kg/day is another useful way of increasing iron excretion and it is recommended for patients who are stable and not in heart failure or do not have an arrhythmia on the days that desferrioxamine is given. Patients with mild myocardial iron loading and T2* of 10–20 msec can also benefit from modest increments in desferrioxamine dose or frequency. With T2* less than 10 seconds or with left ventricular dysfunction, a greater degree of intensification is required.

Rescue Therapy

For patients with acute heart failure, continuous desferrioxamine infusion is recommended. This is usually most conveniently achieved by diluting desferrioxamine in 500 mL of saline and infusing through a peripheral vein. For longer-term infusions, once the patient has been stabilized, an indwelling line is usually necessary, although 24-hour infusion has been successfully achieved by the subcutaneous route in selected cases.[343] Doses in excess of 50–60 mg/kg/day have been used successfully but increase the risk of pulmonary[482] and retinal toxicity.[440] Complications associated with the use of central venous access lines include infection and thrombosis.[333] To limit the thrombotic complications of central venous access lines, close monitoring and prophylactic anticoagulant therapy have been suggested. Intensification, as described previously, has also been successfully used in very severe iron overload without myocardial dysfunction or as a way of reestablishing compliance with chelation therapy with good long-term outcome if compliance is maintained.[333] With evidence of moderately increased myocardial loading or T2* of 10–20 msec, improvement in these measures might be achieved by increasing the dose or duration of exposure or compliance with subcutaneous desferrioxamine above that given for standard therapy. With severe myocardial iron loading and T2* less than10 msec, but without heart failure, intensification of therapy is necessary and can include increasing the dose and/or duration of desferrioxamine exposure without[245,343] or with the addition of deferiprone.

Methods of Delivery for Desferrioxamine

The mode of delivery of standard desferrioxamine is critical to compliance and hence the success of therapy. It is usually infused at night via a thin subcutaneous needle inserted into the abdomen, arm, or lateral thigh region, which is connected to a portable pump over 8–12 hours, five–seven times per week at a daily dose of 20–60 mg/kg. The infusion site needs to be rotated nightly and a solution infused should not damage tissues. The most widely delivery system has been the battery-operated syringe driver, delivering between 10 and 30 mL, depending on the manufacturer. These are best suited to subcutaneous infusions for 8–12 hours daily, but some can also be used for intravenous infusions. Lighter or smaller systems have been developed that might be better suited to continuous

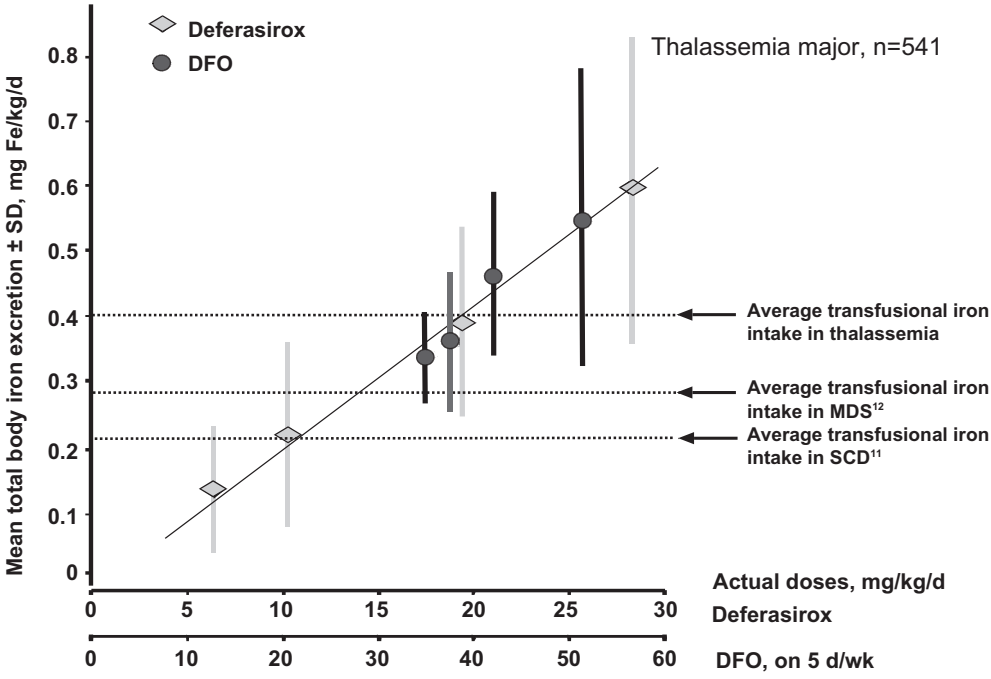

Figure 29.7. Dose–response comparison of DFO and DFX.[212]

infusion. Some battery-operated pumps can take 50–100 mL of desferrioxamine solution, allowing continuous intravenous treatment for up to 1 week. An alternative is to use disposable pumps that expel fluid under the pressure produced by filling an expandable balloon.[491] These devices are light and silent, making them attractive to patients who need continuous infusions, but disposable pumps are expensive. Recently introduced mechanical delivery devices and gas-operated systems are also lighter and more compact than conventional syringe driver models.

Subcutaneous bolus injections have been evaluated as an alternative approach to chelation therapy if pumps are unavailable or impractical. Studies suggest that iron excretion with twice daily subcutaneous injections of desferrioxamine might be comparable to that observed with the same total dose given as an 8-hour subcutaneous infusion.[492,493] In a randomized comparison of twice daily bolus injections and subcutaneous infusion, similar decrements of serum ferritin and approximate liver iron values were seen in both groups of thalassemia patients.[494] This approach might be an alternative when pumps are not available and when patients are prepared to inject twice daily.

Use of Desferrioxamine in Sickle Cell Disease and Thalassemia Intermedia

Sickle Cell Disease

Patients with sickle cell disease who receive long-term transfusion therapy to prevent the complications will eventually require iron chelation therapy unless exchange transfusions are used in preference to simple transfusions. A variety of chronic anemias associated with iron loading, in which regular transfusion is not necessary but erythropoietic reserve might be marginal, such as pyruvate kinase deficiency, sideroblastic anemias, and thalassemia intermedia, may also benefit from chelation therapy if venesection is not feasible.

The optimal dose to achieve iron balance can be referred to the rate of iron loading from transfusion that can easily be calculated from the number of blood units given over a given time period. On the basis of the transfusional loading rate, the optimal dose can be referred to a graph[212] relating dose to iron balance. Thus the dose of desferrioxamine to obtain iron balance will on average be lower in sickle cell disease (20 mg/kg/day) than in thalassemia major (40 mg/kg/day) (see Fig. 29.7).

Although in sickle cell disease, iron distribution to endocrine organs and to the heart is less common than in thalassemia major, chelation therapy is still necessary to maintain iron balance and decrease the risks of iron overload. Iron balance with desferrioxamine and the proportions of fecal and urinary iron excretion appear similar to those seen in thalassemia syndromes.[495] The rate of iron loading varies considerably between patients and depending whether simple transfusion or erythrocytapheresis is used. In a recent multicenter study the average rate of transfusional iron loading was less in sickle cell disease (0.22 mg/kg/day).[225] The use of ferritin for dose adjustment is more problematic in sickle cell disease as discussed previously. LICs above 7 mg/g dry weight are a clear indication for starting treatment because the risk of liver fibrosis increases above this value,[304] which will typically be

exceeded after 21 months of simple transfusion.[303,304] Maximal doses should not exceed those given in thalassemia syndromes, and careful monitoring for toxicity is advisable.

Thalassemia Intermedia

In thalassemia intermedia, iron overload might result from increased iron absorption up to five times the normal rate[217,218] or from sporadic transfusions. Serum ferritin tends to underestimate the degree of iron overloading[234] so that liver iron determination is particularly helpful in planning the optimal regime. In general, because of the lack of regular transfusion, negative iron balance can be achieved at relatively modest doses or frequency of chelation. By referring to the dose response for other diseases (Fig. 29.7), a mean daily dose of desferrioxamine at 10 mg/kg/day would maintain iron balance or put patients into negative iron balance. In practice, iron can be decreased steadily and safely by giving standard doses (40 mg/kg) of desferrioxamine twice or three times a week in such patients, thus achieving mean daily doses of 10–20 mg/kg/day.

Because of the discordance of serum ferritin from body iron burden in both thalassemia intermedia and sickle cell disorders, it might be advisable to quantitate liver iron before making a decision to initiate chelation therapy and to repeat liver iron quantitation at regular intervals during treatment.

ORAL CHELATION THERAPY

Although desferrioxamine is highly efficacious, complying with long-term administration has been problematic for an important subset of patients limiting its effectiveness. This has driven the development of orally absorbed chelators. Inconveniently, the very properties that encourage oral absorption also increase the access of chelators to iron or other metal pools that are necessary for normal physiological functions. Many promising compounds have been discarded because preclinical animal toxicology or clinical evaluation has shown too narrow a margin between the therapeutic and the toxic effects. Two orally absorbed iron chelators are now in widespread clinical use: deferiprone and deferasirox.

Deferiprone

Historical Perspective

The hydroxypyridinones were first described in 1982.[496] Initial clinical trials were conducted without the backing of a major pharmaceutical company and showed promising effects on urinary iron excretion in myelodysplasia and patients with transfusional iron overload.[497,498]

Animal toxicology demonstrated a dose-dependent and time-dependent suppression of the bone marrow, both in iron overloaded and nonoverloaded states.[419,499,500] Several cases of agranulocytosis were also reported in humans.[501–503] Other effects in animal models, such as redistribution of iron from the liver to the heart and liver fibrosis, were later reported with the closely related hydroxypyridine, CP94, in an iron-overloaded gerbil model.[504,505] Thymic atrophy and teratogenic effects at doses close to the effective clinical therapeutic range were later identified.[506] Further development led to trials to establish the efficacy of deferiprone and the frequency of complications, but the original efficacy study was discontinued following disagreements between the pharmaceutical company and clinical investigators.[340] The results of a 4-year toxicity trial have been reported.[507] More recently, prospective randomized studies have been undertaken, particularly focusing on the cardioprotective effects of the drug.[462] Deferiprone was licensed as second-line therapy for transfusional iron overload in Europe in 1999 but is not licensed in North America. The drug is licensed in India under the trade name Kelfer.

Chemistry and Pharmacology

Deferiprone (1,2-dimethyl-3-hydroxypyrid-4-one) (L1, CP20, Kelfer, Ferriprox) is a member of the family of 3-hydroxypyrid-4-one bidentate chelators[496] that bind to iron in a 3:1 ratio. It is less hydrophilic than desferrioxamine with approximately one-third of the molecular weight (139). Although the stability constant for iron (III) is approximately six orders of magnitude higher than desferrioxamine, the pM of 20 is lower than that of desferrioxamine at 26.6.[418] As a consequence, iron (III) coordination is most efficient at high concentrations of the chelator but at concentrations of 1 μM iron and 10 μM chelator, desferrioxamine will scavenge iron more efficiently. The lower stability at lower concentrations of drug also increases the potential to redistribute iron within the body[508] and leads to the potential formation of incomplete 1:1 and 1:2 iron–chelate complexes at low chelator concentrations. Such incomplete complexes have the potential to participate in the generation of hydroxyl radicals.[406] Unlike desferrioxamine, which is positively charged both in its iron free and complexed forms, deferiprone and its 3:1 iron complex are both neutrally charged. This neutral charge, and the less hydrophilic nature of the iron chelator and its complex, encourages a rapid diffusion of the free chelator into cells and its iron complex out of cells. Thus, unlike desferrioxamine, which slowly accumulates within cells at concentrations above those in the plasma with ferrioxamine egressing only slowly, the iron complex of deferiprone egresses relatively quickly.[363,400,411]

Following oral administration, absorption is rapid with the drug appearing in plasma within 5–10 minutes of ingestion. High concentrations are achieved at commonly prescribed doses, reaching levels in excess of 300 μM after oral ingestion of a 50 mg/kg dose.[384,427] These levels are 5–10 times higher than infused desferrioxamine[445,509] (Table 29.10). In vitro studies in myocytes show that these high

concentrations, together with a more rapid access to intracellular iron, might favor the scavenging of chelatable iron by deferiprone.[402] It has been suggested that at clinically relevant desferrioxamine concentrations of 10 μM, the effects of desferrioxamine on preventing and reversing cardiac pathology might result more from prevention of iron uptake into myocytes than from rapid iron removal.[402] With deferiprone, however, these high levels are short-lived with an elimination $t_{1/2}$ of 1.52 hours,[427] and if given three times daily, are punctuated by low levels between doses and negligible nocturnal levels. The drug is metabolized in hepatocytes to the inactive glucuronide, which is the predominant form recovered in the urine.[384,510] In contrast to desferrioxamine, iron excretion with deferiprone is almost exclusively in the urine.[495,509,511] The rapid inactivation of deferiprone in the liver by glucuronidation[421] might explain the relatively less impressive effect of deferiprone on liver iron removal compared with desferrioxamine,[426] but in other cells such as myocytes this would be less of a limitation and could explain why deferiprone appears to be more effective in the heart than the liver. In contrast, the highly hydrophilic nature and high molecular weight will tend to retard access to intracellular iron pools,[372,400,403] and the positive charge of the iron complex will retard egress from cells.[400,411]

Evidence of Efficacy of Deferiprone

Evidence of efficacy with deferiprone has been based on the effects of the drug on iron excretion, serum ferritin, LIC, and more recently the iron-induced cardiomyopathy.

Effects on Iron Excretion and Balance

Early observations demonstrated that urinary iron excretion in response to deferiprone 75 mg/kg was comparable to that with desferrioxamine infused subcutaneously over 8–12 hours at a dose of 40–50 mg/kg.[509] Urinary iron excretion correlated with the serum ferritin and desferrioxamine-induced urinary iron excretion.[509] Formal iron balance studies showed that total iron excretion at 75 mg/kg was 62% of that achieved with subcutaneous desferrioxamine at 50 mg/kg given over 8 hours.[495] Urinary iron excretion did not change significantly in a group of patients receiving 75 mg/kg/day with a mean follow-up of 39 months.[512] Dose equivalence for desferrioxamine and deferiprone has not been determined in iron balance studies.

Effects on Serum Ferritin

Many early small nonrandomized studies have examined the effects of deferiprone on serum ferritin. Ferritin values fell in the most heavily iron overloaded subjects with serum ferritin of 5,000 μg/L and more,[502] but in patients with levels below 2,500 μg/L levels did not typically fall. In a study in India, serum ferritin fell from initially very high levels by an average of more than 3,500 μg/L over 20 months.[513] In a Canadian study of 21 patients given a dose of 75 mg/kg/day, the serum ferritin declined from 3,975 to 2,546 μg/L after a mean follow-up of 3 years.[339] Changes were most marked in patients starting with high ferritin values, whereas in those patients starting with ferritin values below 2,500 μg/L there was no significant further change. In a study from London, there was no overall change in serum ferritin in 26 patients treated for 3 years at 75 mg/kg (initial value 2,937 μg/L, final value 2,323 μg/L).[512] In 52 patients from Turin with a median pretreatment ferritin value of 1,826 μg/L, there was no significant change in the serum ferritin level after 2 years of therapy with deferiprone at a dose of 75 mg/kg/day.[514] Randomized prospective comparisons of desferrioxamine and deferiprone have been undertaken more recently with a combined total 235 patients.[462,515–518] Due to differences in previous treatments, baseline ferritin values, and dosing regimes, pooled comparisons were not particularly revealing. Nevertheless, statistically significant decrease in serum ferritin in favor of desferrioxamine was seen at 6 months[516,517] with no difference at 12 months.[515]

Effect on Liver Iron

Relatively few prospective studies have examined changes in liver iron. Early studies measured LIC after periods of treatment but not before, making interpretation of results difficult. For example, hepatic iron was above 15 mg/g dry weight in 10 of 17 patients (58%) in a 2–4-year follow-up study and below 7 mg/g dry weight in only two patients.[512] In another study of 52 previously well chelated patients treated for 2 years at 75 mg/kg/day, the hepatic iron concentration increased in 69% of patients by a mean of 43%[514] and mean values had increased by 56% from 5.1 to 8.0 mg/g dry weight after 3 years. In a nonrandomized report with 7–8-year follow-up of seven patients, there was an "unexplained resurgence" of serum ferritin after 4–5 years, associated with a concomitant increase in liver iron in three.[519] In 21 patients given deferiprone, LICs were followed prospectively initially for 3.1 years;[339] in 10 previously suboptimally chelated patients, LICs fell from 23 mg/g dry weight to 11 mg/g dry weight ($P < 0.005$) with values above 15 mg/g dry weight in only two patients. In 11 patients in whom desferrioxamine had been effectively taken prior to use of deferiprone, hepatic iron concentrations remained below 15 mg/g dry weight; at 4.6 years, hepatic iron was above 15 mg/g dry wt in seven of 18 patients (39%).[452]

A combined systematic analysis of several randomized studies in a total of 143 subjects has been reported.[518] The patient selection, dosing, and scheduled period of follow-up varied considerably between studies, as did the findings. In a Canadian study, at 33 months of treatment at 75 mg/kg, a mean increase in liver iron of 5 mg/g dry weight in 18 patients was noted with deferiprone compared with a 1 mg/g dry weight increase with desferrioxamine.[520] In an

Italian study, a comparable decrease in LIC was seen with both deferiprone (21 patients) and with desferrioxamine (15 patients) at 30 months.[515] In a 1-year study of other Italian patients given 100 mg/kg daily, a mean decrease of 0.93 mg/g dry weight was seen with deferiprone (27 patients) compared with a decrease of 1.54 mg/g dry weight with desferrioxamine, at a dose of 43 mg/kg five–seven times a week (30 patients).[462] In a small 6-month randomized study, where baseline LIC values were higher than in the aforementioned studies, a greater decrease in LIC was reported with deferiprone (75 mg/kg) (6.6 mg/g dry weight, n = 6) than with desferrioxamine (30–60 mg/kg 5–7 days/week) (2.9 mg/g dry weight).[517] As with ferritin findings, patients with initially high LICs might respond better than those with lower values. Apparent loss of response with time could also reflect changes in compliance with longer periods of observation. Other factors that might account for the variable response between studies are differences in the rate of drug inactivation by glucuronidation or differences in transfusion rates.

Effects on the Heart

Initial data of the effects on myocardial dysfunction, myocardial iron, and the prevalence of heart disease gave conflicting results, most likely reflecting the retrospective nature of patient allocation and differences in prestudy chelation histories. More recently prospective studies have demonstrated a beneficial effect on both heart function and myocardial T2*, particularly at higher doses.

An early study showed continued cardiac mortality in 51 thalassemia patients who previously were poorly chelated with desferrioxamine. Four died of cardiac causes[512] leading to the authors to conclude that in the face of preexisting severe iron overload, deferiprone cannot reliably protect patients from cardiomyopathic mortality. In a large retrospective analysis of 532 Italian thalassemia major patients, nine died of heart failure while being treated with deferiprone.[521] On the other hand, a retrospective study of survival in 157 Italian patients treated with deferiprone between 1995 and 2003 for a median of 4.3 years reported significantly better survival in this group than in 369 patients treated with desferrioxamine. As patients were not randomized to desferrioxamine or to deferiprone the possibility of selection bias cannot be excluded. Furthermore the dropout rate of 31% was particularly high in deferiprone-treated patients. Another Italian study compared cardiac complications and survival over 6 years in 54 deferiprone-treated patients with 75 retrospectively allocated desferrioxamine-treated patients.[522] Three deaths occurred in the desferrioxamine group and none in the deferiprone-treated group; however, the three deaths were in patients who started chelation at a late age. Furthermore, five patients in the desferrioxamine group had New York Heart Association class II–IV cardiac disease at baseline compared with only one in the deferiprone group. Another retrospective analysis of 539 thalassemic patients from Cyprus born after 1960 and followed from 1980 to 2004 showed an increased trend in cardiac mortality between 1980 and 2000 with a subsequent decline after 2000, which the authors attributed to increased deferiprone use.[523] A possible beneficial effect of deferiprone on myocardial T* was first suggested[524] in a retrospective nonrandomized study of 15 patients treated with deferiprone compared with 30 desferrioxamine-treated patients. Desferrioxamine patients were retrospectively matched for serum ferritin from a large group of 160 patients.[524] The authors concluded that the lower incidence of reduced T2* in the deferiprone group was likely to be due to deferiprone treatment rather than any unintentional selection bias resulting from retrospective allocation of comparator groups.

To clarify the apparent inconsistencies between the aforementioned studies, prospective studies are needed. Two studies examining the effect of deferiprone monotherapy have been published. In one prospective randomized trial, 71 patients treated with deferiprone at conventional doses of 75 mg/kg/day were compared with 73 patients treated with standard-dose desferrioxamine. After 1 year, both groups showed a similar and significant improvement in cardiac nuclear MRI signal.[515] By contrast, in a prospective randomized study,[462] 61 thalassemic patients with moderate cardiac siderosis and T2* 8–20 msec were randomized to continue on desferrioxamine at an average dose of 43 mg/kg/day or deferiprone at a higher than usual mean dose of 92 mg/kg/day. In the standard-dose desferrioxamine group, the T2* improved 13%, whereas improvement was 27% in the deferiprone group. Although the ejection fraction was in the normal range at baseline in both groups, it improved significantly in the deferiprone-compared with the desferrioxamine-treated patients (3.1% vs. 0.3%). Taken together, these studies suggest that high-dose deferiprone might be more effective at improving myocardial T2* than standard-dose intermittent desferrioxamine 5 days a week, but at standard doses of deferiprone this advantage is more difficult to show. If patients have evidence of shortened T2* values, particularly with T2* values less than 10 msec, standard doses of desferrioxamine or deferiprone are not recommended; either high-dose deferiprone or intensified desferrioxamine by continuous infusion is recommended. An alternative approach, discussed later, would be to combine the two treatments.

Unwanted Effects of Deferiprone

Neutropenia and Agranulocytosis

Agranulocytosis was initially reported in 3%–4% of patients treated with deferiprone, and mild neutropenia occurred in an additional 4%.[502,525] Neutropenia can last from 4–124 days.[501,526,527] In 532 thalassemic patients treated for a total of 1,154 patient-years, the rates of agranulocytosis

and neutropenia were 0.43 and 2.08 per 100 patient-years, respectively.[521] In a study designed to establish the frequency of agranulocytosis defined as neutrophils 0.0–0.5 $\times 10^9$/L, only one of 187 patients (0.5%) developed agranulocytosis.[527] Nine patients (4.8%) developed milder neutropenia (absolute neutrophil count 0.5–1.5 $\times 10^9$/L). No additional cases of agranulocytosis occurred, but seven new cases of mild neutropenia developed during the next 3 years of treatment.[507] The lower incidence of agranulocytosis compared with some earlier estimates suggests that this might be decreased by monitoring the white count weekly and stopping therapy in a timely manner. There are very few data on evaluation of deferiprone in children aged younger than 6 years, and a study of 44 patients showed no cases of agranulocytosis occurred, but thrombocytopenia was seen in 45% 3 months–1 year after starting deferiprone and was reversible on cessation of treatment.[528] As this was not a randomized study, the significance of this observation is difficult to gauge and further studies are needed in this age group.

The mechanism of agranulocytosis is unclear. It has been suggested that this occurs though a dose-dependent inhibition of DNA synthesis and ribonucleotide reductase[411] or possibly though a zinc-depletion mechanism.[529] Alternatively the effect in humans might be idiosyncratic; however, several observations do not fit this mechanism. First, bone marrow hypoplasia is dose dependent in animal studies,[413] which is not typical of an idiosyncratic response and dose–response studies have not been conducted in humans. Agranulocytosis might appear as a late event after more than 1 year of therapy and can be preceded by previous episodes of neutropenia,[521] a pattern also not characteristic of idiosyncratic reactions. The involvement of other hematopoietic lineages in both animal studies[413,419] and humans[528,530,531] would also be more consistent with a general effect on hematopoietic progenitors. Milder forms of neutropenia might be related to hypersplenism and intercurrent infections rather than to drug toxicity.[532]

Other Unwanted Effects

The largest prospective clinical study designed to characterize the safety profile of deferiprone included 187 patients.[532] Nausea and vomiting were relatively common in the first year of therapy, occurring in 24% of patients, with abdominal pain in 14%, and arthralgia in 13%. Analysis after 4 years of treatment demonstrated that additional gastrointestinal symptoms were infrequent but the overall dropout rate increased from 15% after 1 year to 55% at 4 years.[507] Arthralgia and arthropathy vary greatly among studies, with an incidence 30%–40%[513,533] in the developing world and less than 5% in Italy.[521] The higher iron load in the patients from the developing world might increase the risk of iron redox cycling by incomplete chelate complexes in the joints. The risk of arthropathy appears to increase with the duration of treatment and increased from 6% at 1 year to 13% at 4 years.[507]

In a pooled analysis, fluctuations in liver tests were reported in 44% of patients.[525] Accelerated liver fibrosis was reported in a randomized study comparing deferiprone- (n = 19) with desferrioxamine-treated patients (n = 20) over 3.5 years,[452] and some progression of liver fibrosis was also found in other reports.[519,534] No progression was seen in 34 of 187 patients with available biopsies who were treated for 3.5 years[535] or in a randomized 1-year study with desferrioxamine.[515] None of these studies were designed to evaluate progression of liver fibrosis, and interpretation of the findings is limited by a number of factors such as unclear hepatitis C mRNA status,[452] variations in the duration of treatment,[534] failure to record baseline liver fibrosis,[512,519] and lack of clarity about changes in LIC.[535] Thus long-term prospective data comparing liver fibrosis with desferrioxamine has not been reported.[518] Small decreases in plasma zinc[532] and cases of zinc deficiency[525] not requiring cessation of therapy have been reported.

Recommended Dosing

Formal safety studies have only been conducted at 75 mg/kg in three divided doses and this is the usual dose given. Published tolerability data at 100 mg/kg, a dose also licensed in the European Union, are confined to a single 1-year prospective study in 32 patients.[462] As no excess toxicity was reported, it might be reasonable to increase the dose in otherwise unresponsive patients. Nevertheless it is not known whether tolerability issues such as neutropenia and agranulocytosis increase at doses above 75 mg/kg/day. Few data are available in young children, and this is reflected in the licensing in the European Union, which is confined to patients older than 6 years.

Combined Chelation Therapy: Deferiprone and Desferrioxamine

Pharmacology

When control of iron load or iron distribution is inadequate with monotherapy, the combined use of two chelators might be useful. In principle, two chelators can be given simultaneously or sequentially and the pharmacological implications differ. The use of more than one chelator, often referred to as mixed-ligand therapy,[536] is well established.[536,537] There is often a marked synergism of metal removal when a small kinetically labile ligand is combined with a larger hexadentate chelator. Typical examples are nitrilotriacetate/desferrioxamine for iron removal, penicillamine/DTPA for copper removal[538] and salicylic acid/EDTA for plutonium removal.[536]

Mixed-ligand therapy with deferiprone and desferrioxamine relies on the principle of the low-molecular-weight bidentate deferiprone rapidly accessing chelatable

iron pools unavailable to desferrioxamine and subsequently "shuttling" the chelated iron onto a desferrioxamine "sink."[382,539,540] Although this might increase net iron excretion, it could also increase unwanted effects due to shuttling from key metalloenzymes. If chelators are given sequentially, for example desferrioxamine by night and deferiprone by day, the main effect will be to provide a greater period of chelation exposure, increasing the protection time without significant shuttling of metals and with less risk of interactive toxicities. For example whereas monotherapy with desferrioxamine at night or deferiprone during the day only provides intermittent decrements in labile plasma iron, by alternating desferrioxamine at night with deferiprone by day decreases in labile iron can be obtained. Although deferasirox could also be used together with other chelators, at this time experience is very limited so that the discussion of combined treatment will be limited to desferrioxamine and deferiprone.

Clinical Regimens Assessed in Combined Therapy

Many combinations have been given with various degrees of pharmacological overlap, even within a given study. Combined treatment has often been given as a way of helping patients who comply poorly with desferrioxamine monotherapy or have a poor response with deferiprone monotherapy to achieve more exposure to chelation. For example, a patient with inadequate ferritin or liver iron control on deferiprone given as 75 mg/kg/day in three divided doses would take additionally desferrioxamine two–three times a week. Another group that has been considered for mixed treatment is high-risk cases with particularly low myocardial T2* values or with very high levels of iron overload. The regimens used have tended to have a greater degree of overlap of chelators. For patients with cardiac dysfunction, the additional value of combined therapy over intensive desferrioxamine treatment is presently under investigation in a randomized trial. The effects of combined therapy in controlled trials have recently been included in a systematic review[518] in which the considerable variability in responses between studies has been attributed to the diverse nature of the regimens used and differences in the prestudy treatments.

Effects on Serum Ferritin and Liver Iron

Several prospective randomized studies have now compared the use of various combined treatments with that of desferrioxamine or deferiprone monotherapy. In a small study, no significant difference in serum ferritin was seen between standard desferrioxamine monotherapy 5 nights a week compared with 7 days of deferiprone and 2 nights of desferrioxamine.[541] In another study, effects on ferritin and liver iron were similar with desferrioxamine monotherapy 5 nights a week compared with deferiprone 7 days a week plus 2 nights of desferrioxamine.[542] In a study in which desferrioxamine was given five times a week in the combination arm, the serum ferritin and liver T2* decreased more in the combined group of desferrioxamine five times a week plus deferiprone 7 days a week than with desferrioxamine monotherapy five times a week.[463] Together, these studies suggest that deferiprone given 7 days a week combined with desferrioxamine 2 nights a week will have similar effects on serum ferritin as desferrioxamine monotherapy given 5 nights but a greater effect than with deferiprone monotherapy at 75 mg/kg/day. When patients were randomized to one of three regimens, monotherapy of deferiprone or desferrioxamine or to combined deferiprone 7 days a week with desferrioxamine 2 nights a week, the greatest ferritin decrease was seen with desferrioxamine monotherapy and the least with deferiprone monotherapy.[516] A similar three-armed study is in broad agreement with these findings. Desferrioxamine monotherapy 5 nights a week was compared with deferiprone monotherapy 7 days a week or the same treatment plus desferrioxamine twice a week.[543] This 1-year study measured LIC at baseline and at the end of the study, allowing calculation of iron balance and total iron excretion based on the known transfusion rate. The combination therapy (n = 8) produced a significantly larger decrease in LIC and serum ferritin and a higher total iron excretion that deferiprone monotherapy (n = 12) and a similar effect to desferrioxamine monotherapy (n = 12). Decrease in LIC was only seen in 42% of patients on deferiprone monotherapy but in 88% of patients on combined treatment. These studies suggest that control of iron balance with monotherapy is more likely to be achieved with desferrioxamine than with deferiprone. Combined therapy with daily deferiprone plus desferrioxamine at least 2 nights a week is roughly equivalent to desferrioxamine given five times a week.

Effect on the Heart

Initial observational studies with a variety of combined regimens suggested possible beneficial effects on myocardial T2* or on heart function. In 79 patients treated with deferiprone 7 days a week with a variable desferrioxamine regimen, improvement in left ventricular ejection fraction was found compared with the previous noncompliant desferrioxamine monotherapy.[544] In another observational study, 42 patients given deferiprone 7 days a week plus desferrioxamine 2–6 nights a week over 3–4 years showed improvement in the left ventricular shortening.[545] More recently, a randomized controlled study of 65 patients with moderate heart iron loading and T2* 8–20 msec was undertaken comparing monotherapy with standard desferrioxamine five times a week with the same desferrioxamine treatment plus deferiprone 7 days a week.[463] Despite the relative conservative monotherapy desferrioxamine regimen, T2* improved 3 msec in 1 year but this increased to 6 msec with combined treatment. Although all patients had left ventricular ejection fraction of more than 56%

at baseline, left ventricular ejection fraction increased by approximately 2.5% in the combination arm and 0.5% in the monotherapy arm. In another small randomized study in patients with normal left ventricular ejection fraction at baseline, no difference was found with combination treatment after 1 year or with deferiprone monotherapy, but a small decrease was found with desferrioxamine monotherapy.[543] Interestingly, desferrioxamine was given only twice a week, whereas in the study in which an improvement in left ventricular ejection fraction was seen, desferrioxamine was given five times a week in the combination arm.[463] Prospective studies in patients with abnormal left ventricular ejection fraction are needed but until such data are available, it is recommended that desferrioxamine is given with or without deferiprone for the maximum practicable duration when patients have evidence of decreased left ventricular function.

Safety of Combined Treatment

Formal safety data on combined treatment are limited. In general, alternating regimens are less likely to be an issue for toxicity compared with regimens in which chelation is simultaneous or overlapping. A meta-analysis of the incidence of agranulocytosis with combined regimens compared with deferasirox monotherapy suggested that the risk might be increased several-fold, although the numbers of evaluable patients are small (Macklin, IND submission to FDA, 2004); the increased incidence appeared to occur mostly in those regimens in which the drugs were administered simultaneously. In a recently reported prospective study, one case of agranulocytosis and two of neutropenia were seen at 1 year in the combination arm containing 32 patients.[463] No excess in arthropathy was seen in the combination arm and no new tolerability issues that were not recognized with monotherapy have been reported.

Deferasirox (ICL670, Exjade)

Historical Perspective

Deferasirox is a member of a new class of tridentate (Fig. 29.6) iron-selective synthetic chelators, the bishydroxyphenyl-triazoles. Unlike the clinical development of desferrioxamine and deferiprone that were predominantly clinician led, deferasirox has been taken through a development program that complies with modern regulatory processes involving over 1,000 patients in phase I–IV studies. Preregistration phase I-III trials were designed to last 1 year but many have been extended to 3 years or more. The drug is now licensed for the treatment of transfusional iron overload, including children older than 2 years in most countries. The long-term tolerability profile and longer-term effects on complications of iron overload are still being evaluated.

Chemistry and Pharmacology

The tridentate structure with 2:1 chelator:iron binding results in an iron complex coordinated by four oxygen and two nitrogen atoms with the chemical formula: 4-[3,5-bis(2-hydroxyphenyl)-1,2,4-triazol-1-yl]benzoic acid and a molecular weight of 373. The stability of this complex as estimated by the pM values is intermediate between desferrioxamine and deferiprone (Table 29.10). Deferasirox is lipophilic but highly protein bound in plasma, which appears to confer good tissue penetration with faster mobilization of tissue iron than desferrioxamine.[546] In culture systems, mobilization of myocyte iron appears to be efficient.[381,402] This has been confirmed in studies with iron-overloaded gerbils.[547] The drug has low solubility in water and is given once daily as an oral suspension.

Pharmacokinetics were examined in the first phase I study of single oral doses of deferasirox involving 24 patients with thalassemia major. In this randomized, double-blind study, patients received single oral doses of dispersible tablets ranging from 2.5 to 80 mg/kg.[428] Deferasirox was absorbed promptly and was detectable in the blood for 24 hours. A plasma half-life of 11–19 hours was found, supporting once-daily oral administration. The area under the curve (AUC) at 0–24 hours and C_{max} of deferasirox increased nearly proportionally with the dose. At doses between 10 and 40 mg/kg/day the AUC of the iron complex of deferasirox was approximately 20%–30% of that of the iron free drug. A later study showed that with once daily repeated dosing at 20 mg/kg, peak plasma levels reach a mean of 80 μM with trough values of 20 μM (Table 29.10).[548] The urinary excretion of deferasirox and its iron complex was less than 0.1% of the dose. A further study of using single doses of ^{14}C deferasirox showed that metabolism occurred at several sites with glucuronidation in the liver.[549] Elimination of this and other metabolites was predominantly fecal. It was concluded that the final elimination process of deferasirox, the Fe-complex, and metabolites was by hepatobiliary anion transport and that the metabolic drug interaction potential via cytochrome p450 enzymes was low.

Effects on Iron Balance, LIC, and Ferritin

Initial iron balance studies entailed formal metabolic balance studies. Twenty-four patients randomly allocated to one of three doses or to placebo showed that excretion averaged 0.13, 0.34, and 0.56 mg/kg/day at deferasirox doses of 10, 20, and 40 mg/kg/day, respectively, predicting equilibrium or negative iron balance at daily doses of 20 mg and above.[429] The fraction of iron in the urine was less than 6% of total iron elimination with the majority occurring in the feces. These studies also showed that iron excretion in each patient was linearly related to exposure to the drug as measured by the AUC.

Iron balance over 1 year was assessed in a series of studies which used the Angelucci principle,[318] relating LIC to body iron stores, together with the measured transfusion rate to calculate net iron balance in a range of conditions associated with transfusional iron overload. The pivotal phase III study in 586 thalassemia major patients aged 2–53 years compared changes in LIC, serum ferritin, and net iron balance in 290 patients treated with desferrioxamine with 296 patients treated with deferasirox[453] In this and other similar studies in sickle cell disease[225] and other rare anemias[213] the dosing regimen chosen was conservative, with the dose chosen on the basis of baseline LIC obtained by biopsy or by SQUID. Although this was an understandable precaution to avoid overchelation in patients with a low iron load (LIC <7 mg/g dry weight), it meant that patients who received less than 20 mg/kg/day generally had a positive iron balance.[213,453] At 20 mg/kg/day, iron balance was typically achieved, whereas 30 mg/kg/day resulted in significant reductions in LIC averaging 10 mg/g dry weight over 1 year.[453] A 1-year randomized study in sickle cell disease[225] and a 1-year prospective study in myelodysplastic syndrome, Diamond–Blackfan anemia, and in other rare anemias[213] showed that the dose–response effects and trends in serum ferritin were similar to those in thalassemia, although because the transfusional iron loading rates differed between disease categories, the effective doses varied. In sickle cell disease, the effective doses for iron balance or negative iron balance were less on average than in thalassemia (Fig. 29.7). It is important to point out that there was considerable overlap between patient groups.[213] The efficiency of chelation, or the proportion of administered drug excreted in the iron bound form, was 27%–34% and was essentially the same across all diagnoses and doses tested,[213] being significantly higher than for desferrioxamine in the same studies. Changes in LIC were paralleled proportional to changes in serum ferritin across a range of diagnoses,[213] allowing the trend in serum ferritin to be used as a way of following changes in body iron loading.

Analysis of the combined data from studies in thalassemia, sickle cell disease, and rare anemias has revealed that other factors influence iron balance as seen with desferrioxamine. The most important of these is the transfusional iron-loading rate. The proportion of patients in negative iron balance at 20 mg/kg was 75% at low transfusion rates of less than 0.3 mg/kg/day, but fell to 55% and 47%, respectively, at intermediate (0.3–0.5 mg/kg/day) and high (>0.5 mg/kg/day) transfusion rates.[212] At 30 mg/kg, 96% of patients with a low iron-loading rate were in negative iron balance but at intermediate and high transfusional loading rates, the proportion fell to 80% of patients.[212]

Effects on the Heart

Thus far, experience of the effects of deferasirox on the heart are confined to cell culture, animal data, and preliminary clinical studies. Cell culture[402] and animal studies[548,592] suggested that deferasirox would be effective at accessing myocardial iron. Although studies on myocardial iron estimation were not included as part of the phase II and III trials, preliminary data obtained during these studies in 27 patients treated at doses of 10–30 mg/kg/day showed an improved myocardial T2* at 1 year from 18.7 to 23 msec and improvement was significant for both patients with baseline T2* values below and above 20 msec.[464,550] Prospective studies are ongoing to examine the effects of deferasirox on myocardial iron as measured by T2*. Preliminary results in one of these studies have been reported.[551] Eighteen patients receiving 30 mg//kg for 6 months showed a significant mean improvement in myocardial T2* from 9.5 to 11.2 msec, with improvement in 14 of 18 patients. Randomized comparison of the effects with those of desferrioxamine is also in progress. No data on patients with preexisting myocardial dysfunction are yet available.

Unwanted Effects and their Management

In the key registration phase III study, deferasirox was well tolerated[453] with 5.7% discontinuing drug over 1 year. Common adverse events were generally mild, including transient gastrointestinal events in 15% and skin rash in 11%. The drug is now licensed in European Union and the United States for use in children aged 2 years and older with transfusional iron overload. Follow up data in the five core phase II/III studies are now at a median of 3.5 years with no evidence of new or progressive toxicities.[552] Understandably, it is too early yet to allow any statements on the impact of deferasirox on survival. Recommended patient monitoring includes monthly creatinine and liver function and annual auditory and ophthalmic examinations, including slit-lamp examination and funduscopy.

Gastrointestinal Disturbances

Gastrointestinal disturbances such as diarrhea, constipation, nausea, or vomiting were often self-limiting but in persistent cases were managed by dose modification or by changing the timing of the dose from morning to evening.

Skin Rash

Mild to moderate skin rashes were usually managed by temporary dose reductions followed by subsequent return to the therapeutic dose. Severe skin rashes were usually managed by dose interruptions followed by gradual reintroduction at a smaller dose. Occasional cases of angioedema have been seen for which cessation of drug is recommended.

Renal Effects

Dose-dependent increases in serum creatinine of a third or more above baseline were observed in 38% of patients. These generally remained within the normal range and

never exceeded two times the upper limit of normal. Increases in creatinine typically occurred within a few weeks of starting or increasing therapy, were not progressive, and reversed or stabilized with dose adjustment when necessary. In older myelodysplastic syndrome patients in whom baseline creatinine values were just below the upper limit of normal, some patients increased values above normal but these were managed by dose modification. No cases of progressive increments above the normal range were seen in these studies. Proteinuria has been described with deferasirox but is also seen in thalassemia major patients who are not receiving chelation therapy[553] and in sickle cell disease, and therefore baseline testing for proteinuria should be performed before starting treatment. Monthly testing for proteinuria is recommended. If positive, quantitation might be helpful and if this exceeds 1 mg/mL creatinine on more than one occasion treatment should be temporarily withheld or adjusted.

Liver Function

In general the alanine aminotransferase values were observed to fall as LIC values fell with treatment. Increased liver enzymes judged to be related to deferasirox were observed in two patients in the core studies.[453] Outside core studies, other cases of transaminitis have been seen that respond to dose reduction or drug cessation. Monthly liver monitoring is therefore recommended.

Effects in Children

In five phase II and III studies, approximately half of the 703 patients were children younger than 16 years and included children as young as age 2 years. With follow-up at approximately 3 years, no adverse effects on growth or skeletal development have been found and no specific tolerability issues for children have been identified. Evaluation of pediatric patients has shown that growth and development proceeded normally while on deferasirox, lending support to its use in very young patients.

Other Effects

Deafness, neurosensory deafness, and hypacusis were reported as adverse events irrespective of drug relationship in thalassemia major patients in the 1-year core trial in eight patients on deferasirox and seven on desferrioxamine.[453] Cataracts or lenticular opacities were reported as adverse events irrespective of drug relationship in two patients on deferasirox and five on desferrioxamine. Overall the tolerability profile compared favorably with desferrioxamine.[453] The results of the 4-year extension will be useful in interpreting the significance of these findings. Importantly, no drug-related agranulocytosis was observed in thalassemia or sickle cell disease patients from the core studies.[225,453]

Recommended Dosing Regimen

Deferasirox is taken as a suspension in 100–200 mL of water, orange, or apple juice stirred with a nonmetallic utensil. The relationship between dose and iron balance has been studied in large studies over a 1-year period. A decision needs to be made at the time of therapy whether iron balance alone is sufficient or whether negative iron balance is desirable. Recommended starting dose for iron balance is 20 mg/kg, but as can be seen from Figure 29.7, the required dose can be adjusted upward or downward depending on the iron-loading rate. In patients with low transfusion rates of less than 0.3 mg/kg/day a daily dose of 20 mg/kg should be sufficient to maintain iron balance, whereas the doses for intermediate (0.3–0.5) and high (>0.5) loading rates are 25 mg and 30 mg/kg, respectively.[212] Response rates in myelodysplastic syndrome, rare anemias,[213] and sickle cell disease[225] are consistent with those in thalassemia with respect to dose dependency of LIC and ferritin response. The effective dose in milligram/kilogram is approximately half that obtained with subcutaneous desferrioxamine five times per week. In the first 4 weeks after starting deferasirox, weekly serum creatinine and liver function tests are advisable and repeated monthly thereafter. If the dose is adjusted upward, it is advisable to monitor these same variables for 4 weeks after dose increments. Studies are ongoing at doses up to 40 mg/kg/day to assess the safety and efficacy of such doses for the small proportion of patients who fail to respond to lower doses. The proportion of patients with ferritin values less than 1,000 μg/L in extension studies up to 3 years is falling, but this has not been associated with increased toxicity.[554] At 42 months of deferasirox treatment, 25% of patients had ferritin levels less than 1,000 μg/L, and some patients achieve levels less than 500 μg/L, below which the drug is not licensed. To avoid a stop-go approach, it is sensible to reduce the dose slightly as values fall below 1,000 μg/L so ferritin can be kept between 500 and 1,000 μg/L without stopping treatment.

Future Perspectives with Chelation Therapy

The immediate future for chelation therapy is likely to be exciting as results of prospective studies become available with monotherapy and combined therapies using the currently available iron chelators. With three chelators now licensed in many countries, there is considerable scope for assessing how best to use these in combination if monotherapy fails. Unless this is done in a systematic way, however, the true risks and benefits are likely to remain unclear. New chelators continue to be synthesized and evaluated[555] but have yet to reach beyond phase II of clinical evaluation. Intravenous depot desferrioxamine is an interesting concept that still requires formal evaluation beyond phase I clinical studies.[556] The prospective evaluation of MRI to characterize iron distribution and its

relationship to transfusional iron loading and to the relative effects of different chelation regimens will be valuable in defining how best to use the tools now available for managing transfusional iron overload.

Induction of Fetal Hemoglobin in the Treatment of Sickle Cell Disease and β Thalassemia

Yogen Saunthararajah and George F. Atweh

INTRODUCTION

The beneficial effects of high levels of fetal hemoglobin (HbF) in sickle cell disease and β thalassemia have been recognized for many years. In 1948, Watson et al.[1] noted that newborns with sickle cell disease do not suffer from the clinical complications of their disease until HbF declines to adult levels after the first 6 months of life. Later, it was shown that the majority of patients with sickle cell disease from some regions of Saudi Arabia[2] and India[3] who co-inherit another genetic determinant associated with high HbF levels, have a very mild sickling disorder. More recently, the Cooperative Study of Sickle Cell Disease, a large multicenter study of the natural history of sickle cell disease (see Chapter 19) demonstrated an inverse correlation between HbF levels and the frequency of painful crises and early death.[4,5] These clinical and epidemiological observations are supported by laboratory studies that demonstrate a sparing effect of HbF on polymerization of deoxyhemoglobin S.[6] Similarly, in β thalassemia, an increase in the synthesis of fetal γ-globin chains may decrease the imbalance between α- and non-α-globin chains and ameliorate the severity of the anemia. This appreciation of the beneficial effects of HbF in sickle cell disease and β thalassemia stimulated a great deal of interest in the development of therapeutic agents to increase HbF production in patients with these disorders. In this chapter, we discuss the preclinical and clinical development of the different classes of pharmacological inducers of HbF production including DNA hypomethylating agents such as 5-azacytidine and decitabine, cytotoxic agents such as hydroxyurea, and inhibitors of histone deacetylase such as butyrate.

DNA HYPOMETHYLATING AGENTS

Gene expression is a process that is regulated to an important degree by the packaging of DNA around histones and by methylation of deoxycytosines that precede deoxyguanines (CpG) in the promoters of genes. The DNA methylation patterns that regulate the expression of cell type–specific genes are established by DNA methyltransferase (DNMT) enzymes that recognize and methylate target deoxycytosines. Generally, methylation in the promoter of a tissue-specific gene is associated with nonexpression of the gene. Approximately 65% of all CpG dinucleotides in vertebrate DNA are methylated at the cytosine residue by the action of DNA DNMT enzymes. As would be expected, γ-globin gene promoter DNA is relatively unmethylated at developmental stages when it is expressed, and methylated in adult bone marrow erythroid cells when the genes are not expressed.[7] This suggests that DNA hypomethylating agents might reactivate the expression of the silenced γ-globin gene.

The related compounds 5-azacytidine and decitabine (Fig. 30.1) are cytosine analogs first synthesized more than 40 years ago. Like other nucleoside analogs, they were originally viewed as cytotoxic chemotherapy agents and drug regimens were based on the maximum tolerated dose. It was only with the emergence of the field of epigenetics that inhibition of DNA methylation, reactivation of gene expression, and induction of cellular differentiation were recognized as actions of decitabine (5-azacytidine exerts its DNA hypomethylating effect by being converted to decitabine by ribonucleotide reductase).[8] Importantly, the DNA hypomethylating effect is seen at low and very well-tolerated doses of the drugs.[9] The specific mechanism by which decitabine depletes DNMT in dividing cells explains why low doses of decitabine can hypomethylate DNA without causing cytotoxicity whereas higher doses are toxic: The mechanism of action of decitabine begins with decitabine phosphorylation by deoxycytosine kinase (DCK) and incorporation into the replicating genome, just like natural deoxycytidine. DNMT is covalently trapped as it tries to methylate the 5-N position of the triazene ring of DNA-incorporated decitabine. This covalent trapping/modification depletes cellular DNMT and decreases DNA methylation. At high decitabine doses, hydrolytic cleavage at DNMT–CpG complexes overwhelms the cellular repair machinery, damaging the replicating genome to an extent that results in cell death (cytotoxicity). Lower doses do not overwhelm the cellular repair machinery, and although temporary growth arrest (cytostatic effect) might occur, cell division ultimately continues but with depleted DNMT, DNA hypomethylation, and consequently altered gene expression. 5-Azacytidine, but not decitabine, incorporates into RNA and inhibits protein synthesis. On a mole for mole basis, decitabine is a more potent inhibitor of DNMT than 5-azacytidine.

The γ-globin gene in baboons is structurally and functionally similar to that of human beings. Prompted by the association of γ-globin gene promoter methylation with its developmental silencing, the ability of 5-azacytidine to induce HbF synthesis in baboons was studied.

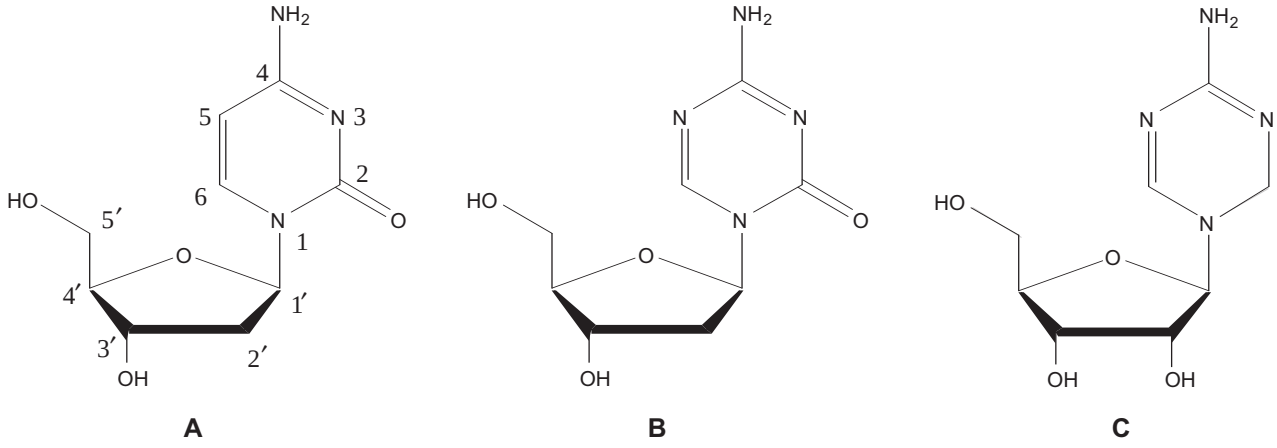

Figure 30.1. Structure of natural deoxycytidine **(A)**, decitabine **(B)**, and 5-azacytidine **(C)**. Decitabine, a deoxynucleotide, is only incorporated into DNA and is a more specific and potent DNA-hypomethylating agent than 5-azacytidine, which is also incorporated into RNA.

5-Azacytidine (injected into anemic baboons at a dose of 2–4 mg/kg/d 5 d/wk for 2 wk) increased HbF levels up to 70% of total hemoglobin (HbF 70%).[11] This effect was achieved at doses of the drug that caused mild neutropenia, but did not seem to change RBC or platelet production. The results in baboons led to a number of clinical studies in patients with sickle cell disease and β thalassemia.[12–14] In two patients with sickle cell disease treated with 5-azacytidine at a dose of 2 mg/kg/day for 5 days, HbF levels increased to 22% without substantial toxicity.[13] The percentage of F cells (Chapter 7) increased up to 80%. There was also improvement in surrogate clinical markers, denoted by decreased irreversibility of sickle cells, dense cells, and indirect bilirubin.[14,15] 5-Azacytidine treatment of three patients with end-stage β thalassemia also produced large increases in total hemoglobin (3–5 g/dL).[16] In these patients with β thalassemia, the total hemoglobin increases consist of HbF. Two of these patients, treated for 30 months (1–2 mg/kg/d, 4 d/wk, 1 time/mo), remained transfusion independent for the duration of treatment.

Despite these very promising early results, further trials with 5-azacytidine were curtailed due to concerns regarding potential carcinogenicity. These concerns were largely based on a study conducted by Carr et al.[17] in the Fisher rat testicular cancer model, which suggested that 5-azacytidine caused tumors in 31 of 70 rats treated with the drug. The study received criticism because the incidence of testicular cancer in the control population of Fisher rats was 0%, which is not in accordance with the usual rate (~20%) of spontaneous testicular cancer development in these rats.[18] Another controversy was whether HbF induction resulted from DNA hypomethylation induced by 5-azacytidine, or cytotoxic effects. If cytotoxicity was the mechanistic basis for HbF induction, then other cytostatic/cytotoxic agents such as the well-tolerated and orally available ribonucleotide reductase inhibitor hydroxyurea might also be effective. This led to studies of hydroxyurea in patients with sickle cell disease and thalassemia, culminating in the Multicenter Study of Hydroxyurea (MSH) in patients with symptomatic sickle cell anemia. The MSH conclusively demonstrated that hydroxyurea reduced the frequency of acute painful episodes, acute chest syndrome, and transfusions.[19]

The historical efficacy of 5-azacytidine in HbF reactivation suggested that DNA-hypomethylating agents could still have a role in the management of sickle cell disease. Decitabine holds two apparent advantages over 5-azacytidine: 1) the majority of preclinical studies suggest chemoprevention of cancer rather than carcinogenicity, and 2) decitabine is exclusively incorporated into DNA (5-azacytidine is also incorporated into RNA) and is a more potent DNA-hypomethylating agent. Therefore, studies are being pursued that focus on the use of decitabine to reactivate HbF synthesis in patients with symptomatic sickle cell disease.

In the first study, eight patients were treated with decitabine at low doses (compared with doses of decitabine used in previous cancer trials) of 0.15 mg/kg–0.30 mg/kg given 5 days per week for 2 weeks.[9] Five of these patients did not have increases in HbF with hydroxyurea treatment (hydroxyurea levels documented compliance), two were low responders to hydroxyurea, and one patient was not in the MSH. The average γ-globin synthesis relative to non–α-globin synthesis prior to therapy was 3.2% and increased to 13.7% after treatment. HbF increased from 3.6% to 13.5%, whereas F cells increased from 21% to 55%. The HbF content per F cell increased from 17% to 24%. Hydroxyurea treatment increased HbF levels in these patients from 2.4% to 2.6%. With decitabine treatment, however, the average HbF increased to 12.7%, and total hemoglobin increased by 1 g/dL in six of eight patients. The only toxicity was transient neutropenia. These studies suggested that the optimal daily dose of decitabine is 0.2 mg/kg, producing greater increases in HbF without much increased

risk of neutropenia compared with decitabine 0.15 mg/kg/day.

A follow-up study examined whether increased HbF and total hemoglobin levels could be maintained without toxicity with repeated cycles administered every 6 weeks over a 36-week period.[20] In six sickle cell anemia patients, the average HbF during the last 20 weeks of treatment was 13.9% ± 2.8% (mean ± standard deviation [SD]) compared with a baseline HbF of 3.1% ± 2.8%. Maximum HbF levels were 18.45% ± 4.5% (mean ± SD). Maximum F cell percentages ranged between 58% and 87%. The average hemoglobin value increased from 7.2 g/dL to 8.8 g/dL (mean ± SD). Maximum hemoglobin values were 9.7 ± 0.5 g/dL. The neutrophil nadirs between weeks 16 and 36 were all less than 1,500/μL, occurred at approximately 5–6 weeks of each treatment cycle, and rapidly recovered. Interestingly, a peak in the platelet count mirrored the neutrophil count nadir. With the exception of neutropenia, there were no other toxicities.

In a subsequent study, the objectives were to 1) evaluate whether decitabine is safe and effective if given by a more practical subcutaneous route; 2) assess whether weekly administration could produce cumulative and stable increases in HbF and total hemoglobin levels; 3) measure additional surrogate clinical endpoints (the pathophysiology of vasoocclusive crises in sickle cell disease involves erythrocyte adhesion to endothelium, endothelial damage, and activation of coagulation and inflammatory cascades; therefore, red cell adhesion to thrombospondin and laminin, markers of endothelial damage, coagulation system activation, and inflammatory activity were measured); and 4) confirm that, at the low doses being used, decitabine hypomethylates DNA without typical chemotherapy-associated myelotoxicity. In addition to hematological parameters, bone marrow morphology, and DNA methylation changes were assessed.[21]

Decitabine was administered subcutaneously at 0.2 mg/kg, one–three times/week in two cycles of 6 weeks each, with a 2-week interval between cycles. Eight patients were studied who either did not respond to or did not tolerate hydroxyurea therapy. All patients demonstrated statistically significant increases in HbF (± SD) from 6.5% ± 1.4% to 20.4% ± 2.0%, and F cells from 38.1% ± 7.6% to 71.4% ± 6.5% with treatment. Three hydroxyurea nonresponding patients had lower HbF levels at baseline but demonstrated a rate of increase in HbF similar to that seen in five hydroxyurea responders. The only toxicity noted was neutropenia, which coincided with increases in the platelet count of up to 860 × 10^9/L. Total hemoglobin increased from 7.6 ± 1 g/dL to 9.6 ± 0.9 g/dL. Both the absolute reticulocyte count and total bilirubin decreased during treatment. The reticulocyte count correlated inversely with total hemoglobin, suggesting that the reticulocyte decrease resulted from decreased hemolysis. There were significant improvements in a spectrum of surrogate clinical endpoints that measure the activity of vasoocclusive pathophysiology: 1) RBCs from patients demonstrated decreased adhesion to the matrix molecules thrombospondin and laminin; 2) D-dimer levels, which are a measure of coagulation system activity, decreased; and 3) soluble vascular adhesion molecule–1 and von Willebrand Factor propeptide levels, which are measures of endothelial damage, decreased.

A number of observations suggest that the mechanism by which decitabine produces HbF elevations is DNA hypomethylation. DNA hypomethylation per se is not necessarily cytotoxic,[10] suggesting that low doses of decitabine might hypomethylate DNA without inducing cytotoxicity. The low doses of decitabine used in the clinical trials and in vitro studies were sufficient to produce DNA hypomethylation.[22] Platelet counts increased during therapy, concurrent with a downward trend in neutrophil and monocyte counts. Although there was a decrease in reticulocyte counts during therapy, there was a strong inverse correlation between the decreasing reticulocyte counts and increasing hemoglobin levels, suggesting that the decreased reticulocyte count resulted from decreased hemolysis. Serial bone marrow aspirate specimens obtained during therapy did not demonstrate a decrease in marrow spicule cellularity. Instead, there was an increase in megakaryocyte numbers and a decrease in the myeloid/erythroid ratio (an increase in the proportion of erythroid cells). In vitro studies with decitabine treatment of human CD34+ hematopoietic cells were consistent with the in vivo results, demonstrating an increase in the proportion of mixed colonies (erythroid and myeloid) formed relative to pure granulocyte–macrophage colonies. Thus, decitabine-induced hypomethylation in the γ-globin gene promoter could contribute to the increased HbF with treatment, but hypomethylation at other genes might also be important because the change in pattern of hematopoietic differentiation could be contributing to the increased HbF.

With regard to pharmacological reactivation of HbF, decitabine has a number of advantages when compared with hydroxyurea. All patients treated to date have had clinically significant increases in HbF. The large increases in HbF could translate into more clinical benefits and potentially some protection from organ complications such as pulmonary hypertension and stroke.[23] The noncytotoxic mechanism of action of decitabine might facilitate prolonged administration and durable responses. Decitabine could potentially synergize with other epigenetically active agents, such as histone deacetylase inhibitors.[24] Presently, there are no data regarding the clinical effectiveness of decitabine in sickle cell disease. The trials conducted to date, which have measured surrogate clinical endpoints such as HbF levels, red cell adhesion, coagulation system activation, and endothelial damage, indicate the promise of this drug as a treatment for sickle cell disease.

Extended phase II/III studies evaluating clinical endpoints such as crisis frequency, quality of life, and survival will be required to demonstrate definitively a clinical benefit. As a further incentive to such studies, off-label treatment

of patients with severe sickle cell disease on a chronic basis produced notable clinical improvement.[25] Although most preclinical studies show negligible mutagenicity and a chemopreventive rather than carcinogenic effect and no unusual cytogenetic abnormalities have been reported in the many patients with myelodysplastic syndrome treated with decitabine thus far, further studies involving chronic dosing of patients with sickle cell disease or thalassemia should attempt to measure the risks of inducing DNA mutations and chromosome instability, perhaps in comparison to the current standard of care, hydroxyurea, which has a similar risk profile. Decitabine is likely to be teratogenic and could have effects on male fertility; these concerns are significant because many of the target patient population are of reproductive age.

HYDROXYUREA

Interestingly, controversy about the mechanism of activation of fetal γ-globin gene expression by 5-azacytidine led to the identification of hydroxyurea as a second therapeutic agent that can stimulate HbF production. Some investigators hypothesized that 5-azacytidine increases HbF production by accelerating erythroid cell differentiation rather than by hypomethylation of DNA.[26] To support this hypothesis, experiments were performed to show that hydroxyurea, an S-phase–specific chemotherapeutic agent without DNA-demethylating activity, can also increase HbF production in phlebotomized monkeys[27] and in patients with sickle cell disease.[28] These interesting observations, however, did not completely resolve the controversy about the mechanism of action of 5-azacytidine or decitabine because these agents appear to be more potent inducers of HbF production than hydroxyurea. Moreover, decitabine was shown to increase HbF levels in sickle cell patients who were resistant to hydroxyurea, suggesting that the two drugs have different mechanisms of action.[9] Nonetheless, hydroxyurea had some significant advantages, it is an oral agent with a relatively good safety profile and it was already in wide use for the treatment of myeloproliferative disorders. Thus, it quickly replaced 5-azacytidine as the agent of choice for stimulating HbF production in patients with sickle cell disease.

Clinical Use of Hydroxyurea

The clinical use of hydroxyurea was discussed in detail in the first edition of this book and elsewhere more recently.[29–32]

Hydroxyurea was first used in a number of small, nonrandomized clinical trials that confirmed its HbF-inducing activity in sickle cell disease.[33–34] These studies provided the proof of principle and led to the identification of an effective dose schedule for the use of this drug in the treatment of patients with sickle cell disease. These phase I/II studies were followed by a large randomized, placebo-controlled MSH that had well-defined clinical efficacy endpoints.[19] This study was terminated prematurely when interim analysis showed a significant reduction in the frequency of crises and acute chest syndrome in the hydroxyurea-treated group compared with the control group. There was also a reduction in the frequency of blood transfusions in the hydroxyurea-treated group but no changes in the frequency of stroke or death during the 2.5 years of study.[19] The effects of hydroxyurea on quality of life were mixed but most evident in patients with the highest HbF response to treatment.[35] On the basis of the controlled clinical trial, hydroxyurea became the first HbF-inducing drug to be approved by the Food and Drug Administration for the treatment of sickle cell anemia, and as a result, hydroxyurea is now widely used in the United States and Europe.

Hydroxyurea should be used in all adults when indications for this treatment are present (Table 30.1). Unfortunately, for complex and poorly understood reasons, only a fraction of patients who might benefit from treatment receive it. In follow-up studies to the MSH, cumulative mortality was reduced nearly 40% and a favorable result was related to the ability of the drug to increase HbF and reduce painful episodes and acute chest syndrome.[36]

Children have a more robust HbF response to hydroxyurea than do adults.[31,32,37–41] In a study of more than 100 children who received maximal drug doses, HbF increased to almost 20% and the treatment effects were sustained for 7 years without clinically important toxicity.[42] Some have proposed using hydroxyurea for secondary and primary prevention of stroke in children, and recent studies suggest that hydroxyurea, by a mechanism still unknown, can in some individuals reduce transcranial Doppler flow rates into the normal range.[43–47] This issue is now being studied in a controlled clinical trial.

The clinical benefits of hydroxyurea in HbSC disease are unknown, although the drug does have effects on the HbSC disease erythrocyte.[48,49] This topic is also just beginning to be studied in a therapeutic trial.

Although hydroxyurea was associated with reduced mortality in follow-up of the MSH, patients still die of complications of this disease while receiving treatment. In a single-center analysis of the 34 patients who died due to sickle cell disease–related causes, acute chest syndrome was the cause of death in 35%. The deceased and surviving patients did not differ significantly in average hydroxyurea dose or HbF response but were older when hydroxyurea was first started, were more anemic, and had significantly higher serum blood urea nitrogen and serum creatinine levels. They might represent a subgroup of older patients, possibly with more severe disease and organ damage who would benefit from earlier treatment.[50]

Preventing the usual HbF to HbS switch in gene expression early in childhood, before HbF levels decline to subtherapeutic concentrations and sickle vasculopathy results, should "cure" sickle cell anemia. Studies using hydroxyurea beginning in the first year of life are underway and focus on

Table 30.1. A method for treating patients with sickle cell anemia with hydroxyurea. Special caution should be exercised in patients with compromised renal or hepatic function and when patients are habituated to narcotics. Contraception should be practiced by both men and women because hydroxyurea is a teratogen and its effects in pregnancy are unknown. After a stable and nontoxic dose of hydroxyurea is reached, blood counts may be done at 4- to 8-week intervals. Granulocytes should be $\geq$2,000/mm^3, platelets $\geq$80,000/mm^3. A fall in hemoglobin level (in most patients who respond, the hemoglobin level increases slightly) and absolute reticulocyte count to $<$80,000/mm^3 should be carefully evaluated. A hemoglobin $<$5.5 g/dL before treatment is not a contraindication to treatment

Indications for Treatment
Adults, adolescents, and after consultation with parents and expert pediatricians, children with frequent pain episodes, history of acute chest syndrome, other severe vasoocclusive complications. Severe symptomatic anemia
Baseline Evaluation
Blood counts, red cell indices, HbF, serum chemistries, pregnancy test, willingness to adhere to all recommendations for treatment, absence of chronic transfusion program
Initiation of Treatment
Hydroxyurea 10–15 mg/kg/d or 500 mg q A.M. for 6–8 wk, complete blood count q 2 wk, HbF q 6–8 wk
Continuation of Treatment
If counts are acceptable, escalate dose in increments of 500 mg every 6–8 wk
Failure of HbF (or MCV) to Increase
Consider biological inability to respond to treatment or poor compliance with treatment. Increase dose very cautiously to 2,000–2,500 mg/d (maximum dose 30 mg/kg). Absent transfusion support or intercurrent illness suppressing erythropoiesis, a trial period of 6–8 mo is probably adequate
Treatment Endpoints
Less pain, increase in HbF (or MCV), increased hemoglobin level if severely anemic, acceptable toxicity

the prevention of organ damage in the spleen, kidney, and central nervous system.[39]

Hydroxyurea is potentially mutagenic and carcinogenic. Cancer and leukemia have been reported in hydroxyurea-treated sickle cell disease patients but whether the incidence is higher than in the general population is not known.[36] In one study, acquired somatic DNA mutations in peripheral blood mononuclear cells were studied after in vivo exposure to hydroxyurea. Children with sickle cell disease exposed to the drug for 30 months had significantly more immunoglobulin gene VDJ mutations than patients exposed for 7 months or those not taking the drug at all. Overall, the studies suggested that although the mutagenic and carcinogenic potential of hydroxyurea is low, young patients should be monitored serially.[51]

Prediction of Response to Treatment. An ability to predict the therapeutic response to hydroxyurea would be clinically useful. In early studies from the MSH, the best HbF-responding patients had the highest initial neutrophil and reticulocyte counts and the largest treatment-associated decrements in these counts. In children, baseline HbF, leukocyte count and reticulocyte count, and the fall in leukocyte and reticulocyte counts also predicted a higher HbF response.[37]

It is likely that HbF levels at baseline and in response to drug treatment are genetically regulated. Genetic elements linked to the β-globin gene–like cluster and quantitative trait loci (QTL) present on chromosomes 6, 8, and on the X-chromosome as well as other regulatory loci are likely to exist, and epigenetic and cellular factors could also have regulatory importance (see Chapter 27). As the increase of HbF in response to hydroxyurea varies among patients with sickle cell anemia, 29 candidate genes within QTL previously reported to be linked to HbF level (6q22.3–q23.2, 8q11–q12, and Xp22.2–p22.3), involved in metabolism of hydroxyurea, or related to erythroid progenitor proliferation were studied in 137 sickle cell anemia patients treated with hydroxyurea. Three hundred and twenty tagging single nucleotide polymorphisms (SNPs) in candidate genes were selected and the association between SNPs and the change of HbF level after 2 years of drug treatment was analyzed. SNPs in genes within the 6q22.3–23.2 and 8q11–q12 linkage peaks and also the *ARG2*, *FLT1*, *HAO2*, and *NOS1* genes were associated with the HbF response to hydroxyurea. These results suggested that polymorphisms in genes regulating HbF expression, erythroid progenitor proliferation, and hydroxyurea metabolism might modulate a patient's response to this agent.[52]

Mechanisms of Action

Although hydroxyurea was shown to have similar HbF-inducing activity to 5-azacytidine in anemic baboons and patients with sickle cell disease, its molecular targets and mechanism(s) of action are still not fully elucidated. It was originally proposed that hydroxyurea might elevate HbF levels by accelerating erythroid differentiation in the bone marrow, leading to the appearance of "fetal-like"

cells in the peripheral blood.[26] More recent studies have shown that hydroxyurea generates nitric oxide in vivo, which results in the activation of the nitric oxide–cyclic guanosine monophophate signaling pathway and the up-regulation of γ-globin gene expression in patients with sickle cell disease.[53] Hydroxyurea has other effects that might also benefit patients with sickle cell disease. For example, hydroxyurea was shown to decrease the adhesion of sickle cells to endothelium and to decrease the level of soluble vascular adhesion molecule-1.[54,55] Owing to its myelosuppressive activity, hydroxyurea reduces circulating leukocyte counts, and likely, the number of adherent leukocytes recruited to the wall of small venules.

In one analysis, the reduction of white blood cell counts was correlated with the clinical benefit from hydroxyurea.[56] This report led to widespread speculation in the field that the clinical benefits of hydroxyurea are not related to its effect on HbF production. Since this publication, an additional report was published in which the clinical and laboratory data that were collected as part of the MSH were analyzed in detail. Curiously, the analysis of long-term follow-up failed to show a correlation between the increase in HbF production and the clinical benefit in patients who received hydroxyurea and suggested that study design issues forced the relationship between leukocyte count and the reduction in painful episodes.[36] This study showed a positive correlation between survival and HbF levels in patients who were treated with hydroxyurea, and no correlation between survival and leukocyte counts.[36] We would caution against the premature conclusion that the beneficial effects of hydroxyurea are a result of its effects on blood leukocytes rather than HbF concentration.

INHIBITORS OF HISTONE DEACETYLASES

In 1985, Ginder et al.[57] reported that the administration of butyrate, a well-known inhibitor of histone deacetylases, to chickens pretreated with 5-azacytidine resulted in the induction of embryonic globin gene expression. Shortly thereafter, Perrine et al.[58] and Bard et al.[59] showed that infants born to diabetic mothers had higher HbF levels at birth than their aged-matched controls. Interestingly, the diabetic pregnant mothers had high levels of butyric acid in their plasma. Perrine et al. went on to demonstrate that butyrate infusions in utero in sheep fetuses prevented the switch from HbF to HbA that is normally seen around the time of birth.[60] This was followed by the demonstration that the administration of butyric acid to adult baboons could partially reverse the switch from fetal to adult globin expression.[61] These preclinical observations formed the basis for clinical trials that investigated the therapeutic potential of butyrate as an HbF-inducing agent in patients with sickle cell disease and β thalassemia.

Perrine et al.[62] first evaluated the effects of arginine butyrate on HbF production in six patients with β-globin disorders (three patients with sickle cell disease and three patients with β thalassemia). Treatment with butyrate resulted in an increase in γ-globin chain synthesis in all six patients following a 2-week infusion of the drug. This initial study was followed by another study that was conducted by Sher et al.[63] in which arginine butyrate infusions were given to five patients with sickle cell disease and five patients with β thalassemia. A 10-week dose escalation course of arginine butyrate resulted in a significant increase in HbF levels in two of the five patients with sickle cell disease. This increase in HbF levels, however, was not sustained with continuous high-dose therapy. Moreover, there was no increase in the total hemoglobin levels in any of the five patients with β thalassemia who were enrolled on this regimen.

Sodium phenylbutyrate was also used to induce HbF production in patients with sickle cell disease. All six patients who received the drug orally showed a rapid increase in the number of circulating F reticulocytes.[64] Two of the six patients who received the drug for 5–6 months increased their HbF levels from 10.6% to 18% and 10.4% to 16%, respectively. Because this oral regimen required the intake of 30–40 tablets/day, poor compliance was a major problem that limited the effectiveness of this agent in the outpatient setting.

The potential role of intravenous arginine butyrate in sickle cell disease has recently been revisited.[65] The first six patients who were enrolled in this new study received arginine butyrate infusions 8 hours per day, 5 days per week. The HbF levels increased in half of these patients but the increase in the HbF levels was not sustained with continuous long-term therapy. These observations and those of Sher et al.[63] summarized above suggested that toxicity resulting from long-term exposure to butyrate might be responsible for the loss of the HbF response. Thus, a regimen in which butyrate is given intermittently to allow recovery of the bone marrow from the well-known antiproliferative effects of butyrate was investigated in 11 patients. The HbF levels of the 11 patients enrolled on this regimen increased from a mean of 7.2% at baseline to a mean of 21.0% on intermittent butyrate therapy. This HbF response to butyrate was sustained in all patients, including one patient who received arginine butyrate for more than 6 years [65] Interestingly, all five patients who did not respond to butyrate in both the continuous and intermittent butyrate studies had baseline HbF levels below 2%, whereas all 10 responders had baseline HbF levels of 2% or above.[65]

Because butyrate is an inhibitor of histone deacetylases, it is widely believed, although never proven, that butyrate increases γ-globin gene expression, at least in part, by increasing histone acetylation at its promoter and regulatory elements. Although studies in the murine globin system have shown that butyrate can induce an increase in the acetylation of histone H4 in the globin cluster, those changes were not associated with the reactivation of the silenced genes.[66] The effects of butyrate on the chromatin structure in the γ-globin genes in patients with sickle cell disease and β thalassemia have not yet been investigated.

More recently, it has been recognized that histone deacetylases can exert their effect regionally through their recruitment to DNA in a sequence-specific manner by binding to transcription factor complexes.[67,68] This might explain the specificity of the butyrate effect and also the clinical observation that the HbF-inducing activity of butyrate requires partially active human γ-globin genes whose regulatory elements may already be occupied by transcription complexes. Interestingly, a number of *cis*-acting elements have been identified in the promoter of the γ-globin genes that appear to be necessary for the induction of γ-globin expression by butyrate.[69] Moreover, other studies have demonstrated an important role for the p38 mitogen-activated protein kinase signaling pathway in mediating the transcriptional effects of butyrate.[70] A model was proposed in which butyrate would open the chromatin structure of the γ-globin gene through its effect on histone acetylation and also activate sequence-specific transcription factor binding through its effect on mitogen-activated protein kinase signaling.[71] Recent studies have shown that butyrate can also induce HbF production by increasing the translational efficiency of γ-globin mRNA.[72] More studies are necessary to define clearly the respective roles of these different activities of butyrate on the induction of HbF production in vivo in patients with sickle cell disease and β thalassemia.

CLINICAL EFFICACY OF HbF INDUCTION THERAPY IN SICKLE CELL DISEASE AND β THALASSEMIA AND OTHER HEMOGLOBINOPATHIES

All the pharmacological agents that have been investigated for their HbF-inducing activity in sickle cell disease have also been tested in β thalassemia. This subject has been reviewed in detail elsewhere.[73] Although HbF-inducing activity of these agents has also been demonstrated in patients with β thalassemia, in most, but not all instances, meaningful hematological and/or clinical responses have been much more difficult to demonstrate.[74,75] It is not clear why the increase in HbF levels does not result in the correction of the anemia in a majority of patients with β thalassemia. There are many potential explanations that require more investigation.[76] It is possible that the magnitude of the induction of HbF that can be achieved with the currently available agents might not be sufficient to correct the globin chain imbalance and the resulting anemia. It is also conceivable that the pharmacological agents that are being used might induce the expression of the α-globin genes at the same time that they induce the expression of the γ-globin genes. This will reduce the beneficial effects of the activation of the γ-globin genes on $\alpha/(\beta+\gamma)$ chain imbalance in β thalassemia. Furthermore, the poor responses to pharmacological induction of HbF in β thalassemia could be, at least in part, a result of the suppression of the HbF response by chronic transfusions, which are used much more frequently in β thalassemia than in sickle cell disease. Although sickle cell disease and β thalassemia result from mutations in the same gene, the pathophysiology of the two diseases is quite distinct. Much more research is necessary to understand fully the molecular basis for the different responses to the pharmacological inducers of HbF in patients with sickle cell disease and β thalassemia.

Hydroxyurea has been used to induce HbF expression in patients with HbS–β^+ thalassemia with good success.[77] Although it has also been used to treat rare sickle hemoglobinopathies such as HbSD disease and unstable hemoglobin disorders, too few cases have been reported to allow comment on its clinical efficacy. In HbE–β thalassemia, some patients appear to respond to treatment with an increase in hemoglobin concentration and a reduced or absent transfusion requirement.[78]

COMBINATION THERAPY

Of the five patients in the study previously summarized who were treated with arginine butyrate but did not respond with an increase in HbF levels, three were treated with hydroxyurea. All three increased their HbF levels above 20% in response to hydroxyurea.[65] A majority of patients who do not respond to hydroxyurea increase their HbF levels in response to decitabine.[9] This absence of cross-resistance to the HbF-inducing activities of 5-azacytidine, hydroxyurea, and butyrate confirms the long-held suspicion that these drugs activate γ-globin gene expression by different mechanisms and makes it likely that the use of these agents in combination therapy regimens would induce HbF production in an additive or synergistic manner. This hypothesis has recently been tested in three patients who were enrolled on a combination therapy protocol consisting of hydroxyurea for several months followed by hydroxyurea and butyrate. All three patients had a marked increase in their HbF levels after butyrate was added to hydroxyurea.[23] Thus, the combination of butyrate and hydroxyurea was more effective in these patients than hydroxyurea alone. In one patient who was totally resistant to the effect of butyrate following both weekly and intermittent therapy, addition of butyrate after hydroxyurea therapy resulted in a large-increment increase in the HbF level. This demonstrates that resistance to butyrate is not absolute and can be reversed following pretreatment with hydroxyurea.[23] Similar advantages of combinations of other HbF-inducing agents were previously described in studies of hydroxyurea with erythropoietin[79] and hydroxyurea with sodium phenylbutyrate.[80]

Before conducting large-scale studies of combinations of HbF-inducing agents, it is important to ask if there is a need for the use of combinations of two or more agents in sickle cell disease. The study of the natural history of sickle cell disease had clearly shown that higher HbF levels are associated with a less severe clinical outcome.[5] This, however, does not preclude the possibility that the clinical benefits of increased HbF levels may plateau when the

levels exceed 20%. Even though patients from Saudi Arabia whose HbF levels are generally above 20% can have a very mild clinical course, they are not always free of sickling complications.[81] Interestingly, Sutton et al.[82] recently described a patient with sickle cell disease who developed progressive pulmonary hypertension although her HbF level was greater than 20% while receiving hydroxyurea. Addition of butyrate to hydroxyurea in this patient resulted in a peak HbF level of 45% and was associated with in a marked amelioration of the pulmonary hypertension. Although there is no definitive evidence yet that HbF levels of 30%–45% are significantly better than levels of 20%–30%, laboratory data support the hypothesis that such high levels might be necessary to inhibit completely intracellular polymerization of deoxyHbS in red blood cells.[83] Thus, with the current availability of multiple drugs that can activate HbF additively or synergistically, we suggest that the aim of pharmacological therapy should be to achieve the highest possible HbF level rather than to settle for the traditionally accepted level of 20%.

In addition to the drugs that stimulate HbF production, a number of other agents that target different aspects of the pathophysiology of sickle cell disease are under investigation. These include antiadhesive agents, antidehydration agents, and possibly antileukocyte agents (Chapter 31). If these newer agents prove to be effective in clinical trials, it would be of considerable interest to investigate combinations of HbF-inducing agents with these newer agents that target different aspects of the pathophysiology of sickle cell disease. After more than 50 years of intense research on sickle cell disease, we might soon be in a position to select, based on the genotype and/or phenotype of a patient, one or more therapeutic agents that target different aspects of the pathophysiology of sickling. It is gratifying to know that the intense study of the molecular and cellular basis of this disease is finally being translated into novel therapies that could make a significant impact on the lives of patients.

Novel Approaches to Treatment

Kirkwood A. Pritchard Jr, Alicia Rivera, Cheryl Hillery, and Carlo Brugnara

INTRODUCTION

Sickle cell disease and β thalassemia should be ideal genetic disorders for which to design specific therapies at the cellular, protein, or gene levels. First, normal and abnormal differentiated cells, bone marrow precursors, progenitors, and hematopoietic stem cells are easily obtained for ex vivo studies. Second, specific mutations of the β hemoglobin gene have been characterized; the abnormal structure of sickled hemoglobin (HbS) detailed at atomic resolution is available, the secondary cellular defects and, beyond the erythrocyte itself, the interactions of the defective erythrocytes with other blood or vascular components are better understood. Third, mouse models are available for in vivo evaluation of new therapies. Despite a detailed understanding of the genetics, molecular biology, and biochemistry of HbS and β thalassemia and their effects on the host erythrocyte, the pathogenesis of the organ and vascular dysfunctions observed in both sickle cell disease and β thalassemia remain incompletely understood and likely involve many complex and heterogeneous steps.

The complex pathophysiology of sickle cell disease, as detailed in earlier chapters, involves erythrocyte dehydration and interactions of sickle erythrocytes, leukocytes and platelets with the endothelium, and hemolysis, among many other factors.[1] Severity of disease differs significantly among patients, whereas the HbS mutation is common to all patients (Chapter 27). Therefore, the original idea that a single pathophysiological mechanism, whose basis is polymerization of deoxygenated HbS that leads to sickling, is inadequate to explain the myriad of clinical variations. This has prompted studies of factors that can potentially modulate sickle vasoocclusion and disease severity.[2–4] It is believed that vasoocclusion begins with a delay in the flow of the sickle erythrocyte through the vasculature, thereby allowing HbS sufficient time to polymerize. In this scenario, the integrity of microvascular endothelial cell monolayer and postcapillary venule play important roles in maintaining steady flow and preventing entrapment of dehydrated sickle erythrocytes. Consequently, inflammatory factors that mediate or alter cell adherence to the endothelium and/or modulate erythrocyte hydration status will likely affect vasoocclusion. Some of these factors include cytokines, adhesive receptors, and oxidized proinflammatory lipids that have been found to be elevated in sickle cell disease and often correlate with disease severity. Thus, besides anticellular dehydration therapy, additional therapies targeting adhesion, inflammation as well as oxidation might be required for optimal protecting against sickle vasoocclusion, painful episodes, and chronic organ injury.

As described in other chapters of this book, cellular therapies – transfusions and hematopoietic stem cell transplantation – have important drawbacks and limitations. New agents activating fetal hemoglobin (HbF) expression are very useful; however, these agents are not without risk and up to now have offered minor benefits for patients with β thalassemia. Finally, hemoglobin gene therapy remains a treatment goal for the future. Consequently, therapies aimed at alleviating the cellular and vascular defects of hemoglobinopathies remain an area of intense research.

Hemoglobin Modifiers

Sickle Cell Disease

Initial attempts at developing specific therapies for sickle cell disease were aimed at decreasing HbS polymerization.[5] Nitrite-generating methemoglobin[6] and carbon monoxide (CO)[7] were tested in an attempt to decrease the proportion of HbS molecules in the deoxy conformation, which promotes polymerization. The incidence of painful sickle cell episodes, used as a criterion for efficacy, was not decreased in these clinical trials. After observing that urea inhibited HbS gelation and sickling of erythrocytes[8] clinical trials with urea were undertaken. The results from these studies were disappointing.[9] Cyanate, which is derived from urea in solution, was also shown to inhibit sickling and HbS polymerization[10] and on the basis of these in vitro findings was tested as a potential treatment for sickle cell disease.[11] The initial attempt was encouraging, decreasing hemolysis and anemia. Cyanate-dependent carbamoylation of the N-terminal amino group of both α- and β-globin chains increased directly the oxygen affinity and the solubility of HbS. Nonetheless one of the major goals of the study, reduction in painful sickle cell episodes, was not achieved. Side effects, such as cataracts and peripheral neuropathy also occurred, thereby prompting the end of clinical trials with oral potassium cyanate.

The design of antisickling agents targeting the hemoglobin molecule has improved with the precise knowledge

Table 31.1. Hemoglobin modifiers as antisickling agents

Agents	Drawbacks
Noncovalent reagents	
Nonspecific reagents	
Urea, organic solvent	High concentration required
Aromatic alcohols or acids	Small and nonspecific effects
Stereospecific inhibitors	
Aromatic acid derivatives	Small effects
Peptides	High concentration required
Organic compounds	
Covalent reagents	
Targeting terminal residues (cyanate, pyridoxal, tucaresol)	Toxicity Immunostimulant
Targeting side chains (glyceraldehyde, nitrogen mustard)	Toxicity
Targeting 2,3-BPG binding site (Diaspirin)	Toxicity
Nitric oxide	Under evaluation

of hemoglobin tertiary structure and allosteric conformations at the atomic level.[12–16] Several potential antisickling agents have been investigated. Table 31.1 summarizes the major potential antisickling agents that have been investigated. Various types of chemically reactive compounds were able to inhibit intermolecular contact or increase the oxygen affinity of HbS. Nitrogen mustards and other alkylating agents,[17] pyridoxal and other aldehydes forming Schiff base adducts,[18–21] esterifying agents,[22] Sulfhydryl reagents targeting cysteine β93,[23] and bifunctional agents,[24] which form intra- or intermolecular crosslinks, were found to be efficient antisickling compounds. Bis(3,5-dibromosalicyl)fumarate crosslinked β 82 lysine residues in the central cavity prevent the binding of 2,3 bisphosphoglycerate and stabilize the deoxy conformation of HbS.[25] Unfortunately, the poor specificity and the toxicity of many of these antisickling agents precluded clinical trials.

At one time, the cyclic aldehyde compounds offered more promising treatment strategies. The initial reagent 12C79 (BW12C) was very efficient in increasing the oxygen affinity of sickle erythrocytes in vitro,[26] or when infused in normal adults in a phase I clinical trial.[27] BW12C specifically bound to the N terminus of α-globin chains[28] and prevented hypoxia-induced death in the SAD transgenic model of sickle cell disease (Chapter 12).[29] The orally active derivative 589C80 (Tucaresol) increased the oxygen affinity and reduced hemolysis in six patients with sickle cell anemia.[30] The oxygen affinity of HbS was increased between 10% and 20% in all patients, depending on the dose. Increases in the hemoglobin level (mean + 2.2 g/dL), 50% decreases in irreversibly sickled cells and decreased hemolysis as measured by a drop in lactate dehydrogenase (16%–52%) were obtained within a few days from initiating therapy and lasted for 1–2 weeks. Three patients developed fever and tender lymphadenopathy between days 7 and 11 from the start of the drug. Schiff base formation on specific amines of the T-cell surface provided a costimulatory signal that activated Na^+ and K^+ transport, enhancing T-cell receptor dependent interleukin (IL)-2 production.[31–33] Therefore, there are no ongoing or planned trials of Tucaresol in sickle cell disease. Other cyclic aldehyde compounds have lower T-cell potentiation and maintain very efficient hemoglobin binding and a left shift of the red cell oxygen dissociation curve.[34,35] Agents that increase the oxygen affinity of HbS could also increase the red cell mass and blood viscosity. Thus, their use might be limited to short-term therapy of severe sickle cell crises in hospitalized patients.

Fifty years after the discovery of sickle hemoglobin and despite the many experimental advantages this single gene mutation affords for studying sickle cell disease, none of the hundreds of antisickling agents that were shown to inhibit HbS polymerization in vitro are in clinical use today. One reason these agents might not have worked is that hemoglobin is at very high concentrations within the erythrocyte, approximately 5 mmol, representing nearly a third of the erythrocyte's mass. As abnormal red cells have fast turnovers, large quantities of therapeutic drugs are required for binding to red cell hemoglobin on an ongoing basis. In addition to preventing HbS polymerization, the effective therapeutic agent should not affect the physiological functions of hemoglobin. The agent has to be not only specific for hemoglobin but also nontoxic at its effective dose. Today, tremendous progress in molecular drug design and the recently refined structure of HbS polymer at 2.05 Å resolution[36] make it possible for screening of new hemoglobin modifiers with specific antisickling properties. The specific inhibition of intermolecular contacts within the HbS molecule by agents that do not affect the oxygen affinity of HbS remains a major goal.

β Thalassemia

Hemoglobin modifiers targeting α-globin chains could be useful therapies in β thalassemia major, the severity of which is related to the excess of unpaired α hemoglobin chains, which are cytotoxic. These unstable α chains oxidize, precipitate, and form Heinz bodies in erythroid cells.

Reduction in α chain instability, heme oxidation and release, could transform thalassemia major into a thalassemia intermedia syndrome, as shown by the clinical benefit of increasing the expression of γ-globin chains of HbF or by coinheritance of α thalassemia determinants, both of which decrease the relative excess of α-globin chains.

α Hemoglobin stabilizing protein (AHSP) (Chapter 4) is a recently described abundant erythroid protein that specifically binds to and stabilizes free α-globin, thereby limiting

its prooxidant activities.[37] When β-globin subunits are present, AHSP is displaced, permitting the formation of HbA ($\alpha_2\beta_2$). AHSP-deficient mice have hemolytic anemia with hemoglobin precipitates and reticulocytosis, reflecting an essential role for AHSP in erythropoiesis.[37] AHSP appears to function as both a chaperone to optimize the correct folding of newly synthesized α-globin[38] as well as a stabilizer of free α hemoglobin (α-globin with heme), whereby the heme iron becomes detoxified by binding to two histidines within the α-globin polypeptide.[39] In agreement with this protective role, AHSP deficiency exacerbates the β thalassemia phenotype in mice.[40] It is possible that variations in AHSP function or expression could affect the phenotype of human β thalassemia by restraining the toxicity of free α-globin (Chapter 27).[41]

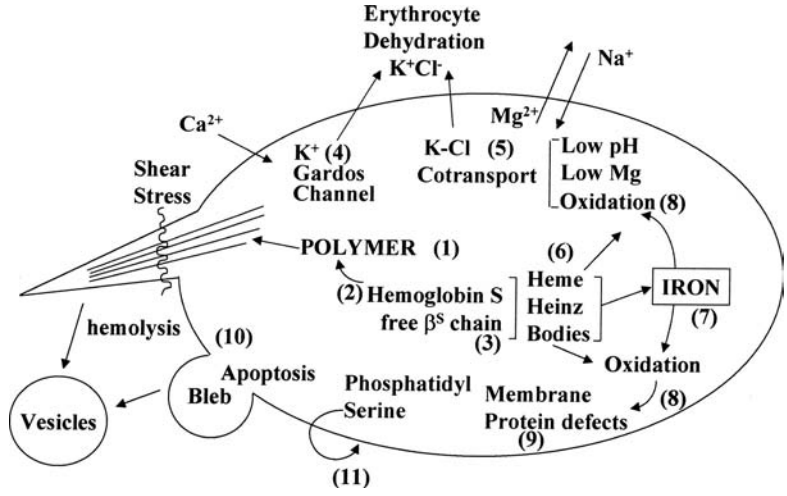

Figure 31.1. Sites of red cell physiology that are targets of experimental therapies. Sickle hemoglobin polymer and free β^S-globin chains, primary defects in sickle cell anemia, are shown in red; secondary defects are shown in green, and tertiary defects in black. (See color plate 31.1.).

In HbH disease, despite a similar degree of hemoglobin chain imbalance, the self-association of β-globin chains into nonfunctional β_4 tetramers, or HbH, induces a less severe anemia, which is mostly hemolytic in contrast to the ineffective erythropoiesis prevalent in β thalassemia major.

Inhibitors of Erythrocyte Dehydration

Sickle Cell Disease

Intracellular concentration of HbS is a major factor for HbS polymerization as the delay time of polymer formation is dependent on the 15th–30th power of hemoglobin concentration.[42] In most physiological conditions hemoglobin polymers are not present in erythrocytes of sickle cell trait carriers who are asymptomatic because the HbS concentration is 13–14 g/dL in cells, which is below the threshold value for polymerization (Chapter 22).

In sickle cell anemia, polymerization of HbS with subsequent cellular dehydration likely plays a major role in the expression of the disease. A substantial number of abnormally dense erythrocytes result from polymerization-induced membrane damage, leading to cell dehydration.[43,44] Because the polymerization process is highly dependent on HbS concentration, these dense erythrocytes are likely to rapidly accumulate HbS polymers at decreased pO2, become distorted and rigid, and contribute to vasoocclusive and hemolytic defects.

Important contributors to sickle cell dehydration are potassium–chloride cotransport (KCl efflux) and the Ca^{2+}-activated K^+ channel, the so-called Gardos channel[45] (Chapter 9). Deoxygenation-induced HbS polymer formation leads to increased membrane permeability to cations, including Ca^{2+} and Mg^{2+}. The transient increase in cellular ionized Ca^{2+} is sufficient to trigger activity of the K^+ channel resulting in water loss. In sickle cell disease, K:Cl cotransport is activated by low pH,[46] low Mg^{2+} content of erythrocytes, oxidative damage, positively charged hemoglobins like HbS, HbC, and HbE, and cell swelling (Fig. 31.1).

Water retention using antidiuretic therapy (desmopressin) and a low-sodium diet was an initial attempt to decrease cellular HbS concentration by inducing hypotonic cell swelling.[47,48] The practical difficulty was in maintaining a significant hyponatremia, and a second trial[49] failed to confirm the initial beneficial results. This nonselective approach to erythrocyte hydration was associated with neurotoxicity. Cetiedil, a membrane active agent that has a low affinity for the Gardos channel and that increases Na^+ permeability, was shown to have some beneficial effects in reducing sickle cell painful events;[50,51] however, no further clinical study of this agent has been conducted. Ca^{2+} channel blockers (Verapamil, Diltiazem, Bepridil, Nifedipine, and Nitrendipine) inhibit sickling and erythrocyte dehydration in vitro [52] but had few effects in vivo. Other membrane modifiers that have an erythrocyte swelling effect, such as Monensin, Tellurite, Nystatin, and Chlorpromazine, have been studied only in vitro.

Blockade of Ca^{2+}-activated K^+ Channel (Gardos Channel)

Clotrimazole and other imidazole antimycotics have been shown to be potent blockers of the Gardos channel in vitro.[53,54] Among imidazoles, clotrimazole is the most potent inhibitor, whereas econazole and miconazole are the most potent inhibitors of plasma membrane Ca^{2+} channels.[53] In vitro studies with human sickle cells indicate that clotrimazole can specifically prevent red cell dehydration and K^+ loss through Gardos channel inhibition.[55]

The efficacy of clotrimazole as a specific inhibitor of the Gardos channel was evaluated in vivo in the SAD mouse (Chapter 12).[56] These mice show clinical and biological features similar to those observed in HbSC disease. The effect of oral administration of clotrimazole was studied during a 4-week period. Oral administration of clotrimazole (160 mg/kg/d) induced a significant inhibition of the Ca^{2+}-activated Rb^{+} transport measured in whole blood and restored the red cell volume after 48 hours of administration. These effects persisted during the 28 days of treatment.[56] The inhibition of the Gardos channel was associated with increased erythrocyte K^{+} content, decreased mean corpuscular hemoglobin concentration (MCHC), and decreased red cell density. All of these changes were reversible within 2 days after clotrimazole was withdrawn at day 7 or 28 of treatment. No toxicity and side effects were observed.

Studies with normal volunteers taking clotrimazole orally identified a dosage range of 10–20 mg/kg of body weight per day that caused marked inhibition of the Gardos channel.[57] This dosage is substantially lower than that used in the treatment of systemic mycosis (100–160 mg/kg/d).[58,59] Clotrimazole metabolites lacking the imidazole ring were detectable in plasma. These metabolites have no antimycotic effects but they maintain a substantial inhibitory activity on the Gardos channel.

A short-term study was performed in sickle cell anemia patients who were treated with clotrimazole at a dosage of 10–30 mg/kg/day. This treatment induced an inhibition of the Gardos channel, a decrease in red cell dehydration and an increase in red cell K^{+} content.[60] The effects of clotrimazole on red cells were more evident in patients with a significant number of dense cells at baseline. Adverse side effects were limited to mild/moderate dysuria in all subjects, likely due to urinary excretion of clotrimazole metabolites, and a reversible increase in plasma alanine transaminase and aspartic transaminase levels in two subjects treated with clotrimazole at the dosage of 30 mg/kg/day.

A novel inhibitor of the Gardos channel (ICA-17043) was developed based on the structure of clotrimazole metabolites. This compound showed increased potency in vitro compared with clotrimazole[61] and favorable pharmacokinetic properties with no serious toxicities.[62] Phase II studies showed that administration of ICA-17043 at the dose of 10 mg/kg/day resulted in significant improvement of anemia and reduction in hemolysis and reticulocytosis in patients with sickle cell disease.[63]

This study was followed by a phase III study (ClinicalTrials.gov identifier: NCT00102791) modeled after the trial that led to the approval of hydroxyurea in early 1990s, with painful events as the primary endpoint. ICA-17403 reduced hemolysis without toxicity, but the trial was terminated prematurely because of the low probability of achieving its primary endpoint, which was a reduction in vasoocclusive events. ICA-17403 is able to reduce the hemolytic rate, probably because it reduces on sickle erythrocyte density. More than 20 years ago, it was noted that coincident α thalassemia, which is associated with reduced cell density and reduced hemolysis in sickle cell anemia, was not associated with a reduction in the number of vasoocclusive events and might have been associated with an increased number of complications that dependent on blood viscosity (Chapters 11 and 19). This suggested that a drug that reduces hemolysis without effecting the intracellular hemoglobin composition might benefit some but not all disease complications. Although some patients enrolled in the phase III trial of ICA-17403 received hydroxyurea, no attempt was made to ensure that HbF levels were maximized. In future trials, it might be wise to craft endpoints that take into account the hemolytic complications of disease, which include premature death, but at this time, no further studies are planned for ICA-17043 in sickle cell disease.

Inhibition of KCl Transport by Mg^{2+}

K:Cl cotransport promotes loss of K^{+} and Cl^{-} with subsequent erythrocyte dehydration and is activated when erythrocytes are exposed to different conditions such as pH lower than 7.40, swelling in hypotonic media, low intracellular Mg^{2+} content and positively charged hemoglobin variants such as HbS or HbC.[64,65] Pharmacological inhibitors of this pathway that could be used to prevent cell dehydration in vivo do not exist. [(Dihydroindenyl)oxy]alkanoic acid can inhibit the K:Cl cotransport system but it is not active at a low enough concentration to be used in vivo.[66]

K:Cl cotransport is exquisitely sensitive to cell Mg^{2+} concentration, and a slight increase in cell Mg^{2+} induces marked inhibition of K:Cl cotransport.[67] When cell Mg^{2+} is increased, Cl^{-} moves into the cell to compensate for the positively charged ions, with an obligatory osmotic water influx and consequent cell swelling.[68] There have been reports of abnormally low cell Mg^{2+} content in sickle erythrocytes, especially in the dense fractions containing irreversibly sickled cells.[69,70]

The effects of oral Mg^{2+} supplementation have been studied in the SAD mouse.[71] In this mouse strain, oral Mg^{2+} supplementation (1,000 ± 20 mg/kg of body weight/day) restored red cell Mg^{2+} and K^{+} content, and reduced K:Cl cotransport activity, MCHC, and cell density. A Mg^{2+}-deficient diet led to worsening anemia, reticulocytosis, and dehydration of SAD mouse red cells, associated with increased K:Cl cotransport activity. Oral Mg^{2+} supplementation prevented additional erythrocyte dehydration and K^{+} loss caused by hypoxemia.

Studies in diabetic patients have shown that dietary Mg^{2+} supplementation with magnesium pidolate can increase red cell Mg^{2+} content.[72,73] Based on the SAD mouse experiments, the effects of oral Mg^{2+} supplementation were evaluated on red cell dehydration in sickle cell anemia.[74] Magnesium pidolate at a dose of 0.6 mEq/kg/day was used as oral supplementation in 10 sickle cell anemia patients. Four weeks of treatment induced an increase in

red cell Mg^{2+} and K^+, and a decrease in the activity of K:Cl cotransport. There were no laboratory or clinical signs of hypermagnesemia, and mild, transient diarrhea was the only reported side effect. A pilot study, using magesium pidolate for 6 months, confirmed the beneficial effects on red cell dehydration and demonstrated a 58% reduction in the number of painful days.[75]

Mg^{2+} supplementation remains a promising therapeutic approach for preventing red cell dehydration in sickle cell disease, especially in HbSC disease in which K:Cl transport is most active. Its use in combination with other agents seems most attractive. A maximum tolerated dose for magnesium pidolate of 0.9 mEq/kg/day has been established when combined with hydroxyurea in children with sickle cell anemia.[76] A phase I trial of magnesium pidolate plus hydroxyurea has been completed in children with sickle cell anemia (NCT00143572). As of this writing a randomized, placebo-controlled phase II trial to evaluate the effects of long-term Mg^{2+} supplementation in patients with HbSC disease, as a single agent and in combination with hydroxyurea (NCT00532883) is ongoing.

β Thalassemia

Mg^{2+} supplementation ameliorated the anemia in a mouse model of β thalassemia[77] and decreased red cell dehydration in human β thalassemia intermedia.[78] Because there was no improvement of anemia in human β thalassemia, the relative dehydration of thalassemic cells does not seem to be critical in the pathogenesis of anemia. Thus, Mg^{2+} supplementation is not likely to be a viable therapeutic strategy for the treatment of anemia in thalassemia.

Antiadhesion Therapy

Sickle Cell Disease

The increased adhesion of sickle erythrocytes to vascular endothelium (Chapter 8) in vitro has been described when using both static adhesion assays[79,80] and endothelialized flow chambers.[81] These observations have been confirmed using live animal models by either infusing human sickle erythrocytes into rats[82–84] or by studying transgenic sickle cell mice.[85,86] In addition, leukocyte interactions with sickle erythrocyte and vascular endothelium likely contribute to the vascular pathologies observed in sickle cell disease.[87] The enhanced interactions among sickle erythrocytes, leukocytes, and the vessel wall likely play important roles in the pathogenesis of vascular occlusion in sickle cell disease.

Observations that sickle erythrocytes adhere to the endothelium to a variable degree and that the level of adhesion correlated with the severity of the disease[88] prompted investigation of the specific receptors involved in this interaction and the possible signaling pathways by which this occurs. Reticulocytes from both normal controls and sickle disease patients express the adhesion molecules integrin α4β1[89,90] and CD36 (GP IV).[89,91,92] Various studies have demonstrated that immature reticulocytes have greater levels of adhesion to endothelial cells compared with mature erythrocytes, pointing to a potential role for reticulocyte adhesion under selected experimental conditions.[80,89,92–94] Potential adhesion molecules that remain present on mature sickle erythrocytes include basal cell adhesion molecule–1/Lutheran (BCAM/Lu), intercellular adhesion molecule (ICAM)-4/Landsteiner-Weiner,[95] integrin-associated protein (CD47), phosphatidylserine (PS),[96] and sulfated glycolipids.[97,98] The sickle erythrocyte likely utilizes multiple adhesive pathways, potentially first binding to the endothelium and inducing localized pathological changes, followed by a second adhesive event with the sickle erythrocyte binding to the newly exposed endothelial or subendothelial adhesive ligands.

A disturbed endothelium also contributes to sickle cell adhesion in vivo. Endothelial adhesive molecules that bind sickle erythrocytes include vascular cell adhesion molecule–1 (VCAM-1),[90,99,100] integrin αVβ3,[93,100,101] E-selectin,[100] and P-selectin.[102] Optimal surface expression of these endothelial adhesion molecules requires induction by cytokines, shear stress or other perturbations of the endothelium, and exposure of endothelium to inflammatory agonists is associated with increased erythrocyte adhesion.[103,104] Increased levels of circulating endothelial cells are found in patients with sickle cell disease, with higher levels at the time of vasoocclusive crises;[105] the circulating endothelial cells have an activated phenotype, including increased expression of tissue factor[106] and adhesion molecules.[105] Increased levels of soluble VCAM-1 are found in patients with sickle cell disease at steady state, with a further marked increase during vasoocclusive crises, consistent with participation of endothelial injury in vasoocclusive disease.[107]

Adhesive plasma and extracellular matrix proteins can also contribute to sickle erythrocyte adhesion. Thrombospondin (TSP) is a 450-kD, homotrimeric glycoprotein present in the subendothelial matrix, plasma, and platelet α storage granules; it can be released in high local concentrations by activated platelets.[108] Both soluble and matrix TSP might play a role in sickle erythrocyte adhesion. In its soluble form, TSP might serve as a linker molecule between sickle erythrocytes and endothelial cells.[93,109] TSP also interacts with sickle erythrocyte CD47,[110] sulfated glycolipids,[111] and a normally cryptic domain of the dominant membrane protein, band 3, which is subject to rearrangement in hematological disorders,[112,113] Laminin, a major constituent of the extracellular matrix, is composed of a family of large heterotrimeric glycoproteins that support cell adhesion and migration and modulate gene expression.[114] Sickle erythrocytes avidly bind both immobilized and soluble laminin.[97,115] Vitronectin, fibrinogen, and von Willebrand have also been shown to support sickle cell adherence.[104]

Integrin-associated protein (CD47) functions as both a binding site for TSP and as an agonist receptor in response to soluble TSP in hematopoietic cells.[110,116,117] CD47 is expressed in normal and sickle erythrocytes[110] and protects normal erythrocytes from immune clearance.[118] CD47 on sickle erythrocytes binds immobilized TSP as a result of shear stress–dependent and G protein–mediated signal transduction pathways.[110]

Integrin α4β1 is a receptor for both fibronectin and VCAM-1.[119] Sickle red cells bind to VCAM-1 on cultured cytokine-stimulated endothelial cells[90] or transfected COS cells[99] and to immobilized fibronectin[120] via α4β1. The activation state of α4β1 is regulated by several factors, including divalent cation concentration and agonist-induced cell signaling.[121] The α4 cytoplasmic domain is directly phosphorylated in vitro by cyclic adenosine monophosphate–dependent protein kinase A,[122] suggesting a role for protein kinase A on activation of α4β1. Ligation of CD47 on sickle reticulocytes activates α4β1 via a protein kinase A–dependent phosphorylation of the α4 cytoplasmic tail.[123] In vitro, α4β1 interaction with endothelial VCAM-1 likely contributed to the adherence of sickle reticulocytes to cytokine-stimulated retinal microvascular endothelial cells.[124] In these studies, sickle erythrocyte binding to cytokine-stimulated retinal endothelium was inhibited by the α4β1 cyclic peptide antagonist TBC772[125] and monoclonal antibody 9H8 that blocks α4β1 adhesion.[89,90,99] Thus, integrin-blocking cyclic peptides such as TBC772 could eventually have potential therapeutic application in sickle cell disease.

The Lutheran blood group proteins, BCAM/Lu, are derived by alternative splicing from the same gene and differ only in the length of their cytoplasmic tails. Sickle erythrocytes overexpress BCAM/Lu, which specifically binds to the α5 subunit of the extracellular matrix protein laminin.[115,126] Erythrocyte ICAM-4, otherwise known as blood group Landsteiner-Weiner, binds β3 integrins, including αvβ3 expressed on vascular endothelial cells.[127] In a rat ex vivo microvascular flow model, ICAM-4-specific peptides inhibited human sickle erythrocyte adhesion to the activated ex vivo microvascular endothelium.[128] Interestingly, both BCAM/Lu and ICAM-1 can be activated by epinephrine in a subset of sickle erythrocyte via a cyclic adenosine monophosphate–dependent pathway that likely involves protein kinase A.[95,129]

CD36 is a nonintegrin adhesive receptor that binds TSP and collagen and is present on the surface of endothelial cells, platelets, and a reticulocyte-rich subpopulation of normal and sickle red cells.[89,92] Sickle red cells bind to endothelial cells in the presence of soluble TSP and this adhesion is blocked by anti-CD36 monoclonal antibodies in both static adhesion assays[92] and under flow conditions.[93]

Sulfated glycolipids avidly bind TSP, von Willebrand factor, and laminin and might play a role in sickle red cell adhesion.[97,98,111] Abnormally exposed or altered lipids in the damaged sickle erythrocyte membrane could mediate sickle erythrocyte adhesion to immobilized TSP; this interaction is inhibited by the anionic polysaccharides high-molecular-weight dextran sulfate and glycosaminoglycan chondroitin sulfate A, but not other anionic polysaccharides of similar charge or structure.[97,98] TSP-induced erythrocyte adhesion to cultured human umbilical vein endothelial cells and sickle erythrocyte adhesion within an ex vivo mesocecum of the rat were both reduced by the same two anionic polysaccharides.[111] Thus, anionic polysaccharides could provide a potential therapeutic avenue to reduce pathological sickle erythrocyte interactions with the injured vessel wall.

Phosphatidylserine (PS) is abnormally exposed on the outer surface of sickle erythrocytes (Chapter 9) and also contributes to sickle erythrocyte adhesion to endothelial cells.[96,130,131] When PS translocates to the cell surface, it serves as an anchor for factors in the hemostatic system, promoting the activation of the coagulation cascade.[132] A strong correlation between the level of sickle erythrocyte PS exposure and the activity of the coagulation cascade in human and murine sickle cell disease is present, suggesting that the loss of sickle cell membrane asymmetry might also contribute to the observed prothrombotic state.[133,134] Furthermore, PS exposure on sickle erythrocytes might contribute to shortened erythrocyte survival in both sickle cell disease and thalassemia.[135,136]

With regard to the vessel wall, integrin αVβ3 likely contributes to sickle erythrocyte adhesion to the endothelial cells.[93,100,101] For example, monoclonal antibodies directed against αVβ3 inhibited human sickle erythrocyte adhesion to platelet-activating factor–treated rat mesocecum vasculature ex vivo. The αVβ3 antagonists, EMD 66203 and EMD 270179, also reduced sickle erythrocyte adhesion to human endothelial cell monolayers under venular shear flow conditions.[137] In the same rat ex vivo mesocecum model, these antagonists not only inhibited adhesion, but also abolished related vasoocclusion and maintained flow transit. These results suggest that the use of receptor antagonists could provide a beneficial therapeutic approach to reducing sickle cell adhesion and subsequent vasoocclusion.

P-selectin is an adhesion molecule that is rapidly expressed by activated platelets and endothelial cells.[138,139] Because P-selectin–mediated adhesive events are theorized to occur early in the evolution of sickle cell adhesion and vascular stasis, this pathway could serve as a model for the development of preventive antiadhesive therapy. Thus, P-selectin–blocking agents will likely best be used for preventing painful vasoocclusion rather than treating acute painful events in which numerous selectin-independent processes might already be active. This is accomplished best by using orally absorbable agents because chronic administration of injectable drugs is usually associated with

poor compliance. Presently, nearly all of the P-selectin–blocking agents under development must be administered parenterally.[140] Specificity of P-selectin blockage also is critical to these considerations, and experience with selectin knockout mice has shown that chronic deficiency of P-selectin alone is not associated with risks of immune deficiency or hemorrhage,[141] but knockout of two or all three selectins is associated with serious clinical consequences.[142,143] Thus, blockage of P-selectin on a long-term basis must not also block E- or L-selectin.

Heparin also inhibits sickle cell adhesion to endothelial cells, potentially via either inhibition of sickle erythrocyte adhesion to endothelial P-selectin,[144,145] or by blocking the N-terminal heparin binding domain of TSP that can link sickle erythrocytes to endothelial cells.[109] In this regard, unfractionated heparin in sub-anticoagulating concentrations could have the advantage of blocking P-selectin in a concentration-specific manner,[146] but has the disadvantage of being poorly[147] and inconsistently[148] absorbed when administered orally. A preliminary trial of long-term low-dose subcutaneous heparin prophylaxis in four patients with sickle cell disease was reported. Patients experienced a reduction in painful crises while on therapy, with minimal toxicity.[149] To date attempts at developing orally absorbable heparin are still in their infancy.[150,151] The potential of developing oral heparins and other inhibitory compounds for chronic P-selectin inhibition, improved microvascular blood flow, and reduced frequency of painful vasoocclusion hinges on whether formulations with greater and more consistent oral absorption can be created.

RheothRx (poloxamer 188) is a nonionic surfactant copolymer with hemorheological properties that improve microvascular blood flow by lowering viscosity and frictional forces. RheothRx has been shown to block hydrophobic adhesive interactions (cell–cell, cell–protein, and protein–protein) in blood, resulting in the reduction of erythrocyte aggregation, adherence of erythrocytes to vascular endothelium, and an improvement in microvascular flow.[152] In a randomized, double-blind, placebo-controlled, pilot phase II study, RheothRx was well tolerated when 50 patients received 48-hour infusions of either RheothRx or placebo for moderate or severe pain lasting at least 4 hours, but less than 18 hours after presentation to the hospital.[153] A 48-hour infusion at doses of 30 mg/kg/hour of RheothRx significantly reduced total analgesic use, pain intensity, and showed trends to shorter duration of painful episodes and total days of hospitalization. This first formulation of poloxamer 188 was, however, associated with reversible nephrotoxicity in patients with heart failure. This toxicity was shown to be due to impurities in the formulation. Studies of a new highly purified version of poloxamer 188, Flocor™, were tested and found to be safe, but not efficacious for the general treatment of sickle cell disease vasoocclusive episodes, although children younger than 15 years and patients already taking hydroxyurea appeared to have a benefit from treatment (NCT00004408).[154]

Although the use of antiadhesive therapy is still in its infancy for many diseases, antiintegrin agents are already well-established therapies for the treatment of myocardial ischemia syndromes.[155] The ability to design rational approaches to inhibit the pathological adhesive properties of the sickle erythrocyte is dependent on a more complete understanding of the predominant pathological adhesive interactions in this disease. Furthermore, these findings suggest the possibility of selectively modulating adhesive interactions so that unwanted interactions associated with pathology can be ameliorated without compromising other functions.

Antithrombotic Therapy

Sickle Cell Disease and β Thalassemia

Individuals with either sickle cell disease or thalassemia have increased risk for thromboembolic complications and laboratory evidence for increased activity of platelets and the coagulation pathway.[156–158] There is increased thrombin generation in steady-state sickle cell disease with elevated levels of thrombin–antithrombin complexes, fibrinopeptide A, prothrombin fragment 1+2, and fibrin D-dimer levels that tend to increase further during acute vasoocclusive episodes.[158,159] Increased tissue factor activity with decreased factor VII levels consistent with higher factor VII turnover is also found.[159] Activated endothelial cells and monocytes with increased levels of tissue factor expression might contribute to this observation. Increased expression of tissue factor was found in circulating endothelial cells recovered from individuals with sickle cell disease.[106] Furthermore, increased levels of tissue factor–positive microparticles, derived from both monocytes and endothelial cells, were present in the plasma;[160] the levels of tissue factor–positive microparticles increased further during acute vasoocclusive events.[160] In different murine models of sickle cell disease, increased levels of endothelial tissue factor expression on pulmonary veins were found in the more severe models.[161] Exposure to hypoxia followed by oxygenation increased the expression of tissue factor of the milder sickle cell disease mice to levels similar to the more severe Berkeley mice.[161]

Increased exposure of PS on sickle and thalassemic erythrocytes promotes surface-dependent coagulation reactions and correlates with increased activity of coagulation parameters in sickle cell disease.[133,156,162,163] Furthermore, the levels of the natural anticoagulants, protein C and protein S, are decreased in patients with sickle cell disease and thalassemia.[164]

Platelet numbers and activity are increased in individuals with either sickle cell disease[158,165–167] or thalassemia.[156] As noted, the release of TSP by activated platelets might

contribute to sickle erythrocyte adhesion. Alternatively, sickle erythrocyte adhesion to endothelial cells could damage the endothelium,[100] increase tissue factor expression,[168] and initiate the procoagulant activity.

Few clinical trials of anticoagulation in sickle cell disease have been reported. In one study, high-dose warfarin therapy minimally reduced painful vasoocclusive episodes but was associated with major bleeding complications.[169] In another, low-dose warfarin therapy successfully reduced the prothrombin fragment 1+2 level by 50% in seven patients;[170] however, clinical efficacy was not addressed. More recently, a pilot study of low-dose acenocoumarol in 22 patients with sickle cell disease demonstrated significant decreases in prothrombin fragment 1+2 levels, thrombin–antithrombin complexes, and D-dimer fragments but found no effect on the incidence of vasoocclusive episodes.[171] In 19 of these 22 patients on low-dose acenocoumarol, there was no difference in their measured levels of soluble VCAM-1, soluble cellular fibronectin, and von Willebrand factor antigen.[172]

Despite the evidence for platelet activation and consumption during vasoocclusive events, there has been no clear clinical benefit in small, nonrandomized clinical studies of aspirin,[173,174] ticlopidine,[175] or aspirin plus dipyrimadole.[176] Antiplatelet therapies have not been specifically tested for the primary or secondary prevention of arterial disease, such as sickle cell stroke or pulmonary hypertension. These limited observations are insufficient to establish the efficacy of anticoagulation therapy in preventing sickle vasoocclusion.

Given the overwhelming biochemical evidence for increased activity of the coagulation pathways linked with the higher incidence of thromboembolic complications in both sickle cell disease and thalassemia,[156–158] it makes sense to initiate large well-designed clinical trials to study the safety and efficacy of anticoagulation therapies.

Antiinflammatory Therapy

Sickle cell disease is a proinflammatory condition. The leukocyte count is elevated and correlates with a more severe clinical course, including increased risk of stroke and early death.[177–180] Moreover, patients have chronically elevated acute phase proteins, which increase further during acute events.[181] The plasma levels of the proinflammatory cytokines IL-1β, IL-6, interferon-γ, and tumor necrosis factor–α have been also reported elevated in at steady state with further increases during acute vasoocclusive events.[182,183] Endothelin-1 (ET-1),[184,185] transforming growth factor–β,[186] stem cell factor,[186] serum transferrin receptor,[186] IL-8,[187] and platelet activating factor[188,189] have been reported to be increased. These cytokines and chemokines might induce activation of the vascular endothelium, circulating erythrocytes, leukocytes, and platelets and contribute to the pathogenesis of painful vasoocclusive episodes.[183,190]

Sulfasalazine and Nuclear Factor–κB

Murine models of sickle cell disease have proven useful in the study of the inflammatory components of this disease. The more severe sickle cell disease mice exhibit an inflammatory response profile that is similar to that in humans and is characterized by increased expression of endothelial adhesion molecules[191] and activation of nuclear factor–κB (NF-κB).[192,193] Intravital examination studies showed activation of vascular endothelium and increased leukocyte–endothelium interactions that should cause abnormal blood flow and vasoocclusive episodes. These findings parallel observations in humans with sickle cell disease that showed that vasoocclusive crisis is often preceded by infection.[194–196] Inflammation elicits increased generation of oxidants that activate NF-κB, which in turn increases expression of endothelial adhesion molecules involved in leukocyte–endothelium interactions.[197,198] These experimental studies suggest that the use of targeted antiinflammatory therapy could be an effective means of decreasing inflammation and sickle vasoocclusion.

A small pilot study was conducted to evaluate the potential effect of the antiinflammatory molecule, sulfasalazine, on endothelial activation.[191] Sulfasalazine is an antiinflammatory agent that has been used to treat inflammatory bowel disease in humans. Its antiinflammatory effects are attributed to its ability to inhibit NF-κB activation.[199,200] Sulfasalazine decreased the expression of VCAM, ICAM, and E-selectin in human circulating endothelial cells.[191] The effects of sulfasalazine on endothelial cell activation were studied in transgenic sickle mice.[201] Although sulfasalazine can decrease expression of endothelial adhesion molecules in humans and transgenic sickle cell disease mice, it does not appear to decrease tissue factor expression.[191] In transgenic mice, sulfasalazine attenuated leukocyte adhesion and improved microvascular flow. Treatment of sickle cell mice with the antioxidant polynitroxyl albumin, which inhibits NF-κB activity, decreased the expression of VCAM-1, ICAM-1 in the liver and lung, and limited leukocyte rolling and vascular stasis in dorsal skin microvessels following hypoxia reoxygenation.[202] The level of inhibition of NF-κB activation correlated with the level of reduction in cell adhesion molecule expression and improved vascular flow.[202] These results support the concept that inflammation plays an important role in the pathogenesis of sickle vasoocclusion and they warrant further investigation.[105,106,192]

Targeting Endothelin-1

Sickle erythrocytes can interact with vascular endothelial cells, stimulate the release of ET-1, and modulate the expression of ET-1 in cultured endothelial cells.[203] ET-1 can also activate the Gardos channel through a protein kinase C–dependent mechanism in mouse erythrocytes.[204] These data suggest that activation of the Gardos channel might be

coupled to receptors such as C-X-C (PAF), C-C (RANTES), and ET receptor subtype B-1, which implies an important role for inflammatory cytokines in the activation of the endothelium and erythrocyte dehydration.[204–206] In vivo treatment of sickle mice with the ET-1 receptor antagonist BQ-788 decreased MCHC and the percentage of dense cells while increasing mean cellular volume and decreasing Gardos channel activity.[207] These results provide strong evidence that ET-1 receptor antagonists represent a compelling target for the development of novel therapies to inhibit red cell sickling and endothelial cell activation.

Further support for the idea of using ET-1 receptor antagonists to treat complications associated with sickle cell disease comes from the fact that ET-1 receptor antagonists are already being used to treat pulmonary hypertension and asthma. As in sickle cell disease, these conditions are associated with increased plasma levels of ET-1.[208–210] In a mouse model of pulmonary hypertension, ET-1 receptor antagonists prevented pulmonary vascular remodeling and even reversed hypoxia-induced pulmonary remodeling. Furthermore, treatment with bosentan, a nonselective blocker of ET-1 receptors, was reported to reduce the levels of proinflammatory molecules that are associated with the development of asthma.[209] A phase III clinical trial testing the safety and efficacy of the ET-1 receptor blocker, bosentan, in sickle cell disease patients diagnosed with pulmonary hypertension has been started (ASSET-2; NCT00313196).

Antioxidant Therapy Targeting the Vasculature

HbS appears to undergo autooxidation at faster rates than HbA.[211,213] It is argued that because of the higher rates of autooxidation sickle erythrocytes experience significantly greater levels of oxidative stress as indicated by their increased susceptibility to lipid peroxidation.[213] Sickle erythrocytes also have increased ability to generate reactive oxygen species.[214] This is important because reactive oxygen species are well recognized for depleting cells of their natural antioxidants. Chronic increases in oxidative stress and inflammation as a result of increased HbS autooxidation and xanthine oxidase and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity are believed to play a key role in the mechanisms eroding antioxidant defenses of the vessel wall. Indeed, increased reactive oxygen species production has been shown to oxidize a variety of proteins, lipids, and DNA. Taken together the ability of hemoglobin to undergo autooxidation coupled with chronic shifts in the balance of nitric oxide (NO) and superoxide should have adverse effects on the vessel wall.

Nitric Oxide

NO biology is discussed in detail in Chapter 10. NO is a chain-breaking antioxidant, which explains its ability to inhibit low-density lipoprotein oxidation and subsequently, inflammation.[215,216] The major source of NO in the vessel wall is endothelial nitric oxide synthase (eNOS). NO plays important protective roles in maintaining normal blood flow and vascular function. Therapies aimed at improving endothelial cell function and eNOS-dependent NO generation might have a major impact on vascular function in sickle cell disease and thalassemia.

Loss of NO bioactivity is one the earliest changes in vascular physiology associated with vascular injury. eNOS requires tetrahydrobiopterin (BH4), Ca^{2+}/calmodulin, L-arginine, hsp90–dependent chaperone activity and post-translational phosphorylation for optimal activity.[217–220] Interestingly, disruption of signaling mechanisms, loss of essential cofactors (BH4 and L-arginine) or chaperone-dependent activity leads to the uncoupling of eNOS activity from L-arginine oxidation and therefore increases production of superoxide anion ($O_2^{\bullet}$) rather than NO. Such observations and the fact that sickle cell disease patients have lower L-arginine levels due to increased release of red cell arginase[221] provided some of the earliest rationale for treating sickle cell disease with L-arginine. L-Arginine supplementation in murine models of sickle cell disease increased total NO production, decreased lipid peroxidation and increased glutathione (GSH) levels, superoxide dismutase, catalase, and GSH peroxidase activity.[222] The importance of restoring eNOS-coupled activity is underscored by yet another study showing that BH4 supplementation with sepiapterin improved eNOS function and decreased vascular endothelial cell activation.[223] Such observations support the notion that preserving coupled eNOS activity plays an important role in increasing NO bioactivity that inhibits lipid peroxidation and decreases oxidative stress. Several clinical studies are examining the efficacy of BH4 or L-arginine supplementation in the treatment of sickle cell disease patients. In a phase II trial of arginine supplementation in children and adults with sickle cell disease (NCT00513617) in which the primary endpoints were NO levels, Gardos channel activity, and erythrocyte density, no effect was seen. Arginine has also been studied for its effect on chronic leg ulceration (NCT00004412).

Chronic release of hemoglobin in sickle cell disease inhibits vascular NO activity by scavenging NO and converts it to nitrate, which is ineffective for promoting vasodilation.[224] Second, free hemoglobin increases production of lipid peroxides that further increase vascular instability.[225]

The importance of NO to the sickle red cell was suggested by studies showing that low concentrations of NO specifically increase the oxygen affinity of sickle erythrocytes.[226] The left shift of the oxygen dissociation curve was obtained within 45 minutes after exposure of deoxygenated sickle cells to NO and was dose dependent in the range 20–80 ppm of NO. Breathing NO (80 ppm for 45 minutes) restored normal oxygen dissociation curves to sickle cells in eight of nine patients with sickle cell anemia.

In contrast, NO did not affect the oxygen affinity of normal erythrocytes in vitro or in vivo and the formation of methemoglobin was negligible. Unfortunately, these studies have not been confirmed and the effects of inhaled NO on the sickle erythrocyte and hemoglobin remain controversial.

Nevertheless, a randomized, placebo-controlled trial of 20 patients demonstrated that inhaled NO reduced the duration of acute painful events in young patients and decreased the amounts of opioids used; further phase II trials of inhaled NO for acute painful events in adults and children are ongoing (NCT00094887 and NCT00142051).[227] Inhaled NO prevented some of the changes induced by hypoxia and reoxygenation in transgenic sickle mice.[228] Transgenic sickle cell mice treated with the NO-donor S-nitroso albumin showed decreased hypoxia-induced pulmonary injury based on lung histology and gene expression profiling.[229]

Therapies aimed at preserving eNOS-dependent NO production might have beneficial effects at several levels: 1) at the erythrocyte level, by possibly decreasing polymer formation, 2) at the leukocyte level by decreasing adherence, 3) at the platelet level by decreasing aggregation, 4) at the vascular level by increasing vasodilation and decreasing endothelial cell activation, and 5) at the inflammation level by inhibiting lipid peroxidation and oxidative stress. Because this line of research continues to yield insight into the mechanisms by which endothelial cells maintain eNOS function, new therapies targeting eNOS function could improve vascular function in both sickle cell disease and β thalassemia.

Apolipoprotein A-I Mimetics

As chronic increases in oxidative stress seem to be one of the primary mechanisms by which sickle cells impair vascular function, an alternative approach might be to protect vascular function by improving high-density lipoprotein (HDL) function. Recent reports indicate that small peptides, mimicking defined structures of apolipoprotein (Apo) A-I, improve vascular function[230] and decrease lesion formation in murine models of hypercholesterolemia.[231,232] When sickle mice were treated with L-4F, marked increases in endothelial- and eNOS-dependent vasodilation were observed.[230] Binding studies reveal that the 4F peptide has a 10,000 higher affinity for oxidized phospholipids than unaltered phospholipids.[233] This property is not shared by apo A-I. Such findings begin to explain why 4F, when added to plasma, partitions the HDL particle into two particles with the oxidized lipids accompanying 4F and the unaltered lipid remaining with the native HDL particle.[234] These studies indicate that the 4F acts as a molecular sponge preferentially binding oxidized phospholipids over native lipids. The importance of this unique property is that where an antioxidant might scavenge a lipid peroxide, the antioxidant has no mechanism to remove the modified lipid from the site of inflammation. In contrast, the 4F peptide not only binds oxidized lipids but also decreases their accumulation in vascular tissues and HDL.[235] Failure to remove the oxidized lipid species means that it is still able to induce inflammation in the vessel wall. For these reasons treatment of sickle mice and potentially patients with 4F represents a novel and effective means of decreasing the accumulation of oxidized lipids in the vessel wall and, therefore, improving endothelial- and eNOS-dependent NO production. Changes in the vessel wall might help attenuate vasoocclusive crises. Presently, L-4F is in phase II clinical trials for healthy volunteers and patients with coronary heart disease (NCT00568594).

Other apo A-I mimetics might also act by similar mechanisms. For example 37pA, a dimer of 18A, has been found to promote cholesterol efflux by an *ABCA1*-dependent and -independent mechanisms.[236] On the basis of these observations, this small peptide might also protect the vessel wall in animal models of vascular disease. Small, thiol-bearing peptides patterned after apo A-I_{Milano} have been shown to retain the antioxidant activity of the apo A-I_{Milano}.[237] No studies have been reported addressing the ability of these peptides to inhibit vascular disease in animal models.[237,238] Finally, synthetic HDL has been successfully used to decrease lesion size not only in animals but also humans;[239] however, the expense associated with producing sufficient quantities of recombinant HDL for chronic treatments precludes its use on a large scale.[240]

Statins

Pretreatment with lovastatin reduced significantly the expression of tissue factor expression after hypoxia–reoxygenation to induce ischemia–reperfusion injury in sickle transgenic mice.[161] It has been proposed that statins might be beneficial in sickle cell disease not only for their antiinflammatory properties but also for their ability to increase eNOS and eNOS-dependent production of NO.[241] These studies suggest a provocative new idea for using statins to treat sickle vasculopathy, based on the ability of statins to attenuate reperfusion injury and the effects of vasoocclusive-inducible factors.

Xanthine Oxidase Inhibitors

Vascular injury due to increased oxidative stress can occur through a number of different mechanisms. Based on histological studies showing depletion of xanthine oxidase in sickle cell disease mouse hepatocytes accompanied by increased xanthine oxidase staining of sickle cell disease mouse vascular endothelium, it was proposed that chronic and repeated bouts of vasoocclusive injury to the liver resulted in the release of hepatic xanthine oxidase stores and accumulation of endothelial-associated xanthine oxidase at distant sites.[242] As xanthine oxidase accumulates on the vessel wall, it creates a new region of increased superoxide anion production that subsequently increases

consumption of vascular NO and impairs vasodilation.[242] Likewise, release of myeloperoxidase from neutrophils increases the nitration of vascular surface tyrosine residues to increase vascular inflammation.[243] Although there are higher circulating levels of xanthine oxidase in both human and murine sickle cell disease with associated vascular injury[242] and evidence for oxidative injury in both sickle cell disease and thalassemia,[244] there have been no reported clinical trials testing the safety and efficacy of xanthine oxidase inhibitors as a therapeutic strategy for the treatment of individuals affected with either sickle cell disease or thalassemia.

Hypoxia–reoxygenation induces greater endothelial oxidant generation in sickle mice compared with controls, which was significantly reduced by antioxidant therapy.[201] Allopurinol, an inhibitor of xanthine oxidase activity, reduced the inflammatory effect of hypoxia–reoxygenation in sickle transgenic mice. Furthermore, pretreatment of these mice with superoxide dismutase and catalase inhibited the increased oxidant production and subsequent leukocyte accumulation following hypoxia–reoxygenation.[201] Although allopurinol might target xanthine oxidase and therefore superoxide, this study found that treating with superoxide dismutase and catalase at the onset of reoxygenation was more effective than allopurinol alone in restoring the microvascular flow and endothelial-dependent vascular function to control values.[201] The fact that superoxide dismutase and catalase effectively scavenge both superoxide anion and H_2O_2, the substrate for myeloperoxidase, during hypoxia suggests that the mechanisms by which sickle cell disease impairs vascular function are more complex than just an increase in xanthine oxidase and that broader approaches are needed to inhibit vascular oxidative stress effectively in sickle cell disease.

Antioxidant Therapy Targeting the Erythrocyte

Deferiprone (L1)

Increased lipid peroxidation and protein thiol oxidation due to generation of reactive oxygen species could also arise from an increase in intracellular iron levels and unstable heme moieties in both sickle and thalassemic erythrocytes.[211,245] Thus, the membrane abnormalities observed in these erythrocytes might be in part due to iron-mediated oxidative damage.[246] Accordingly, agents that target free iron and protect the erythrocyte from oxidative damage should be of therapeutic benefit in both sickle cell disease and thalassemia. Deferiprone (L1) is an oral iron-chelating agent with an enhanced ability to permeate cell membranes (Chapter 29). Therefore, L1 should limit iron-mediated oxidative damage to the erythrocyte membrane. Preincubation of erythrocytes with L1 effectively reduced H_2O_2-mediated damage to both sickle and thalassemic erythrocyte membranes.[247] Furthermore, treatment of six patients with β thalassemia with L1 reduced membrane free iron and reduced lipid peroxidation and malonyldialdehyde production in their erythrocytes.[247] These data demonstrate that binding free iron removes what appears to be a significant portion of redox-active iron from erythrocyte membranes and in so doing significantly attenuates free iron–mediated oxidant damage.

Oral Glutamine

Sickle erythrocytes cells have decreased levels of reduced nicotinamide adenine dinucleotide (NADH) and increased total NAD+.[248] Sickle cell disease patients with pulmonary hypertension had decreased levels of GSH and glutamine. It was hypothesized that defects in GSH and glutamate metabolism were involved in red cell hemolysis and NO consumption.[249] Supplementation with a precursor of NADH, L-glutamine, might increase NADH in sickle erythrocytes.[250] Oral L-glutamine therapy increased NADH levels in sickle erythrocytes and was associated with a subjective improvement in chronic pain and energy level of patients.[251,252] These data suggested that glutamine could play a role in increasing sickle erythrocytes defenses against oxidative damage with attendant positive clinical effects. Although the mechanism for this improvement is unclear, it was postulated that glutamine might act an antioxidant through the GSH pathway.[252] L-glutamine therapy also reduces sickle erythrocyte adhesion to cultured endothelial cells, providing additional potential therapeutic benefit.[251] Although the exact mechanisms by which glutamine supplementation improves erythrocyte function are not known, glutamine-induced increases in NADPH might help restore erythrocyte GSH levels.[249]

Oral N-Acetyl-Cysteine Therapy

Reduced GSH is key factor for the antioxidant activity of erythrocytes. Its depletion might contribute to the increase in oxidative damage in both sickle cell disease and thalassemia. N-acetyl-cysteine is an effective precursor of cysteine for cellular GSH synthesis.[253] Several other antioxidants such as vitamin C and vitamin E have also been shown to decrease oxidative damage in sickle cell disease, suggesting that antioxidant treatment of patients with sickle cell disease could reduce oxidative damage to blood cells and the vasculature, thus potentially reducing sickle cell–induced pathologies.[254,255] In sickle cell disease, in vitro studies have found that N-acetyl-cysteine blocked dense cell and irreversible sickle cell formation in vitro.[256,257] A phase II double-blind, randomized clinical trial found that N-acetyl-cysteine therapy reduced sickle dense cell, but not irreversible sickle cell formation, and enhanced erythrocyte GSH levels.[258] N-acetyl-cysteine was also associated with a reduction in the frequency of vasoocclusive episodes.[258] Because N-acetyl-cysteine has minimal toxicity and is inexpensive, it is a good candidate for future phase III clinical studies in human sickle cell disease.

Based on the aforementioned preliminary studies, targeting oxidant generation might constitute another promising therapeutic approach for the treatment of both erythrocyte and vascular dysfunction in sickle cell disease.

CONCLUSION

Therapeutic approaches to reduce the incidence and severity of vascular obstruction and hemolysis in sickle cell disease are derived from the current knowledge of the disease pathophysiology and will continue to evolve. Murine models of hemoglobin disorders have been essential to accelerate answers to specific questions and confirm proof of principle in vivo, before performing clinical trials. Now it is possible to change a single genetic or treatment factor in transgenic mice to modulate the expression of the disease and to define or confirm therapeutic targets. The major studies to date have been designed to reduce the primary event of HbS polymerization, including antisickling agents, induction of HbF synthesis, and rehydration of the sickle erythrocyte. Therapies designed to ameliorate the more complex secondary pathological effects of HbS, including the enhanced adhesive properties of the sickle erythrocyte, the severe vascular pathologies and the increased activity of the coagulation and inflammatory pathways are in promising initial stages of investigation. Because the vascular dysfunction and organ pathologies observed in sickle cell disease and thalassemia are the culmination of a complex multifactorial process, short of a genetic cure, an array of therapies, targeting both the abnormal erythroid cell and the myriad secondary vascular and systemic pathologies, should be beneficial for improving the survival and function of diseased erythrocytes, organ function and life expectancy and the quality of life in the many individuals who suffer from severe hemoglobin disorders.

INTRODUCTION

Homozygous β thalassemia is characterized by absent or defective β-globin chain synthesis. This defect causes imbalance in chain production and accumulation of unstable α-globin tetramers in red blood cells or their precursors, leading to intramedullary destruction, apoptosis and hemolytic anemia (chapter 17). Regular transfusions and iron chelation has, in developed countries, transformed this disease from one fatal in infancy to a chronic disease with prolonged survival.[1–3] Medical treatment is expensive and requires a complex multidisciplinary approach. In underdeveloped countries, where most patients reside, thalassemia remains fatal early in life because of poor access to modern medical treatment. Curing β thalassemia by hematopoietic cell transplantation, with the cost efficiencies inherent in this approach, is therefore an attractive option.

As in β thalassemia major, the objective of hematopoietic cell transplantation for sickle cell disease is to replace recipient erythropoiesis, or to reduce its clinical impact, by the expression of donor β-globin chains. The clinical benefit of this cellular replacement is the elimination, or significant amelioration, of the clinical complications caused by polymerized sickle hemoglobin. More than a decade ago, the initial clinical trials of hematopoietic cell transplantation for sickle cell disease indicated that the replacement of donor for sickle erythropoiesis might eliminate not only the hematological manifestations of the underlying disorder, but also stabilize and even reduce the organ damage caused by recurrent vasoocclusion occlusion and hemolysis.[4–7] As in malignant disorders, there is utility in assigning a risk-based approach to applying transplantation for sickle cell disease. Unfortunately, defining risk characteristics is difficult in the absence of randomized, prospective trials that compare therapeutic interventions among high-risk patients. Nonetheless, the appropriate broader application of hematopoietic cell transplantation hinges on three important objectives. The first is to identify those patients who have the greatest risk of developing sickle-related complications and who are most likely to benefit from hematopoietic cell transplantation. The second is to reduce transplant-related complications by minimizing the short- and long-term toxicities of hematopoietic cell transplantation, but in such a way that does not diminish the likelihood of a successful transplantation outcome. The third, which is common to sickle cell disease and β thalassemia, is to increase the availability of hematopoietic cell transplantation to potential recipients by expanding the pool of suitable donors, either by using alternate sources of hematopoietic stem cells or by overcoming human leukocyte antigen (HLA) disparity and its formidable barrier to donor–host immunological tolerance.

HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR β THALASSEMIA

In simple terms, the purpose of treating β thalassemia by allogeneic hematopoietic stem cell transplantation is to affect a "cure," that is, to replace ineffective erythropoiesis with effective erythropoiesis capable of producing sufficient number of circulating red cells that contain an adequate amount of hemoglobin. This simple statement, however, implies several major problems, which are biological, clinical, and ethical.[8]

The First Cases

In December 1981, a 14-month-old child with β thalassemia, who had undergone transfusion with a total of 250 mL of packed red blood cells, received a bone marrow transplant in Seattle, Washington from his HLA identical sister.[9] The transplant was successful and the patient is now more than 25 years old and in excellent health without any manifestations of β thalassemia. Two weeks later, a 14-year-old patient with advanced thalassemia who had received more than 150 red blood cell transfusions underwent transplantation in Pesaro, but had recurrence of β thalassemia after rejection of the graft.[10]

The Pesaro Experience

In the early 1980s, the initial Pesaro studies were concentrated on patients with advanced β thalassemia. Of the first six patients who were aged 16 years or older and who underwent transplantation after receiving high doses of cyclophosphamide and total body irradiation, four died of causes related to graft-versus-host disease (GVHD) within the first 100 days; one died of infection 235 days after hematopoietic cell transplantation; and one had recurrence of thalassemia 48 days after hematopoietic cell transplantation, dying of thalassemia-related cardiac disease more than 6 years later.[10]

In view of this experience, subsequent studies concentrated on enrolling patients who were younger than 17 years. Results in young patients were encouraging[10–12] and in 1990 the Pesaro group reported experience through August 1988 in treating 222 consecutive patients younger than 16 years.[13] All of these patients received HLA-identical marrow allografts: in 10 cases from parents and in the other cases from siblings. All patients were prepared for transplantation after conditioning with regimens that contained busulfan (14 mg/kg) and cyclophosphamide (200 mg/kg). In this series, the probabilities of survival and thalassemia-free survival plateaued after 1 year at 82% and 75%, respectively.[13] Analysis of the influence of pretransplant characteristics on the outcome of transplantation was conducted in 116 patients who were all treated similarly. This analysis demonstrated that hepatomegaly and portal fibrosis were associated with a significantly reduced probability of survival. In a multivariate analysis, history of poor compliance with iron chelation therapy could not be distinguished from hepatomegaly as a predictor of survival and thalassemia-free survival. The influence of pretransplant characteristics on the outcome of transplantation was reexamined in late 1989[14] by which time 161 patients younger than 17 years had been treated with the same regimen. The quality of chelation therapy was characterized as regular when deferoxamine therapy was initiated not later than 18 months after the first transfusion and administered subcutaneously for 8–10 hours continuously for at least 5 days each week. Chelation therapy was defined as irregular for any deviation from this requirement. The degree of hepatomegaly (> or <2 cm), the presence or absence of portal fibrosis in the pretransplant liver biopsy,[15] and the quality of chelation (regular or irregular) given through the years before transplantation were identified as variables permitting the categorization of patients younger than 17 years into three risk classes: class 1 patients had none of these adverse risk factors; class 3 patients had all three; and class 2 patients had one or two adverse risk factors.

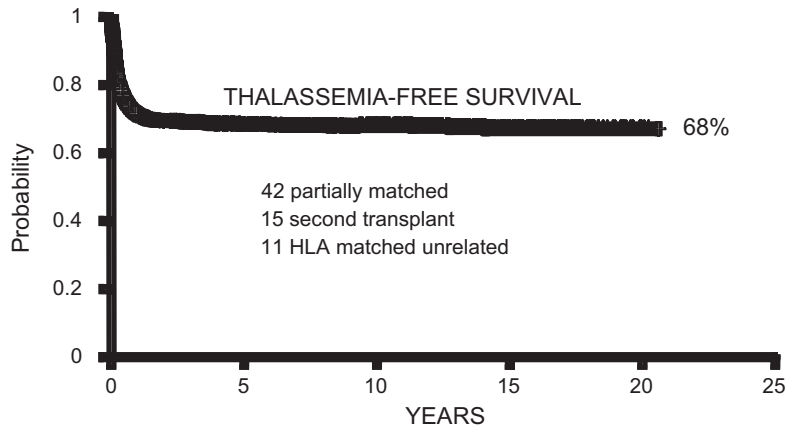

Figure 32.1. A total of 1,003 consecutive thalassemia patients between the ages of 1 and 35 years underwent transplantation in Pesaro from 1981 to January 2003. This survival curve includes 950 patients who underwent transplantation from an HLA-identical donor, 42 patients from a partially matched-related donor, and 11 from a matched-unrelated donor.

Between 17 December 1981 and 31 January 2003, a total of 1,003 consecutive patients, aged from 1 to 35 years, underwent transplantation in Pesaro (950 from an HLA-identical related donor, 42 from partially matched related donor, and 11 from a matched unrelated donor). Overall, the greater than 20-year Kaplan–Meier probability of thalassemia-free survival was 68% (Fig. 32.1).[16]

With regard to predictors of transplant outcome, patients younger than 17 years were stratified on the basis of the risk factors of hepatomegaly, a history of irregular chelation, and hepatic fibrosis. Class 1 (low risk) and 2 (intermediate risk) patients underwent transplantation after conditioning with the combination of busulphan (14 mg/kg) and cyclophosphamide (200 mg/kg). This conditioning regimen has remained unmodified since 1985. Class 3 patients (advanced disease) underwent transplantation based on protocols that included lower dosages of cyclophosphamide (120–160 mg/kg). These results are shown in Table 32.1. Transplantation in class 3 children, with treatment of a reduced dose of cyclophosphamide, was characterized by a 30% risk of thalassemia recurrence.[17] In contrast, in adults with the same dose of cyclophosphamide, thalassemia recurrence was only 4%, but there was a 35% transplant-related mortality.[18]

Because class 3 children had the problem of thalassemia recurrence whereas adults had the problem of transplant-related mortality, a new preparative regimen was introduced for class 3 patients with the aim of increasing the rate of sustained engraftment while decreasing transplant-related mortality. This regimen was characterized by a 30-day preconditioning period designed to produce erythroid cytoreduction and immunosuppression before a conditioning regimen using a reduced dose of cyclophosphamide. In a pilot study of 33 consecutive class 3 thalassemia children, the 5-year Kaplan–Meier probability of survival and disease-free survival was 93% and 85%, respectively.[19]

Table 32.1. Transplant outcome. Pesaro results in children and adults

Class of risk	Regimen	% Survival	% Thalassemia-free survival
1	Bu 14-Cy 200	93	90
2	Bu 14-Cy 200	87	84
3	Bu 14-Cy 120–160	79	58
Adults	Bu 14-Cy 120–160	66	62

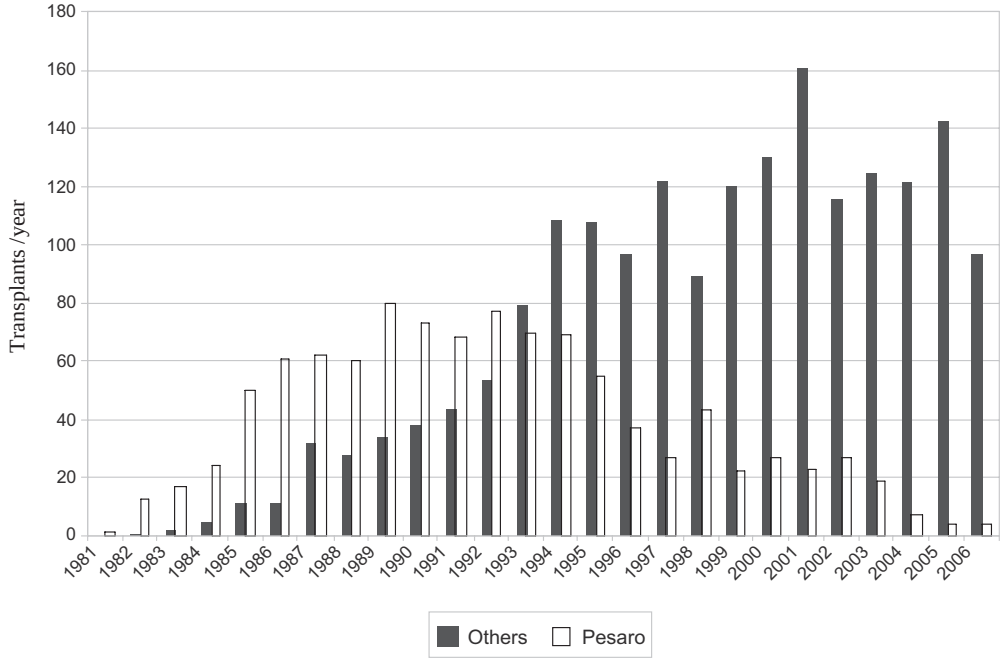

Figure 32.2. Hematopoietic stem cell transplants for hemoglobinopathies performed between 1981 and 2006 in centers reporting data to the European Group for Blood and Bone Marrow Transplantation. Transplants performed in Pesaro versus all other centers (2006 data incomplete).

ALTERNATIVE SOURCE OF HEMATOPOIETIC STEM CELLS

The results reported in the previous section were obtained using bone marrow derived, unmanipulated hematopoietic stem cells, and today, most centers continue to use bone marrow hematopoietic stem cells in lieu of mobilized peripheral blood progenitor cells. From a survey conducted by the European Group for Blood and Bone Marrow Transplantation (unpublished data), approximately 10% of the transplants performed for hemoglobinopathies involved the use of mobilized peripheral blood progenitor cells. Even in the absence of a randomized clinical trial to compare these two sources of hematopoietic cells in thalassemia, it is reasonable to predict that a reduced incidence of chronic GVHD is a very good reason to choose bone marrow hematopoietic stem cells for this nonmalignant disorder for which GVHD offers no benefit.

Recently confirmatory results have been reported when using cord blood as a source of HLA genotypically identical hematopoietic stem cells for class 1 and 2 children[20] with a 2-year survival and disease-free survival of 100% and 79%, respectively.

Reduced-intensity Transplants

Because of the excellent results of conventional transplantation for β thalassemia, no systematic study of reduced-intensity or nonmyeloablative transplantation has been reported. The relatively high incidence of thalassemic recurrence in children after conventional myeloablative hematopoietic stem cell transplantation[16] makes it is reasonable to suppose that a nonmyeloablative regimen will have to contend with very high frequencies of thalassemic recurrence. If an investigation is to be proposed, additional tools to ensure sustained engraftment such as donor lymphocyte infusions will probably be necessary.

Experience of Other Transplant Centers

Following the Pesaro experience, hematopoietic cell transplant programs for thalassemia have been established in several parts of the world where the disease is prevalent. Overall, approximately 80% of patients survive long term and of these, nearly 90% are "cured."[21]

The recently developed hemoglobinopathy registry of the European Group for Blood and Bone Marrow Transplantation provides demonstration of the diffusion of the procedure worldwide (Fig. 32.2). Preliminary outcome data analyses confirm reproducibility of Pesaro Class of risk in a multicentric setting and demonstrate a 90% 5-year survival rate for patients who underwent transplantation in the 1990s.

Alternative Donors

Approximately 60%–70% children with β thalassemia do not have HLA-identical family members[22] and therefore are not candidates for transplantation. Expanding the number

of available donors would have a major impact on the management of this disease.

HLA-nonidentical Related Donor Transplant. The use of HLA-nonidentical family member donors in the treatment of β thalassemia has not been comprehensively studied in recent years because the results in leukemia were not sufficiently promising to justify a large trial. The results reported are anecdotal and therefore it is difficult to extrapolate useful information.

As of December 1998 in Pesaro, 29 thalassemia patients were transplanted from a family member donor who was not an HLA-identical sibling. The number of mismatched HLA antigens was one in 15 cases, two in five cases, and three in three cases. Results have been unrewarding, with only six successes, 10 transplant-related deaths, and 13 patients who had recurrence of thalassemia.[23]

Between 1969 and 1996, 60 cases were reported by 22 different teams to the International Bone Marrow Transplant Registry but only 11 (17%) underwent transplantation after 1993. Forty-seven of the 60 patients survived and 16 of the survivors had recurrence of thalassemia. In this group of 60 patients, 24 received a transplant from an HLA phenotypically matched parental donor, 11 had related donors with one HLA mismatch, and four had donors with two HLA mismatches.[24] Although most of these patients would not have benefited from improved supportive care techniques and DNA typing technologies that were established after 1993, it is clear that HLA-mismatched related donor transplantation is not a favored option at present in the early management of patients who can access and tolerate medical therapy. A pilot study involving the use of the mother as an HLA haploidentical donor is ongoing but results have not yet been published.

Transplant From Matched Unrelated Donors. Unrelated donor transplantation has significant potential in thalassemia because of the possibility for many patients to remain healthy for a long time under medical treatment until an "optimal" hematopoietic stem cell donor is identified. In recent years, improvements in HLA typing technology, improved control of GVHD and infectious diseases, and expanded pools of unrelated volunteer donors together have generated significant improvements in the outcome after unrelated marrow transplantation in patients affected by malignancies and by inborn errors of metabolism. In leukemia, unrelated transplant results are now very similar to those achieved using an related HLA-identical donor. On the basis of this finding, an investigation of HLA-matched unrelated donor transplantation for β thalassemia that included six Italian transplant centers was established in 1996. Patients with pretransplant evidence of cirrhosis or cardiac disease were excluded, and a high degree of histocompatibility between patient and the potential donor was required. The clinical trial also required extended HLA–haplotype identity, which means that matching donor/recipient HLA alleles extending from locus HLA-A to locus HLA-Dq on the same chromosome is required.

Thus far, 68 patients (median age 15, range 2–37 years) have been transplanted in the unrelated donor trial. With a median follow-up of 30 months, nine patients (13%) had recurrence of thalassemia, 14 (20%) died, and 45 (67%) had successful transplants.[25] The incidence of acute GVHD grades II–IV was 40% and that of chronic GVHD 18%. After a median follow-up of 40 months, overall and disease-free survival rates were 79% and 65%, respectively. In the 30 patients who were classified as class 1–2, overall survival and disease-free survival rates were both 97%. These data confirm the relevance of the patients' condition to transplant outcome in the setting of matched-unrelated and matched-related donor transplant, and once again, emphasize the adverse clinical characteristics of advanced thalassemia major. Nevertheless, hematopoietic cell transplantation from HLA-matched unrelated donors is still an approach that should be limited to experienced transplant centers. As a public health issue, the probability of finding a closely matched unrelated marrow donor would be higher than in the general population if representative marrow donor registries were established in areas with the highest incidence of thalassemia.

The Thalassemia Patient Undergoing Bone Marrow Transplantation

Patient Selection and Classes of Risk. All patients who require chronic red cell transfusions are potential candidates for hematopoietic cell transplantation. Patients with advanced liver [Child–Pugh grades B–C] and cardiac disease are ineligible for transplantation. Thalassemia intermedia patients can be considered for marrow transplantation in selected situations.[26]

The development of a regimen of regular transfusions combined with regular iron chelation therapy has transformed the prognosis for thalassemia children in industrialized countries from a disease fatal in infancy to a chronic disease permitting prolonged survival.[27–29] The critical factor for survival of thalassemic patients undergoing transfusion and chelation therapy is control of the iron overload (Chapter 29). If good compliance is achieved with chelation therapy, iron overload can be controlled but not abolished.[1,3,30] Nevertheless, hematopoietic cell transplantation remains the only definitive curative approach and any clinical decision must be approached with this assumption.

Classification of patients in pretransplant classes of risk permits an assessment of an individual's probability of "cure" by hematopoietic cell transplantation independent of the patient's response to treatment, and therefore adequate information can be obtained from survival curves. The clinical significance of the Pesaro classification has sometimes been misinterpreted. This classification was developed for transplant purposes only and reflects

progression of disease severity. Although it is based primarily on the liver status, it does not predict a liver-related cause of death. Liver status must be considered as a "window" on the patient's global health situation. A major criticism of the Pesaro classification is that two of the variables, chelation and hepatomegaly, are qualitative and subject to intra- and interobserver variability.[31] This is a valid criticism and quantitatively defined risk factors based on a defined unit of measure would obviously increase the precision and accuracy of the classification. It is hoped that such criteria could be introduced in the future, but so far all attempts to identify such criteria have failed. Variables such as serum ferritin or hepatic iron concentration did not achieve significance in the statistical analyses as predictors of transplant outcome. This reflects the complexity in assessing the global clinical condition of a thalassemic patient. Any quantitative laboratory value reflecting iron overload, for example, serum ferritin or hepatic iron concentration, reflects the situation at a certain moment in life and does not necessarily reflect the impact on tissue damage of years of exposure to a toxic element like iron.

The inclusion of a patient in class 2 and particularly, in class 3, represents failure of conventional therapy and this reflects the clinically progressive nature of the disease whose optimal treatment is based on a delicate balance among the degree of anemia, body iron content, and iron chelation.

Recurrence of Thalassemia. In a variable percentage of cases, the patient can reject the graft. Rejection can be followed by persistent marrow aplasia or by return of thalassemia. The first situation is relatively rare and can be reversed only with a second transplant. By analogy to the behavior of malignant tissue, it might be supposed that a largely expanded hematopoietic tissue mass would be difficult to eradicate and likely to recur after transplantation. Leukemic relapse is, however, characterized by the reappearance of leukemia in the presence of a persistent immune system of donor origin. In contrast, the return of thalassemia usually occurs in the context of a return of host-type immune reconstitution. This event has aspects of both rejection and relapse.

Mixed Chimeric State. An important finding that became evident during the Pesaro transplant experience was the demonstration that in a significant group of patients, the clinical control of the disease was achieved with a partial engraftment. This defines mixed chimerism – the simultaneous presence in the bone marrow of cells of both donor and host origin. Although early chimerism is a risk factor for thalassemia recurrence, late chimerism, detected at least 2 years after transplantation, is a stable condition called persistent chimerism.[32] All 31 patients with persistent chimerism studied yearly for up to 11 years of follow-up had stable engraftment. Despite limited allogeneic engraftment – some patients had only 20% donor cells – these patients had normal hemoglobin values, were transfusion free, and had no signs of ineffective erythropoiesis.[32]

Effect of Bone Marrow Transplantation on Thalassemia

Transplantation in thalassemia provides what appears to be a permanent cure of the marrow defect in nearly all patients. Thalassemia patients who have acquired normal bone marrow as a result of transplantation cannot be accurately described as "cured" per se. They have homozygosity for the mutant gene in every cell of the body except in the hematopoietic cells and carry all the clinical complications there were acquired during years of transfusion and chelation therapy before transplantation. The treatment of patients with thalassemia is not always completed after a successful hematopoietic cell transplant has been achieved. Good health and a normal life expectancy can only be achieved after the organ damage acquired during years with thalassemia and its treatment is reversed. These features are mainly iron overload and hepatitis C virus infection. Thus, the care of patients after transplantation should be divided into transplant-related complications and thalassemia-related complications.

Transplant-related Complications. Transplant-related complications include chronic GVHD and secondary malignancy. The most serious long-term marrow transplant complication is GVHD, which is associated with significant morbidity and mortality. A retrospective study was performed in Pesaro that included 734 consecutive thalassemic patients, 614 of whom were evaluable for chronic GVHD.[33] The overall incidence of chronic GVHD was 27.3% (168 of 614 evaluable patients). The probabilities of mild, moderate, and severe chronic GVHD were 20%, 8%, and 2%, respectively. In 67% of the affected patients, chronic GVHD was limited and in 33% it was extensive. No difference in incidence was observed among the three classes of risk. Of the 168 patients who developed chronic GVHD, 85.1% recovered from the complication, 8.9% died, and 6% were still being treated at the end of the study.

As of August 2005, four cases of early malignancies, defined as occurring within the first year after transplantation, were recorded in patients from Pesaro. These included three cases of B-cell lymphoproliferative disease and one case of cardiac myxoma. Two of the patients with lymphoproliferative disease died of progressive disease and one is alive and well more than 15 years after radiotherapy. The patient with cardiac myxoma died 6 years later in a car accident while in continuous remission after surgical removal of the tumor.[34] Five cases of late, solid tumors have been recorded. One patient developed Kaposi sarcoma while receiving treatment for mild chronic GVHD that spontaneously reversed after discontinuation of immunosuppressive therapy.[35] A second patient with chronic GVHD developed lip spinocellular cancer and died of progressive cancer 13 years after hematopoietic cell transplantation. Another patient with resolved mucosal chronic GVHD developed lip carcinoma 17 years after transplantation. Two other cases were registered in patients without chronic GVHD (one osteochondroma and one colon cancer 7 and

20 years after transplantation, respectively). These last three patients are alive and well after combined surgical and medical treatment. Overall, the incidence of secondary solid tumors in thalassemia after transplantation is less than 10/100,000 patient-years, a rate that does not appear higher than that reported in patients undergoing medical treatment for β thalassemia.[36–38] These findings are consistent with data reported by the International Bone Marrow Transplant Registry; patients undergoing hematopoietic cell transplantation for nonmalignant diseases had an incidence of secondary malignancies that was not significantly increased when compared with the expected value in the normal population.[39] Thus, a concern about late malignancy is not a reason to deny transplantation.

Thalassemia-related Complications. Thalassemia-related complications are those acquired during years of thalassemia and its treatment.

Iron Overload

Hematopoietic cell transplantation will not eliminate excess iron acquired during treatment.

Iron overload causes significant morbidity and mortality and progression of liver disease to cirrhosis after transplantation has been documented.[40,41] A prospective analysis of annual liver biopsies in patients not treated by iron chelation and in whom thalassemia was cured by hematopoietic cell transplantation demonstrated that iron overload and hepatitis C virus infection were independent and mutually reinforcing risk factors for progressive liver fibrosis. Patients who were hepatitis C virus positive and also had very high levels of hepatic iron had an 80% risk of developing progressive hepatic fibrosis 10–12 years after successful transplantation. Conversely, patients with a liver iron level less than 16 mg iron/g liver dry weight and who were also free of evidence of active hepatitis C virus infection,showed no signs of progressive hepatic fibrosis.

Due to the presence of normal erythropoiesis, phlebotomy in the posttransplant thalassemia recipient appeared to be the appropriate method for rapidly removing excess iron.[42] Phlebotomy is safe, inexpensive, and highly efficient, and therefore it is the treatment of choice in this situation even in patients who received a transplant from a donor with thalassemia minor. With this approach, excess iron can be completely mobilized from the body without any relevant side effect (Figs. 32.3 and 32.4). Following completion of the phlebotomy program, significant improvement in liver function was observed, particularly in patients infected with hepatitis C virus.[42] Several cases of reversion of pretransplant severe hepatic fibrosis and even early cirrhosis have been reported.[43] Patients with early cardiac involvement characterized by left ventricular diastolic dysfunction and impaired left ventricular contractility demonstrated regression of subclinical cardiac disease after iron depletion.[43] In posttransplantation thalassemic patients with high iron levels who cannot be treated by phlebotomy because of young age or difficult peripheral venous access, daily subcutaneous administration of desferrioxamine has proved to be useful in reducing iron stores.[44] Because of the development of deferasirox, an effective oral chelator with no reported marrow toxicity (Chapter 29) there is no reason to use desferrioxamine as a second-line therapy for patients who cannot have repeated phlebotomies.

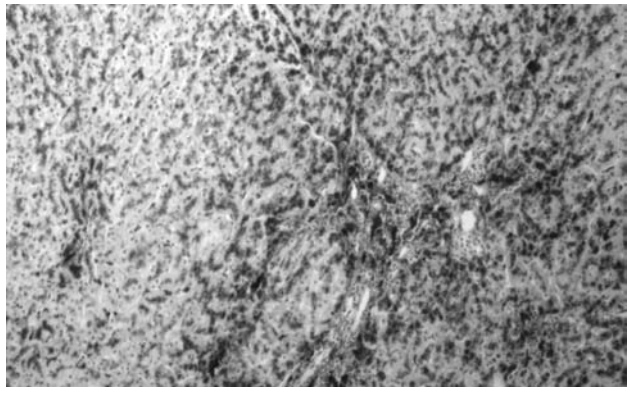

Figure 32.3. Pretransplant liver biopsy of a thalassemia patient. The biopsy was prepared using Perls technique. Hepatic iron concentration was 23 mg/g dry weight. (See color plate 32.3.)

Hepatitis

After hematopoietic cell transplantation, patients with thalassemia have a life expectancy that approaches normal, and mild chronic liver disease has to be considered with this perspective. Viral liver disease is probably the only significant factor that might limit survival in ex-thalassemics, thus avoiding progression of liver damage and cirrhosis in follow-up over 20–30 years is fundamental. In approximately half of hepatitis C–seropositive patients, transaminase levels normalized and the histological activity index significantly improved after iron depletion,[45] resulting in the dilemma of whether to recommend interferon therapy

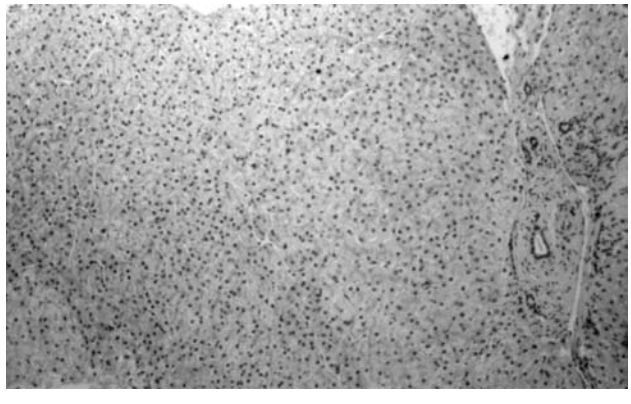

Figure 32.4. Liver biopsy (Perls technique) of the same patient as in Fig. 32.3 years after BMT. Hepatic iron concentration was 1.41 mg/g dry weight, normal value <1.6 mg/g (Weinfeld, 1964). The patient had been treated by a course of sequential phlebotomies starting during the third year after transplant. (See color plate 32.4.)

routinely. Also, in patients presenting with active hepatitis after iron removal, interferon treatment has proven to be a rational approach several years after transplant, with a success rate not different from that obtained in the normal population.[46] The absence of thalassemia and of iron overload makes it easier to treat other complications such as viral hepatitis, somewhat contradicting the assessment that the "cure" of thalassemia by transplantation does not modify the other complications acquired before hematopoietic cell transplantation.[31]

Endocrine Dysfunction

Hypogonadism is the most common endocrine disorder in medically treated patients with thalassemia major, affecting approximately half the patients.[47,48] In a study involving 68 children after hematopoietic cell transplantation, 32% reached an advanced or complete puberty spontaneously (34% of girls and 63% of boys),[49] despite clinical and hormonal evidence of gonadal impairment in most cases. In this group, iron overload and the conditioning regimen were the major factors influencing endocrine function. Preliminary observations in young children who undergo transplantation in the early phase of thalassemia indicate a good prognosis for growth and fertility. In a case report, a woman who was treated at age 10 years became pregnant naturally and delivered a healthy child.[50] Subsequently, five young men and four young women had normal and spontaneous paternity/maternity 3–12 years following allogeneic hematopoietic cell transplantation.

Impaired glucose tolerance and diabetes mellitus are common complications of iron overload. The administration of busulfan, cyclophosphamide, and cyclosporine after transplantation did not appear to have an adverse affect on pancreatic β cell function. In a prospective, unpublished study of 93 patients, only three with impaired oral glucose tolerance test and cirrhosis before transplant demonstrated worsening of glucose intolerance, whereas more than half of those with impaired glucose tolerance before transplant demonstrated improved pancreatic β cell function after transplantation.

HEMATOPOIETIC CELL TRANSPLANTATION FOR SICKLE CELL DISEASE

Unlike β thalassemia major, where the genotype directs a reasonably reliable phenotype in the vast majority of cases, the clinical expression of sickle cell anemia is quite variable and difficult to predict based upon the hemoglobin genotype alone (Chapter 27). Thus, in standard practice, hematopoietic cell transplantation for sickle cell disease currently is reserved almost exclusively for patients with clinical features that portend a poor outcome or significant sickle-related morbidity, in part due to the toxicity of this intensive therapy.[51] These clinical indications, which were adapted from the multicenter investigation of bone marrow transplantation for sickle cell disease, are listed in Table 32.2. These criteria have been applied almost exclusively to children, for whom the risk–benefit ratio is most advantageous in terms of years-of-life gained among those who survive with sustained engraftment of donor cells. Less certain is how to apply inclusion criteria to adults with sickle cell anemia, in whom the experience of transplantation is limited, but for whom the risk of significant transplantation-related toxicity remains substantial. For all patients, clinicians must carefully weigh therapeutic alternatives to hematopoietic cell transplantation, with particular attention to safety, efficacy, availability, and the cost of intervention.[52–55]

Table 32.2. Indications of hematopoietic cell transplantation for sickle cell disease

Patients with sickle cell anemia or HbS–β^0 thalassemia, aged <16 y
One or more of the following complications:
Stroke or central nervous system event lasting >24 h
Impaired neuropsychological function with abnormal cerebral MRI and angiography
Recurrent acute chest syndrome
Stage I or II sickle lung disease
Recurrent vasoocclusive painful episodes or recurrent priapism
Sickle nephropathy (glomerular filtration rate 30%–50% of predicted normal)
Other indications to consider:
Abnormal transcranial Doppler
Pulmonary hypertension
Silent cerebral infarction

Current Results of Hematopoietic Cell Transplantation for Sickle Cell Disease

The worldwide experience of conventional myeloablative hematopoietic cell transplantation for sickle cell disease is summarized in Table 32.3.[5–7,57,59,60,63] In the collective experiences of these studies, the transition of hematopoietic cell transplantation from an experimental intervention reserved for severely affected patients, to one in which younger children with early signs of sickle-related morbidity are targeted, has been observed. Several series in Europe and North America have reported very similar results after HLA-identical sibling transplantation.[4,5,7] The principal aim of these multicenter clinical studies was to define more completely the risks and benefits of this therapy, and to characterize the natural history of those surviving free of sickle cell disease. The results of transplantation were best when performed in children with sickle cell disease who had HLA-identical sibling donors. Even though many children who received allografts had significant sickle-related complications such as stroke and recurrent episodes of acute chest syndrome, the disease-free

survival rate was 80%–85% in several series; however, 5%–10% of patients died of complications related to transplantation, with GVHD and its treatment the leading cause of death.

In the multicenter investigation of hematopoietic cell transplantation for sickle cell disease, 59 children aged between 3.3 and 15.9 years (median 9.9 years) received HLA-identical sibling allografts between September 1991 and April 2000.[7] Patients received a myeloablative combination of busulfan, cyclophosphamide, and equine antithymocyte globulin, and most received a combination of methotrexate and cyclosporine after hematopoietic cell transplantation to prevent GVHD. Fifty of 59 children survive disease-free after hematopoietic cell transplantation. The Kaplan–Meier probabilities of survival and disease-free survival are 93% and 84%, respectively (Fig. 32.5). A recent publication from the Center for International Blood and Marrow Transplantation Research reported very similar results.[59] Outcomes after HLA-matched sibling hematopoietic cell transplantation in 67 patients with sickle cell disease between 1989 and 2002 were described, in which the leading indications for transplantation were stroke and recurrent vasoocclusive crisis occurring in 38% and 37% of patients, respectively. The median age at transplantation was 10 years. Ninety-two percent received busulfan and cyclophosphamide in the conditioning regimen and bone marrow was the predominant source of hematopoietic cells. Most patients achieved hematopoietic recovery and there were no deaths during the early post transplantation period. Rates of acute and chronic GVHD were 10% and 22%, respectively. Sixty-four of 67 patients are alive; 5-year probabilities of disease-free and overall survival rates are 85% and 97%, respectively.

Results among 101 patients who received conventional myeloablative HLA-identical sibling hematopoietic cell transplantation in Europe were remarkably similar, with an overall survival probability of 88% and disease-free survival rate of 80%.[5] A recent update included 87 consecutive patients treated between November 1988 and December 2004 at 14 centers in France.[60] The median age was 9.5 years and the leading indication for hematopoietic cell transplantation was stroke or transient ischemic attack (n = 36) and the development of abnormal cerebral arterial flow velocity as detected by transcranial Doppler flow studies (n = 8). Five of the 18 patients who did not receive antithymocyte globulin had graft rejection. One patient with 50% mixed chimerism developed aplastic anemia 15 months posttransplantation and received a second successful allograft, whereas the other four patients had autologous reconstitution and recurrent sickle cell disease. The rate of

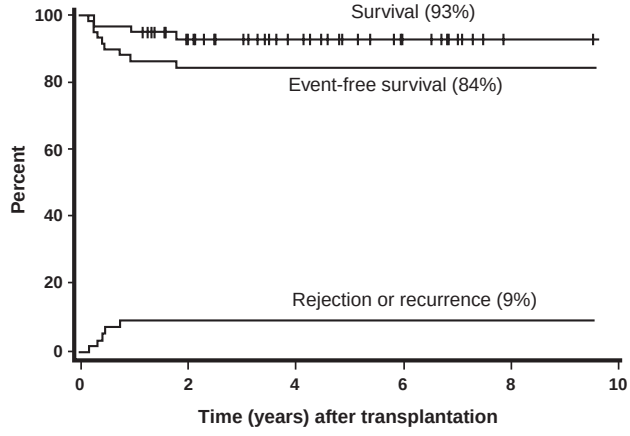

Figure 32.5. Kaplan–Meier estimates of survival and event-free survival after hematopoietic cell transplantation for sickle cell anemia. Events were defined as death, sickle cell disease recurrence, and graft rejection. A cumulative incidence curve for graft rejection and return of sickle cell disease is also shown.

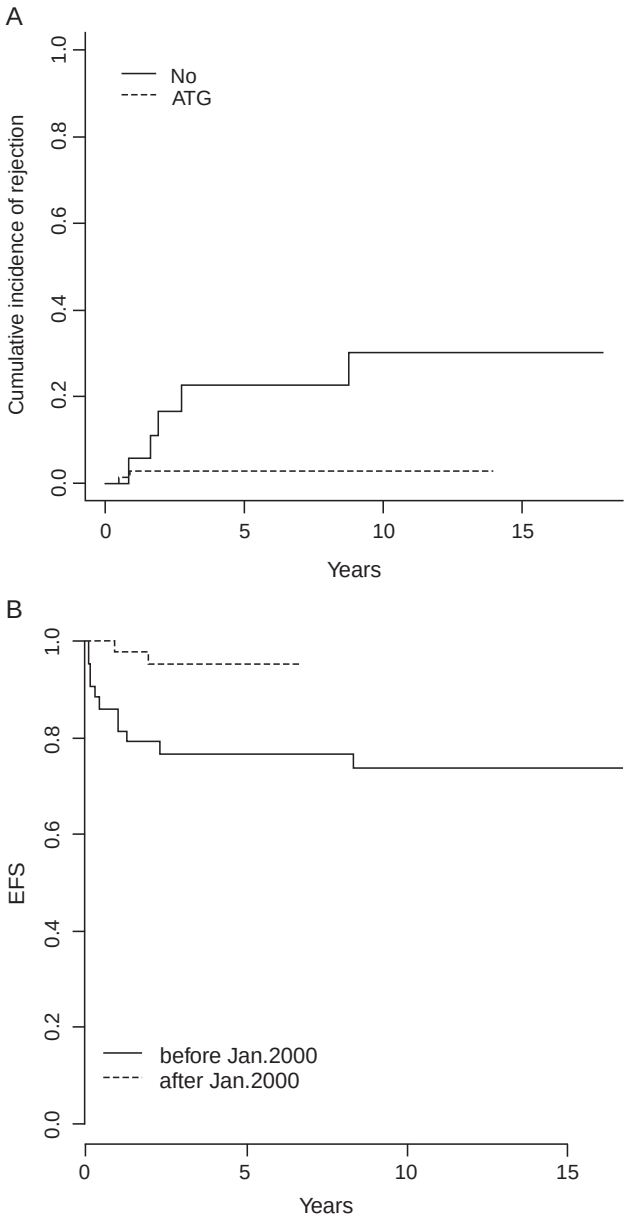

Figure 32.6. **(A)** Comparison of the cumulative incidence of rejection in patients conditioned with and without antithymocyte globulin (ATG). **(B)** Comparison of event-free survival (EFS) in patients who underwent transplantation before (43 patients) and after January 2000 (44 patients).

graft rejection declined from 22.6% to 2.9% after the addition of antithymocyte globulin to the conditioning regimen (Fig. 32.6A). The Kaplan–Meier estimate of event-free survival at 5 years was 86.1%. Multivariate analysis showed that the date of transplantation was the only significant risk factor. The 5-year event-free survival rate was 95.3% in patients treated after January 2000 compared with 76.7% in patients treated earlier (Fig. 32.6B).

A retrospective review of 24 Belgian patients with sickle cell disease analyzed the impact of pretransplant antithymocyte globulin and hydroxyurea on outcome. When hydroxyurea was received before hematopoietic cell transplantation, there was a significantly lower rate of graft rejection compared with patients who did not receive hydroxyurea, but the administration of antithymocyte globulin before transplantation did not affect the rate of engraftment. Overall, 20 of 24 patients had stable engraftment of donor cells after hematopoietic cell transplantation, but none of those who received hydroxyurea before transplantation with antithymocyte globulin in the conditioning regimen had graft rejection or a late recurrence of sickle cell disease. This suggests that the augmentation of pretransplantation immunosuppression might be necessary to overcome the immunological barrier of tolerance to donor histocompatibility antigens. The propensity for graft rejection even after HLA-identical sibling hematopoietic cell transplantation supports the hypothesis that multiple transfusion exposures before hematopoietic cell transplantation induce sensitization to minor histocompatibility antigens expressed on the surface of transfused cells. It appears possible that leukocytes present in blood products are not alone in this ability to cause sensitization because erythrocytes might also present histocompatibility antigens via the HLA Class I pathway to elicit expansion and activation of host CD8+ T cells.[61]

Stable Donor–Host Chimerism After Myeloablative Hematopoietic Cell Transplantation for Sickle Cell Disease. As in thalassemia major, the observation of donor–host hematopoietic chimerism after conventional myeloablative hematopoietic cell transplantation has lent substantial support to the notion that persistence of even a fraction of normal erythropoiesis might elicit a curative clinical effect.[62] The basis of this effect appears to be twofold: improved survival of healthy donor erythrocytes in the blood compared with sickle erythrocytes, and ineffective erythropoiesis in the sickle cell disease marrow that lends a competitive advantage to normal donor erythroid progenitors. Approximately 25% of children with sickle cell disease developed stable mixed chimerism after HLA-identical sibling hematopoietic cell transplantation.[63] In the multicenter investigation of bone marrow transplant for sickle cell anemia, five patients had a proportion of donor cells that ranged from 11% to 74%. Their hemoglobin levels varied between 11.2 and 14.2 g/dL (median 11.3; mean 12.0). None experienced painful events or other clinical complications related to sickle cell disease after transplantation. One patient who had a stroke before transplantation had no further strokes after transplantation and magnetic resonance imaging (MRI) demonstrated stable brain abnormalities, despite having only 10% donor cells detectable in peripheral blood. In the French series, low levels of residual host hematopoiesis were observed significantly more frequently in patients who did not receive antithymocyte globulin before hematopoietic cell transplantation ($P = 0.04$ at 12 months and $P = 0.002$ at 24 months posttransplant).[60] A higher fraction of residual host cells was observed in patients who received antithymocyte

globulin ($P = 0.03$ at 12 months and $P = 0.001$ at 24 months posttransplant), and this level of donor–host chimerism remained stable in the long term. These observations are consistent with the idea that chimerism, even with a minority of donor cells, can have a significant ameliorative effect so that full engraftment of donor cells is not a requirement for successful hematopoietic cell transplantation and that the donor chimerism fraction remains stable 12 months and longer after hematopoietic cell transplantation.

Nonmyeloablative Hematopoietic Cell Transplantation for Sickle Cell Disease. Due in part to the observations discussed in the previous section, it was reasoned that pretransplantation therapy might be adjusted to promote stable engraftment of a threshold fraction of donor cells that would be sufficient to prevent sickle vasoocclusion and that this regimen could be administered more safely than conventional myeloablative conditioning. Toward this end, several groups have attempted to apply nonmyeloablative stem cell transplantation to sickle cell disease, utilizing conditioning regimens of varying intensity.[61,64–68] Although these investigations are continuing, it has been difficult to identify a regimen that is sufficiently immunosuppressive to ensure stable engraftment of donor cells from HLA-identical siblings, yet also meets the objective of "reduced toxicity" with a risk that is distinguishable from conventional allografting. A minimally toxic regimen was first developed in a large-animal model and translated successfully into human trials for older adult patients with hematological malignancies. When applied to sickle cell disease, this approach was safe, generated little or no acute GVHD, and in most cases was associated with an initial period of donor engraftment. Unfortunately, in nearly all cases, withdrawal of postgrafting immunosuppression was followed by graft rejection with disease recurrence (Table 32.4). In another series of nonmyeloablative hematopoietic cell transplantation, there was a twofold higher expression of donor β-globin RNA compared with total genomic DNA in the blood after nonmyeloablative hematopoietic cell transplantation. Direct bone marrow analysis revealed ineffective erythropoiesis of recipient erythroblasts, with a progressive increase in representation of donor erythrocytes during erythrocyte maturation.[69,70] These findings were associated with clinical benefit after transplantation, and with improvements in hemolysis, endothelial function, and nitric oxide bioavailability; however, they did not persist after graft rejection.

An increasing number of patients have received regimens that are less intense than a myeloablative regimen, but retain a moderate degree of the myelosuppressive effect to suppress the host-versus-graft reaction and promote engraftment. These regimens require hospitalization, and their risk of regimen-related toxicity is related to the profound immunosuppression of the regimens and an accompanying risk of opportunistic infection. A group of older sickle cell patients who received such "reduced-intensity" conditioning regimens also received augmented pregrafting immunosuppression to facilitate donor cell engraftment. Nevertheless, three of 12 recipients experienced graft rejection (Table 32.3). Acute and chronic GVHD were also more frequent (4 of 12 patients) in this group, and GVHD was fatal in two cases. Thus, in older recipients the problem of transplant-related mortality was not

eliminated by the reduced-intensity conditioning regimen. In contrast, donor chimerism was successfully established in children who received a reduced-intensity regimen consisting of busulfan, fludarabine, antithymocyte globulin, and total lymphoid irradiation (500 cGy).[66] Five patients who were aged between 6 and 18 years received HLA-identical sibling bone marrow transplantation with cyclosporine and mycophenolate mofetil for postgrafting immunosuppression. Treatment-related toxicity was minimal, and all the patients had evidence of stable donor engraftment. Another study that included 16 children with nonmalignant disorders included one patient with sickle cell anemia.[71] The patients received melphalan, fludarabine, and an anti–T cell antibody, Campath-1, before transplantation and included seven patients who received unrelated or HLA-mismatched related donor allografts. Twelve of the 16 (75%) patients survive disease-free after transplantation and none of the surviving patients had graft rejection. These encouraging results in younger patients suggest that future application of reduced-intensity conditioning regimens should focus on children who already have or are at risk for symptomatic disease.

Effect of Donor Hematopoiesis on Sickle Vasoocclusion

After successful hematopoietic cell transplantation for sickle cell disease, patients with stable engraftment of donor cells have not experienced clinical complications or required transfusions after transplantation, even when there was stable mixed donor–host hematopoietic chimerism.[4,5,63] In addition, investigators have reported improvements in splenic function and osteonecrosis.[72,73] Patients treated by hematopoietic cell transplantation also had stabilization of the underlying cerebrovascular disease. Forty-six of 55 patients who were enrolled in the multicenter study underwent cerebral MRI performed a median of 25.4 months after transplantation. These studies were compared with pretransplantation baseline examinations in all but four of the patients. Among those 29 who had a history of stroke before transplantation, one patient with graft rejection had a second stroke and 28 survive stroke free. Of the 28 patients with stroke studied after transplantation, all but the patient with a second stroke had a stable or improved appearance on cerebral MRI. Ten patients had evidence of silent cerebral infarction before transplantation, and of these, all eight with posthematopoietic cell transplantation studies had stable or improved appearance. There were no strokes after hematopoietic cell transplantation in this group. Sixteen patients had no documented central nervous system disease before transplantation. MRI appearance was normal in all 10 patients in this group after hematopoietic cell transplantation and none had stroke. Together, these observations suggest that there is stabilization of cerebral vasculopathy after hematopoietic cell transplantation. These data also suggest that in those with silent cerebral infarction who are at risk of developing stroke, there is protection from disease progression and a first stroke.

A similar experience was reported by the French group.[60] Among the 36 patients with a history of stroke before hematopoietic cell transplantation, two had a recurrent stroke. One patient experienced a transient ischemic attack 10 days after hematopoietic cell transplantation whereas the other, who had severe cerebrovascular injury with Moyamoya disease, had a fatal intracranial hemorrhage 32 days after hematopoietic cell transplantation. With a median follow-up of 6 years, the risk of recurrent stroke was 5.6%, which mirrors the rate of second stroke observed in sickle cell disease patients treated by regular transfusion therapy after a first stroke. Vascular occlusions tended to persist after hematopoietic cell transplantation and the long-term outcome varied somewhat: In five, the arterial stenosis resolved, in 16 there was no change, and in two cases, there was progression. None of the patients had a clinical stroke or silent ischemic lesion among those with durable donor engraftment, including the two patients who had progressive cerebrovascular narrowing. Cortical atrophy worsened in two cases. In addition, the cerebral artery blood flow velocity was significantly decreased ($P < 0.001$) 1 year after hematopoietic cell transplantation in the 49 patients in whom a pre-hematopoietic cell transplantation transcranial Doppler examination was performed. The transcranial Doppler velocity declined from 138 ± 50 cm/s before hematopoietic cell transplantation to 100 ± 34 cm/s as measured in the right middle cerebral artery, and 138 ± 46 to 103 ± 40 cm/s in the left middle cerebral artery. The transcranial Doppler velocity also normalized by 3 months after hematopoietic cell transplantation in two patients who had abnormal measurements before hematopoietic cell transplantation, even though both had been treated by regular transfusions before transplantation.

In other series, patients with stroke before hematopoietic cell transplantation have experienced transient ischemic attacks and intracranial hemorrhages in the era before measures to prevent these adverse events were instituted.[74–76] After the institution of preventive measures, neurological complications still occurred after transplantation, but these tended to be self-limited events such as seizures, with no long-term sequelae. More recently, one group observed radiographic changes in some patients with sickle cell anemia who underwent hematopoietic cell transplantation for stroke.[77] Five of nine patients had either new or slightly increased size of cerebral lacunae or leukoencephaly that stabilized 2–7.5 years after hematopoietic cell transplantation. Thus, it is possible that these observations reflect the evolution of cerebrovascular disease that existed before transplantation. Of interest, these cerebral MRI changes were not associated with progressive neurocognitive deficits.

Table 32.5. *P* values from each comparison of the hematopoietic cell transplantation cohort to CSSCD and HUG-KIDS groups

	Height				Weight			
	Baseline		Velocity		Baseline		Velocity	
Comparison group	Male	Female	Male	Female	Male	Female	Male	Female
CS sickle cell disease	0.37	0.22	0.01*	0.12	0.30	0.02†	0.0004‡	0.08
HUG–KIDS (Pre)	0.06‖*	0.72	0.15	0.72	0.89	0.66	0.73	0.53
HUG–KIDS (HU)	0.15	0.87	0.68	0.25	0.01§	0.51	0.30	0.92

* Between the baseline ages of 3.3 years and 11.6 years, the linear height velocity was greater for the hematopoietic cell transplantation group than the predicted velocity for the CSSCD group.

† Three females older than 11 years in the hematopoietic cell transplantation group had low baseline weight, creating an illogical decreasing trend in the baseline weight curve.

‡ Until the baseline age of 12.1 years, the linear weight velocity during follow-up in the hematopoietic cell transplantation group was greater than the predicted linear velocity during follow-up for the CSSCD disease group.

‖ The males in the HUG-KIDS (Pre) group tended to be approximately 4.0 cm taller than the males in the hematopoietic cell transplantation group, regardless of age.

§ The males in the HUG-KIDS (HU) group tended to be 2.7 kg heavier than the males in the hematopoietic cell transplantation group, regardless of age.

Growth and Development after Hematopoietic Cell Transplantation for Sickle Cell Disease

There remains concern about possible growth impairment after hematopoietic cell transplantation for sickle cell anemia. The potential for growth impairment stems, in part, from the gonadal toxicity associated with myeloablative doses of busulfan, particularly in females. Although it is difficult to predict the impact of busulfan on linear growth in patients with sickle cell anemia, there is also the possibility that by removing the energy requirements associated with the hemolytic anemia of sickle cell anemia,[78] growth might improve after transplantation.[79] A recent report compared four groups of children with sickle cell anemia in an analysis of growth after hematopoietic cell transplantation. Children who were enrolled in the Cooperative Study of Sickle Cell Disease (CSSCD) comprised one supportive therapy comparison group. Children who were enrolled in the HUG-KIDS trial, a study of hydroxyurea in children with sickle cell anemia made up the remaining two comparison groups.[80] These two groups included children who had pretreatment growth measurements (HUG-KIDS Pre) and the same children who again had measurements for at least 1 year after achieving the maximum tolerated dose of hydroxyurea (HUG-KIDS HU).

There were no statistically significant differences in the estimated height (weight) velocity curves between the hematopoietic cell transplantation and the three comparison groups among females; however, there were significant differences between males in the hematopoietic cell transplantation and CSSCD groups (Table 32.5, Fig. 32.7). An age-dependent growth effect in the secondary analysis of the CSSCD/hematopoietic cell transplantation height and weight comparisons in boys appeared to exist. The predicted height velocity during follow-up in the hematopoietic cell transplantation group was greater than the velocity in the CSSCD disease group aged between 3.3 years and 11.6 years. After this period of 8.4 years, there was no apparent growth benefit associated with hematopoietic cell transplantation. As a result, the predicted height velocity in hematopoietic cell transplantation males who were more than 12 years of age at transplantation was less than the velocity in CSSCD males. Similarly, until the baseline age of 12.1 years, the linear weight velocity in the hematopoietic cell transplantation group was greater than in the CSSCD group. In the HUG-KIDS Pre and hematopoietic cell transplantation male height comparison, secondary analysis showed a statistically significant group effect on linear height velocity during follow-up after adjusting for estimated baseline height ($P = 0.04$). In summary, growth after transplantation for sickle cell anemia was not impaired, except in older boys. These data suggest that conventional myeloablative hematopoietic cell transplantation generally had no adverse effect on height or weight gain in young children.

Gonadotropin and sex hormone levels of surviving patients have also been monitored, and these confirm the toxic effect of busulfan on gonadal function. Among seven surviving females in the multicenter study who were aged more than 13 years after hematopoietic cell transplantation, an interim analysis showed that five had primary amenorrhea and five had corresponding elevated luteinizing hormone (LH) and follicle stimulating hormone (FSH) levels that were associated with decreased serum estradiol levels in four. One individual receiving hormonal replacement therapy had elevated LH and FSH levels and a normal serum estradiol. One postpubertal female had normal serum FSH and estradiol levels. Of seven males who were more than 13 years old, none of four tested had elevated serum LH/FSH levels. Two males who were aged

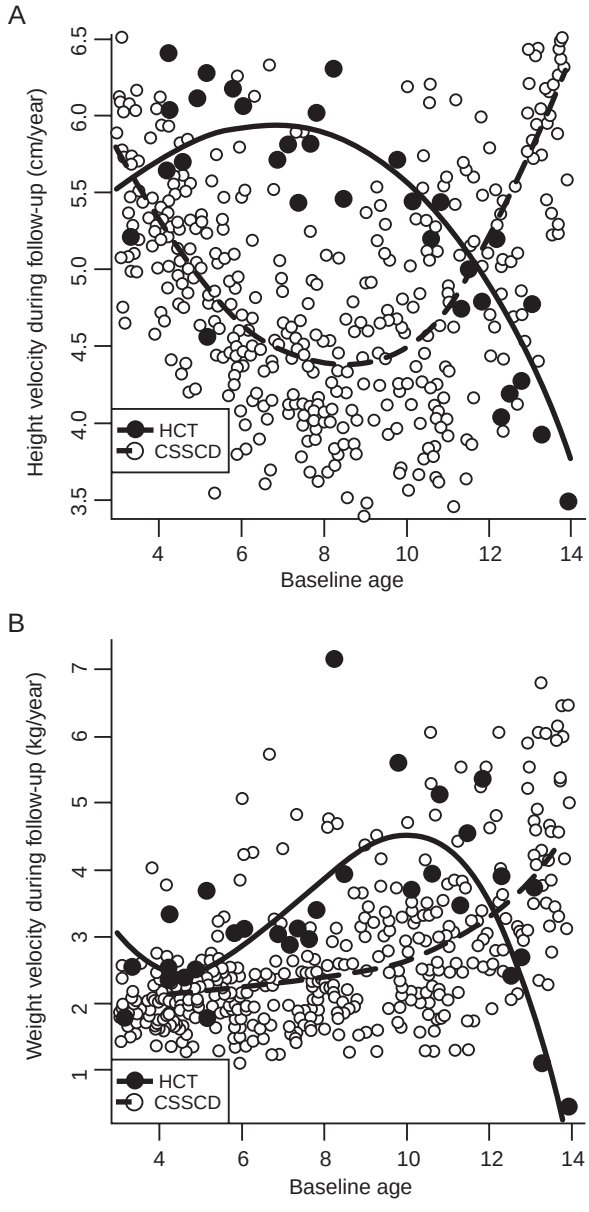

Figure 32.7. **(A)** Height velocity during follow-up in sickle cell disease. The height velocity in centimeter/year is depicted as a function of the baseline age during the follow-up period. The open circles represent height velocities as determined by an HLM for the male CSSCD comparison group and the accompanying dashed line shows the predicted velocity curve. The solid circles represent height velocities as determined by an HLM for the male hematopoietic cell transplantation group and the accompanying solid line represents the predicted velocity curve. **(B)** Weight velocity during follow-up in sickle cell disease. The weight velocity in kilogram/year is depicted as a function of the baseline age during the follow-up period. The open circles represent weight velocities as determined by an HLM for the male CSSCD comparison group and the accompanying dashed line shows the predicted velocity curve. The solid circles represent weight velocities as determined by an HLM for the male hematopoietic cell transplantation group and the accompanying solid line represents the predicted velocity curve.

14 and 16 years had low testosterone levels that were correlated with gonadotropin levels in the prepubertal range. Among six evaluable prepubertal girls in the Belgian cohort, five had primary amenorrhea with elevated serum LH and FSH.[5] Two postpubertal females developed secondary amenorrhea. Testicular function was also adversely affected in four of six evaluable boys who demonstrated decreased testosterone and elevated FSH levels. In the French series, seven postpubertal females, aged 13–22 years, developed amenorrhea after hematopoietic cell transplantation with decreased serum estradiol and elevated LH and FSH levels and received hormone replacement therapy.[60] In addition, most girls who were prepubertal before hematopoietic cell transplantation received hormone replacement therapy to promote the development of secondary sexual characteristics after they reached a bone age of 13 years. Two younger girls (aged 6.4 and 8.3 years) experienced spontaneous pubertal development, raising the possibility that hematopoietic cell transplantation performed in very young patients might not be associated with delayed puberty. It is anticipated that many, if not most of the females, will require hormonal replacement therapy after hematopoietic cell transplantation.

Alternative Sources of Donor Hematopoietic Cells

The use of umbilical cord blood in lieu of bone marrow in transplantation for sickle cell disease is of interest, primarily because of a lowered risk of GVHD. This benefit is balanced by a higher rate of graft rejection and a longer duration of hematological recovery that accompanies umbilical cord blood transplantation.[81,82] Thus, to overcome these risks, investigators have modulated pre- and postgrafting immunosuppression and intensified supportive care to optimize outcomes. In a report of 44 patients that included 11 with sickle cell disease who received HLA-identical or 1-antigen HLA-mismatched sibling umbilical cord blood allografts, the overall 2-year sickle cell disease-free survival rate was 91% with one patient experiencing recurrent disease.[20] Among patients who received thiotepa or fludarabine in addition to the busulfan/cyclophosphamide backbone, and who did not receive methotrexate with postgrafting immunosuppression, the outcome after umbilical cord blood transplantation was superior, particularly among recipients with β thalassemia major. In addition, only four of 44 patients experienced acute, and two, chronic GVHD after umbilical cord blood transplantation, and there were no deaths related to GVHD. In another series of related donor umbilical cord blood transplantation for hemoglobinopathies, 18 of 22 patients survive event free after transplantation.[83] Thus, it is possible that umbilical cord blood might be utilized as an effective source of hematopoietic stem cells in hemoglobinopathies. The current experience with unrelated donor umbilical cord blood transplantation for sickle cell disease is quite limited, but it illustrates the potential for success and the challenges yet to be investigated. In one series, seven patients were conditioned with myeloablative (n = 4) or reduced-intensity preparative regimens.[84] The indication for cord blood transplantation was stroke, and

all received cord blood grafts that were mismatched at two HLA antigens. Five of seven patients (71%) experienced significant adverse events of graft rejection or death. Currently, 43% survive disease free after umbilical cord blood transplantation due to a successful second cord blood transplantation in one patient, and one of seven (14%) subjects died of transplant-related causes. These preliminary findings suggest the possibility of success after unrelated donor cord blood transplantation in high-risk patients. It is the introduction of transplantation in patients like these at risk of progressive neurovascular injury, and who are also very likely to need long-term transfusion support with its attendant risk of life-threatening transfusional iron overload, where risk–benefit considerations might achieve a suitable balance. To tip the balance in favor of transplantation, the problems of graft rejection and GVHD after unrelated donor cord blood transplantation will require better control.

That the broader application of hematopoietic cell transplantation for sickle cell disease is limited can be illustrated by the observation that only 14% of sickle cell anemia recipients are likely to have an HLA-identical sibling donor.[85] Not surprisingly, lacking a suitable donor is the major barrier to hematopoietic cell transplantation for sickle cell anemia.[86] An expanded availability of HLA-compatible unrelated donor sources is necessary to pursue hematopoietic cell transplantation as a therapeutic option in most patients with sickle cell disease. Donors who are matched at six (HLA-A, B and DRB1 loci) to 10 HLA-antigens (including HLA-C and DQB1 loci) can be identified via the National Marrow Donor Program in approximately 80% of Caucasian recipients; however, the likelihood of identifying a similarly HLA-matched unrelated donor is less likely in other ethnic groups due to underrepresentation of these groups in the volunteer donor pool. The reduced likelihood of identifying a suitable donor is a difficult problem in hematopoietic cell transplantation for sickle cell disease and can limit the application of hematopoietic cell transplantation among those who might benefit most.[87,88] The feasibility of identifying suitable donors was suggested by surveys in which 60% of sickle cell disease patients had at least one potential suitable unrelated donor and 26% had three or more potential donors. The challenge of identifying a donor might also be mitigated by the possibility of umbilical cord blood transplantation. An unrelated donor search for 40 sickle cell disease patients showed that 100% and 50% had HLA 4/6 and 5/6 antigen-matched unrelated donor cord blood units, respectively.[89]

Thus, it appears feasible to pursue alternate donors suitably matched at HLA alleles in the treatment of individuals with severe sickle cell disease. It is quite possible and even likely that the successful translation of unrelated donor hematopoietic cell transplantation for sickle cell disease will hinge on our ability to establish bidirectional donor–host immunological tolerance and that this will involve the administration of more intensive immunosuppression than we are accustomed to using in this clinical setting. This represents a shift from the notion that marrow ablation and elimination of sickle cell progenitor cell populations are the principle objectives in performing a successful hematopoietic cell transplantation. There are many reasons for this, not the least of which is that the immunological milieu of sickle cell disease is one of inflammation, in which innate stimulation of graft-versus-host and host-versus-graft reactions is very likely to occur. In the course of inhibiting these reactions by pharmacological means, controlling the emergence of opportunistic viral and other infections will take on greater importance than has been appreciated previously after transplantation for hemoglobin disorders. These concerns have been taken into consideration in the design and implementation of the United States trial to study unrelated donor hematopoietic cell transplantation in children with severe sickle cell disease.

SUMMARY

In general, the experience of hematopoietic cell transplantation from HLA-identical sibling donors to treat clinically significant hemoglobin disorders has been outstanding. Most individuals with sickle cell disease and β thalassemia survive after hematopoietic cell transplantation without anemia or the need for blood transfusion support. In survivors with sickle cell disease, new vasoocclusive episodes do not occur. It is also possible to treat preexisting complications such as transfusional iron overload after hematopoietic cell transplantation and thereby eliminate the risk of disease-related morbidity. The experience of hematopoietic cell transplantation for thalassemia is more extensive than in sickle cell disease, which reflects the greater reliability of the genoptype–phenotype relationship in β thalassemia. Thus, indications of hematopoietic cell transplantation for sickle cell disease continue to evolve as the genotype–phenotype relationship is more completely defined. With the possibility of alternate donor hematopoietic cell transplantation, the availability of hematopoietic cell transplantation is likely to expand, thereby opening the possibility of hematopoietic cell transplantation where none existed previously. The application of hematopoietic cell transplantation in adults with β thalassemia and sickle cell disease has been less successful, due in part to the higher risk of transplant-related mortality that occurs in high-risk recipients. Decisions about treatment options in the future are very likely to be influenced by perceptions about the nature of these chronic illnesses, and whether the short-term risk of mortality inherent to hematopoietic cell transplantation is balanced by the possibility of survival without symptoms or treatment. Ideally, future clinical trials about interventions for both disorders would focus on addressing these decision-making considerations.

Prospects for Gene Therapy of Sickle Cell Disease and Thalassemia

Derek A. Persons, Brian P. Sorrentino, and Arthur W. Nienhuis

INTRODUCTION

It has been four decades since the concept of gene therapy for human disease began to be considered and discussed in earnest. With the advent of recombinant DNA technology in the 1970s and the concurrent discovery that viruses could carry novel genetic information into target cells, gene therapy was seen as having significant future potential. A major step in the development of gene therapy for hematopoietic disorders occurred in 1985 when the laboratories of Bernstein and Anderson simultaneously showed that the genome of mouse hematopoietic stem cells (HSCs) could be permanently modified using a genetically engineered retrovirus capable of integrating into host cell DNA.[1,2] These results suggested that a patient's own HSCs could be harvested, genetically modified ex vivo, and then returned, perhaps following administration of radiation or chemotherapy to eradicate the diseased HSCs. From that time, it took almost a decade before functional correction of human disease model was demonstrated using retroviral-mediated, HSC-targeted gene transfer. The first such description was that of Heard and colleagues[3] when they demonstrated the successful treatment of a murine model of the lysosomal disorder, mucopolysaccharidosis type VII. Subsequently, murine models of two immunodeficiencies – chronic granulomatous disease[4] and a form of severe combined immunodeficiency due to *JAK3* deficiency[5] – were also successfully treated using gene therapy. These successes seemed to fulfill the stated goals of the Orkin and Motulsky NIH panel,[6] which called for more basic science research into gene therapy and the use of murine disease models to demonstrate efficacy prior to clinical trials.

After improvements in conditions for transducing primitive hematopoietic cells, these results were translated into successful clinical trials for severe combined immunodeficiencies (SCID). As recently reviewed[7] and discussed in more detail later in this chapter, more than 30 patients with SCID secondary to deficiency of the common γ chain of interleukin-2 or secondary to adenosine deaminase deficiency (ADA) have been successfully treated by ex vivo transduction and reinfusion of autologous primitive hematopoietic cells. Vector-mediated insertional activation of nearby protooncogenes initiated the development of leukemia in five patients, highlighting the importance of vector design to enhance the safety of gene therapy.[7] These otherwise successful trials do establish the potential efficacy of stem cell–targeted gene therapy for hemoglobin disorders. Globin gene vectors with the required regulatory elements have proved challenging to design and produce.[8–12] In this chapter we will review the viral vector systems relevant to HSC-targeted gene therapy, the issues relevant to obtaining efficient gene transfer into human HSCs, the factors unique to globin vector design, the recent remarkable progress in human clinical trials, and the prospects for eventual successful treatment of hemoglobin disorders such as sickle cell disease and β thalassemia.

THE SCIENCE OF VIRAL VECTORS

Successful gene therapy for hemoglobin disorders will require permanent genetic modification of pluripotent HSCs with long-term repopulating ability (Fig. 33.1). Among the various viral vector systems that have been considered, only efficiently integrating retroviruses that become a permanent part of the genome of the target cell and its progeny are potentially useful. As recently reviewed,[13] retroviruses share several features that are of interest for gene delivery. The characteristic that defines retroviruses is their ability to convert their single-stranded RNA genome into double-stranded DNA prior to integration of their genome into a host-cell chromosome. The initial vectors used in clinical gene therapy trials were γ-retroviruses derived from murine leukemia viruses (MLV). In the context of their clinical use, such vectors had the most advanced packaging systems for generating vector particles. Complex lentiviruses such as the human immunodeficiency virus (HIV) have many potential advantages including the ability to transduce nonmitotic cells. Furthermore, the mechanisms that have evolved to facilitate transport of unspliced HIV RNA species to the cytoplasm allow the assembly of vectors having complex genomes. The third class of retroviruses that have been considered for gene therapy applications are the spumaviruses including the human foamy virus (HFV). This virus is also able to transduce quiescent cells with relative efficiency.

Other vector systems without well-developed integration mechanisms nonetheless have important potential clinical applications. Recombinant adeno-associated viral (rAAV) vectors have been shown to transfer and express human γ-globin genes upon transduction of human erythroleukemia cells[14] or human erythroid progenitors,[15] and

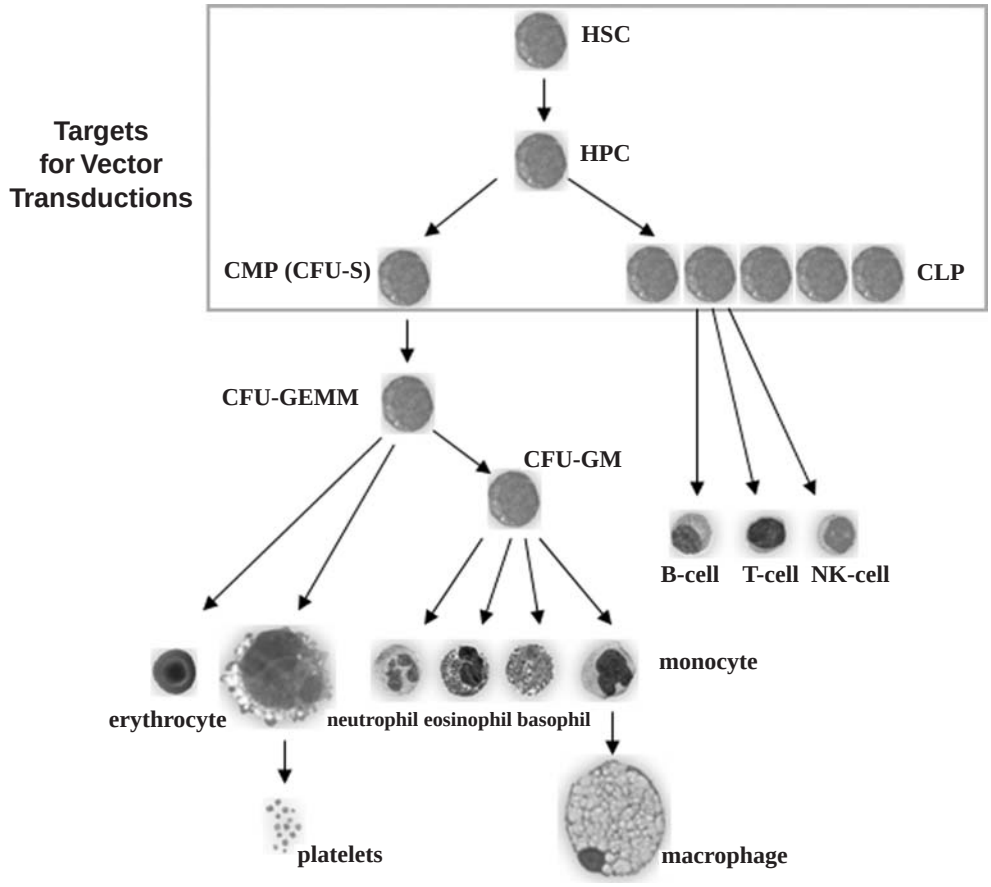

Figure 33.1. Hematopoietic cell targets for gene therapy. This figure shows the general hierarchical structure of hematopoiesis. Hematopoietic stem cells (HSCs) give rise to primitive progenitor cells (HPC), which in turn generate common myeloid progenitors (CMP) and common lymphoid progenitors (CLP). These progenitor cells then give rise to all formed elements of the blood through a number of intermediates including the granulocyte/erythrocyte/monocyte/macrophage colony forming unit (CFU-GEMM) and the granulocyte/monocyte colony forming unit (CFU-GM). The cells contained within the green outline are the desired targets for retroviral vectors because they all give rise to multiple mature cell types and because, to greater or lesser degrees, they can self-renew and lead to the persistence of genetically modified cells over time. The target cell population can differ for various diseases. For instance, for SCID, targeting of the CLP with an appropriate vector will result in long-term reconstitution of all lymphocyte subsets. In contrast, treatment of hemoglobin disorders required targeting of the most primitive HSC to have long-term persistence of stably modified erythrocytes after transplantation. The biology and frequency of the various target cell populations differs and are variable in determining the gene transfer efficiency. (See color plate 33.1.)

transient gene expression can be achieved in more primitive hematopoietic cells.[16] Some have argued that stable transduction of stem cells can be achieved with rAAV vectors[17] but the weight of evidence suggests that stable integration occurs infrequently in dividing cell populations. The ability of rAAV vectors to transduce nondividing cells in vivo with resulting long-term gene expression make them potentially useful for treating a wide variety of diseases as summarized in the recent review.[19] Other viral vector systems such as adenoviral vectors[20] Herpes simplex viral vectors,[21,22] and SV40 viral vectors[23] all have important potential clinical applications and interested readers are directed to recent reviews about each. A hybrid adenoviral/AAV vector containing a large fragment from the human β-globin gene locus has the interesting property of preferential integration into the cellular β-globin locus,[24] although the overall efficiency of integration appears to be relatively low.

Murine Retroviral Vectors

During the two decades following the discovery of reverse transcriptase,[25,26] much was learned about the biology of the retroviral life cycle as summarized in a review published in 1988.[27] Attention focused on the γ-retroviruses of mice that have the capacity to induce tumors and therefore were of great interest in efforts to understand cancer pathogenesis. Such viruses initiate cell entry by interaction with one or more specific proteins that act as a receptor (Fig. 33.2). Entry of the core of the viral vector into the cell

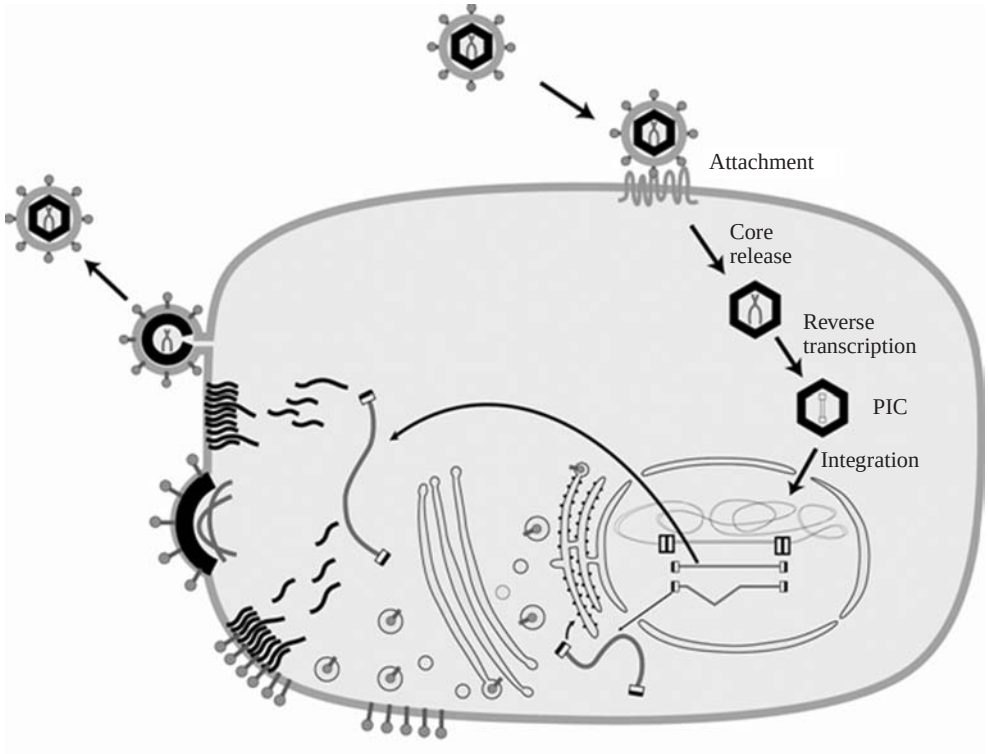

Figure 33.2. Retroviral life cycle. Entry of a retrovirus into a cell is initiated by interaction of its envelope proteins with one or more cellular membrane proteins that act as a receptor followed by internalization through membrane fusion or phagocytosis. The vector core is released and the RNA serves as a template for formation of the reverse transcription complex (RTC). The RTC includes additional viral proteins and is moved by the microtubule system from the cell periphery to the nucleus as it matures to become the preintegration complex (PIC). The PIC gains access to chromatin during mitosis, or in the case of lentiviruses, by ingress through the nuclear membrane. Following integration into host-cell DNA, the retroviral genome is expressed in RNA molecules that are transported to the cytoplasm to serve as a template for synthesis of new viral proteins and, in the case of unspliced RNA species, as a substrate for formation of new viral particles. (See color plate 33.2.)

then is accomplished either by endocytosis or fusion with the cell membrane depending on the envelope protein with which the particle was formed. Retroviruses have a unique capacity to convert their single-stranded RNA genome into a double-stranded DNA molecule, which is then integrated through the action of host cell and viral proteins, particularly viral integrase, into a cellular chromosome. Upon integration, the viral genome may be expressed into spliced and unspliced transcripts. Spliced and unspliced transcripts serve as templates for protein synthesis and unspliced transcripts may also be packaged into new viral particles. Ultimately the viral particles are assembled on the cell surface and new viral particles are released.

Increasing knowledge about the organization of the genome of murine γ-retroviruses suggested strategies for deriving vector particles free of replication-competent retroviruses[28,29] that were potentially useful for gene therapy applications. The fundamental principle underlying the use of potentially pathogenic viruses as therapeutic vectors reflects the ability to express viral proteins from independent genetic elements and deleting most or all of the coding information from the vector genome and replacing it with a therapeutic transgene. Coexpression of the vector genome and viral proteins in cultured cells leads to the production of vector particles encoding the therapeutic transgene without replication-competent retroviral particles (Fig. 33.3).

Only the long terminal repeats (LTRs) and sequences at the 5′ end of the viral genome are required for efficient packaging of RNA molecules into γ-retroviral vector particles. The GAG, POL, and envelope (ENV) gene products are cleaved by cellular and viral proteases to yield multiple proteins. GAG products make up the viral capsid and the POL-derived products include a protease, the integrase, and reverse transcriptase.[13] The coding sequences for these viral proteins can largely be eliminated from the vector genome. Conversely, expression cassettes for the viral proteins have been constructed that allow their expression in packaging cells as RNA molecules that lack both the LTRs and packaging sequences.[28,30] Separating the GAG and POL genes from the ENV gene on two separate transcriptional units (so-called split packaging lines) substantially reduced the possibility for regeneration of replication-competent retrovirus.[31,32] Second- and third-generation vector genomes contain a larger packaging signal that extends into the GAG coding region, thereby

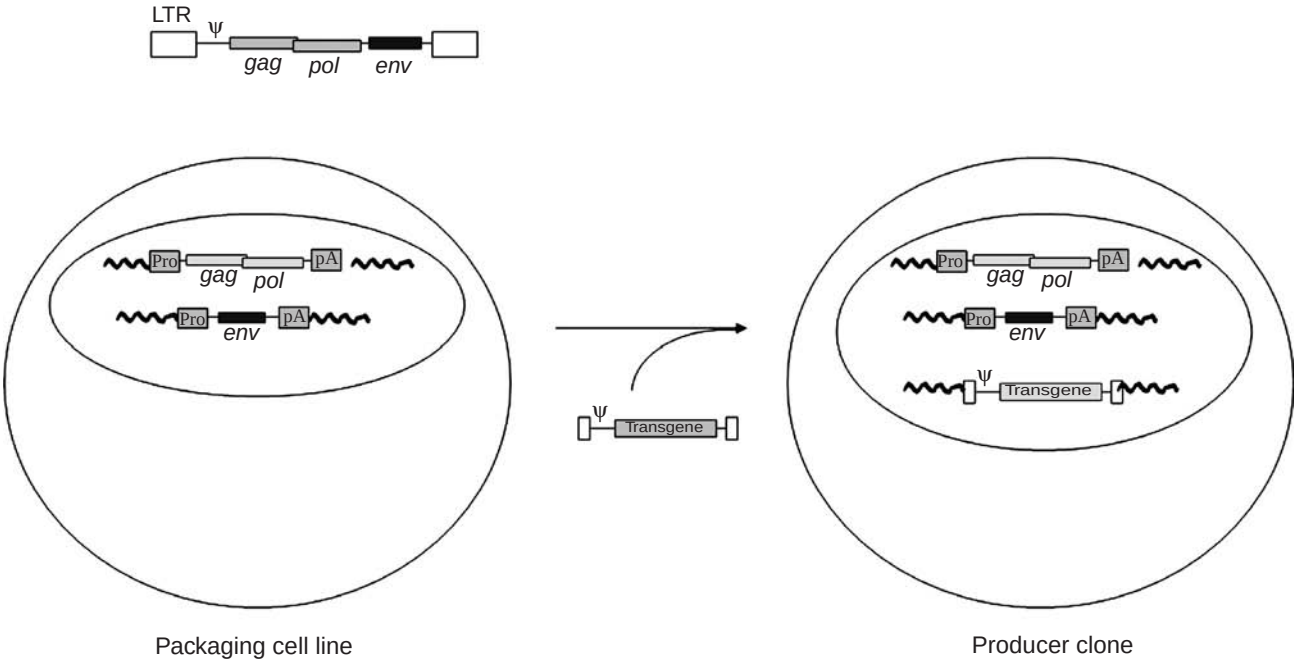

Figure 33.3. Production of retroviral vector particles. This figure illustrates the concept of the strategy used to derive retroviral vector preparations free of replication-competent virus. The diagram at the top shows the organization of a retroviral genome. Murine oncoretroviruses have coding sequences for matrix proteins (gag), reverse transcriptase, integrase and protease (pol), and envelope proteins (env). The LTR contains the viral promoter and enhancer. Immediately downstream is a sequence essential for packaging the genomic RNA (ψ). To reduce the risk of recombination and generation of replication-competent particles, these coding sequences are separated on two or more expression cassettes before transfer into a tissue culture cell line. The coding sequences for viral proteins are replaced by the coding sequences for the intended therapeutic protein in the vector. Various strategies are used for introducing the vector genome into the packaging cell that initiates production of replication-defective retroviral vector particles that can be used to introduce the therapeutic transgene into target cells. In the packaging and producer cells, the viral protein constructs are driven by exogenous promoters (Pro). (See color plate 33.3.)

improving vector production.[33] Despite this extended overlap with the transcriptional unit encoding GAG, the risk of emergence of replication-competent retrovirus by homologous recombination has been controlled by introduction of mutations into the GAG sequences of the vector genome[34] and by using split-function packaging lines. Most packaging lines and producer clones have been based on murine 3T3 fibroblast cell lines, but packaging lines based on human cells have also been generated using this general strategy.[35,36] The vector particles produced by such cell lines are more resistant to destruction by human complement and thus may prove more useful for various gene therapy applications.

Different classes of viruses use different proteins for receptors. For example, ecotropic viruses that infect murine and other rodent cells rely on a cationic amino acid transporter to initiate cellular entry,[37,38] whereas amphotropic viruses, whose broader host range includes human cells, use a sodium-dependent phosphate transporter.[39,40] Over the years, γ-retroviral particles have been assembled or pseudotyped with a number of different envelope proteins including that from gibbon ape leukemia (GAL) retrovirus,[41] the feline endogenous retrovirus (RD114),[42] and the feline leukemia virus type C retrovirus (FLVC).[43] GAL pseudotyped particles have been used in one of the successful clinical trial for X-SCID. The FLVC receptor is expressed at higher levels on primitive hematopoietic cells than are the receptors for other envelope proteins,[43] focusing attention on the evaluation of this particular envelope for pseudotyping vector particles for HSC-targeted gene transfer. A useful review summarizing strategies to target γ-retroviral and lentiviral vectors should be consulted for further information.[44]

The viral core is released into the cell cytoplasm following fusion of the virion membrane with either the cytoplasmic membrane or internal endosome membrane.[45] In the case of MLV, the capsid proteins remain associated with the viral genome in a reverse transcription complex (RTC) that associates with the cytoskeleton.[46] The RTC is actively moved by cytoskeletal components through the viscous cytoplasm, ultimately reaching the nucleus where the capsid proteins disassociate from the final preintegration complex. Movement of the viral genome with associated matrix proteins and enzymatic activities into the nucleus requires dissolution of the nuclear membrane during mitosis.[47] Thus, retroviral vectors that are based on the Moloney virus and other murine γ-retroviruses require cell division for genome integration. Furthermore,

the preintegration nucleoprotein complex of oncoretroviruses is highly unstable;[48] therefore successful transduction requires genome integration within hours of exposure of target cells to the retroviral vector particles. Various cells possess innate mechanisms that restrict retroviral infection,[49–51] which undoubtedly complicate and restrict gene transfer with retroviral vectors. These mechanisms include the apolipoprotein B mRNA–editing catalytic polypeptide-like 3 (APOBEC3) factor that has cytosine demethylating activity and the TRIM5α protein, which interacts with the viral capsid proteins.

After integration, expression of the genes encoded by the proviral genome requires continued activity of promoter and enhancer sequences within the LTR. Unfortunately, silencing is all too common and may be mediated both by methylation[52] of proviral sequences and at the level of chromatin structure.[53] MLV LTRs seem particularly prone to silencing in embryonic stem cells and in primitive hematopoietic cells. Later vectors have been designed to resist such silencing. Such vectors include one based on the murine stem cell virus (MSCV)[54] and another based on the myeloproliferative sarcoma virus.[55] The latter vector has also been modified to eliminate a negative control region from the LTR and has a substituted primer-binding site that also enhances expression. A recent version of the MSCV has a self-inactivating (SIN) design in which the enhancer/promoter is eliminated from the 3′ LTR. During reverse transcription and vector genome integration, the 3′ LTR is duplicated to create the 5′ LTR of the integrated provirus. Thus, the SIN vectors lack an enhancer/promoter in both LTRs and depend on an internal promoter to express the transgene. The modified SIN MSCV vector achieved stable γ-retroviral expression during embryonic stem cell–derived in vitro hematopoietic development, a very stringent test of vector silencing.[56] Production of SIN γ-retroviral vectors has been problematic in stable producer clones but substitution of a stronger or an inducible promoter for the viral transcript improves titer.[57] Recently a SIN γ-retroviral vector having an internal cellular promoter has been derived for treatment of X-SCID due to common γ-chain deficiency.[58]

Expression of more than one gene product from a proviral genome is often desirable. Several designs have been tested for creating multigene vectors. One that has been tested extensively is the insertion of a second promoter downstream from the first open reading frame followed by the second open reading frame. Unfortunately, promoter interference often results in poor expression from the internal promoter.[59] Another technique that has been much more successful involves the inclusion of an internal ribosomal entry site between the two open reading frames, creating a vector genome that encodes a polycistronic transcript.[60] Using this design, several genes have been expressed in tandem with the coding sequences for green fluorescent protein, a readily assayable and selectable marker.[61,62] Self-cleaving peptides such as the 2A peptide from Picornavirus have also been used to obtain expression of multiple protein products from a single vector transcript.[63]

Another approach is to place a complete transcriptional unit in reverse orientation within the 3′ LTR of the proviral genome.[64] After replication of such a genome and insertion into a target cell, the transcriptional unit within the 3′ LTR is duplicated, becoming part of the integrated 5′ LTR. Such double-copy vectors often result in a much higher level of expression than can be achieved with an internal promoter configuration, particularly when a deletion mutation is introduced in the 3′ LTR to create a "self-inactivating vector" that lacks LTR promoter activity in target cells.[64]

As discussed in detail later, low levels of globin mRNA are generated by γ-retroviral vectors that contain globin cDNA sequences. Vectors that incorporate an intact genomic globin gene in reverse transcriptional orientation with associated regulatory elements[65–68] have been tested extensively in an effort to achieve therapeutically useful levels of globin in target hematopoietic cells, but these efforts have not met with ultimate success.

Lentiviral Vectors

A major breakthrough in efforts to develop gene therapy for hemoglobin disorders was made by the laboratory of Michel Sadelain in 2000 when they demonstrated that lentiviral vectors could be used to transfer and express a globin gene in the erythroid cells of thalassemic mice.[69] In contrast to simple γ-retroviral vectors, complex vectors such as HIV encode multiple protein products in addition to the products of the GAG, POL, and ENV coding sequences. The tat protein is involved in enhancing transcription, the rev protein interacts with the rev responsive element to facilitate nuclear to cytoplasmic transport of unspliced mRNA species and the vif, vpr, vpu, and nef proteins are virulence factors. Also, in contrast to γ-retroviruses, lentiviruses can transduce nondividing cells.[48] Multiple nuclear localization signals within the matrix, vpr, and integrase proteins and in the central polypurine tract of the viral transcript were thought to mediate transport into the nucleus via nuclear pores.[70–73] Recent evidence, however, has cast doubt on the relevance of these nuclear localization signals.[74] Addition of a nuclear localization signal to the matrix of spleen necrosis virus does not allow efficient gene transfer into quiescent cells with a vector based on this virus.[75] In addition, elimination of all of the known nuclear localization signals from the HIV genome and proteins showed that no combination of the virally encoded nuclear localization signals is essential for the ability of HIV to infect nondividing cells.[76] Evidence has recently been presented for direct involvement of the capsid protein, CA, in HIV infection of nondividing cells. Its role in conferring this property to HIV may occur following nuclear entry of the preintegration complex.[77,78] The preintegration complex of lentiviral vectors is relatively

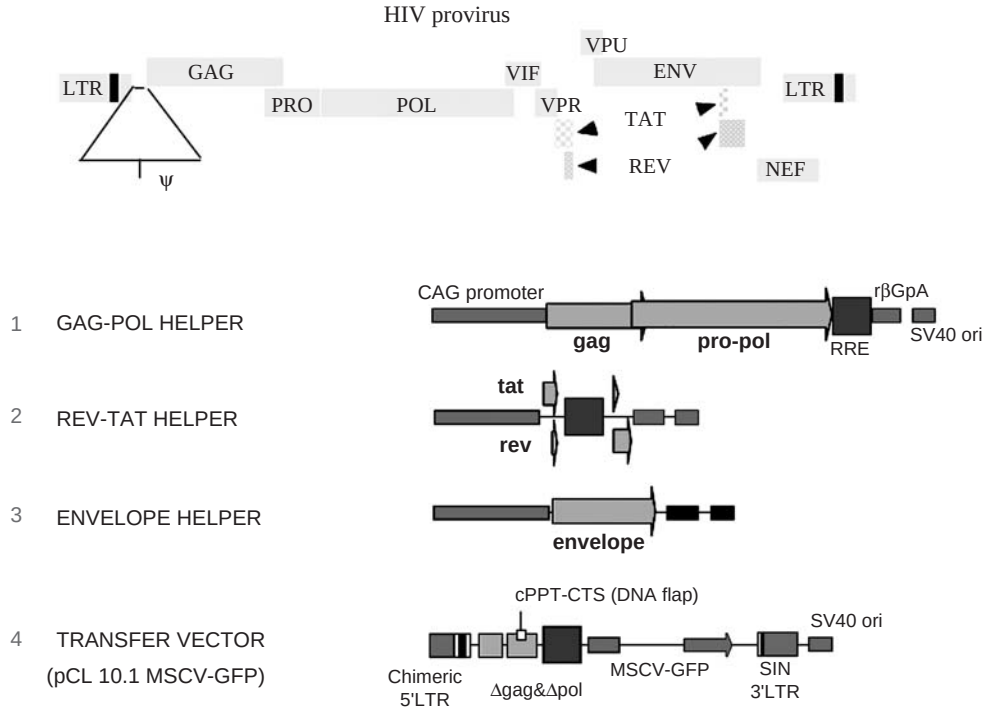

Figure 33.4. Organization of the HIV provirus and development of a packaging system for generation of vector particles free of replication-competent retrovirus. The HIV-1 genome encodes 15 proteins as shown in the top row of this figure. The GAG polyprotein is processed to yield viral core proteins including MA (matrix), CA (capsid), NC (nucleocapsid), and p6. The ENV protein product is processed to yield two proteins, SU (surface) and TM (transmembrane) components of the mature envelope proteins. The POL region encodes the enzymes PR (protease), RT (reverse transcriptase), and IN (integrase). TAT and REV are regulatory proteins that facilitate transcription or nuclear to cytoplasmic transport of unspliced RNA species, respectively. The accessory proteins NEF, VIF, VPR, and VPU are viral virulence factors, which are not required for vector particle formation. Shown below in rows 1–4 are components of a system developed to generate vector particles. Each of the transcriptional units encoding viral proteins includes the powerful chimeric CMV enhance/β-actin promoter, the β-globin large intron (CAG promoter), the rabbit β-globin polyadenylation sequence (rβGpA), and the rev responsive element (RRE), which facilitate nuclear to cytoplasmic transport. The SV40 origin of replication (ORI) is included in each expression plasmid to allow its amplification in cells expressing SV40T antigen. Three separate helper plasmids are used as shown in 1–3. The transfer vector includes a portion of the gag region required for packaging and a portion of the pol region, which includes the central polypurine tract (cPPT) and the central termination sequence (CTS). These elements together constitute the DNA flap that was described as a crucial determinate for lentiviral vector nuclear import and gene transduction of primitive human hematopoietic cells. The U3 region of the 5′ LTR in the vector has been replaced with the CMV enhancer and a deletion in the U3 region of the 3′ LTR renders the vector SIN. Not shown is the fact that a portion of the U5 region of the 3′ LTR has been removed and replaced with rabbit β-globin polyadenylation site to enhance safety and improve the efficiency of vector production. Vector production occurs when a mixture of the four plasmid DNAs are transfected into human embryonic kidney (293T) cells and conditioned media is harvested over the next 3–4 days. Depending on the envelope used, the vector preparation may be concentrated by ultracentrifugation or ultrafiltration. (See color plate 33.4.)

stable. For example, a partial reverse transcriptase product formed in quiescent T lymphocytes can be rescued by cell activation for at least 7–8 days postinfection. In contrast, the nucleoprotein complex of oncoretroviruses disappears within 24 hours of infection of nondividing cells.[48]

HIV-based vector development uses a general strategy similar to that used successfully with murine retroviral vectors (Fig. 33.4). The vector genome includes *cis* active sequences necessary for generation of the RNA form of the viral genome and the sequences required for efficient packaging, reverse transcription, and integration. Needed for these purposes are portions of the LTRs, the 5′ end of the genome, which includes the 5′ splice donor site, a portion of the GAG gene required for efficient packaging, and ENV sequences that contain the rev responsive element needed for nuclear to cytoplasmic transport of the unspliced RNA species.[79–81] Advanced versions of lentiviral vectors[82] now include the central polypurine track[72,73] and the central termination sequence.[83] Fortunately, the coding sequences for the virulence genes can all be deleted from the vector genome.[84] The packaging genome contains the sequences for GAG and POL under the control of a heterologous promoter (e.g., the cytomegalovirus [CMV] promoter and heterologous RNA processing signals). Codon optimization of the GAG and POL genes whereby the codons found in highly expressed mRNAs are used to assemble the coding sequences enhances production of the viral

proteins and eliminates homology between the packaging and vector plasmids, thereby improving the safety of the packaging system.[85] The rev coding sequences have also been codon optimized in a separate expression plasmid to enhance expression and to eliminate overlap of the tat and rev coding sequences. Because native HIV viral particles have a limited host range that is dependent on cell surface expression of CD4, alternative envelope proteins are used to generate vector particles. Pseudotyping of vector particles with the ENV protein of amphotropic γ-retrovirus or vesicular stomatitis virus creates vector particles with a broader host range. To date, most vector preparations have been derived by cotransfection of three[82] or more[86] helper plasmids encoding viral proteins along with a vector plasmid into human kidney (293T) cells.[87] Typically titers are approximately 10^7 infectious units (IU)/mL.

Several of the HIV proteins are toxic, limiting the ability to derive packaging lines in which the helper components are stably integrated. This limitation has been overcome by placing both the GAG-POL and envelope genomes under the control of tetracycline-modulatable promoters.[88] As noted previously, it is possible to eliminate coding sequences for the accessory proteins, vif, vpr, vpu, and nef, and still generate vector particles capable of transducing quiescent cells.[84,89] Elimination of these genes increases the safety of HIV-based lentiviral particles because each has a role in the pathogenicity of HIV. Another innovation in the development of stable packaging lines and producer clones has been the introduction of the coding sequences for the viral proteins in the form of γ-retroviral vector genomes.[90,91] This modification eliminates plasmid sequences that have the potential to attract silencing mechanisms.[92] A recent report describes inducible packaging cells for large-scale production of lentiviral vectors in serum-free suspension culture.[93] Our colleague at St. Jude Children's Research Hospital, Dr. John Gray, has also recently succeeded in deriving a fully inducible producer clone for a SIN vector encoding the marker GFP that yields titers in excess of 10^7 IU/mL (Gray J, unpublished observations). He has also derived globin vector producer clones that yield titers of 10^6 IU/mL. Such producer clones should be highly useful for mass cultures to generate sufficient vector particles for downstream processing and purification of vector particles.

Safety will be a paramount concern as HIV-based vectors gain clinical application. As noted, elimination of the accessory and ENV genes greatly reduces the potential pathogenicity of any replication-competent retroviruses that might arise during packaging. As constructed, the vector and packaging genomes with codon optimization have limited homology, greatly reducing the probability of generating replication-competent retroviruses by homologous recombination. HIV is dependent on the expression of the *trans*-acting proteins, tat and rev, that are absent from the target cell population. The HIV LTR, because of its dependence on tat, is naturally at least partially "self-inactivating." Nonetheless, most modern vectors have a SIN design in that they are constructed by removing the enhancer/promoter sequences from the 3′ LTR so that both LTRs of the integrated proviral genome lack transcriptionally active sequences. Further improvement in safety may be sought by improving the transcriptional termination of HIV vectors.[94]

Another safety modification involves the addition of a chromatin insulator to the 3′ LTR in the vector plasmid. By placing an insulator in the 3′ LTR, it is copied over into the 5′ LTR so that the integrated proviral genome has insulator elements flanking an internal gene. Insulator elements have both enhancer blocking and chromatin barrier functions[95] and therefore have the potential to enhance the safety of retroviral vectors by shielding nearby cellular genes from the actions of transcriptional elements within the vector genome and also may improve vector function by preventing silencing.[96] Recent evidence supports the enhanced safety of such a vector design in that a SIN-insulated vector with an internal γ-retroviral LTR exhibited diminished clonal dominance, presumed secondary to gene activation by integrated vector genomes, compared with the control vector without the insulator in short-term cultures of transduced lymphoid cells.[97] Furthermore, the insulator element was shown to block promoter activation by an integrated γ-retroviral LTR in lymphoid cells in which the integration event in the first intron of the LMO2 gene in one of the X-SCID patients with leukemia had been recreated.[18]

Lentiviral vectors are proving highly useful for deriving transcriptional units that rely on expression from cellular promoters. For example, a retroviral vector has been constructed using the native proximal promoter for the Wiskott-Aldrich Syndrome (WAS) protein to achieve hematopoietic-specific expression of the WAS protein coding sequences, which is intended for use in a planned gene therapy trial for WAS.[98] A recent study suggests that adding the distal promoter in tandem enhances WAS protein expression in myeloid cells.[99] Lentiviral vectors have been found to transduce efficiently quiescent cell populations in vivo, including myocytes and hepatocytes,[100] neurons,[81,101,102] and retinal cells.[103] Lentiviral vectors can transduce quiescent human primitive hematopoietic cells that are capable of establishing human hematopoiesis in immunodeficient mice.[80,82,99,104]

A recently reported screen that was based on small interfering RNAs resulted in the identification of more than 250 host HIV dependency factors (HDFs).[105] Two hundred and thirty-seven of these HDFs had not been implicated in the HIV life cycle previously whereas 36 host factors were known to be important to HIV pathogenicity. Individual HDFs were involved in the nuclear pore complex, retrograde vesicular transport, nuclear transport, and HIV transcription. Although the primary screen was performed in HeLa cells, 33% of the HDFs were enriched for genes with high expression in immune cells.[105] Thus the interaction of lentiviral vectors with the intended target population is

likely to be highly complex with relatively high expression of host factors that are required favoring transduction and the relatively high level of expression of factors that confer resistance to transduction such as the APOBEC3 factor and the TRIM5α protein[50,51,106] diminishing transduction. One example of the complexity of these interactions is the identification of a mutation in the HIV capsid protein which significantly diminishes infection of nondividing HeLa cells but has little effect in reducing infection of nondividing monocytes suggesting a role for a cell-type specific factor.[78] Another example is the fact that cells from the monkey species, *Macaca nemestrina*, lack a functional TRIM5α and are highly susceptible to HIV infection whereas cells from rhesus macaques express a variant of TRIM5α that renders them highly resistant to HIV infection.[107] Undoubtedly, many such potential target cell specific vector interactions that may influence transducability of specific target cells remain to be discovered.

Foamy Virus Vectors

Human foamy virus (HFV), a retrovirus that is a member of the Spumavirus family, is also being explored for potential gene therapy applications.[108] Its advantages and disadvantages, relative to γ-retroviral and lentiviral vectors have recently been reviewed.[109] Although HFV was isolated from a human nasopharyngeal carcinoma, its origin is now thought to be from a chimpanzee as a result of an early trans-species transmission.[110] Foamy virus infections have frequently been reported in persons occupationally exposed to nonhuman primates,[110] but person-to-person transmission of foamy viruses has not been reported.[109] Foamy viruses are nonpathogenic both in nonhuman primates and in humans.

The originally isolated foamy virus known as HFV has been the focus of most work on this family of viral vectors, although a suggestion has been made because it originated from a non-human primate, that it be redesignated prototype FV (PFV).[109] Foamy viral (FV) vectors are of interest to those focused on developing gene therapy for hemoglobin disorders because of their broad host range which includes human clonogenic progenitors[111] as well as long-term mobilized peripheral blood–derived cells capable of establishing human hematopoiesis in immunodeficient mice.[112] Indeed a direct comparison of the three retroviral vector systems for transduction of these primitive human hematopoietic cells suggests superiority with respect to efficiency for the FV vector tested compared with γ-retroviral and lentiviral vectors.[113] These results have been obtained despite an early report suggesting that there was low-level expression of functional foamy virus receptor on hematopoietic progenitor cells.[114] Indeed a recent report describes FV-mediated gene transfer into canine repopulating cells[115] and canine leukocyte adhesion deficiency has been successfully treated with an FV vector.[116]

The organization of the FV genome is described in a recent review.[109] Like all retroviruses, it includes GAG, POL, and ENV coding sequences. In addition, it encodes several bel proteins, one of which (also called tas) is a DNA-binding protein that activates both an internal promoter and the LTR, whereas a different bel protein (called bet) may sequester APOBEC from being incorporated into vector particles. *Cis*-acting RNA signals have been identified in both GAG and POL coding sequences and both are absolutely required for packaging of a vector genome. FV vector particles cannot be pseudotyped with any other envelope protein. In keeping with this observation, the organization of the FV envelope protein is significantly different than that of other retroviral viruses of interest to gene therapists.[109] Packaging systems in which the GAG, POL, and ENV coding sequences are present on individual plasmids and the vector genome has a Tas independent promoter have been described.[117–119] The FV proteins are toxic to cells and no stable packaging cells or producer clones have been derived. Reverse transcription of FV genome begins in the packaging cell and indeed vector genomes can be integrated in such cells.[109] Full-length vector genomes can also be found in vector particles and the DNA/RNA ratio is higher in FV vector particles than in either γ-retroviral or lentiviral vector particles. Indeed the ability of FV to transduce quiescent cells that divide rarely is thought to reflect the stability of the DNA genome in target cells where it may persist for several days before cell division occurs.[120] FV vectors accommodate more than 9 kb of foreign DNA and therefore it should be possible to construct vectors encoding globin along with the required erythroid-specific regulatory elements although none have yet been reported.

RETROVIRAL-MEDIATED GENE TRANSFER INTO HEMATOPOIETIC STEM CELLS

Gene Therapy for Hemoglobinopathies Will Require High-Level Gene Transfer into Hematopoietic Stem Cells

Arguably, the most important current obstacle to effective gene therapy for hemoglobinopathies is the need for relatively efficient, stable gene transfer into HSCs. Although current gene therapy methodologies are sufficient to correct several of the severe immunodeficiency disorders,[121,122] the strong selective advantage for corrected cells in these disorders negates the requirement for highly efficient HSC transduction. Data from X-SCID patients that have undergone natural reversions of their original mutation suggests that even a single normal HSC is sufficient to correct the immunodeficiency disorder. In these patients, all lymphocytes contain the reverted, normal allele although the proportion of this clone in myeloid cells, which display no advantage for the revertant clone, is extremely low.[123] This appears to also be true in X-SCID gene therapy patients, where the proportion of transduced

myeloid cells is less than 1% whereas virtually all the T cells contain the vector.[124]

In contrast, the degree of selective advantage for normal stem cell clones in hemoglobinopathy patients is significantly less. Based on preclinical mouse models[125] and clinical data from sickle cell patients that have partial chimerism after allogeneic transplant,[126] it is estimated that between 15% and 20% of all engrafted stem cells would be required to be transduced with a therapeutic globin-expressing vector to achieve clinical benefit.

There has been steady progress in increasing HSC transduction efficiency in human and nonhuman primate HSCs. In a rhesus macaque gene therapy model, recent results when using SIV-based lentiviral vectors show gene-marking levels in peripheral blood granulocytes ranging between 5% and 15%.[127] Considering that this result was achieved with a simple GFP vector rather than a complicated, lower-titer globin vector it seems likely that further advances in HSC transduction efficiency will be required to cure humans with sickle cell anemia or severe β thalassemia. Fortunately, new information is rapidly emerging regarding HSC biology, vector development, and in vivo selection of transduced cells that may allow for such an advance in the foreseeable future.

Biological Obstacles for Transducing Human Hematopoietic Stem Cells

Early enthusiasm for a gene therapy approach to hemoglobinopathies was in part based on successful retroviral-mediated gene transfer into murine HSCs. Using γ-retroviral vectors based on MLV, it is possible to achieve routinely gene transfer and expression in 80%–90% of blood cells in transplanted mice. What has become clear is that transduction of human and nonhuman primate HSCs is fundamentally more difficult and less efficient. Although all the critical differences are not well understood, several biological differences between mouse and primate cells have been identified as being important. The first step in HSC transduction involves binding of the vector particle to specific receptors on the cell surface. In the mouse model, investigators have utilized vectors that express the ecotropic envelope protein, which binds to the ecotropic receptor, a relatively abundant amino acid transporter on murine HSCs. The ortholog for this transporter in human cells does not function as a receptor for ecotropic retroviruses so that alternate envelope proteins are necessary for transduction of human cells. Commonly used viral envelopes for human cell transduction are the amphotropic envelope protein and the GAL virus protein. Although the receptors for these proteins are expressed in human HSCs, the overall level of expression is low compared with the ecotropic receptor.[128] To circumvent this limitation, alternative envelope proteins have been explored for human HSC transduction. One envelope is the RD114 protein, which has yielded relatively efficient transduction of human and rhesus reconstituting cells when used with γ-retroviral vectors. Another promising choice is the envelope from FLVC, which has been shown to yield an increased transduction efficiency of human HSCs in a xenogeneic sheep model.[43] Another choice more suitable for use in lentiviral vectors is the envelope protein from the vesicular stomatitis virus-G (VSV-G). This envelope protein has been widely used and has the advantage that it utilizes a ubiquitously available membrane phospholipid for cell entry. This property also confers concentration-dependent toxicity due to its ability to induce cell fusion and syncytias, particularly in concentrated vector preparations. Another potential issue is that the membrane fusion entry mechanism used by VSV-G is different from the endocytic internalization process associated with the other viral envelope receptors. At this point, it is not clear what the optimum viral envelope protein is to achieve cell entry. This is particularly important in the context of lentiviral vectors in which alternate envelopes may lead to a decrease in infectious titers.[82]

Another important difference between mouse and primate HSCs is that fewer primate HSCs are in cycle at any point in time and that nonhuman primate HSCs cycle much more slowly.[129,130] This is most relevant to transduction with γ-retroviral vectors that require breakdown of the nuclear membrane during mitosis to gain access to chromosomes. It is also relevant to lentiviral vectors, which despite a relatively enhanced ability to transduce nondividing cells, still display some degree of cell cycle sensitivity.[131] One approach to increase transduction efficiency is to enhance cycling of HSCs in culture while exposing them to vector particles, however the challenge is to induce specific self-renewal divisions rather than induce the production of differentiated progeny. Hematopoietic cytokines have been used to induce self-renewal during culture and result in a modest degree of HSC expansion that is nevertheless self-limited over time.[132]

New Approaches for Transduction of Human Hematopoietic Stem Cells

Recently, a number of novel factors have been identified that can be used to expand HSCs in culture.[133] Investigators are now testing these factors to determine if they can be used to improve HSC transduction efficiency. Some of the more promising examples include a membrane traversing form of the HOXB4 transcription factor,[134] mediators of canonical Wnt signaling pathway,[135] and angiopoietin-like ligands and insulin growth factor binding protein 2.[136,137] These factors have been shown to lead to expansion of murine and human HSCs during in vitro culture, and many are now being tested in the context of HSC transduction protocols. Even when the correct signaling moieties are identified for HSC expansion, other modalities may be necessary to prevent loss of HSCs during the culture phase. It has recently been recognized that HSCs are sensitive to

oxidative stress, which limits their lifespan.[138] This oxidative stress activates DNA damage repair pathways that can cause loss of HSCs.[139,140] This may be a particular problem during the hyperoxic conditions associated with cell culture and may require the use reducing compounds such as N-acetylcysteine to reduce accumulation of reactive oxygen species in cultured HSCs.

Another obstacle to be considered is the potential to induce engraftment defects in cultured HSCs. Induction of cycling in HSCs causes an engraftment defect during the $S/M/G_2$ phase of the cell cycle.[141] This has led to approaches that induce a "resting phase" after transduction that allows transduced HSCs to return to the G_0/G_1 phase of the cell cycle. Data from monkeys that have undergone transplantation indicates that culturing transduced HSCs in stem cell factor alone induced quiescence and led to an increase in engraftment of transduced cells.[142] Another consideration regarding engraftment is the induction of CD26, a peptidase on the surface of HSCs that can disrupt SDF1-mediated migration and adhesion of stem cells.[143] Treatment of human cells with CD26 inhibitors leads to enhanced engraftment in immunodeficient mice.[144] This approach may be useful as an adjuvant for engraftment of genetically modified cells.

Vector Titer and Multiplicity of Infection: Critical Variables for Hematopoietic Stem Cell Transduction

The titer of the vector is an important consideration for HSC transduction efficiency. When titers are adequately high, cells can be cultured at a high multiplicity of infection, which leads to efficient transduction of the target cells. This issue is of particular importance to globin gene transfer protocols because the titers of globin vectors are often relatively low. For example, simple lentiviral vectors that contain a viral promoter and a GFP reporter gene can typically be produced at titers of $1–2 \times 10^7$ transducing particles per milliliter. In contrast, lentiviral vectors containing all the globin regulatory elements usually have much lower titers that require high degrees of concentration when using techniques such as ultracentrifugation or membrane dialysis.[145] Although higher concentrations of vector particles can be achieved, the degree to which these procedures can be used in large-scale production protocols has yet to be established. Another concern is that these procedures may also concentrate interfering activities or toxic components of the supernatant that will interfere with efficient transduction. Further advances in the technical aspects of globin vector production, such as the derivation of stable producer clones, are likely to be necessary to achieve efficient stem cell production.

In Vivo Selection Strategies to Enrich for Transduced Hematopoietic Stem Cells

Another method to compensate for inefficient transduction of HSCs is the use of in vivo selection strategies to amplify and enrich a minor component of transduced HSCs. By including an appropriate selective marker into the vector and then treating the transplant recipient with the selective agent, it is possible to increase the proportion of transduced HSCs in a variety of preclinical models.[146] One approach has been to use drug resistance genes that have been identified in studies on tumor cell drug resistance. Studies using dihydrofolate reductase variants together with antifolate drugs have been shown to be useful for in vivo selection of HSCs in transplanted mice;[147] however, analogous studies in nonhuman primates have not led to stable selection of HSCs using dihydrofolate reductase vectors.[148] This is probably due to differences in the biological properties of mouse versus primate HSCs such as the lower percentage of cycling cells in primates and the lower baseline marking obtained in primate versus mouse systems.

To date, the most promising selection system is based on the methylguanine methyltransferase (MGMT) drug resistance gene which confers resistance to several potent hematopoietic toxins such as BCNU and temozolomide. Point mutations in MGMT have been identified that confer resistance to MGMT depletion due to 6-benzylguanine (6-BG), allowing for drug combinations that can kill cells expressing wild-type MGMT but not the vector-encoded, mutant forms.[149] Cells expressing MGMT have the ability to repair the DNA lesions caused by these drugs prior to the induction of apoptosis. Normal HSCs express relatively low levels of endogenous MGMT and are therefore generally sensitive to these drugs; which is one of the reasons for the efficacy of MGMT systems for in vivo selection of HSCs. Murine transplant studies from several laboratories have confirmed the ability to select transduced HSCs to a high degree of efficiency by using either BCNU plus 6-BG[150] or temozolomide plus 6-BG.[151]

This approach has been used to achieve therapeutic numbers of transduced HSCs in a mouse model of β thalassemia.[152] When bone marrow cells from normal mice were transduced with a MGMT vector and transplanted into β thalassemic recipient mice, low levels of engraftment were obtained and there was no evidence of a therapeutic effect. When some of these mice were then treated with temozolomide and 6-BG to select for normal HSCs, there was a significant increase in peripheral erythrocytes that expressed the normal β-globin genes. Most important, drug treatment resulted in a significant increase in hemoglobin concentration that corresponded with correction of red blood cell abnormalities in the peripheral blood smear. This study provides proof of principle that in vivo selection may be useful in hemoglobin gene therapy applications.

Selection of HSCs using the MGMT system has been validated in several large-animal models. Work done using a dog transplant model has shown that allogeneic HSCs can be enriched by treating with BCNU and 6-BG to select for cells expressing a oncoretroviral vector containing the P140K MGMT cDNA.[153] In a subsequent study from the same group, selection of autologous HSCs in dogs

was demonstrated using temozolomide and 6-BG, providing a proof of principal for the anticipated use of selection for treating genetic diseases with gene therapy.[154] High levels of stable polyclonal selection were obtained in this study. Currently, studies are in progress to determine whether MGMT-mediated selection can be successfully implemented in nonhuman primate models. Issues that remain to be resolved is which of the available drugs are most useful in primate models, what degree of selection can be obtained, whether there is a minimal marking frequency necessary for in vivo selection, and what toxicities will be apparent from the drug selection protocol.

PRECLINICAL DEVELOPMENT OF GLOBIN LENTIVIRAL VECTORS

Initial Efforts to Develop Integrating Globin Retroviral Vectors

The hemoglobin disorders of β-thalassemia and sickle cell disease were prime contenders for the development of gene therapy as retroviral vectors were developed in the 1980s, given that the molecular defects of the β-globin gene in both were well-defined at the time and the β-globin gene cluster had been cloned.[155–165] For β-thalassemia, in which little or no β-globin is produced in developing erythroid cells, transfer of an exogenous β- or γ-globin gene into HSCs with subsequent high-level expression in erythroid progeny could be therapeutic. Similarly in the context of sickle cell disease, transfer and high-level expression of γ-globin chains, when coupled with endogenous α-globin chains, could augment fetal hemoglobin (HbF), a potent antisickling molecule, to therapeutic levels. Several attempts using γ-retroviral vectors in the late 1980's were made to transfer and express a human β-globin gene under the transcriptional control of a minimal β-globin promoter in mouse transplant models.[8,166] Unfortunately, poor gene transfer was obtained and the vectors produced very low levels of β-globin mRNA, at most only a few percent of that of the endogenous β-globin gene.

Discovery of Globin Gene Locus Regulatory Elements Essential for High-level Expression

Contemporaneously, investigators were in the process of identifying powerful DNA enhancer elements from the β-globin locus control region (LCR),[10,11,167,168] located on human chromosome 11, that were necessary for the nearby globin genes to be expressed at the very high levels required in erythroid cells. Tuan showed that these elements, termed "hypersensitive sites," were requisite for active transcription of the downstream globin genes.[167] These "hypersensitive sites" consisted of regions of chromatin, located upstream from the globin genes, that were exceedingly sensitive to the enzyme micrococcal nuclease. This suggested that the chromatin was likely in an "open" configuration, such as that which occurs when protein complexes are bound to the DNA. Grosveld[11] showed in transgenic mice that these sequences could be used to direct high-level, copy number–dependent β-globin gene expression, in some instances near endogenous levels. Forrester[168] demonstrated that deletion of this region led to silencing of the transcription of the globin genes. Thus, it became clear that the β-globin LCR was essential to high-level globin gene expression. The LCR, now defined as an approximate 15-kb region approximately 50–60 kb upstream of the β-globin gene, encompasses four or five separate 200–400 core sequences that constitute the hypersensitive sites. These findings led investigators to incorporate these elements, or portions thereof, into the globin γ-retroviral vector design. Including these sequences led to genetic instability of the viral vector and poor vector production.[12] Ultimately, after much molecular optimization, vectors were derived that were capable of transmitting the genome containing the globin gene in an unrearranged fashion.[66,67] Both vector titers and expression levels still remained subtherapeutic in mouse transplant models.

The Development of Mouse Models of β Thalassemia and Sickle Cell Disease

Critical to the preclinical evaluation of globin vectors was the prior development of murine models of both β thalassemia and sickle cell disease. The first mouse model for β thalassemia was described in 1983 as a naturally occurring mutant mouse strain.[169] Mice have two β-globin genes – β-major and β-minor or β^s and β^t – depending on the strain, which reside in tandem on each chromosome 7. This strain had an approximate 3.3-kb deletion of the regulatory and coding sequences for the β-major globin gene. Mice homozygous for this deletion demonstrated a hypochromic, microcytic anemia with anisocytosis and poikilocytosis. Although these mice had moderate anemia, subsequent generation of additional mouse strains bearing different genetically engineered alterations led to a more severe β thalassemia phenotype. In 1995, two groups generated mice having a large deletion of both the murine β-major and β-minor globin genes on chromosome 7. Mice homozygous for this deletion did not survive due to the lack of adult hemoglobin production in late gestation. Heterozygous mice, however, demonstrated a severe anemia akin to that of classical β thalassemia intermedia.[170] All three of these models were subsequently used to test globin lentiviral vectors.[69,152,172,173]

The first attempts at developing a murine model of sickle cell disease led to the generation of mice with high levels of human α- and β^S-globin chains.[174,175] These mice and several others subsequently, although showing some sickle cell disease pathology, retained the mouse hemoglobins that inhibited full expression of the sickle phenotype.[176] Subsequently, Fabry and colleagues[177] developed the first mouse in which a deletion of mouse β-major was present, thereby increasing the levels of the human globins. Although this mouse showed enhanced pathological attributes, the

presence of the murine α-chain, which partially inhibits polymerization of HbS,[178] did not allow the full phenotype to become manifest. In 1995, two groups generated mice with a deletion of the adult α-globin genes.[179,180] These mice, like the described β thalassemia strains, were critical to the eventual development of a sickle cell mouse lacking both murine α- and β-globin chains. Such a sickle transgenic/mouse globin gene knockout strain was subsequently described by two groups in 1997.[181,182] These strains were derived by microinjection of DNAs consisting of a β-globin LCR fragment linked to human γ-β globin fragment and also, in a separate fragment, to an α-globin DNA fragment. These mice expressed adequate amounts of human γ-globin during late gestational development to allow significant numbers of affected animals to survive. These mice have extensive pathology and a severe hemolytic anemia. One of the strains, termed the BERK strain, has a modest α- to β-globin chain imbalance, resulting in a phenotype more representative clinically of sickle–β thalassemia. In contrast, several lines in the second strain appear to have more balanced α- and β-globin chain production. All of the mice demonstrate vasoocclusion and thrombosis in several organs, glomerulosclerosis and renal dysfunction, cardiomegaly, and vascular ectasia representative of that in human in sickle cell disease. The BERK strain can be bred in numbers that are experimentally useful and has been used by a variety of investigators in the field.[182–187]

In 1998, another transgenic knockout strain was developed in which a yeast artificial chromosome was used to deliver a 240-kb β-globin locus containing the γ-globin and β^S-globin genes in their natural context.[188] The result was inadequate γ-globin expression during late gestation, leading to significant prenatal and perinatal death of affected animals. Although the few surviving mice had severe disease, the inability to obtain sufficient numbers of mice has limited the utility of this strain.

In 2001, Fabry et al.[189] reported the derivation of the NYC1-knockout model, which also lacked all mouse globins. These mice, having balanced chain synthesis, were developed to also express some human γ-globin to allow survival. In fact, three derivative strains expressing γ-globin at varying levels, resulted in dose-dependent amelioration of sickle cell pathology.[183,190] Thus far, no gene therapy studies have been reported in which this unique model was used.

β-Globin Lentiviral Vectors: Correction of Murine Models of β Thalassemia and Sickle Cell Disease

A major advance in the globin gene therapy field was the derivation of an HIV-based, globin lentiviral vector for correction of mouse β thalassemia (Fig. 33.5).[69,191] It is believed that the HIV rev responsive element contained within the vector backbone, in the context of the rev protein in the vector producer cells, suppressed potential vector genome splicing and rearrangement from occurring. This allowed significant production of unrearranged vector mRNA, which in turn allowed production of vector particles capable of faithful genome transmission. In these studies, long-term hematological and pathological correction of the severe β thalassemia mouse model was demonstrated.[191,69] β-globin transgene mRNA levels of 16% that the level of one copy of an endogenous allele were obtained, which resulted in chimeric hemoglobin molecules (murine α_2, human β_2) comprising approximately 21% of the total hemoglobin in red cells. This level was obtained in the context of virtually every transplanted HSC being genetically modified with the globin vector.

In a subsequent study by Humphries and colleagues,[173] using a β-globin vector containing 2.7 kb of LCR sequences, disease correction was also achieved, but this time improvement depended on a relatively high vector copy number of three in the transplanted HSCs. In fact, animals having only one vector copy per HSC had little or no improvement and expressed the human β-globin gene at low levels in only 30% of the erythroid progeny. In another later study, using the most severe model of murine β thalassemia, which relies on transplanting fetal liver HSCs lacking both endogenous β-globin alleles, Rivella et al.[192] remarkably achieved nearly complete correction of the phenotype in one animal; however, all other animals in the study remained severely anemic with Hb levels of 4.2–7.5 g/dL despite all HSCs likely having at least one vector copy. Together these studies highlighted the significant accomplishment of phenotypic correction of severe β-thalassemia using globin lentiviral vectors containing LCR elements. Importantly, one or more vector copies on average were needed in each HSC, suggesting inconsistent, variable expression from individual globin vector integration sites. This phenomenon, know as position effect variegation, was first demonstrated in mice in the setting of transgenic animals in which different lines containing transgenes at differing chromosomal sites displayed varying expression of the integrated transgene. Using a γ-globin vector, Persons et al.[152] demonstrated that globin vector site of integration heavily influences subsequent expression in erythroid progeny. The development of vectors containing elements designed to diminish this effect has subsequently been the focus of an intensive effort by several laboratories.

Subsequent to the initial finding that lentiviral vectors could mediate therapeutic gene therapy in murine β thalassemia, Leboulch and colleagues[183] used a lentiviral vector containing an antisickling human β-globin gene to ameliorate the disease phenotype in mouse models of sickle cell disease. The β-globin gene that was used contained a mutation at amino acid 87 that corresponds to the residue in γ-globin that is thought to mediate its antisickling activity. A 2.7-kb configuration of LCR sequences was used to drive expression of the variant β-globin gene. High levels of expression of the antisickling β-globin chain were achieved in the context of three vector copies per HSC, which led to

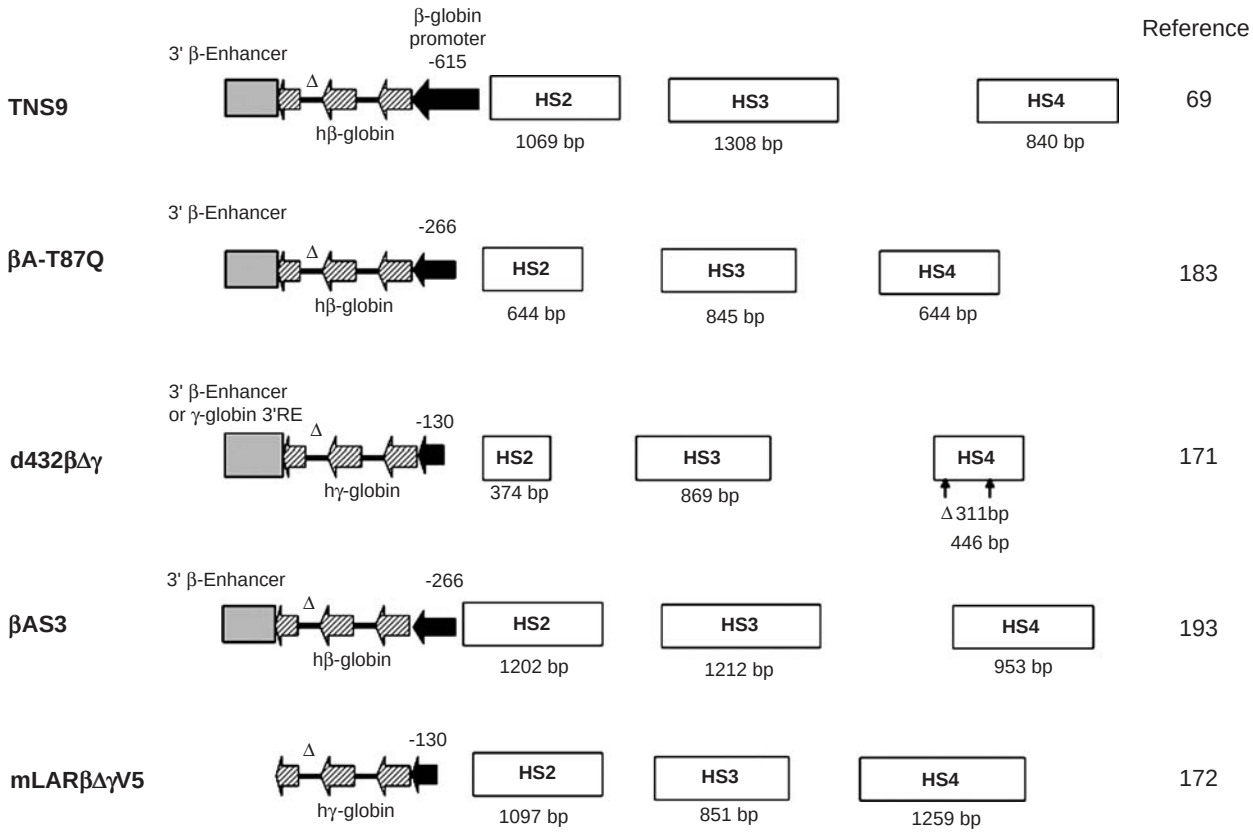

Figure 33.5. Schematic representation of various lentiviral globin vectors used to correct murine models of β thalassemia and sickle cell disease. DNA fragments containing the hypersensitive sites and flanking sequences are shown as open horizontal rectangles, the solid horizontal arrow indicates the β-globin promoter, and the hatched horizontal arrows indicate the genomic β- or γ-globin sequences contained in the mature mRNA. The solid lines connecting the three arrows represent intronic sequences; all of the vectors utilized a deletion in intron 2 to improve vector performance. The solid gray rectangle indicates the 3′ β-globin enhancer sequence or the 3′ γ-globin regulatory element (RE). The fragment sizes of the DNA elements derived from the β-globin LCR that contain the indicated hypersensitive sites (HS) and form the "enhancer" activity are shown below each horizontal rectangle, and the GenBank coordinates (accession number U01317) of the sequences are shown above each rectangle. Self-inactivating lentiviral vectors (SIN) include the d432βΔγ, β^{AS3}, and mLARβΔγV5 vectors. All vectors except TNS9 contain the DNA flap/central polypurine tract element from HIV-1, which can confer improved titer. (Reproduced with permission, from ref. 231.)

levels of the mutant β-globin chain in some mice equaling that of the endogenous β^s allele. Resolution of anemia and diminishment in end-organ damage was observed. Evaluation of vector expression in clonal populations of erythroid cells however demonstrated that there was significant variability of expression with copies number per cell ranging from two to five, again consistent with position effect variegation. Using a different model of sickle cell disease characterized by more severe anemia, Townes and colleagues[193] evaluated a vector encoding 3.4 kb of LCR sequences and an anti-sickling β-globin gene containing the above change at amino acid residue at position 87, and, additionally, two other mutations designed to enhance effectiveness (Fig. 33.5). With an average vector copy number of 2.2 in every HSC, they were able to achieve expression of the globin protein at approximately 20%–25% that of endogenous β^s allele, resulting in an improvement of the Hb level from 2.7 g/dL to 7.3 g/dL. Although still anemic, organ damage was ameliorated in treated mice.

γ-Globin Lentiviral Vectors

Because increased levels of HbF can significantly ameliorate β thalassemia as well as sickle cell disease, both γ-globin γ-retroviral vectors and γ-globin lentiviral vectors have been the focus of study by several groups of investigators. Bodine and colleagues[194] were able to use a γ-retroviral vector that, instead of LCR sequences, utilized ankyrin enhancer/promoter regulatory sequences to drive expression of human γ-globin. Message RNA levels of 3%–8% that of endogenous globin were obtained in wild type mice. Emery and colleagues[195] also obtained similar levels of γ-globin mRNA using a γ-retroviral vector utilizing an α-globin enhancer element coupled to a minimal β-globin promoter. No data are yet available regarding the performance of these vectors in the disease models. Using a lentiviral vector containing a 1.7-kb LCR configuration and a minimal β-globin promoter (Fig. 33.5), Persons et al.[171] were able to obtain significant disease

correction in a severe model of β thalassemia intermedia. Animals with vector copy numbers of 2.4 in HSC displayed an average level of 21% HbF protein, which resulted in a 2.5 g/dL increase in the Hb level. This study also provided direct evidence of chromosomal position effects on vector expression by utilizing an analysis of clonal populations of transduced erythroid clones. Many vector integrations did not result in significant expression. Subsequently, this group showed that by including extended sequences surrounding the core enhancers of the LCR HS sites (Fig. 33.5), much more consistent expression could be obtained, and with it improved therapeutic efficacy.[172] In fact, the majority of animals could be essentially cured with one vector copy per HSC.

Recently, this same laboratory has shown that an optimized γ-globin lentiviral vector effectively cured the BERK model of murine SCD through HSC-targeted gene transfer and transplantation.[196] Mice receiving transplants of lineage depleted, steady-state sickle cell bone marrow cells transduced with the globin vector showed hematological correction, compared to animals receiving transplants of cells transduced with a control vector. Importantly, secondary organ damage was prevented by gene therapy, including renal, pulmonary, hepatic and splenic disease. Renal function was found to preserved as determined by the ability to concentrate urine following exposure to limited access to water. These results reinforce the concept that permanent high level expression of HbF is therapeutic for SCD.

Correction of Human β Thalassemia Erythroid Cells

Globin lentiviral vectors have also recently been evaluated in cells from patients with β-thalassemia major. Malik and colleagues[145] demonstrated that the β thalassemia phenotype could be corrected in cultures of erythroid cells derived from patients' $CD34^+$ cells after transduction with a β-globin vector concentrated 10,000-fold. On average, this correction required 2.2 vector copies per cell. This study utilized a β-globin vector containing 3.1 kb of LCR sequences and a 250-bp β-globin promoter. A unique feature of this vector was that it also included a 1.2-kb element from the chicken β-globin LCR HS4 region. This element had previously been described as a genetic insulator element which acts to block interactions between neighboring chromosomal DNA regions.[95,197] Subsequent work by this group confirmed the function of this insulator in diminishing the negative effect on expression of position effect variegation.[198]

The Conundrum of Position Effects Dampening Globin Vector Expression

A major finding from all these studies is that significant phenotypic correction required multiple vector genomes in virtually all of the primitive cells from which the erythroid cells were derived. This fact, and direct experimental data, highlight that consistent expression of globin vectors is problematic and could impact negatively on the potential for clinical success. Although improved expression, as described previously, can be obtained with insulators, this change in vector design caused a significant diminishment in titer of the globin vector as well as other vectors. Encouragingly, recent efforts indicate that a small portion of the 1.2-kb insulator used above may have nearly equivalent functional activity and may not cause as significant a diminishment in vector titer.[199] Further testing of a globin vector with the smaller insulator element in animal models is needed to verify this potential solution.

PROGRESS AND PROBLEMS IN HUMAN STEM CELL GENE THERAPY

Successful Treatment of Patients with Immunodeficiencies

Immunodeficiency disorders were among the first diseases to be identified as candidates for gene therapy because of the low numbers of corrected cells estimated to be necessary and because appropriate expression of the transgene was relatively easy to achieve.[200] Several trials were performed throughout the 1990s in patients with ADA deficiency; however, these pioneering studies did not yield convincing evidence of efficacy.[201,202] In these studies, low levels of marking were observed and clinically significant immune reconstitution was not seen. It was recognized that at least part of the problem was that concomitant enzyme replacement therapy blunted the selective advantage for corrected cells.[203] Another problem was that the engraftment level of transduced HSCs was very low in the absence of myeloablative conditioning. There appeared to be no significant toxicity due to the gene therapy vectors or the transduction procedure.

A groundbreaking study in France that was reported in 2000 showed the first convincing proof that gene therapy could be used successfully to treat patients with SCID.[204,124] This study focused on X-linked SCID, which is caused by mutations in the common γ_c gene that is necessary for multiple cytokine signaling receptors required for normal development of T, B, and natural killer lymphocytes. Studies of rare patients that showed spontaneous recovery of immune function revealed that reversion of mutations that presumably occurred in single stem cells was sufficient for phenotypic correction, illustrating the strong selective advantage for low numbers of corrected cells.[123] This natural selection for corrected cells bypasses the requirement for transducing larger proportions of repopulating cells and can be demonstrated directly in animal models.[205]

In the French study, CD34+ bone marrow cells were collected from patients, usually within the first year of life, and were transduced with a simple MLV vector that expressed the γ_c cDNA under control of the viral promoter in the LTR. Transduced cells were then infused back into the patients without any myeloablative conditioning. In the majority of cases, there was significant recovery of T- and B-cell function and clear clinical improvement with resistance to

opportunistic infections. Immune reconstitution was stable in patients with more than 5 years of follow-up.[124] A parallel trial was performed in the United Kingdom that showed similar results with unequivocal immune reconstitution in most patients.[206] Another important advance was the successful treatment of infants with ADA-deficient SCID by gene therapy. In a trial done in Italy, bone marrow CD34+ cells were transduced with a MLV vector expressing an ADA cDNA, but unlike earlier trials, patients were preconditioned with a subablative dose of busulfan to increase engraftment of transduced HSCs. Patients were then followed without enzyme replacement therapy and in all cases were shown to have increased T- and B-cell function as well as partial reconstitution of ADA enzyme levels in blood cells.[207] These patients have remained stably corrected for up to 4 years.[208]

The Unexpected Occurrence of Insertional Mutagenesis in Immunodeficiency Gene Therapy Trials

The stunning success of stem cell–targeted gene therapy for treating SCID disorders has provided strong proof of principle that this approach may be extrapolated to other genetic blood disorders. These pioneering clinical studies have also revealed an important and unanticipated toxicity, the occurrence of insertional mutagenesis leading to leukemia. In 2002, two of the patients in the French X-SCID trial developed a progressive accumulation of phenotypically mature, monoclonal T cells in the peripheral blood.[209] This disorder behaved like an acute T-cell leukemia and was successfully treated using standard cytotoxic chemotherapy. With time, two more patients in the French trial have developed T-cell leukemia and it has recently been reported that a fifth patient in the UK trial has developed leukemia. Although all the molecular data have not been published, it is clear that most cases involve activation of the LMO2 oncogene due to local vector insertion sites.[209,210,215] In the first two patients, the vector was inserted either in a sense orientation immediately upstream of the first exon or in an antisense orientation within the first intron. LMO2 has been identified as a oncogene in translocations seen in T-cell leukemia and functions as part of a transcription factor complex.[211] Constitutive activation of Lmo2 in transgenic mice results in a differentiation block in the thymus, followed by a delayed development of leukemia.[212] It seemed likely that at least some of these cases of oncogene activation are the direct result of interactions of the strong enhancer within the γ-retroviral LTR with the LMO2 promoters. This has now been directly demonstrated by inserting the MLV LTR in a reverse orientation into the first intron of LMO2 in a human T cell line, in the same site noted in one of the patients who developed leukemia.[18] This study directly demonstrated the ability of the enhancer within the LTR to activate cellular LMO2 promoters. Interestingly, no transformation has yet been seen in the small number of ADA patients who have been successfully treated with γ-retroviral vectors, although some of these patients have been shown to harbor vector insertions within the LMO2 gene of circulating blood cells.[208]

There are several reasons why the field did not expect this complication. First, it was widely assumed that integration of γ-retroviral vectors would occur randomly throughout the genome and that the probability of insertions within an oncogene was too low to be significant. Subsequent studies have shown that γ-retroviral vectors preferentially integrate at the transcription start site of actively transcribed genes.[213] Furthermore, in human CD34+ cells, 21% of all γ-retroviral integrations occur in recurrent insertion sites that are enriched for protooncogenes.[214] In contrast, lentiviral vectors have a distinct pattern of integration that is less likely to localize to a potentially dangerous region of the genome,[215] a characteristic that may reduce the risk associated with lentiviral globin vectors.

T-cell leukemias were not seen in studies of gene therapy in X-SCID mouse models probably because of the relatively low frequency of transformation and the small numbers of mice used in these studies.[217] A recent mouse model has been described that is highly sensitive to vector-induced transformation and recapitulates many of the aspects of this leukemic syndrome.[218] Mice that have homozygous ablation of the γ_c gene and homozygous deletion of the Arf tumor suppressor gene have been used as bone marrow cell donors. Deletion of the Arf tumor suppressor gene was based on the fact that it is universally mutated in human T-cell leukemia.[219] When these cells are transduced with γ-retroviral vectors expressing the γ_c gene and transplanted into recipients, approximately 85% of the animals develop T-cell lymphomas/leukemia after 1 year. In most cases, these leukemias were associated with retroviral integrations into known murine oncogenes, although interestingly, Lmo2 integrations were not detected.

One important finding using this model was that the X-SCID background itself is a significant risk factor for transformation. When cells were used from $\gamma_c^{+/+}$, $Arf^{-/-}$ mice, the incidence of leukemia was significantly lower than that seen using $\gamma_c^{-/-}$, $Arf^{-/-}$ cells. This observation suggests that X-SCID gene therapy may carry a uniquely elevated risk of transformation and that gene therapy for other disorders, such as hemoglobinopathies, may carry less risk. This conclusion is consistent with a review of large animals that have been transplanted with MLV-derived vectors.[220] This study examined the consequences of transduction with MLV vectors in 42 rhesus macaques, 23 baboons, and 17 dogs with significant levels of gene transfer. These animals were transplanted in various centers and followed for a median of 3.5 years. In this report, no cases of abnormal hematopoiesis or leukemia were noted. Two years following this report, one case of a vector-induced tumor was observed in a rhesus macaque that had undergone transplantation.[221] In contrast to the T-cell leukemias that have been noted in X-SCID patients and animal models, this case presented as a myeloid tumor with an insertion into BCL2-A1, an anti-apoptotic gene.

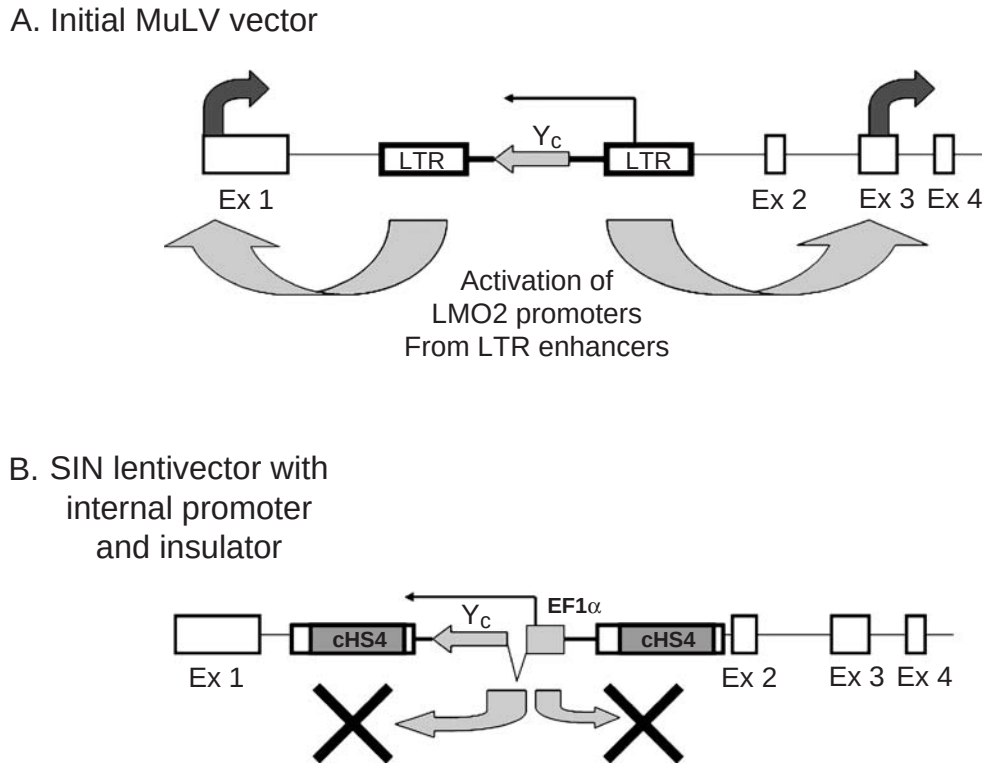

Figure 33.6. Safety design considerations for lentiviral vectors. **(A)** The upper diagram shows the safety problems associated with using γ-retroviral vectors with intact LTRs in the French X-SCID trial.[209] In this case, the vector has integrated into the first intron of the LMO2 gene in a reverse orientation. The strong viral enhancers present in the LTRs activate both cellular LMO2 promoters as shown by the blue and red arrows. This results in oncogene expression in cells that normally would not express LMO2.[18] **(B)** This is a safety modified lentiviral vector that has inactivating mutations in the viral LTRs creating a so-called self-inactivating or SIN design. A copy of the cHS4 chromatin insulator is present in each LTR so that any internal enhancer activity will be blocked from interacting with adjacent cellular promoters (large X). The γ_c transgene is expressed from a single cellular promoter, in the case from the EF1α gene. This promoter itself has much little enhancer activity on its own. This design has been shown to result in no significant LMO2 activation when inserted into the LMO2 locus in a human T cell line.[18] (See color plate 33.6.)

The genetics of insertional transformation for X-SCID versus myeloid disorders are likely to be specific and fundamentally different. In a German gene therapy trial for chronic granulomatous disease, two patients exhibited clonal expansion based on insertions into the MDS1/EVI, PRDM16, and SETBP1 genes.[222] In particular, the MDS1/EVI locus has been identified as a hot spot for MLV insertions in mice[223] and in transplanted rhesus monkeys.[224] Perhaps this is not surprising given that this locus was initially identified as a MLV insertion site. Therefore, just as in the case of other human leukemias, the genetics for lymphoid and myeloid leukemia due to insertional mutagenesis appear to be distinct, with a favoring for LMO2 in lymphoid tumors from X-SCID patients and for MDS/EVI1 in myeloid disorders.

Moving Forward: Can Insertional Mutagenesis be Avoided?

Much work in the field is now focused on generating safer vector systems that are less prone to causing insertional mutagenesis. It is clear from the clinical cases that have been studied to date that the most common mechanism for inducing transformation is activation of oncogene promoters by the strong viral enhancer in the MLV LTRs. This can be avoided by deleting these sequences from the retroviral vector to create SIN vectors. This design requires the use of an appropriate internal promoter to drive expression of the therapeutic transgene (Fig. 33.6). In the case of globin vectors, this is typically the β-globin promoter; however, other erythroid promoters may be useful.[194] A second approach that can be used together with SIN vectors is the use of chromatin insulators to block potential interactions of vector-encoded enhancers with adjacent cellular promoters. A widely used insulator, cHS4, is derived from the chicken β-globin locus and has been shown to be useful both for blocking vector-induced alterations in adjacent cellular genes and in improving expression of the vector-encoded globin gene by shielding the transgene from chromatin effects leading to position site variegation.[195] A 1.2-kb version of cHS4 has been shown to reduce substantially LMO2 activation due to insertion of a MLV-based LTR into the first intron,[18] suggesting that this strategy

may also be useful in designing newer vectors for X-SCID. Another question is whether lentiviral vectors may be less prone to inducing insertional mutagenesis due to their intrinsically different pattern of insertion site preferences.[214,225] In this regard, it is notable that no evidence of lentiviral insertions have been reported into either the LMO2 or the MDS1/Evi locus to date. Further evidence for increased safety with lentiviral vectors has recently been generated in a tumor-prone mouse model.[226]

Much effort has been dedicated to developing appropriate assays for insertional mutagenesis to test whether modified vectors are in fact safer than their original MLV counterparts. Previously existing assays that have been used to identify oncogenes commonly utilize replication competent MLV as the mutagen.[227] This system results in continuous virus production in vivo and relatively high viral copy numbers in transduced cells. In contrast, much lower copy numbers are obtained using replication-incompetent vectors so that a challenge has been to develop systems of adequate sensitivity. One approach has been to use tumor-prone mice to assay for an increase in the basal transformation rate. This approach has been successful using mice deleted for Ink4a[226] and Arf [218] and investigators are currently developing appropriately sensitive models for erythroid transformation.

Recent work in our laboratory has directly addressed the issue of the potential genotoxicity of lentiviral vectors containing globin regulatory elements.[228] The question was addressed in primary, clonal murine β thalassemic erythroid cells present in spleen colonies derived from primitive, transduced hematopoietic progenitors. Eleven percent of all genes analyzed within a 600-kb region surrounding vector-insertion sites demonstrated altered expression; however, there was no indication that perturbation of expression interfered with hematopoiesis or was associated with clonal dominance. These results are in keeping with other studies in which it was shown that globin regulatory elements enhanced promoter activation and expression of a trapping cassette in an erythroleukemia cell line but not in nonerythroid (HeLa) cells.[229] Promoter activation in erythroleukemia cells by vectors containing globin regulatory elements was significantly reduced by addition of flanking insulator elements. Studies have also been performed in a mutant mouse strain (Spi1) that suggest that a lentiviral vector with globin regulatory elements and an insulator in the LTRs does not enhance the rate or frequency of leukemia in vivo in this mouse model. Overall, the data suggest that globin vectors will be relatively safe, although additional safety studies are planned.

Recently published work from Jaenisch and Townes demonstrated the ability to generate embryonic stem cell-like cells, termed induced pluripotent stem cells (iPS) from primary fibroblasts derived from SCD mice.[230] These iPS cells could be successfully targeted by homologous recombination to correct the sickle mutation. Subsequent derivation and transplantation of HSCs from these corrected iPS was shown to correct the SCD mouse model. This study highlights the potential for correcting the mutation while minimizing or significantly reducing the issue of vector insertional mutagenesis. However, this technique did rely on the use of a HOXB4 retroviral vector to facilitate production of HSCs from the genetically corrected iPS clone. Future research will determine whether factors can be identified that can substitute for the use of HOXB4 gene transfer to generate HSCs. Additional studies are also needed to determine the quality of HSCs so generated.

FUTURE PROSPECTS

Success in the treatment of immunodeficiencies by gene transfer provides encouragement that the hemoglobin disorders will also ultimately be amenable to gene therapy intervention. If this can be achieved, it would significantly increase the number of patients who would be eligible for a curative, transplantation-based treatment. Indeed, a phase I/II clinical trial has begun to enroll patients with thalassemia or sickle cell disease in France and undoubtedly this trial will yield important information as to whether the current methodologies for vector production and stem cell transduction are amenable to a positive therapeutic outcome. Our own perspective is that a transition to the use of stable producer clones with the ability to generate large volumes of conditioned media for downstream processing and purification of vector particles, advances which seem within our grasp, will make success in a clinical trial more probable. The need to transduce approximately 20% of the stem cells remains a challenge. Amplification of a minority population of gene corrected red cells is likely to enhance efficacy in thalassemia but perhaps less so in patients with sickle cell disease. Since the introduction of lentiviral vectors for globin gene transfer approximately a decade ago, progress has been steady in that hematological correction in the murine models of thalassemia and sickle cell anemia has been achieved as has the correction of the ineffective erythropoiesis in human thalassemic red cells in vitro. These advances and growing knowledge of stem cell biology and the interactions of vectors with cells make us confident that success in the use of gene therapy for the treatment of hemoglobin disorders will come in the future.

Index

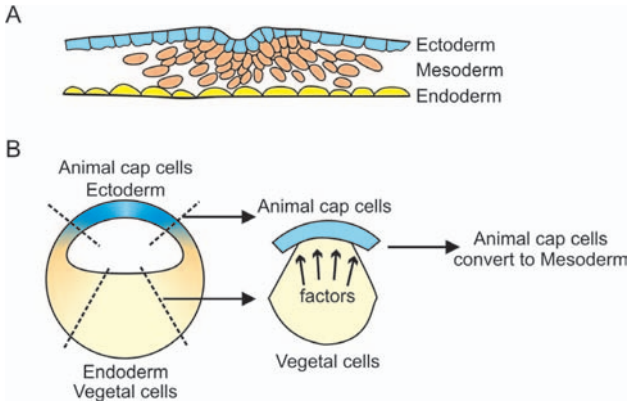

Plate 1.1. Schematic diagram of germ layer development in vertebrate embryos. **(A)** Mesoderm arises from an inductive interaction between ectoderm and endoderm. **(B)** Experimental scheme in Xenopus embryos that shows that mesodermal cells arise from the ectoderm (animal cap cells) under the inductive influence of the endodermal vegetal fragment.

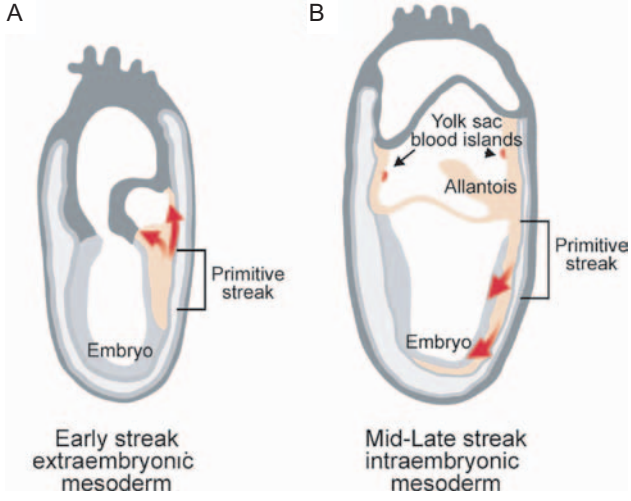

Plate 1.2. Mesodermal migration during mouse embryogenesis. **(A)** Schematic diagram of a mouse conceptus at the early primitive streak stage. Emerging from the posterior primitive streak are waves of yolk sac mesoderm (red arrows) migrating to form this extraembryonic tissues. Slightly later, this mesoderm also forms the allantois. Hemangioblasts are found in the posterior primitive streak. **(B)** Schematic diagram of a mouse conceptus at the mid–late primitive streak stage. Mesoderm emerging from the anterior primitive streak forms the paraxial and lateral mesoderm of the trunk region of the embryo (mesoderm for the prospective PAS/AGM region). At this stage the allantois is visible, as are the first primitive erythroid cells in the yolk sac blood islands. (Drawings adapted from ref. 3.)

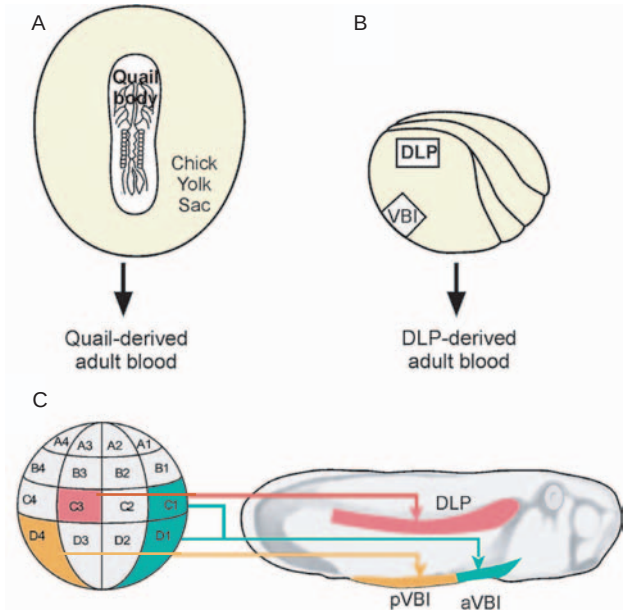

Plate 1.3. Nonmammalian vertebrate embryo–grafting experiments used for determining the origin of the adult hematopoietic system. **(A)** A schematic diagram of the avian embryo grafting strategy in which quail embryo bodies were grafted onto chick yolk sacs at the precirculation stage of development. **(B)** A schematic diagram of the amphibian embryo grafting strategy in which genetically marked dorsal lateral plate (DLP) or ventral blood island (VBI) regions were transplanted onto unmarked Xenopus or Rana embryos. **(C)** Genetic marking experiment in 32 blastomere Xenopus embryo (left). Marking of the C3 blastomere, D4 blastomere, and C1 and D1 blastomeres allowed the tracing of progeny cells to the DLP, pVBi, and aVBI, respectively, at the larval stage (right). (Drawings adapted from ref. 3.)

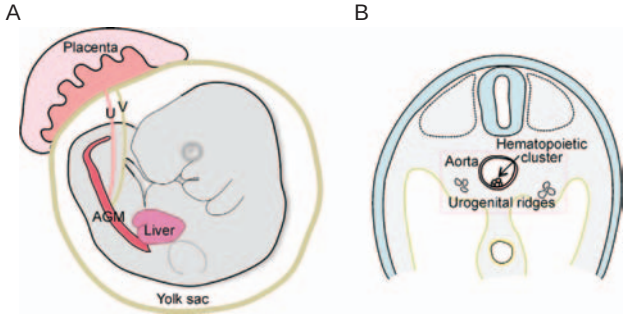

Plate 1.4. Sites of hematopoietic activity in the midgestation mouse conceptus. **(A)** A whole E10.5 mouse conceptus is shown. The placenta, AGM, yolk sac, and the vitelline (V) and umbilical (U) vessels harbor and/or generate hematopoietic cells at this time. **(B)** Transverse section through the AGM region of an E10.5 mouse embryo is shown. The dorsal aorta is located in the midline, with the neural tube on the dorsal and gut on the ventral side. The urogenital ridges laterally flank the aorta. Hematopoietic cell clusters are found in the lumen of the dorsal aorta as they emerge from the ventral hemogenic endothelium.

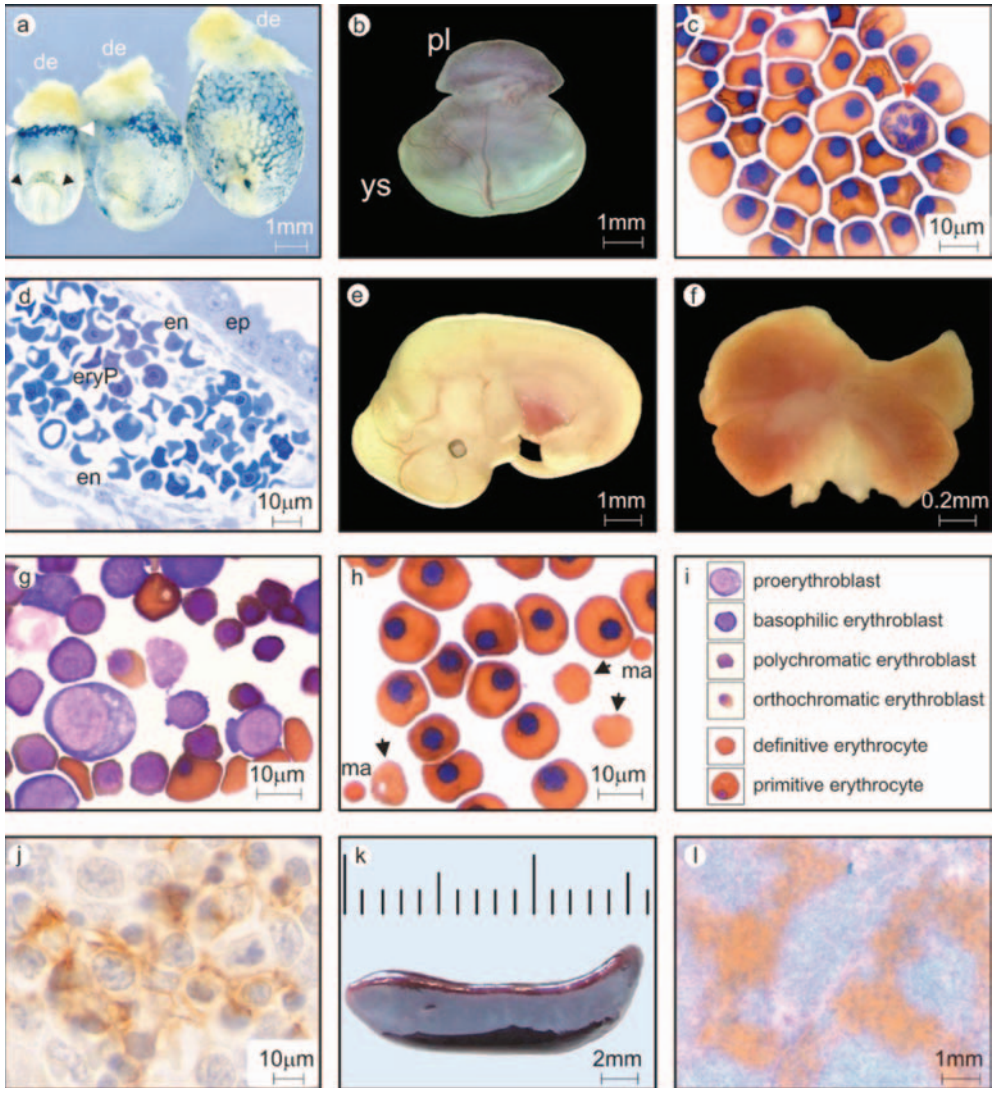

Plate 2.1. Erythropoiesis during mouse development. **(a)** E8.5 embryos, inside their yolk sacs, carrying a *LacZ* reporter gene driven by β*-globin* regulatory elements. Erythroid cells appear blue after staining for LacZ activity. White arrowheads point at the blood islands emerging as a ring at the top of the yolk sac. These are spreading through the developing vasculature, illustrated by the two embryos on the right that are progressively more advanced in development. The black arrowheads indicate the linear heart tube that already appears to contain erythroid cells before the yolk sac cells have reached the embryo. de = decidua, remaining maternal tissue. **(b)** E11.5 embryo inside its yolk sac. The blood-filled yolk sac vasculature is apparent. ys = yolk sac; pl = placenta. **(c)** Cytospin of E11.5 peripheral blood, stained with dianisidine and histological dyes.[207] Nuclei are blue, the hemoglobin-filled cytoplasm brown. Red arrow: cell in mitosis. **(d)** Section of a yolk sac vessel at E12.5, stained with toluidine/methylene blue. eryP = primitive erythrocytes; en = endothelial cells; ep = columnar epithelial cells. **(e)** E12.5 mouse embryo; the fetal liver area is indicated by a dotted line. **(f)** E12.5 fetal liver. **(g)** Cytospin of E12.5 fetal liver cells, stained as in (c). **(h)** Cytospin of E12.5 blood, stained as in (c). ma = contaminating maternal erythrocyte **(i)** key to (g) and (h). **(j)** Erythroblastic island in E13.5 fetal liver. The cytoplasmic extensions of the central macrophage (stained with the F4/80 antibody [brown]) are surrounding erythroid cells at various stages of differentiation. **(k)** Spleen of an adult mouse. **(l)** Section of adult mouse spleen stained as in (c). Red pulp, containing the erythroid cells, is stained brown; white pulp is stained blue.

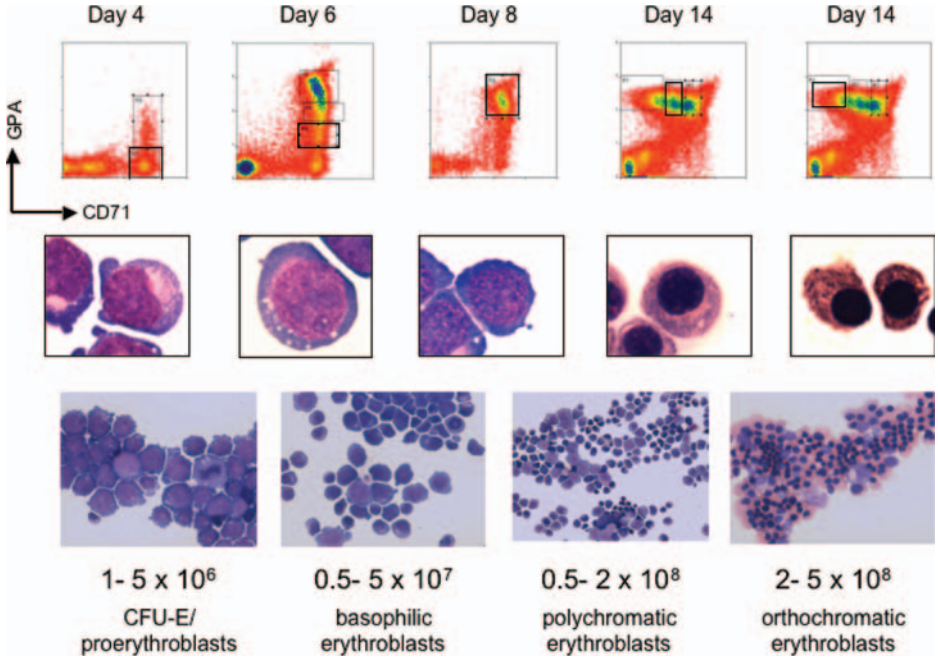

Plate 2.3. Purification of human erythroblasts. Top: FACS analysis of human erythroblasts grown in vitro by the method of Fibach et al; days refers to the time in phase 2 of culture. Middle: High-power view of cells sorted from the gate shown as a bold rectangle in the plot above. Bottom: Low-power view of the same sorted cells, together with representative cell numbers obtainable from mononuclear cells from 1 U of blood.

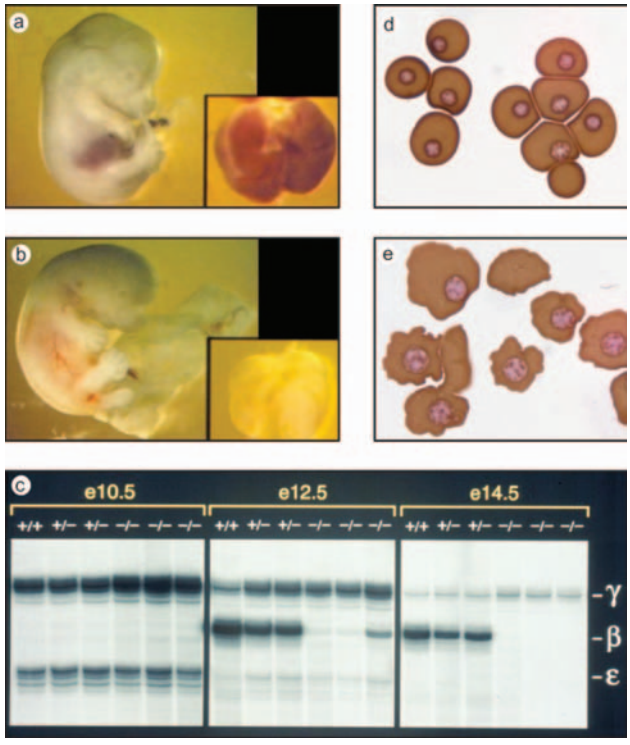

Plate 2.8. Phenotype of EKLF knockout fetuses. **(a)** E13.5 wild-type fetus. Inset: fetal liver. **(b)** E13.5 EKLF knockout fetus, displaying obvious pallor of the fetal liver (inset). **(c)** Mice carrying a human β-globin locus transgene were crossed with EKLF knockout mice. Expression analysis of the human β*-like globin* genes is shown at various gestational ages. Note that in the EKLF knockout background ($-/-$) the adult β*-globin* gene fails to be activated, whereas expression of the embryonic ε*-globin* and *fetal* γ*-globin* genes is not affected. **(d)** Cytospin of E12.5 blood from wild-type fetus, displaying primitive erythrocytes. **(e)** Cytospin of E12.5 blood from EKLF knockout fetus displaying primitive erythrocytes. Note the irregular shape of the cell membranes, compared with (d). (d) and (e) Adapted from ref. 191.

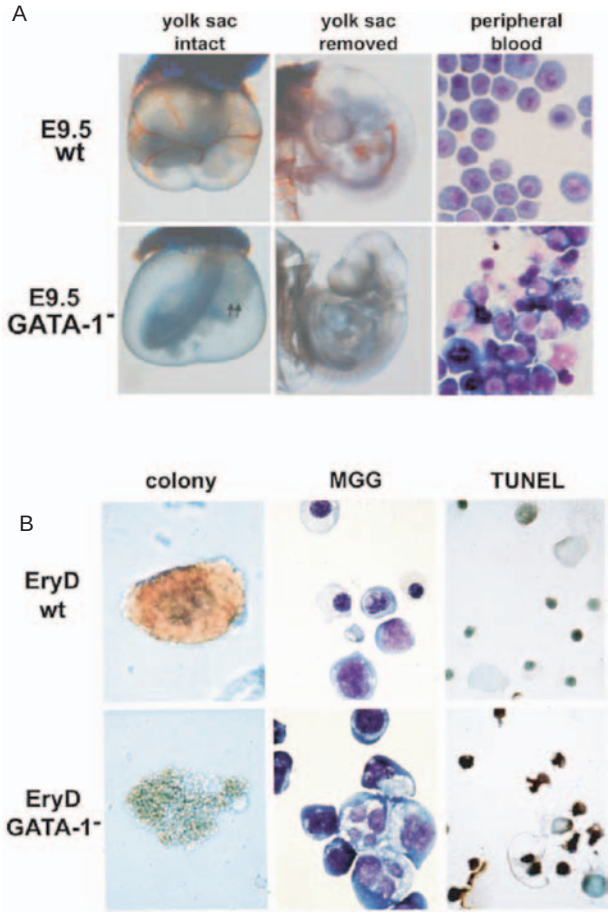

Plate 4.5. Loss of GATA-1 blocks erythroid maturation. **(A)** Impaired primitive erythropoiesis in *Gata1*-embryos. **(B)** Developmental arrest and apoptosis of cells within definitive erythroid (EryD) colonies generated by in vitro differentiation of *Gata1*-ESCs. (Modified from Weiss et al. and Fujiwara et al. Copyright 1995 and 1996, National Academy of Sciences, U.S.A. Photographs in panel A provided by Yuko Fujiwara and Stuart Orkin.)

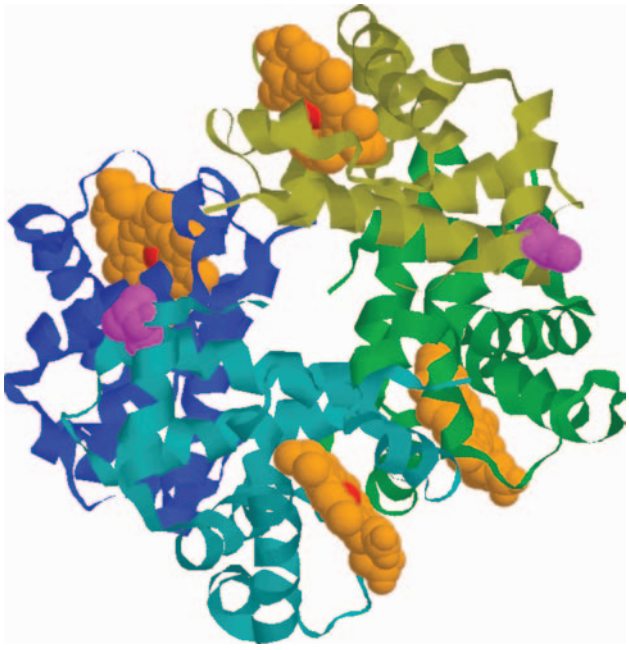

Plate 6.1. Ribbon diagram of a sickle cell hemoglobin tetramer. Each of the four subunits is shown in a different color. Four heme groups (yellow-orange) are shown with an iron (red) atom in the middle. The valine residues resulting from the single point mutation causing sickle cell disease are shown at the β6 position on each β subunit (purple). The molecule is shown looking down the axis where 2,3 bisphosphoglycerate binds. Except for the substitution of valine for glutamate, normal HbA would appear the same as the molecule shown. (The illustration was derived from the Protein Explorer (http://www.umass.edu/microbio/rasmol/) and data from the Protein Data Bank.)

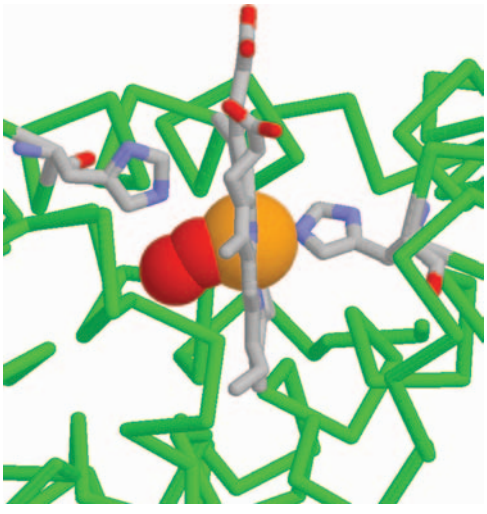

Plate 6.2. Close up of oxygen bound to the heme. Looking down the heme, the iron atom (yellow-orange) is shown bound to an oxygen molecule (red). The proximal histidine side chain is also shown bound to the iron and the distal histidine is also clearly visible on the other side of the proximal one. (The illustration was derived from the Protein Explorer (http://www.umass.edu/microbio/rasmol/) and data from the Protein Data Bank.)

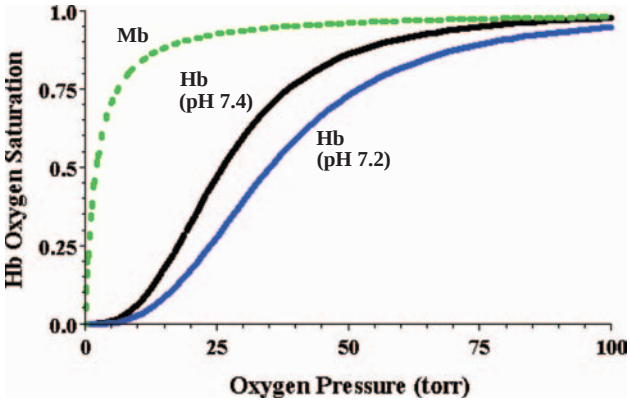

Plate 6.3. Hemoglobin and myoglobin oxygen binding curves. The myoglobin oxygen binding curve was drawn according to Equation 6.1 with P_{50} taken as 2 mm Hg. The hemoglobin oxygen binding curves were drawn using Equation 6.2 with $n = 2.8$ and P_{50} taken as 26 mm Hg at pH 7.4 and as 35 mm Hg for pH 7.2.

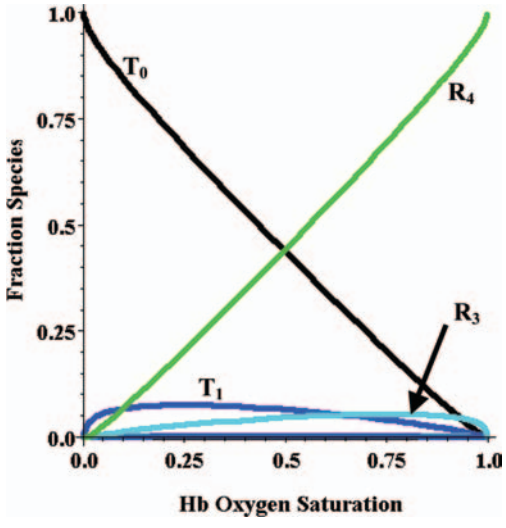

Plate 6.4. Fraction of hemoglobin states. The fraction of each state is plotted vs. hemoglobin oxygen saturation. Only the species T_0, T_1, R_3, and R_4 are present at large enough fractions to be visible. At zero oxygen saturation the hemoglobin is virtually all in the T_0 state and at 100% oxygen saturation it is all in the R_4 state. The parameters used were $L = 2 \times 10^6$, $c = 0.001$, and $K_T = 1/(75\ \text{mm Hg})$.

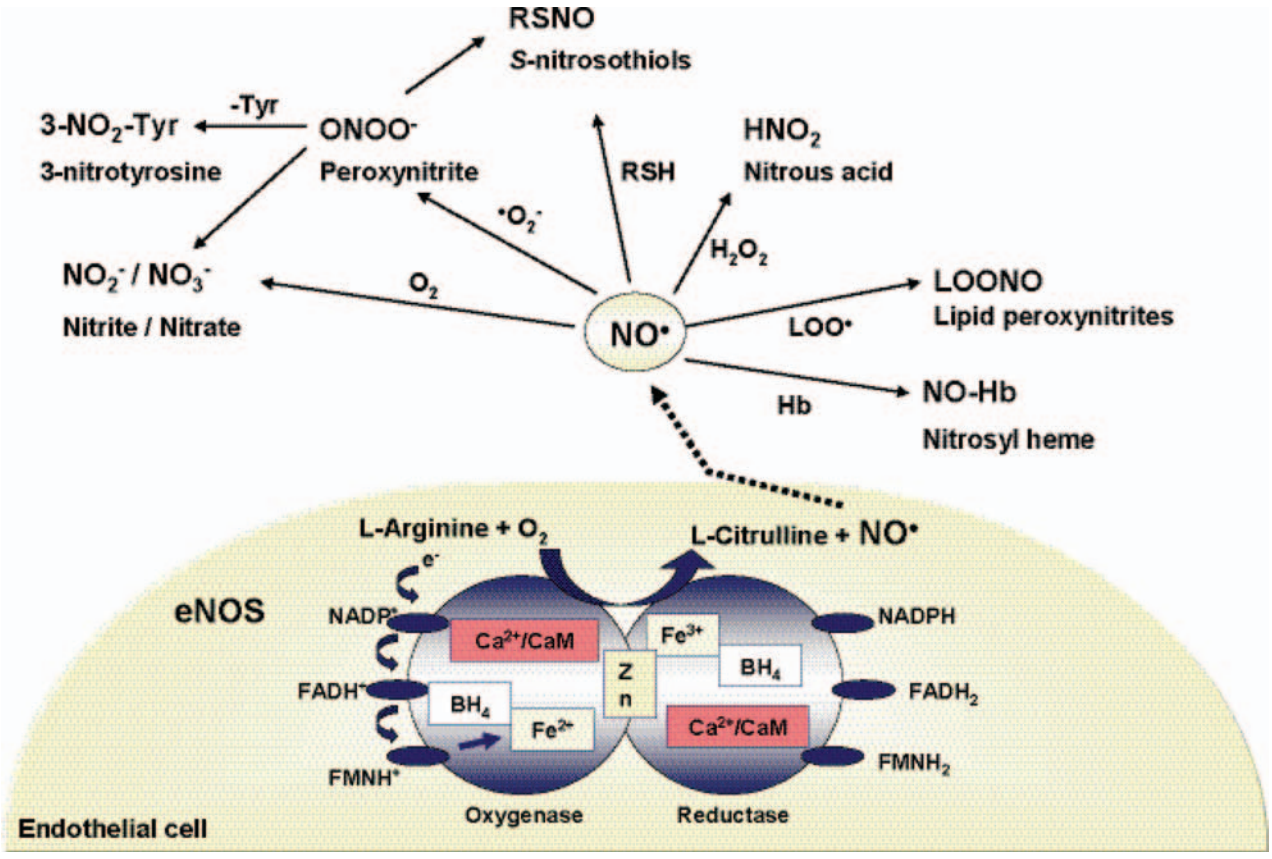

Plate 10.1. Biological source and reactions of nitric oxide. Nitric oxide (NO•) is synthesized in endothelial cells by the endothelial isoform of nitric oxide synthase (eNOS) via the five-electron oxidation reaction of L-arginine to L-citrulline. eNOS is activated by Ca^{2+}/calmodulin (Ca^{2+}/CaM) and the reaction requires molecular O_2 and NADPH as cosubstrates and flavin adenine dinucleotide ($FADH^+$), flavin mononucleotide ($FMNH^+$), and tetrahydrobiopterin (BH_4) as cofactors to facilitate electron transfer to the NOS heme moiety. Once generated, NO• diffuses into the interstitium and the bloodstream where it reacts with molecular O_2, superoxide anion ($•O_2^-$), R-SH groups, hydrogen peroxide (H_2O_2), lipid oxides (LOO•), and hemoglobin (Hb) to generate NO species – some of which have biological activity.

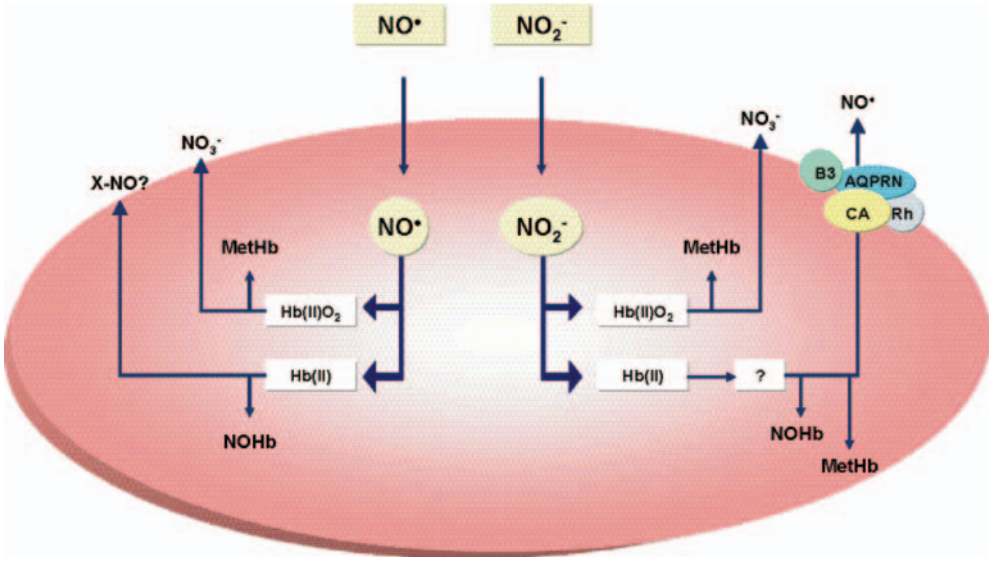

Plate 10.2. Reactions between NO and hemoglobin in erythrocytes. Nitric oxide (NO•), synthesized by the endothelium, or nitrite (NO_2^-) circulating in plasma, diffuses into the erythrocyte where it reacts with oxyhemoglobin [Hb(II)O_2] to yield methemoglobin (MetHb) and nitrate (NO_3^-), or with deoxyhemoglobin [Hb(II)] to generate nitrosylhemoglobin (NOHb) and NO adducts (X-NO). Nitrite also diffuses into the erythrocyte and reacts with deoxyhemoglobin and, via a possible intermediate species (?), produces nitrosylhemoglobin and methemoglobin. Once formed, NO• and NO• adducts are thought to exit the cell through a functional metabolon that is composed of oxy- and deoxyhemoglobin, Rh channels (Rh), aquaporin (AQPRN), band-3 complex (B3), and carbonic anhydrase (CA). These channels theoretically may transport NO• through the erythrocyte membrane.

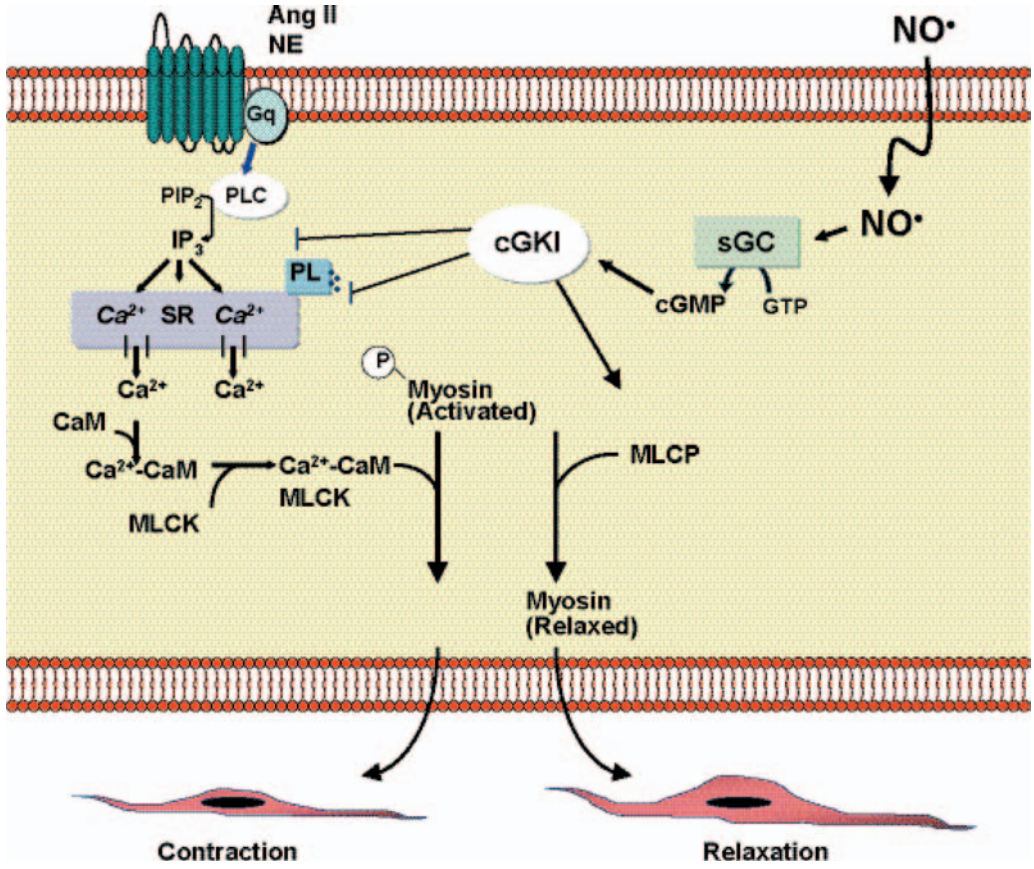

Plate 10.3. NO and vascular smooth muscle relaxation. NO•, synthesized by the endothelium, diffuses into the vascular smooth muscle cytosol and reacts with the heme iron of soluble guanylyl cyclase (sGC). This activates the enzyme, which in turn generates cGMP. As cGMP levels rise, cGMP-dependent kinase I (cGKI) is activated to inhibit inositol 1,4,5,trisphosphate (IP_3)-mediated release of Ca^{2+} from the sarcoplasmic reticulum (SR). cGKI activates phospholamban (PL), which facilitates this process by stimulating Ca^{2+} sequestration by the SR. This effect in turn also limits the ability of the Ca^{2+}-calmodulin (CaM)-myosin-light chain kinase (MLCK) complex to phosphorylate myosin and initiate contraction. cGKI also promotes vascular smooth muscle relaxation by stimulating myosin-light chain phosphatase (MLCP) to dephosphorylate myosin.

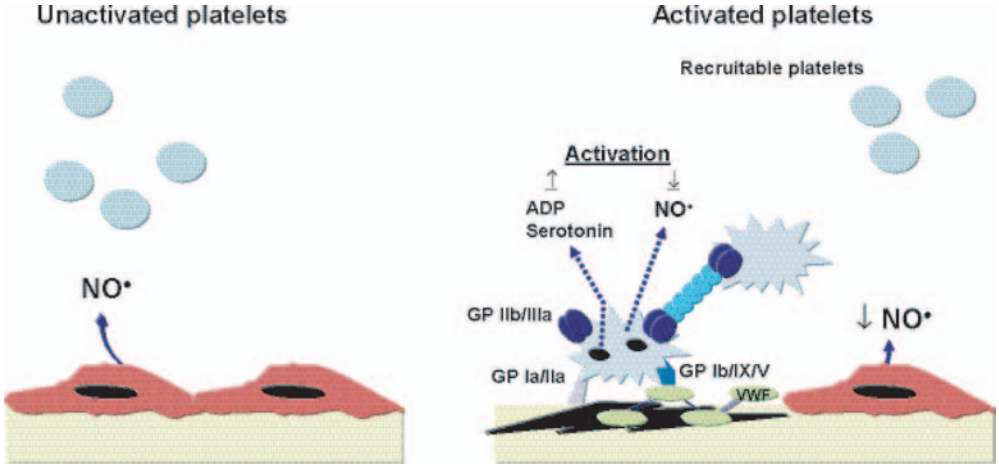

Plate 10.4. NO and platelet activation. Under basal conditions, the vascular endothelium elaborates NO• to maintain a nonthrombogenic surface. In contrast, when the endothelium is disrupted and NO• levels are decreased, platelets become activated and adhere to collagen via the cell surface receptor glycoprotein Ib/IIa (GP Ia/IIa) and glycoprotein Ib/IX/V (GP Ib/IX/V) that binds to the interstitium by von Willebrand factor (VWF). These activated platelets undergo shape change and release adenosine diphosphate (ADP) and serotonin to recruit and activate additional circulating platelets to the growing thrombus, and increase expression of the conformationally active fibrinogen receptor, glycoprotein IIb/IIIa (GP IIb/IIIa) to increase platelet aggregation and thrombus formation; the concomitant release of NO limits platelet aggregation. Platelet-derived NO limits recruitment of platelets to the growing platelet-rich hemostatic plug (or thrombus).

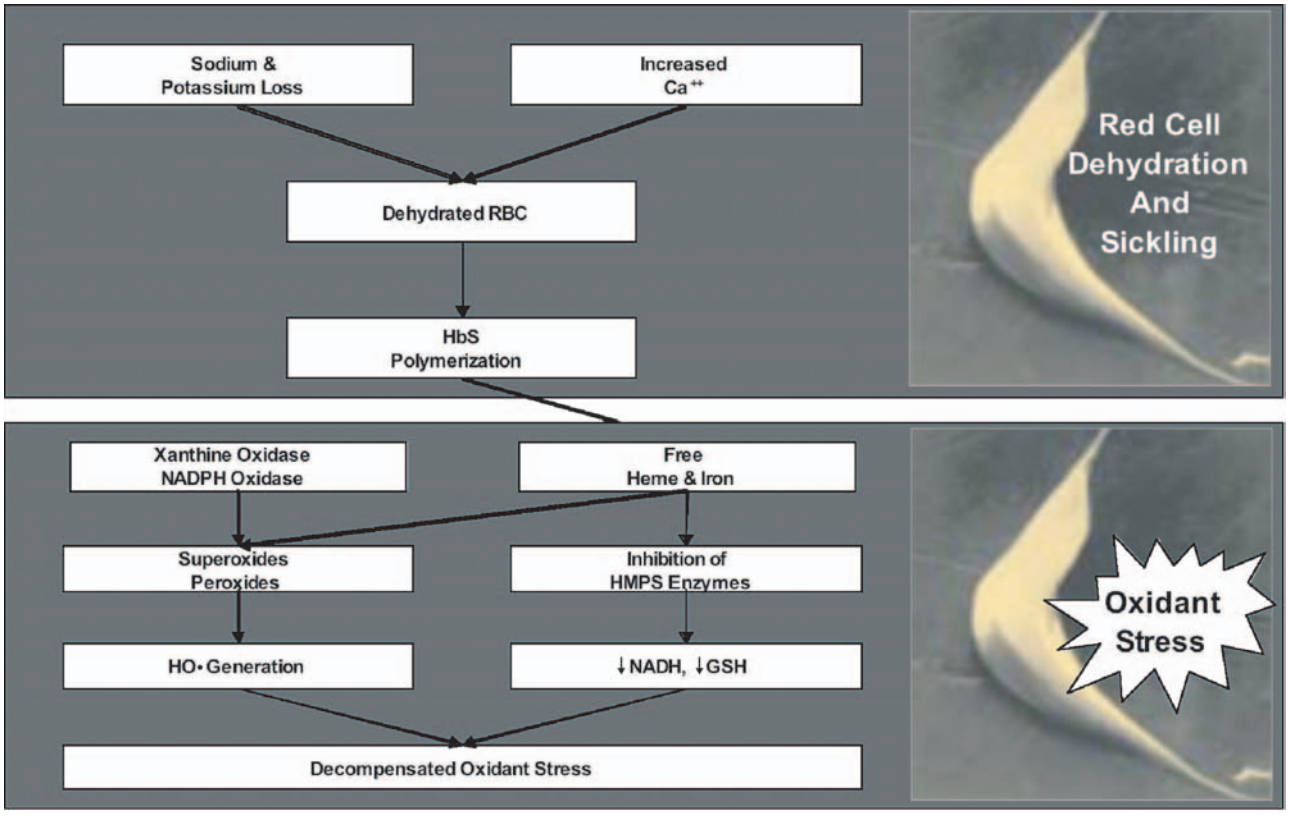

Plate 11.1. Factors leading to sickling and oxidant stress in erythrocytes in sickle cell disease. Solute loss and increased intracellular calcium promote red cell dehydration, which raises the intracellular concentration of sickle hemoglobin. This promotes polymerization of sickle hemoglobin, which is associated with generation of increased levels of oxidant species and depletion of cellular antioxidants, leading to a heightened state of oxidative stress. Each of these steps is described in the text, although the exact sequence of these events is somewhat speculative.

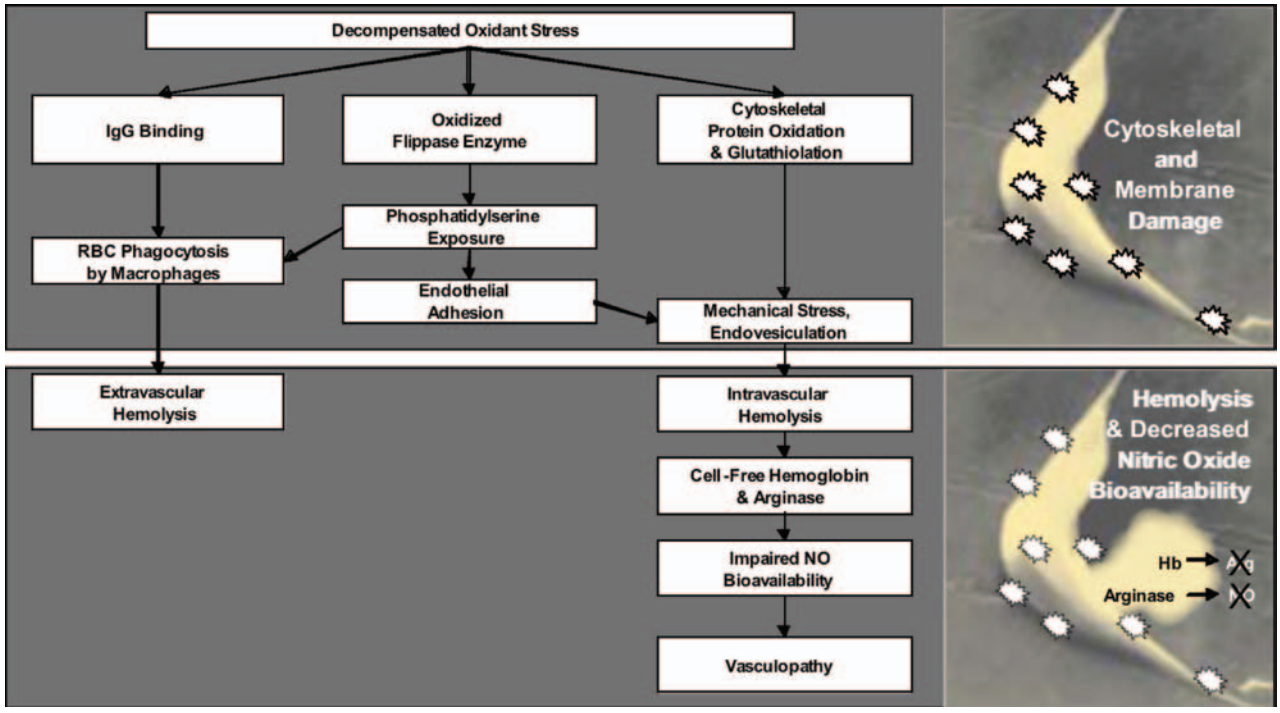

Plate 11.2. Factors promoting hemolysis in sickle cell disease. Decompensated oxidative stress in the sickle erythrocyte is associated with multiple lesions in its cytoskeleton and membrane. These lesions are responsible for binding of immunoglobulin to the membrane, promoting Fc receptor–mediated endocytosis of the damaged red cell by reticuloendothelial macrophages, considered extravascular hemolysis. Oxidative damage to the flippase enzyme is proposed to cause externalization of phosphatidylserine and phosphatidylethanolamine that also stimulate uptake of the red cell by macrophages, in addition to adhesion to endothelium. Oxidative damage and glutathiolation of the cytoskeleton can trigger endovesiculation of the membrane and release of membrane microparticles, and mechanical fragility of the damaged red cell. These latter events tend to produce intravascular hemolysis, resulting in the decompartmentalization of erythrocyte contents into plasma.

Plate 14.9. Upper the typical peripheral blood films of an infant with the Hb Bart's hydrops fetalis syndrome, showing many immature red cell precursors and hypochromic, microcytic, and anisopoikiolytic red cells. Lower the typical clinical features of a hydropic infant at birth (see text).

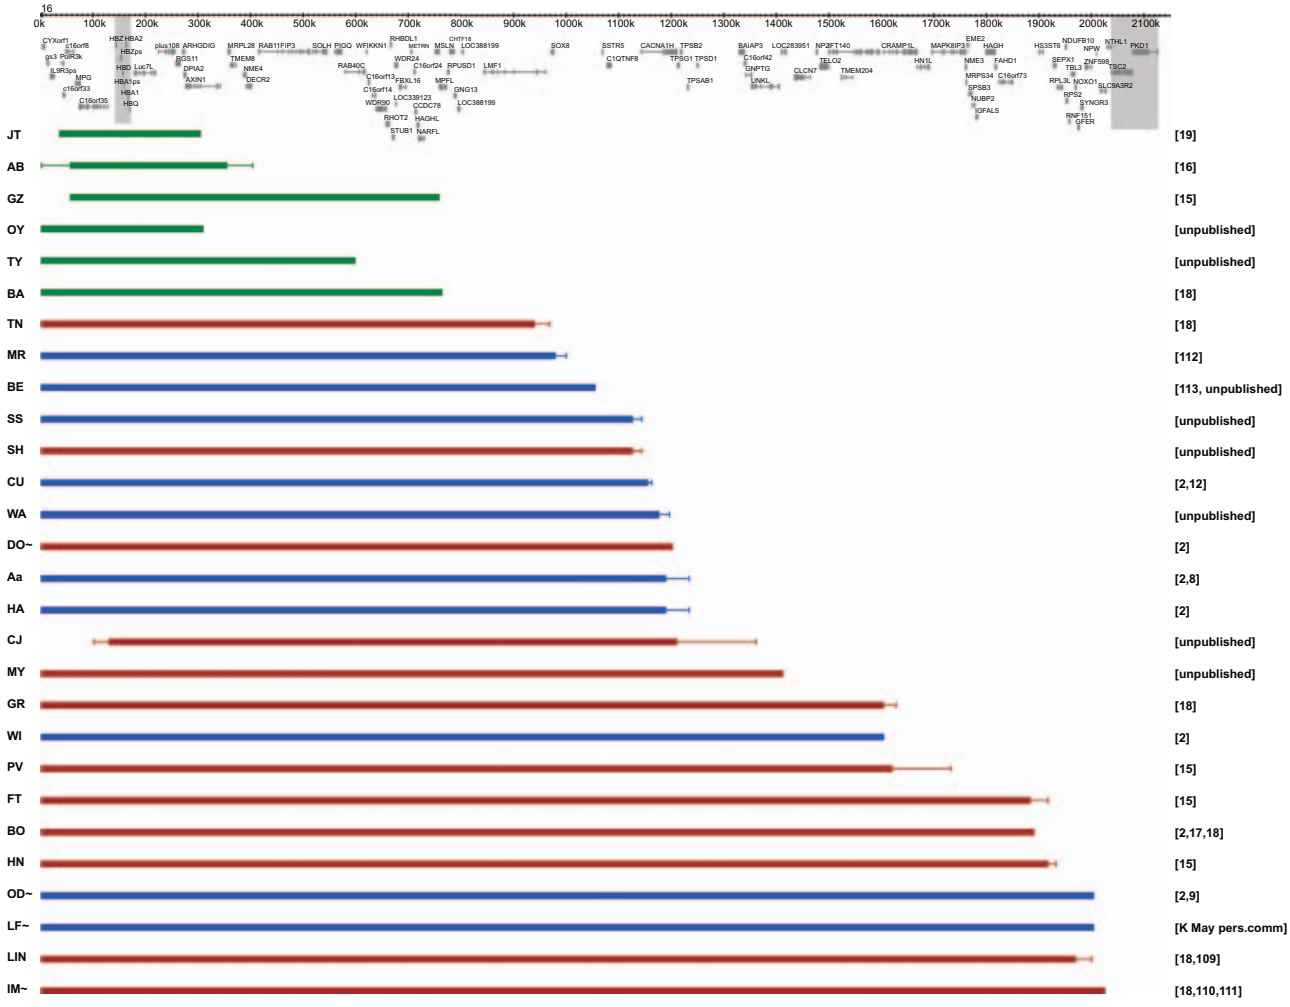

Plate 15.2. Summary of known ATR-16 deletions. The positions of the α-globin cluster and other genes within this region are indicated. Below, the extent of each deletion is shown with the patient code alongside (see Table 15.1). Deletions known to result from pure monosomy for this region are shown in either green (no abnormalities other than thalassemia) or red (ATR-16 phenotype). Chromosomal translocations (all with ATR-16 phenotypes) are shown in blue. Solid bars indicate regions known to be deleted and fine lines indicate the region of uncertainty of the breakpoints. The α genes and the genes that when mutated are associated with tuberous sclerosis and adult polycystic kidney disease are shown (shaded boxes).

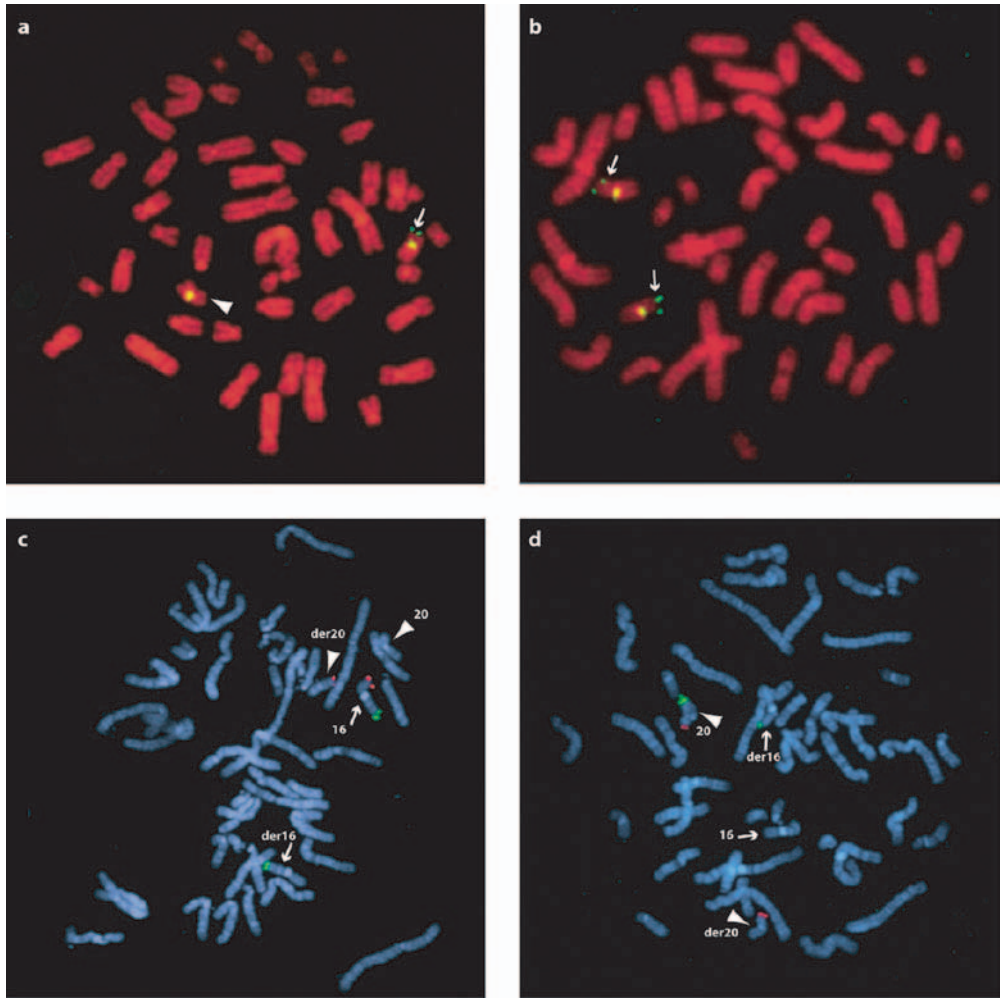

Plate 15.4. High-resolution chromosome analysis using FISH. **(a** and **b)** Examples of FISH on metaphase chromosomes of deletion patient JT. In each case chromosome 16 is identified by a chromosome 16–specific centromere probe. In **(a)** using a cosmid (cGG1) located close to the telomere, fluorescent signal was seen on the normal chromosome (arrow) but not the abnormal copy of chromosome 16 (arrowhead). **(b)** Using a second cosmid located closer to the centromere (not deleted in JT) a signal is seen on both normal and abnormal chromosomes (arrows). **(c** and **d)** FISH on metaphase chromosomes of the mother of WA showing a balanced translocation. In **(c)** and **(d)** both homologs of chromosome 16 are indicated by arrows and chromosome 20 by arrowheads. In **(c)** the subtelomeric probes for 16p and 16q were hybridized to metaphase chromosomes. Green fluorescent signal was seen on the q arm of both homologs of chromosome 16. Red fluorescent signal was seen on the p arm of the normal chromosome 16 and the q arm of the derivative chromosome 20 (der 20) but was absent from the deleted chromosome 16 (der 16). In **(d)** the subtelomeric probe for 20p (red) was seen on both homologs of chromosome 20. Fluorescent signal for 20q (green) was seen on the normal chromosome 20 and the p arm of the derivative 16 (der 16).

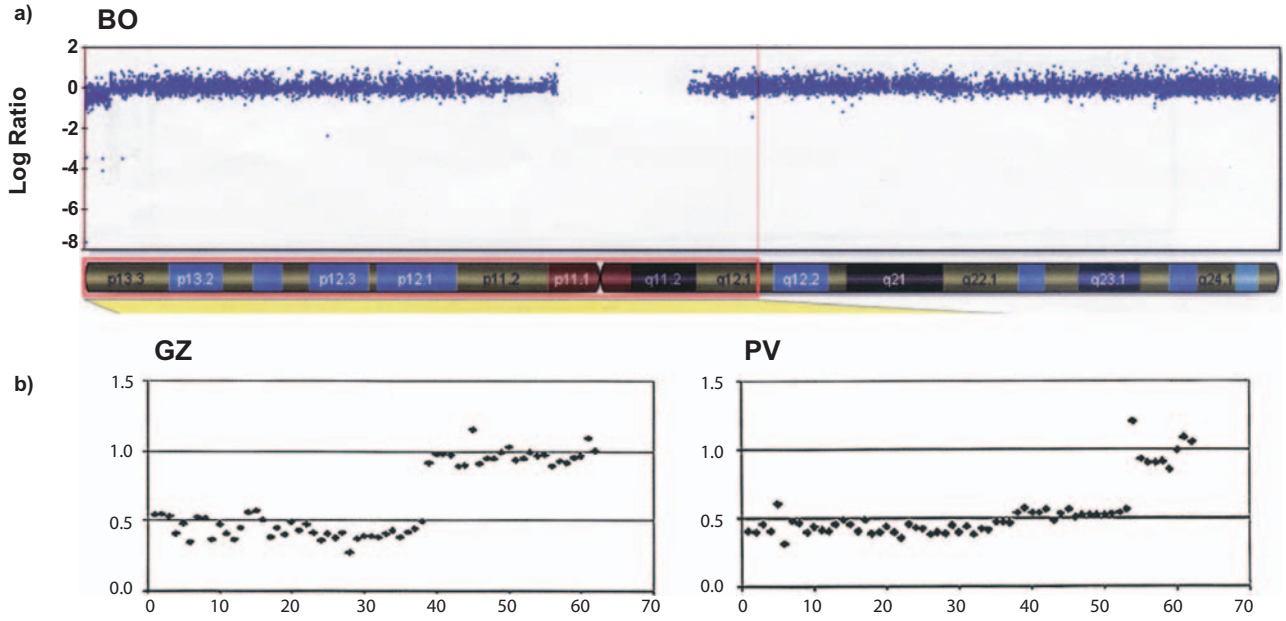

Plate 15.5. Detection of deletions. **(a)** Analysis of chromosome 16 in patient BO with ATR-16 using the QuantiSNP protocol. The Y-axis indicates the log ratio between normal and the test and the X-axis represents the distance along chromosome 16. **(b)** Analysis of two patients (GZ and PV and Fig. 15.2) with large deletions of 16p13.3 using the multiplex ligation–dependent probe amplification protocol). The Y-axis represents the ratio peak height of the test divided by the normal control and the X-axis represents the distance along chromosome 16.

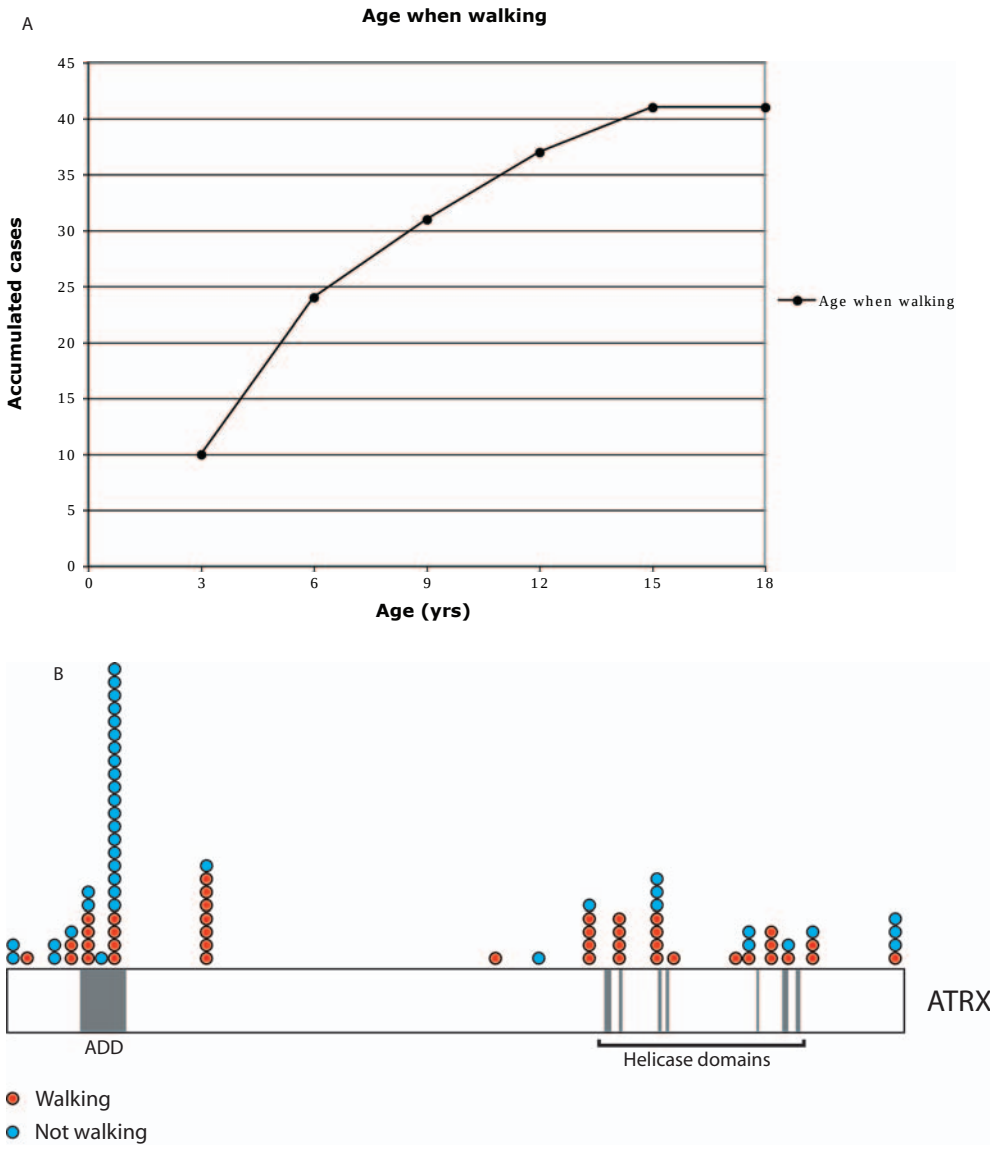

Plate 15.9. A measure of gross motor function is whether the children are able to walk and the age at which this is achieved. Forty-one affected individuals were able to walk. **(A)** Shows the age at which this was achieved. Approximately 75% of these were able to walk by the age of 9 years. None learned to walk after the age of 15 years. **(B)** This figure correlates the ability to walk with the location of the mutation. The 42 individuals who were unable to walk excluded cases who were younger than the age of 9 years at the time of assessment; the range of the ages for this group was 9–30 years.

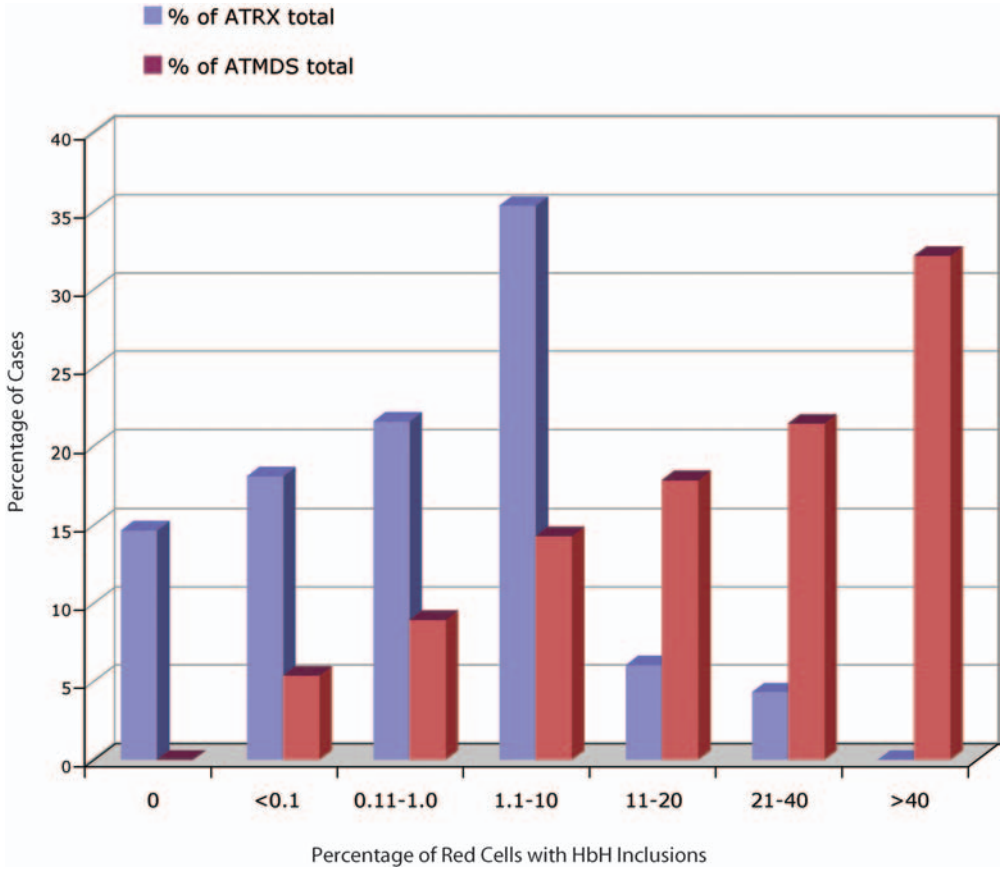

Plate 15.10. Percentage of cells with HbH inclusions in cases of ATR-X syndrome in which the presence of inclusions has been demonstrated and quantified.

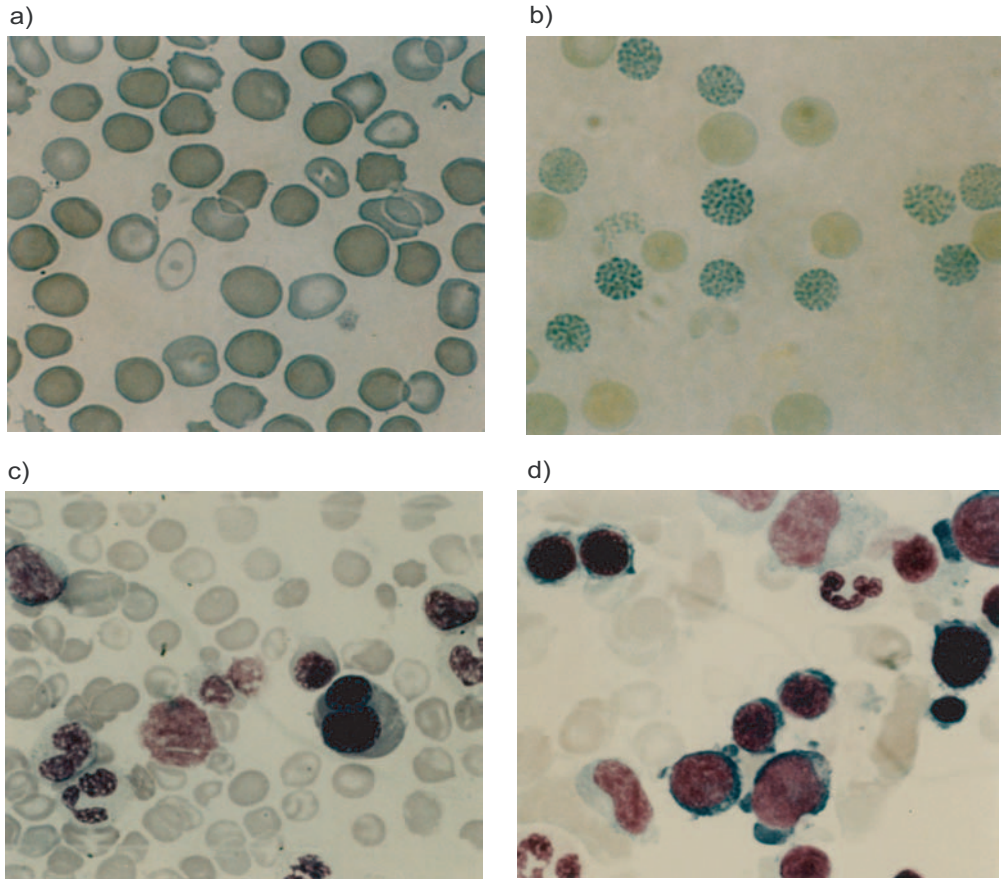

Plate 15.11. (a) May-Grünwald-Giemsa–stained peripheral blood smear from an elderly woman with ATMDS (original magnification, 400X). Many red cells are hypochromic, microcytic, or both, whereas others look relatively normal. As expected, the red blood cell distribution width (RDW) was elevated (19%; normal range, 11%–15%) in this patient. Iron studies were unremarkable. **(b)** Brilliant cresyl blue–stained peripheral blood smear from a 56-year-old man with ATMDS who had characteristic microcytic, hypochromic red cell indices: in this case, an MCH of 19 pg and MCV of 66 fL (original magnification, 600X). Abnormal inclusion-containing "golf ball cells" are easily distinguished from normal reticulocytes and red cells and confirm the presence of HbH (β-globin tetramers.) In this case, supravital staining was performed by incubating fresh blood for 24 hours with 1% brilliant cresyl blue in 0.9% normal saline. **(c)** and **(d)** Bone marrow samples from patients with ATMDS showing dyserythropoietic erythroblasts including binucleate cells.

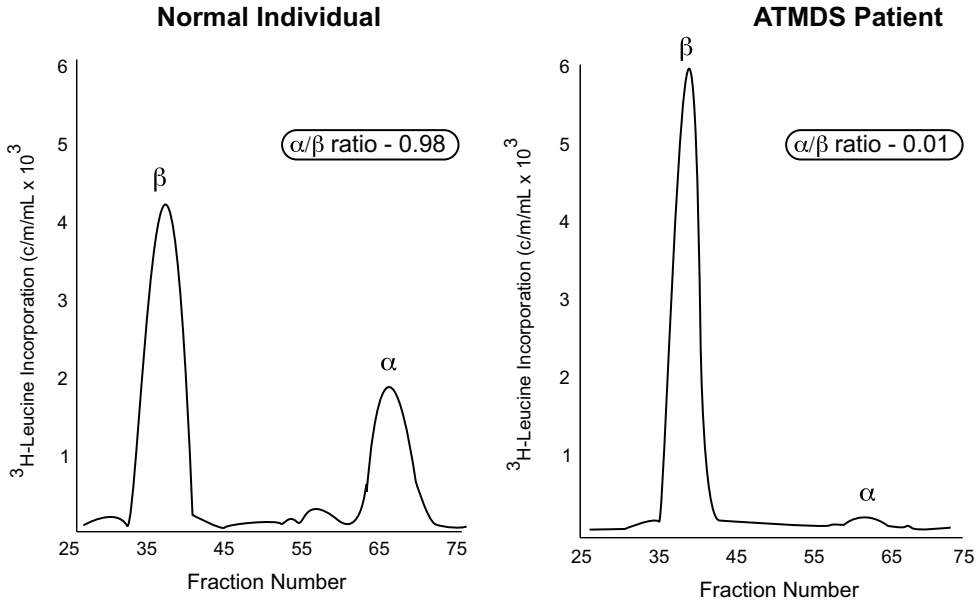

Plate 15.12. Measurement of reticulocyte α/β-globin chain synthesis ratio by radioisotope labeling and CM cellulose chromatography in a patient with ATMDS. In this case, α-globin production was markedly downregulated, and the α/β-chain synthesis ratio estimated by an area-under-the-curve method was only 0.01 (normal, 0.9–1.2). A normal chromatogram is depicted at left, for comparison.

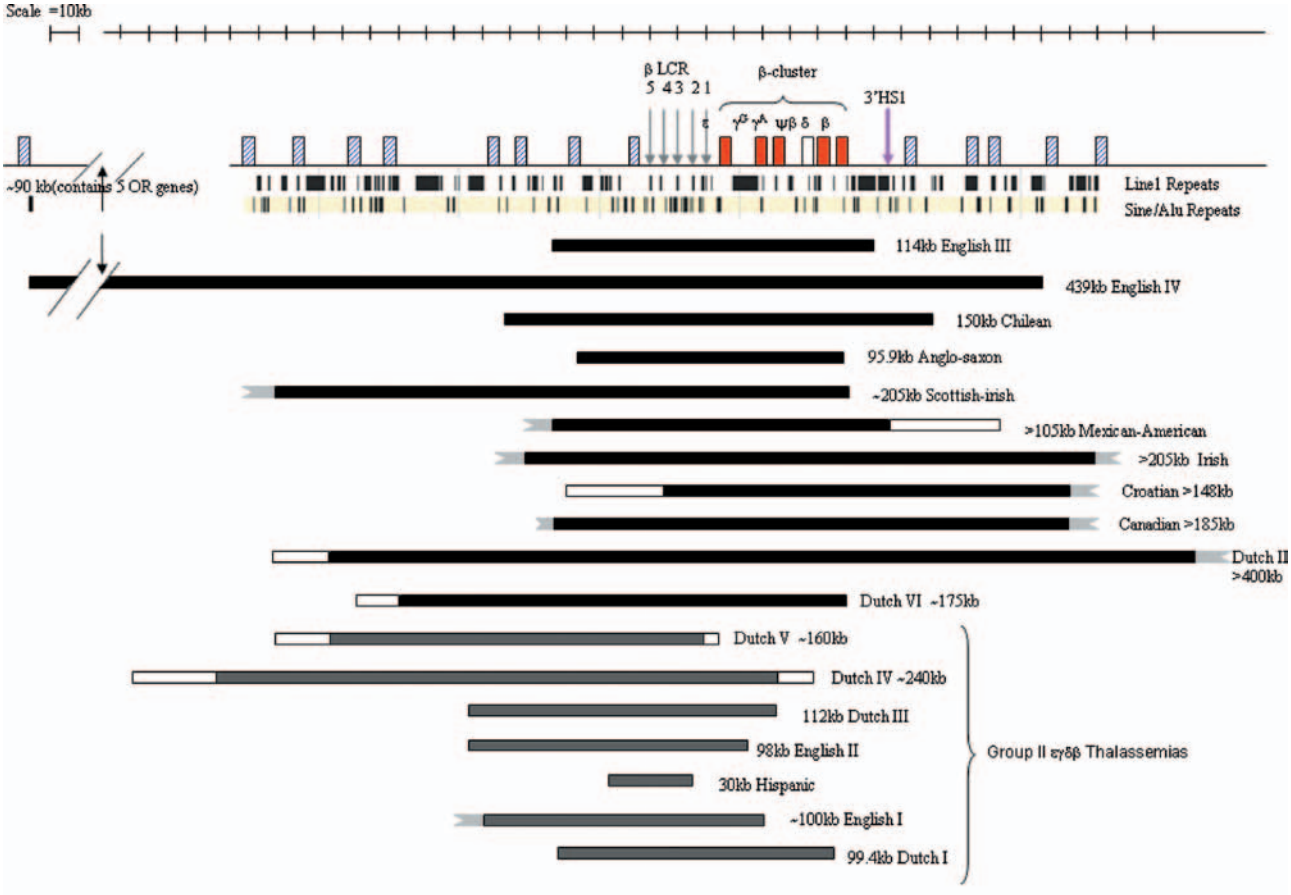

Plate 16.5. Deletions of the β-globin gene cluster causing $(\varepsilon\gamma\delta\beta)^{\circ}$ thalassemia. Top part of the figure shows the β-globin cluster and its flanking regions on chromosome 11p. The ε, $^{G}\gamma$, $^{A}\gamma$, δ, and β-globin genes are shown as gray boxes, whereas the hatched boxes represent the human olfactory receptor genes (HOR) named according to ensemble database (Ch 11:5110000–5600000). The 5′ hypersensitive sites that comprise the β LCR and the 3′ hypersensitive site (3′HS1) are shown as vertical arrows. The Line 1 and Sine/Alu repeat sequences are shown below the β-globin gene cluster as short vertical lines and boxes. The 18 deletions causing εγδβ thalassemia are shown below; the extents of the deletions are marked as complete boxes if endpoints have been determined precisely, jagged ends if undetermined, and white boxes as endpoint regions. Boxes in black are the deletions that include the β-globin gene (group I) and gray boxes represent the group II upstream deletions that leave the β-globin intact.

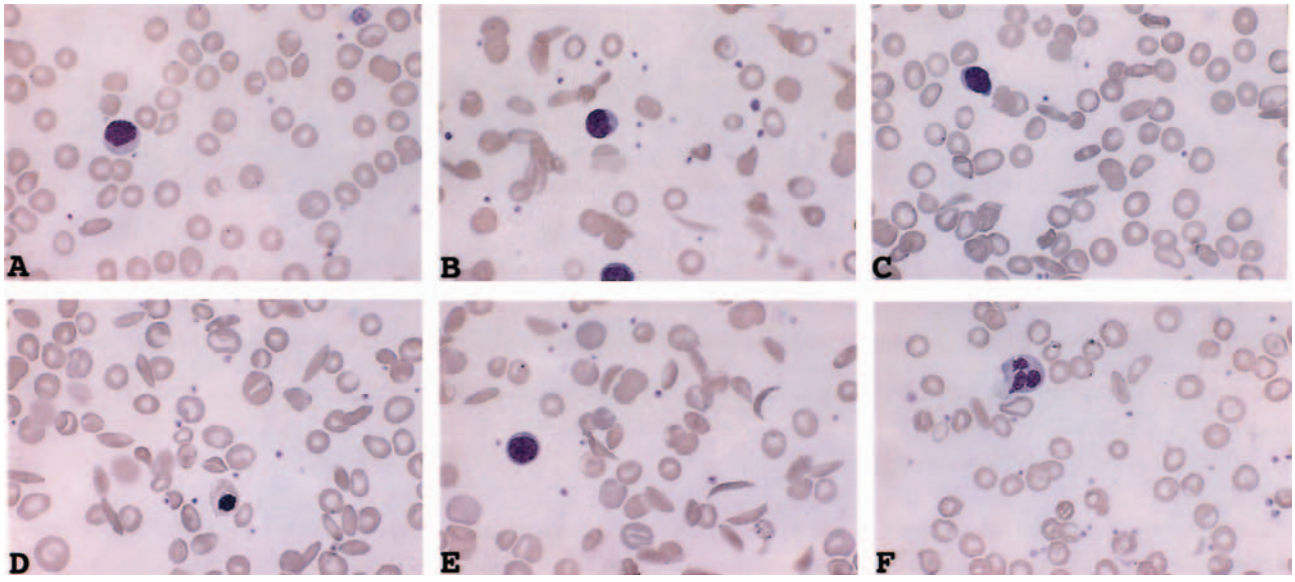

Plate 19.1. Blood films in patients with sickle cell anemia and average or low HbF levels. HbF in these patients are **A**-0.5%, **B**-1%, **C**-4%, **D**-5%, **E**-7%, and **F**-10%. Patients C and F were taking hydroxyurea. Although some of these patients have more ISCs than patients depicted in Figure 19.2 who have high HbF concentrations, note that patient A with the lowest HbF level has very few sickled cells.

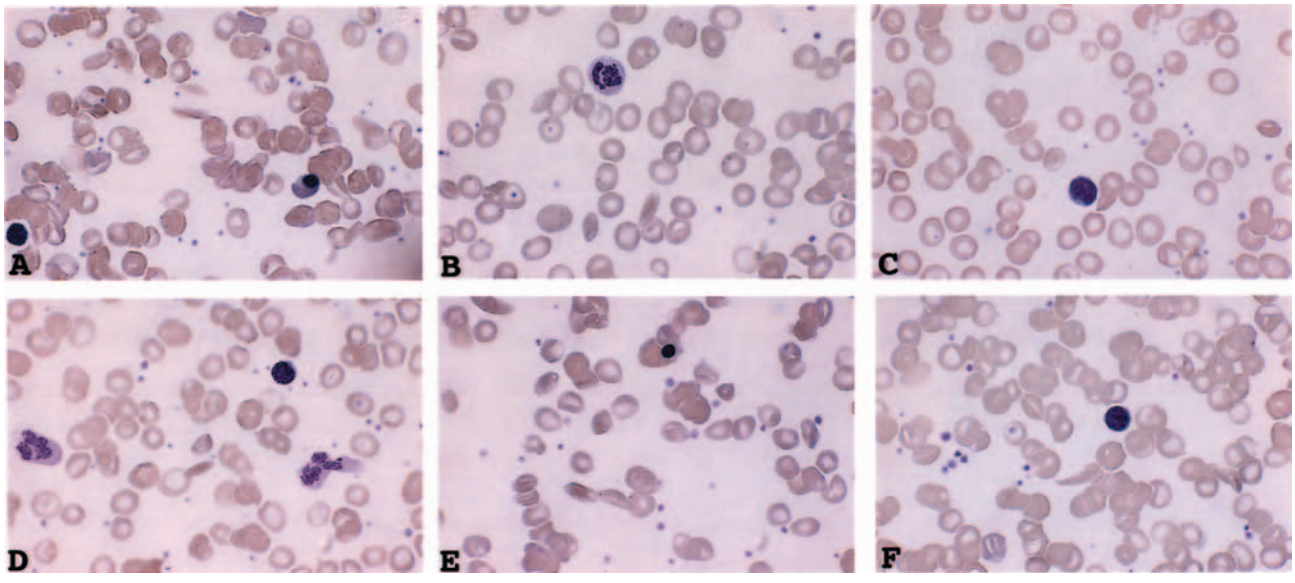

Plate 19.2. Blood films in patients with sickle cell anemia and high HbF levels. HbF in these six patients are **A**-19%, **B**-18%, **C**-19%, **D**-21%, **E**-20%, and **F**-23%. All patients were receiving hydroxyurea. All still have sickled cells in the blood and these are particularly prominent in patient A. Also note nucleated red cells in A and E.

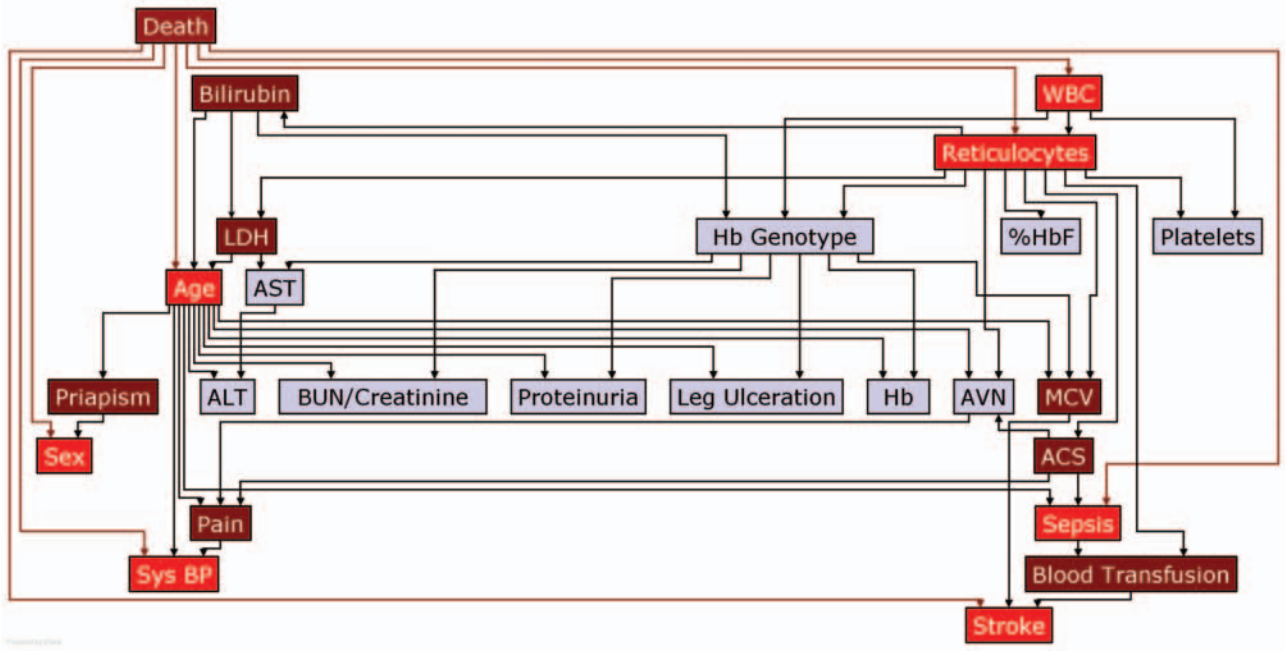

Plate 19.3. A Bayesian network model of the risk of death in sickle cell disease.[44]

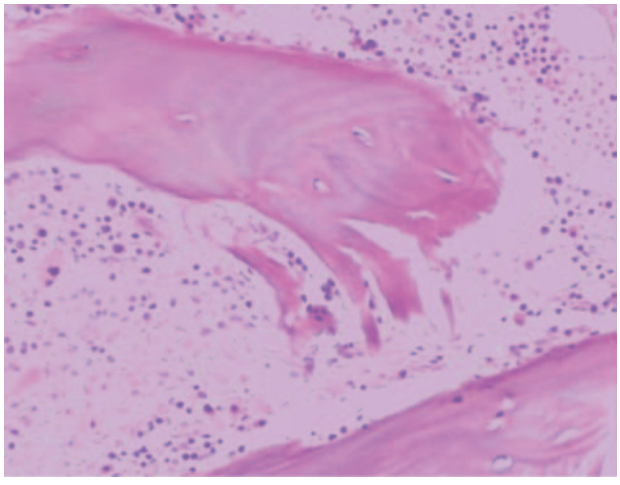
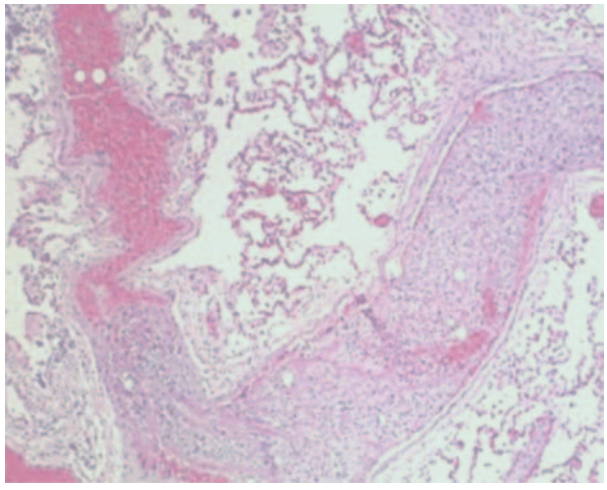
A



B



C

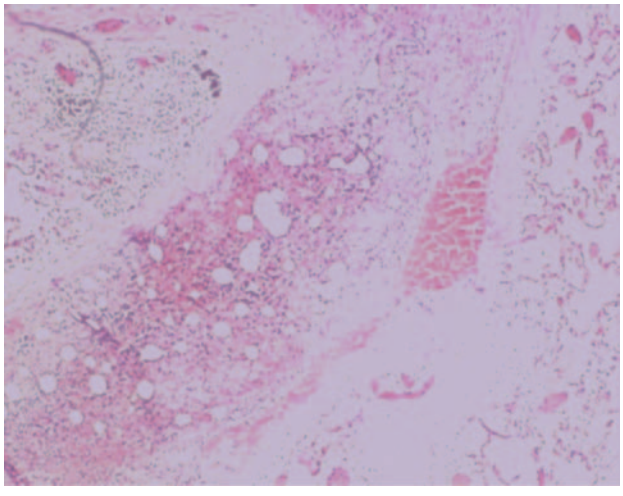


Plate 19.5. Necrotic bone marrow in the lungs of a patient with HbSC disease, who was in reasonable health, and died suddenly with severe acute chest syndrome and multiorgan failure. **(A)** Necrotic bone marrow. **(B)** Pulmonary embolus of fatty, necrotic marrow (low power). **(C)** Higher power view of necrotic marrow in a pulmonary artery.

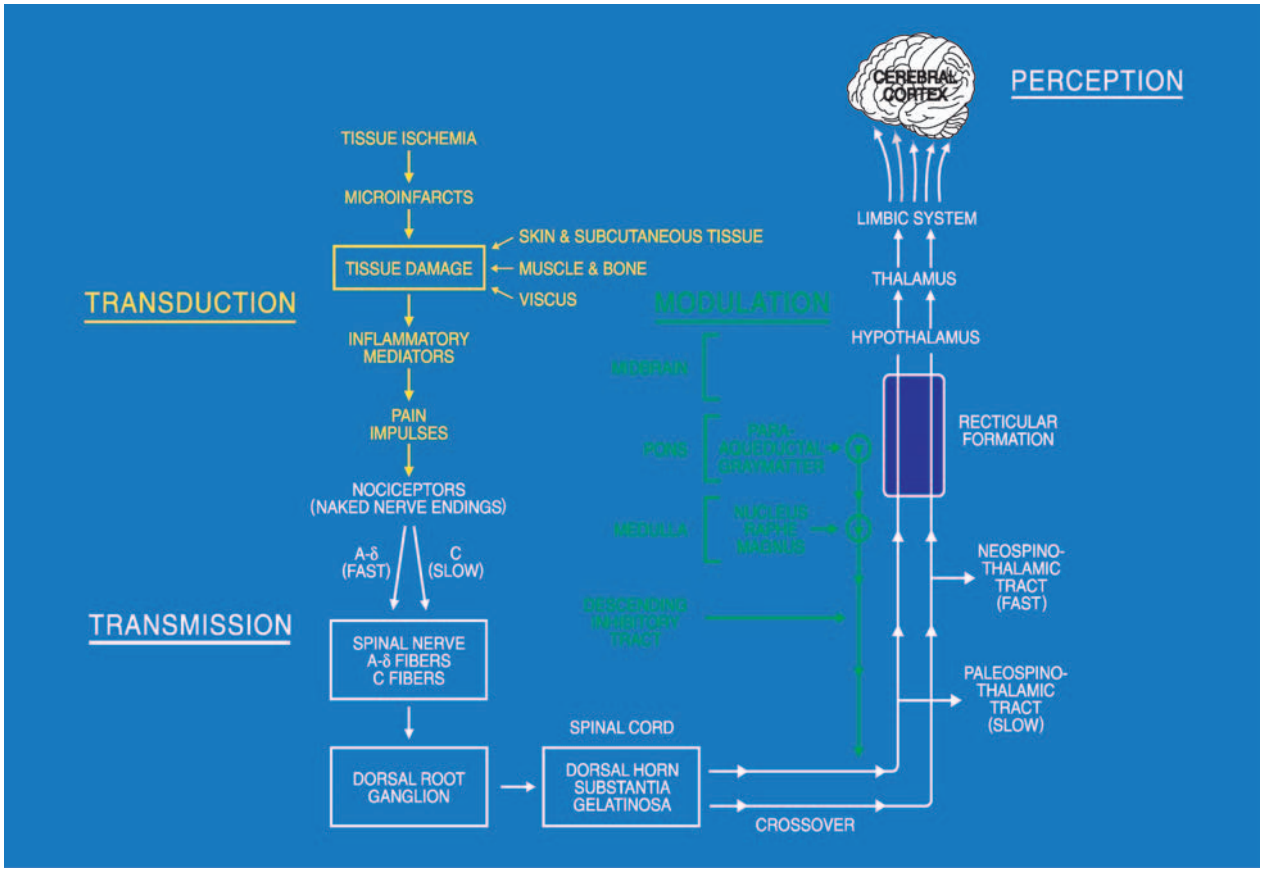

Plate 20.2. Anatomical pathways of pain in sickle cell disease. (Modified from ref. 39 with permission.)

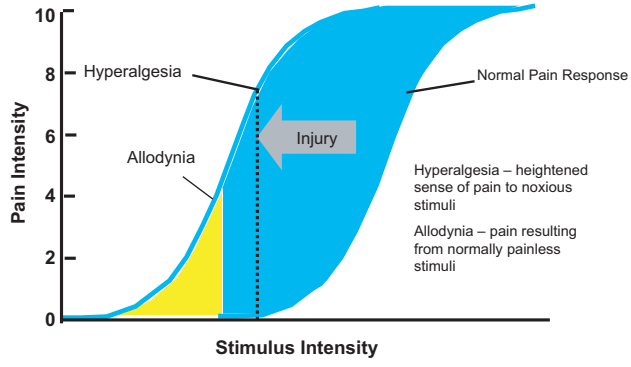

Plate 20.8. Pain hypersensitivity induced by injury. In the normal pain response, pain intensity increases as the stimulus intensity increases. Sensitization following injury causes the curve to shift to the left, resulting in hyperalgesia, in which noxious stimuli cause greater and more prolonged pain, as well as allodynia, in which pain results from normally painless stimuli. Sensitization is the manifestation of neuronal plasticity. (From ref. 139 with permission.)

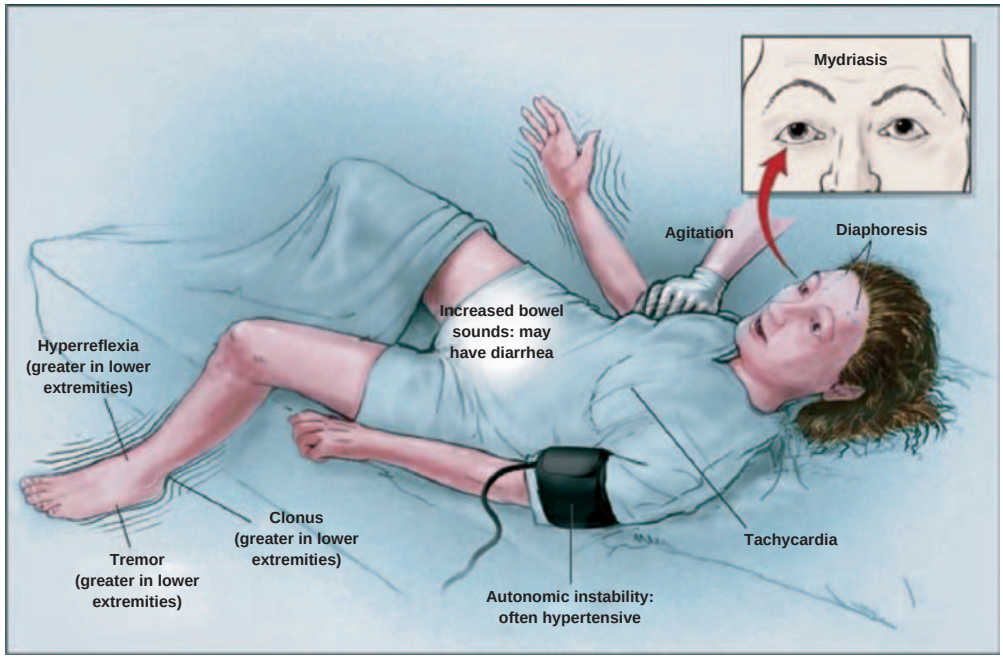

Plate 20.9. Findings in patients with moderately severe serotonin syndrome. Hyperkinetic neuromuscular findings of tremor or clonus and hyperreflexia should lead the clinician to consider the diagnosis of the serotonin syndrome. (From ref. 149 with permission.)

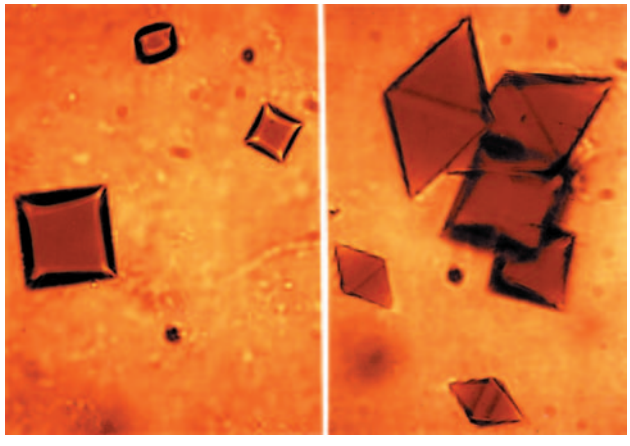

Plate 21.2. Crystal forms observed in hemolysates of patients with HbC. **(A)** Cubic crystals, generated in hemolysates of compound heterozygotes for HbC and Hb Korle-Bu. **(B)** Tetragonal crystals observed intracellularly and in hemolysates of patients homozygous for HbC, with HbSC disease and compound heterozygotes for HbC and HbA and other mutants.

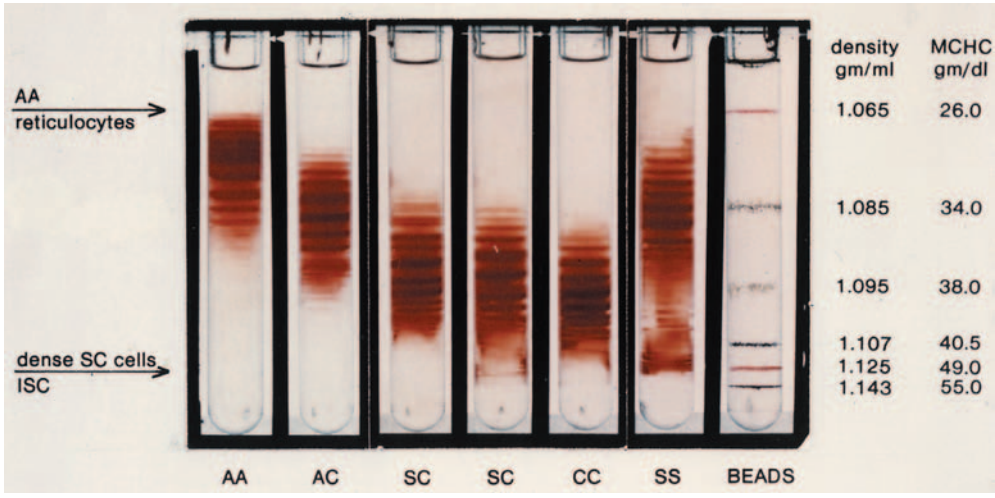

Plate 21.10. Percoll–Strachan (Larex) density separation of whole blood from normal hemolysate (AA), HbC trait (AC), and three different HbSC disease individuals and one sickle cell anemia patient. Beads: Color-coded density beads to establish the density at different levels of the gradient after centrifugation.

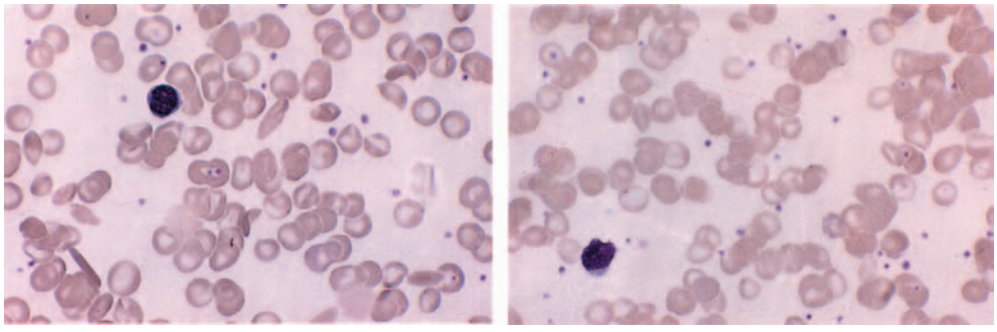

Plate 23.1. Blood films in two patients with HbS–β^0 thalassemia. In the left panel, the patient has an HbF level of 5%. Sickled cells are prominent beside microcytosis. In the right panel, with an HbF of 2%, microcytosis and hypochromia are prominent and few typical sickled cells are seen. Despite similar HbF levels, for unknown reasons, the numbers of sickled cells are quite different. This suggests the possibility of different cellular distributions of HbF or other genetic modifiers.

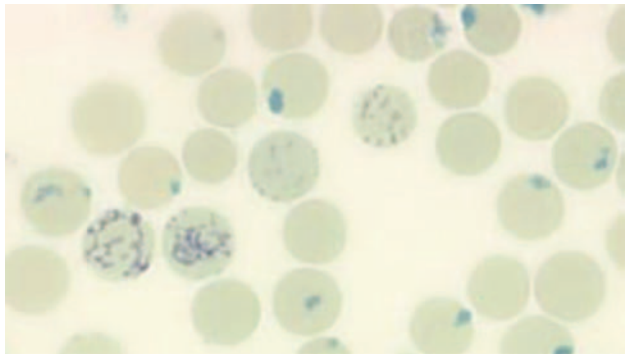

Plate 24.2. Heinz bodies. Heinz bodies are the large, single basophilic inclusions inside erythrocytes. Other red cell inclusions represent reticulocytes.

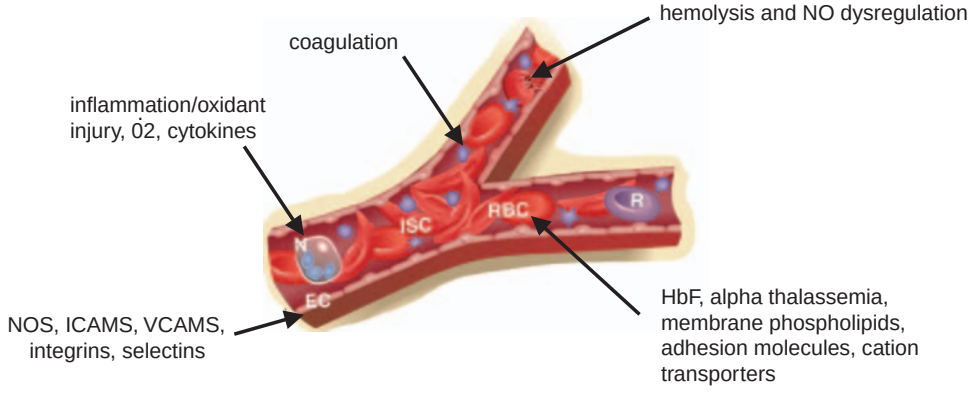

Plate 27.3. Some facets of sickle cell disease pathobiology that might be genetically modulated.

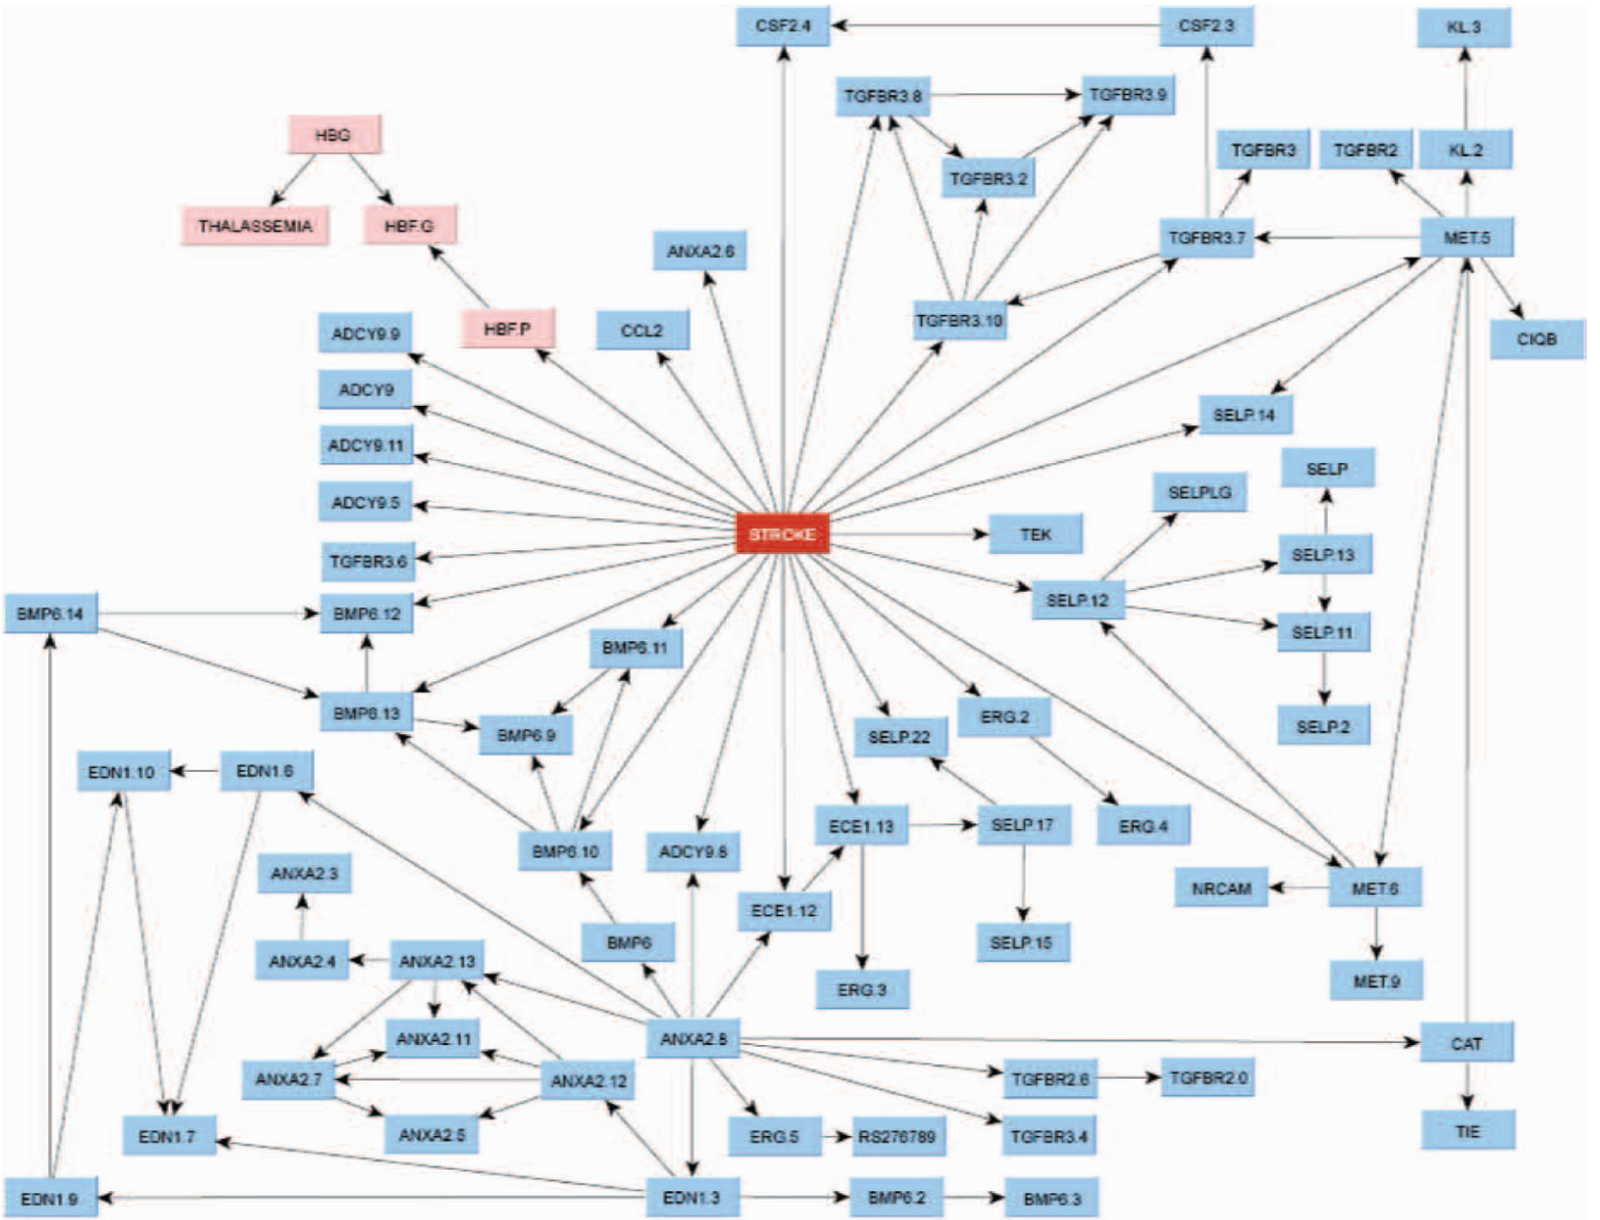

Figure 27.5. A bayesian network describing the associations of SNPs in candidate genes with the likelihood of developing nonhemorrhagic stroke in sickle cell anemia.[72]

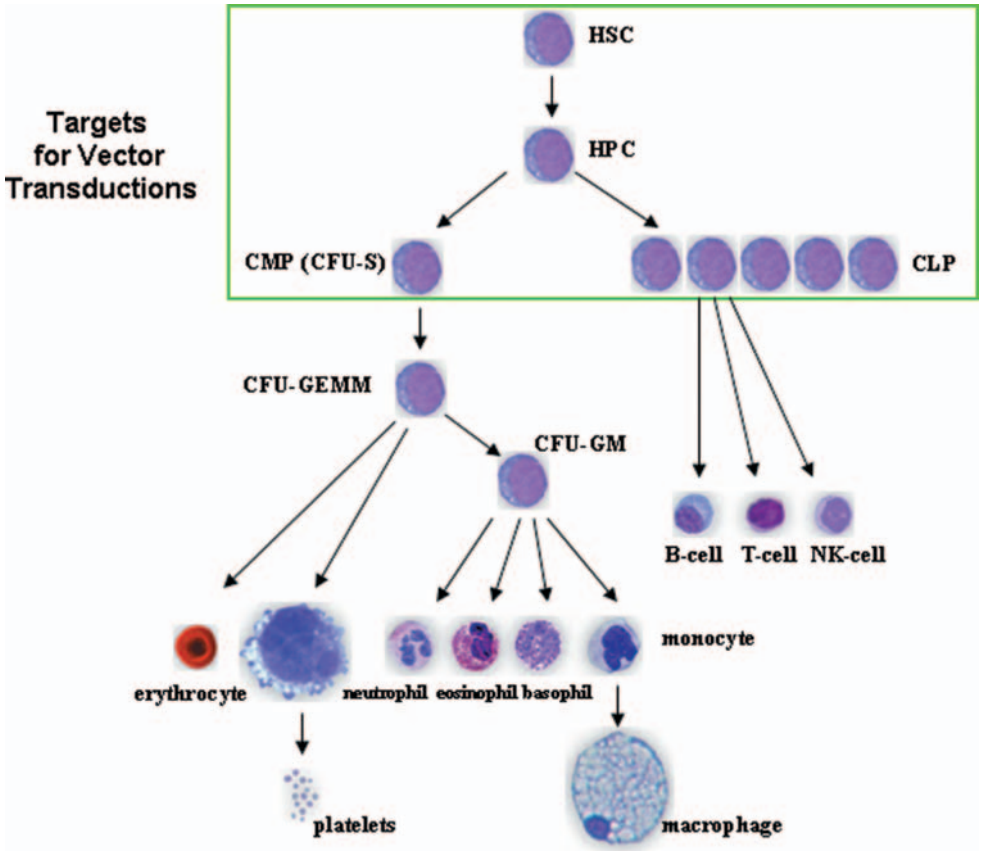

Plate 33.1. Hematopoietic cell targets for gene therapy. This figure shows the general hierarchical structure of hematopoiesis. Hematopoietic stem cells (HSCs) give rise to primitive progenitor cells (HPC), which in turn generate common myeloid progenitors (CMP) and common lymphoid progenitors (CLP). These progenitor cells then give rise to all formed elements of the blood through a number of intermediates including the granulocyte/erythrocyte/monocyte/macrophage colony forming unit (CFU-GEMM) and the granulocyte/monocyte colony forming unit (CFU-GM). The cells contained within the green outline are the desired targets for retroviral vectors because they all give rise to multiple mature cell types and because, to greater or lesser degrees, they can self-renew and lead to the persistence of genetically modified cells over time. The target cell population can differ for various diseases. For instance, for SCID, targeting of the CLP with an appropriate vector will result in long-term reconstitution of all lymphocyte subsets. In contrast, treatment of hemoglobin disorders required targeting of the most primitive HSC to have long-term persistence of stably modified erythrocytes after transplantation. The biology and frequency of the various target cell populations differs and are variable in determining the gene transfer efficiency.

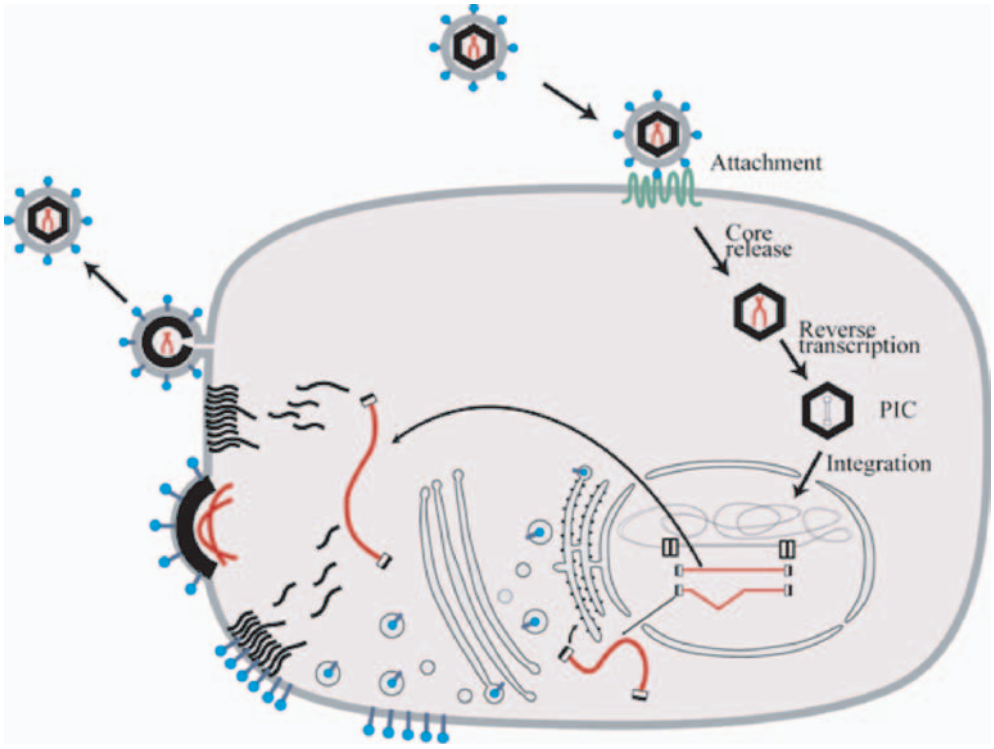

Plate 33.2. Retroviral life cycle. Entry of a retrovirus into a cell is initiated by interaction of its envelope proteins with one or more cellular membrane proteins that act as a receptor followed by internalization through membrane fusion or phagocytosis. The vector core is released and the RNA serves as a template for formation of the reverse transcription complex (RTC). The RTC includes additional viral proteins and is moved by the microtubule system from the cell periphery to the nucleus as it matures to become the preintegration complex (PIC). The PIC gains access to chromatin during mitosis, or in the case of lentiviruses, by ingress through the nuclear membrane. Following integration into host-cell DNA, the retroviral genome is expressed in RNA molecules that are transported to the cytoplasm to serve as a template for synthesis of new viral proteins and, in the case of unspliced RNA species, as a substrate for formation of new viral particles.

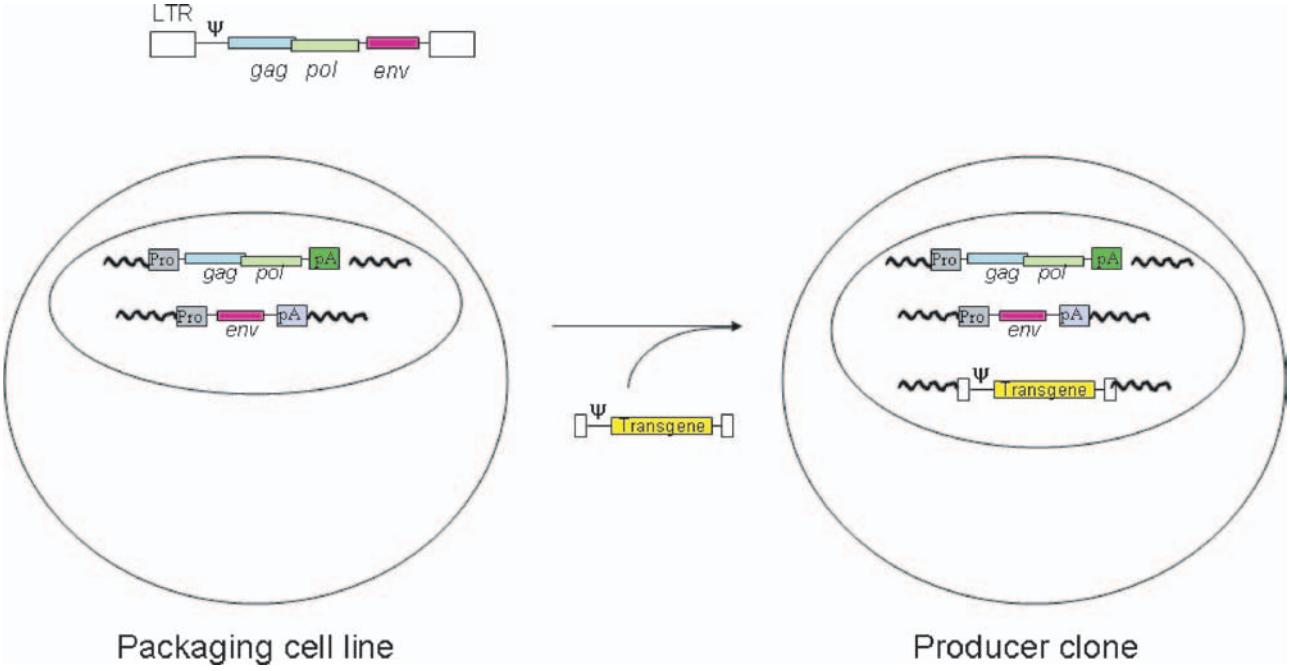

Plate 33.3. Production of retroviral vector particles. This figure illustrates the concept of the strategy used to derive retroviral vector preparations free of replication-competent virus. The diagram at the top shows the organization of a retroviral genome. Murine oncoretroviruses have coding sequences for matrix proteins (gag), reverse transcriptase, integrase and protease (pol), and envelope proteins (env). The LTR contains the viral promoter and enhancer. Immediately downstream is a sequence essential for packaging the genomic RNA (ψ). To reduce the risk of recombination and generation of replication-competent particles, these coding sequences are separated on two or more expression cassettes before transfer into a tissue culture cell line. The coding sequences for viral proteins are replaced by the coding sequences for the intended therapeutic protein in the vector. Various strategies are used for introducing the vector genome into the packaging cell that initiates production of replication-defective retroviral vector particles that can be used to introduce the therapeutic transgene into target cells. In the packaging and producer cells, the viral protein constructs are driven by exogenous promoters (Pro).

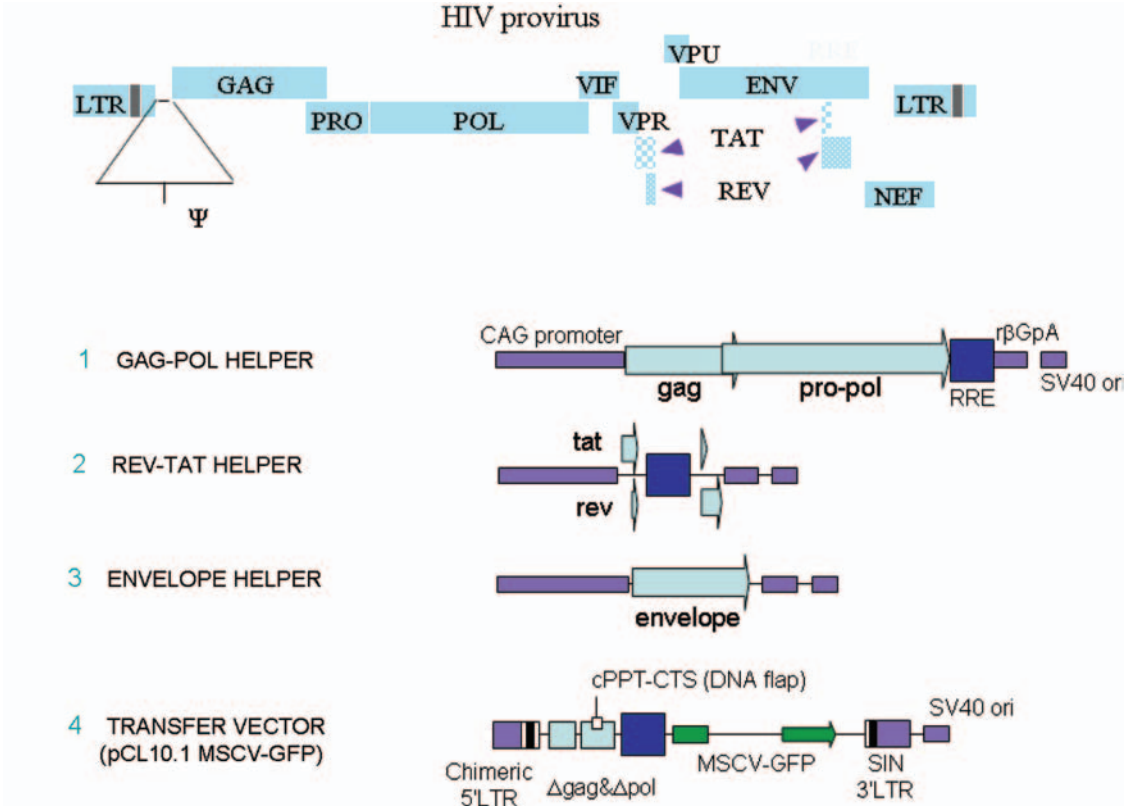

Plate 33.4. Organization of the HIV provirus and development of a packaging system for generation of vector particles free of replication competent retrovirus. The HIV-1 genome encodes 15 proteins as shown in the top row of this figure. The GAG polyprotein is processed to yield viral core proteins including MA (matrix), CA (capsid), NC (nucleocapsid), and p6. The ENV protein product is processed to yield two proteins, SU (surface) and TM (transmembrane) components of the mature envelope proteins. The POL region encodes the enzymes PR (protease), RT (reverse transcriptase), and IN (integrase). TAT and REV are regulatory proteins that facilitate transcription or nuclear to cytoplasmic transport of unspliced RNA species, respectively. The accessory proteins NEF, VIF, VPR, and VPU are viral virulence factors, which are not required for vector particle formation. Shown below in rows 1–4 are components of a system developed to generate vector particles. Each of the transcriptional units encoding viral proteins includes the powerful chimeric CMV enhance/β-actin promoter, the β-globin large intron (CAG promoter), the rabbit β-globin polyadenylation sequence (rβGpA), and the rev responsive element (RRE), which facilitate nuclear to cytoplasmic transport. The SV40 origin of replication (ORI) is included in each expression plasmid to allow its amplification in cells expressing SV40T antigen. Three separate helper plasmids are used as shown in 1–3. The transfer vector includes a portion of the gag region required for packaging and a portion of the pol region, which includes the central polypurine tract (cPPT) and the central termination sequence (CTS). These elements together constitute the DNA flap that was described as a crucial determinate for lentiviral vector nuclear import and gene transduction of primitive human hematopoietic cells. The U3 region of the 5′ LTR in the vector has been replaced with the CMV enhancer and a deletion in the U3 region of the 3′ LTR renders the vector SIN. Not shown is the fact that a portion of the U5 region of the 3′ LTR has been removed and replaced with rabbit β-globin polyadenylation site to enhance safety and improve the efficiency of vector production. Vector production occurs when a mixture of the four plasmid DNAs are transfected into human embryonic kidney (293T) cells and conditioned media is harvested over the next 3–4 days. Depending on the envelope used, the vector preparation may be concentrated by ultracentrifugation or ultrafiltration.

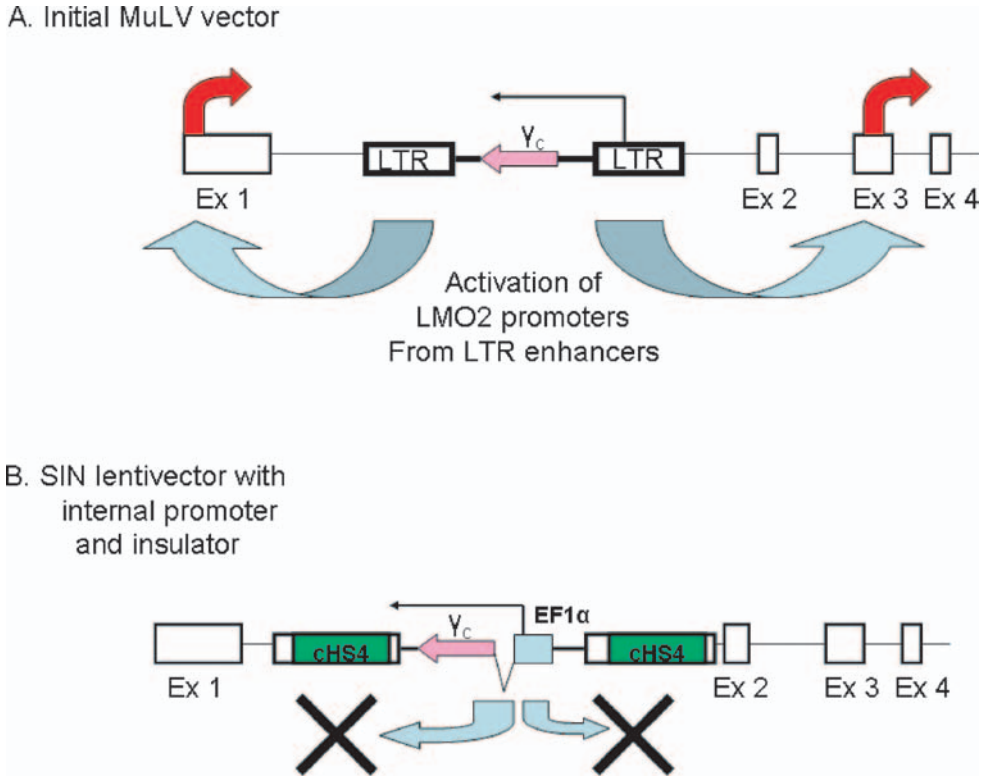

Plate 33.6. Safety design considerations for lentiviral vectors. **(A)** The upper diagram shows the safety problems associated with using γ-retroviral vectors with intact LTRs in the French X-SCID trial. In this case, the vector has integrated into the first intron of the LMO2 gene in a reverse orientation. The strong viral enhancers present in the LTRs activate both cellular LMO2 promoters as shown by the blue and red arrows. This results in oncogene expression in cells that normally would not express LMO2. **(B)** This is a safety modified lentiviral vector that has inactivating mutations in the viral LTRs creating a so-called self-inactivating or SIN design. A copy of the cHS4 chromatin insulator is present in each LTR so that any internal enhancer activity will be blocked from interacting with adjacent cellular promoters (large X). The γ_c transgene is expressed from a single cellular promoter, in the case from the EF1α gene. This promoter itself has much little enhancer activity on its own. This design has been shown to result in no significant LMO2 activation when inserted into the LMO2 locus in a human T cell line.
