Some types of *Schistosoma* infections (also called *Bilharzia*), mainly *mansoni*, tend to localize in the spinal cord, causing an acute or subacute myelitis that is concentrated in the conus medullaris. The clinical picture is of a subacutely developing transverse cord lesion. There is often preceding leg or radicular pain and bladder control is affected prominently. We have observed a few cases in students returning from Africa; their lesions were in the conus. Unless treated immediately, there may be permanent paralysis of the legs and bladder from inflammatory and microvascular destruction of the lower cord.

Eosinophilia is common in symptomatic individuals and there is a serologic test but it often becomes negative soon after the initial infection. Examination of the CSF in the myelitic form discloses a pleocytosis, sometimes with an increase in eosinophils (more than half of patients), increased protein content, and increased pressure. Diagnosis is made by the finding of eggs in stool or urine. Serology is probably more sensitive. The other major trematode, *Paragonimus*, has been known to invade the brain in up to one-quarter of cases, where it creates a solitary granulomatous nodule comparable to that seen in schistosomiasis.

Treatment This consists of praziquantel orally in a dosage of 20 mg/kg tid. In one series, 8 of 9 patients with epilepsy caused by cerebral schistosomiasis became seizure-free after treatment with praziquantel. Surgical excision of spinal granulomatous tumors is sometimes indicated, but the results are unpredictable. Corticosteroids are often given concurrently.

Eosinophilic Meningoencephalitis and Meningitis Caused by Parasites

An eosinophilic meningoencephalitis, often with cranial nerve and painful polyradicular findings, has been reported with *Angiostrongylus cantonensis*, *Gnathostoma*, *Paragonimus*, and *Toxocara canis* and *cati* infections. In *Angiostrongylus* infections, snails, freshwater prawns, and unwashed lettuce carry the nematode. The resulting illness may last for weeks to months, with pain, paresthesias, sensorimotor abnormalities, and a confusional state as the main manifestations. Cook has reviewed these and other protozoan and helminthic infections of the CNS. An interesting outbreak in a group of medical students who returned to the United States from Jamaica has been described by Slom and colleagues; they highlighted paresthesias and dysesthesias but noted eosinophilia in the blood or CSF in only half of their patients. Meningeal Hodgkin disease, other lymphomas, and cholesterol emboli also occasionally incite eosinophilic meningitis.

More detailed descriptions of parasitic diseases of the nervous system can be found in the monographs of Bia and of Gutierrez.

Viral Infections of the Nervous System, Chronic Meningitis, and Prion Diseases

A number of viruses share the unique tendency to primarily affect the human nervous system. Included in this group are the human immunodeficiency viruses (HIV-1 and HIV-2), herpes simplex viruses (HSV-1 and HSV-2), herpes zoster or varicella zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), poliovirus, rabies, and several seasonal arthropod-borne viruses (Flaviviruses). Some of these are neurotropic, exhibiting an affinity for certain types of neurons: for example, poliomyelitis viruses and motor neurons, VZV and peripheral sensory neurons, and rabies virus and brainstem neurons. Yet others attack nonneuronal supporting glial cells; JC virus causing progressive multifocal leukoencephalopathy is the prime example. For many of the rest, the affinity is less selective in that all elements of the nervous system are involved. Herpes simplex, for example, may devastate the medial parts of the temporal lobes, destroying neurons, glia cells, myelinated nerve fibers, and blood vessels; and HIV may induce multiple foci of tissue necrosis throughout the cerebrum. These relationships and many others, which are the subject of this chapter, are of wide interest in medicine. In some conditions, the systemic effects of the viral infection are negligible; it is the neurological disorder that brings them to medical attention.

Pathways of Infection

Viruses gain entrance to the body by one of several ways. Mumps, measles, and VZV enter via the respiratory passages. Polioviruses and other enteroviruses enter by the oral-intestinal route, and HSV enters mainly via the oral or genital mucosal route. Other viruses are acquired by inoculation, as a result of the bites of animals (e.g., rabies), ticks, mites, or mosquitoes (arthropod-borne or arbovirus infections). The fetus may be infected transplacentally by rubella virus, CMV, and HIV. In all these cases, viremia is an intermediate step to seeding the brain or CSF.

Another pathway of infection is along peripheral nerves; centripetal movement of virus is accomplished by the retrograde axoplasmic transport system. HSV, VZV, and rabies virus utilize this peripheral nerve pathway, which explains why the initial symptoms of rabies occur locally, at a segmental level corresponding to the animal bite. It has been shown experimentally that HSV may spread to the CNS by involving olfactory neurons in the nasal mucosa;

the central processes of these cells pass through openings in the cribriform plate and synapse with cells in the olfactory bulb (CNS). Another potential pathway is the trigeminal nerve and gasserian ganglion, however, the role of these pathways in human infection is not certain. Of the different routes of infection, the hematogenous one is by far the most important for the majority of viruses.

Additionally, VZV resides in the sensory ganglia and becomes reactivated later in life, causing shingles decades after the primary infection that produces chicken pox. The JC virus also is latent in tissues, possibly the kidney and bone marrow, only to reemerge under conditions of immunosuppression, to infect the brain.

Mechanisms of Viral Infections

Viruses, once they invade the nervous system, have numerous clinical and pathologic effects. One reason for this diversity is that different cell populations within the CNS vary in their susceptibility to infection with different viruses. To be susceptible to a viral infection, the host cell must have on its cytoplasmic membrane specific receptor sites to which the virus attaches. Thus, some infections are confined to meningeal cells, enteroviruses being the most common, in which case the clinical manifestations are those of aseptic meningitis. Other viruses involve particular classes of neurons of the brain or spinal cord, giving rise to the more serious disorders such as encephalitis and poliomyelitis. The virus or its nucleocapsid must be capable of penetrating the cell, mainly by the process of endocytosis, and of releasing its protective nucleoprotein coating. For viral reproduction to occur, the cell must have the metabolic capacity to transcribe and translate virus-coated proteins, to replicate viral nucleic acid, and, under the direction of the virus's genome, to assemble virions. Certain agents depend on cell-surface receptors to ingress into the cell; these relationships have potential therapeutic interest as, for example, the use of serotonin receptor for entry of the JC virus into oligodendrocytes.

The pathologic effects of viruses on susceptible cells vary greatly. In acute encephalitis, neurons are invaded directly by virus and the cells undergo lysis. There is a corresponding glial and inflammatory reaction. Neuronophagia (phagocytosis of affected neurons and their degenerative products by microglia) is a mark of this

phenomenon. In progressive multifocal leukoencephalopathy (PML), there is a selective lysis of oligodendrocytes, resulting in foci of demyelination. In certain congenital infections, e.g., measles and rubella, the virus persists in nervous tissue for months or years. In still other circumstances, a viral infection may exist in the nervous system for a long period before exciting an inflammatory reaction (e.g., subacute sclerosing panencephalitis, SSPE); in these cases the disease may be so indolent as to simulate a degenerative disease.

Differentiating cells of the fetal brain have particular vulnerabilities, and viral incorporation may give rise to malformations and to hydrocephalus; an example is mumps virus with ependymal destruction and aqueductal stenosis.

In experimental animals cerebral neoplasms can be induced when certain viral genomes are incorporated into the DNA of the host cell. There is suggestive evidence of such a mechanism relating to EBV in B-cell lymphoma of the brain. The prions have yet other means of affecting cells that do not conform to the traditional concepts of infection and are discussed in a later section of this chapter.

CLINICAL SYNDROMES

A large number of viruses are able to affect the nervous system. Among the enteroviruses alone, nearly 70 distinct serologic types are associated with CNS disease, and additional types from this family of viruses and others are still being discovered. There is no need, however, to consider them individually, as there are only a limited number of ways in which they express themselves clinically: (1) acute aseptic ("lymphocytic") meningitis; (2) a less-common recurrent meningitis; (3) acute encephalitis and meningoencephalitis; (4) ganglionitis (herpes zoster); (5) chronic invasion of nervous tissue by retroviruses, i.e., HIV and tropical spastic paraparesis (TSP); (6) acute anterior poliomyelitis; (7) chronic viral infections including the agent causing PML and subacute sclerosing panencephalitis (SSPE) and (8) the prion agents that are discussed later in the chapter.

ACUTE ASEPTIC MENINGITIS

The term *aseptic meningitis* was first introduced to designate what was thought to be a specific disease—"aseptic" because bacterial cultures were negative. The term is now applied to a symptom complex that is produced by any one of a number of infective agents, the majority of which are viral but a few of which are bacterial (mycoplasma, Q fever, other rickettsial infections). Because aseptic meningitis is rarely fatal, the precise pathologic changes are uncertain but are presumably limited to the meninges. Conceivably, there may be some minor changes in the underlying brain itself, but these are of insufficient severity to cause neurologic symptoms and signs or to show changes on imaging studies.

In outline, the clinical syndrome of aseptic meningitis consists of fever, headache, signs of meningeal irritation, and a predominantly lymphocytic pleocytosis in the spinal fluid with normal glucose. Usually the onset is acute and the temperature is elevated, from 38 to 40°C (100.4 to 104°F). Headache that is more severe than that associated with other febrile states is the most frequent symptom. A variable but usually mild degree of lethargy, irritability, and drowsiness may occur. Photophobia and pain on movement of the eyes are common additional complaints. Stiffness of the neck and spine on forward bending attests to the presence of meningeal irritation (meningismus), but at first it may be so slight as to pass unnoticed. Here the Kernig and Brudzinski signs help little, for they are often absent in the presence of manifest viral meningitis. When there are accompanying neurologic signs, they too tend to be mild or fleeting; paresthesia in an extremity, or wavering Babinski signs.

Systemic symptoms and signs aside from fever are infrequent and depend mainly on the more mundane effects of the invading virus; these include sore throat, nausea and vomiting, vague weakness, pain in the back and neck, conjunctivitis, cough, diarrhea, vomiting, rash, petechia, hepatitis, adenopathy, or splenomegaly. The childhood exanthems associated with meningitis and encephalitis (varicella, rubella, mumps) produce well-known eruptions and other characteristic signs. An erythematous papulomacular, nonpruritic rash, confined to the head and neck or generalized, may also be a prominent feature, particularly in children, of certain echoviruses and Coxsackie viruses. An enanthem (herpangina), taking the form of a vesiculoulcerative eruption of the buccal mucosa, may also occur with these viral infections.

In milder cases, in the first hours or day of the illness, there may be no abnormalities of the spinal fluid, and the patient may erroneously be thought to have migraine or a headache induced by a systemic infectious illness. Microorganisms cannot be demonstrated by conventional smear or culture. As a rule, the glucose content of the CSF is normal; but infrequently, mild depression of the CSF glucose (never below 25 mg/dL) occurs with the meningitis caused by mumps, HSV-2, lymphocytic choriomeningitis, or VZV.

Causes of Acute Aseptic Meningitis

Aseptic meningitis is a common occurrence, with an annual incidence of approximately 20 cases per 100,000 population (Beghi et al; Ponka and Pettersson). Most are caused by viral infections. Of these, the most common are from enterovirus—mainly echovirus and Coxsackie virus. These make up 80 percent of cases in which a specific viral cause can be established. HSV-2 is perhaps next in frequency in adults, followed by varicella, HIV, mumps in children, lymphocytic choriomeningitis (LCM), HSV-1, and adenovirus infections. The next most frequent group comprise EBV (infectious mononucleosis), CMV, leptospira, HSV-1, and the bacterium *Mycoplasma pneumoniae* (see Chap. 32), and in some parts of the world, tick-borne encephalitis virus and *Borrelia*, including the Lyme agent (Kupila et al), or during local outbreaks anywhere, arboviruses. Influenza

virus, adenoviruses, and numerous sporadic and otherwise innocuous agents are at times isolated from the spinal fluid in cases of aseptic meningitis. The California and West Nile viruses, which are arthropod-borne viruses ("arboviruses" in the family of Flaviviruses) are responsible for a small number of cases; they usually cause an encephalitis or meningoencephalitis in brief regional outbreaks as discussed further on.

It is also recognized that infection with HIV may present as acute, self-limited aseptic meningitis with an infectious mononucleosis-like clinical picture. While HIV has been obtained from the CSF in the acute phase of the illness, seroconversion occurs only later, during convalescence from the meningitis (see further on). HSV-1 has been isolated from the CSF of patients with recurrent bouts of benign aseptic meningitis (so-called Mollaret meningitis), but this finding has not been consistent (Steel et al). As discussed in Chap. 47, it is now believed that this virus also underlies many if not most cases of what has been traditionally considered idiopathic Bell's palsy.

Two other aspects of the virology of aseptic meningitis should be noted: first, in most published series of cases from virus isolation centers, a specific cause cannot be established in one-third or more of cases of presumed viral origin; second, most agents capable of producing aseptic meningitis also sometimes cause encephalitis.

Differential Diagnosis of the Cause of Viral Meningitis

Clinical distinctions between the many viral causes of aseptic meningitis cannot be made with high reliability, but useful clues can be obtained by attention to certain details of the clinical history and physical examination. Inquiry should be made regarding recent respiratory or gastrointestinal symptoms, immunizations, past history of infectious disease, family outbreaks, insect bites, contact with animals, and areas of recent travel. The presence of a local epidemic, the season during which the illness occurs, and the geographic location, are other helpful data.

Because the common enteroviruses, including polio, grow in the intestinal tract and are spread mainly by the fecal-oral route, family outbreaks are usual and the infections are most common among children. A number of echovirus and Coxsackie virus (particularly group A) infections are associated with exanthemata and may be associated with the grayish vesicular lesions of oral herpangina. Pleurodynia, brachial neuritis, pericarditis, and orchitis are characteristic of some cases of group B Coxsackie virus infections and there are certainly other causes. Pain in the back and neck and in the muscles should suggest poliomyelitis or dengue. Lower motor neuron weakness may also occur with echo, West Nile, and Coxsackie virus infections, but it is usually mild and transient in nature. The peak incidence of enteroviral infections is in August and September.

Mumps meningitis occurs sporadically throughout the year, but the highest incidence is in late winter and spring. Males are affected three times more frequently than females. Other manifestations of mumps infection—parotitis, orchitis, mastitis, oophoritis, and pancreatitis—may

be, but most often are not, present. It should be noted that orchitis is not specific for mumps but occurs occasionally with group B Coxsackie virus infections, infectious mononucleosis, and lymphocytic choriomeningitis. A definite past history of mumps aids in excluding the disease as an attack confers lifelong immunity.

The natural host of the *LCM virus* is the common house mouse, *Mus musculus*. Humans acquire the infection by contact with infected hamsters or with dust contaminated by mouse excreta. Laboratory workers who handle rodents may be exposed to LCM. The meningitis may be preceded by respiratory symptoms, sometimes with pulmonary infiltrates. The infection is particularly common in late fall and winter, presumably because mice enter dwellings at that time.

Parvovirus causes fifth disease in young children, characterized by high fever and markedly flushed cheeks but not associated with neurologic symptoms beyond irritability and sometimes, febrile seizures. However, when contracted from the child by an adult, various neurologic manifestations such as brachial neuritis can occur. There have also been reports of encephalitis and meningitis with the B-19 strain, particularly in children and sometimes in individuals with altered immunity. By a difficult to understand complication, some patients have had strokes as discussed in the review by Douvoyiannis and colleagues.

HSV and HIV meningitis may be associated with a cauda equina neuritis. In the case of HSV, there is often a preceding genital infection with the virus (see Chap. 46). The presence of sore throat, generalized lymphadenopathy, transient rash, and mild icterus is suggestive of *infectious mononucleosis caused by EBV* or, at times, *CMV infection*. Icterus is a prominent manifestation of viral hepatitis and some serotypes of leptospirosis and, at times, of Q fever. Among the bacterial and spirochetal cause of an aseptic meningitis syndrome, *leptospirosis*, *M. pneumoniae*, and *Lyme borreliosis* are notable as discussed in the previous chapter.

Certain forms of encephalitis occur particularly in individual who are immunosuppressed from HIV, chemotherapy for neoplasm, organ transplantation, or hematologic and lymphoid malignancy. The manifestation is usually encephalitis but aseptic meningitis is known to occur. The main causative organisms in this group are HHV-6, CMV, and VZV.

Laboratory findings suggest certain organisms as the cause of aseptic meningitis. Most cases of infectious mononucleosis can be identified by the blood smear and specific serologic tests (heterophil or others). LCM should be suspected if there is an intense lymphocytic pleocytosis. Counts above 1,000 cells/mm³ in the spinal fluid, particularly if the cells are all lymphocytes, are most often due to LCM but may occur occasionally with mumps or echovirus 9. In the last of these agents, neutrophils may predominate in the CSF for a week or longer. Slightly depressed glucose in the spinal fluid is consistent with mumps meningitis and with the viruses mentioned earlier, but it is more often indicative of bacterial or fungal infection.

Liver function tests are abnormal in many patients with EBV infection and leptospiral infections; the hepatitis viruses are not known to produce meningitis. In the

majority of patients with *M. pneumoniae* infections, cold agglutinins appear in the serum toward the end of the first week of the illness.

Panels of serologic tests for the main viruses that cause aseptic meningitis are available; most use complement fixation or enzyme-linked immunosorbent assay (ELISA) techniques; an infection is demonstrated by a fourfold increase in titer from acute to convalescent serum drawn at least 10 days apart, but these, of course, do no more than confirm the diagnosis after the illness has mostly passed. In some instances, elevation of specific IgM antibody directed at an infectious agent is useful. Serologic reactions of CSF for syphilis should be interpreted with caution, because inflammation of many types, including infectious mononucleosis, can produce a false-positive reaction. In the last few years, the polymerase chain reaction (PCR) has been applied to the diagnosis of viral infections of the nervous system, among them being CMV and HSV. The test is most sensitive during the active stage of viral replication, in contrast to serologic tests, which are more accurate later in the course of the infection. There are numerous false-negative and fewer false-positive PCR tests for CMV, but they are nonetheless useful in some circumstances, such as the early diagnosis of fulminant CMV infection in AIDS patients (see later in this chapter). For the most part, neither serologic nor PCR testing is required in clinical practice.

Nonviral Causes of Aseptic, Chronic, and Recurrent Meningitis

In addition to the aforementioned bacterial infections that can cause meningitis, several other categories of disease may cause a sterile, predominantly lymphocytic or mononuclear reaction in the leptomeninges: (1) foci of bacterial infection lying adjacent to the meninges, such as spinal or cranial epidural abscess (parameningeal infection); (2) partially treated bacterial meningitis; (3) meningeal infections in which the organism is difficult or impossible to isolate—fungal and tuberculous meningitis are at times in this category and parasitic infections are in this group; (4) neoplastic invasion of the leptomeninges (lymphomatous and carcinomatous meningitis); (5) granulomatous, vasculitic, or other inflammatory diseases such as sarcoidosis, Behçet disease, and granulomatous angiitis; and (6) acute or chronic recurrent inflammatory meningitides as a result of chemical irritation, drug-induced allergic reactions, including an aseptic *chemical meningitis* incited by rupture of a craniopharyngioma or other cystic structure containing proteinaceous fluid. These are described further on under “Chronic Persistent and Recurrent Meningitis.” (7) Rarely, children with scarlet fever or streptococcal pharyngitis develop meningeal signs and slight pleocytosis, the result of a sterile serous inflammation that does not involve invasion of the meninges by organisms. The same occurs in bacterial endocarditis.

An idiosyncratic, presumably immunologic meningitis may result from the use of nonsteroidal antiinflammatory drugs, intravenous immune globulin (due probably to a carrier chemical in the solution), and, rarely, from other drugs, including certain antibiotics. Individuals with systemic

lupus erythematosus have an increased risk of aseptic meningitic reactions to antiinflammatory medications.

In respect to the first two categories, parameningeal and partially treated bacterial infections, smoldering paranasal sinusitis or mastoiditis may produce a CSF picture of aseptic meningitis because of epidural or subdural extension into the intracranial compartments; it is infrequent that the entire syndrome of meningitis is present. Uncomplicated sinusitis alone does not cause a meningeal reaction.

Antibiotic therapy given for a systemic or pulmonary infection may suppress a bacterial meningitis to the point where mononuclear cells predominate, glucose is near normal, and organisms cannot be cultured from the CSF although they may still be evident by Gram stain. Careful attention to the history of recent antimicrobial therapy permits recognition of these cases.

Syphilis, cryptococcosis, and tuberculosis are the important members of the third group that cause aseptic meningitis and in which the organism may be difficult to culture, as detailed in Chap. 32. Tuberculous meningitis, in its initial stages, may masquerade as innocent aseptic meningitis and the diagnosis may be delayed. Similarly, the diagnosis of cryptococcosis, other fungal infection, or nocardiosis is occasionally missed because the organisms may be present in such low numbers as to be overlooked in smears, especially in AIDS patients. Brucellosis (Mediterranean fever, Malta fever) is a rare disease that may present as an acute meningitis or meningoencephalitis, with the CSF findings of aseptic meningitis. The diagnosis depends on the detection of high serum antibody titers and *Brucella*-specific immunoglobulins, using the ELISA or serum agglutination testing.

In the neoplastic group, leukemias and lymphomas are the most common sources of meningeal infiltrations. In children, leukemic “meningitis” with cells (lymphoblasts or myeloblasts) in the CSF numbering in the thousands may occur. In leptomeningeal metastases (carcinomatous meningitis), neoplastic cells extend throughout the leptomeninges and involve cranial and spinal nerve roots, producing a picture of meningo-radicularitis with normal or low CSF glucose values. Lymphocytic meningitis that is accompanied by cranial-nerve palsies may prove to be tuberculous if the patient is febrile and the CSF glucose is low (or even without these signs in an endemic area); it is likely to be neoplastic if the patient is afebrile and the CSF glucose is normal or mildly decreased. Concentrated cytologic preparations usually permit identification of the tumor cells. Chapter 31 discusses neoplastic meningitis in detail.

Occlusion of many small cerebral blood vessels by cholesterol emboli may also excite a reaction in meningeal vessels and a pleocytosis that includes eosinophils.

CHRONIC PERSISTENT AND RECURRENT MENINGITIS (Table 33-1)

Chronic and recurrent meningitides always pose diagnostic problems. Such patients may have a low-grade fever, headache of varying severity, stiff neck, and a

Vogt-Kayanagi-Harada disease
 No cause determined in one-third of cases

predominantly mononuclear pleocytosis, sometimes with slightly raised CSF pressure. There may be limited focal neurologic signs such as a slight pronator drift or Babinski sign. A viral or some other type of infective inflammation is always suspected, but a search by culture methods and serology usually yields negative results. Herpesvirus has been demonstrated to be the cause of a few cases, as in the recurrent Mollaret type of meningitis noted later. The process often improves without identification of the cause over a period of months or a year or more; in other cases, the cause is eventually found. Only a few end fatally.

In a group of such patients studied at the Mayo Clinic, 33 of 39 underwent a natural resolution and 2 died; 14 were still symptomatic at the time of the report (Smith and Aksamit). In another series from New Zealand of 83 patients, Anderson and colleagues ultimately found tuberculosis to be the most common identifiable cause, a smaller number being accounted for by neoplastic and cryptococcal meningitis; in fully one-third of the patients, no cause could be established. Charleston and colleagues reported a subgroup of these patients who were responsive to steroids; in only 7 of 17 patients could medication eventually

be withdrawn without recurrence; 4 required treatment indefinitely; and the remaining 6 died after many months or years. The outcome and response to steroids in our patients have been much the same. These series excluded chemical or irritative meningitis, which should be considered if there had been spinal surgery or infusion of even apparently innocuous substances into the spinal space.

The special problem of *chronic neutrophilic meningitis* has been mentioned in the preceding chapter in relation to *Nocardia*, *Aspergillus*, *Actinomyces*, or certain *Mycobacterium* species; other causes include coccidioidomycosis, histoplasmosis, and blastomycosis, (see Peacock, cited in Chap. 32).

A reasonable approach in patients with chronic meningitis is to repeat the lumbar puncture several times to obtain all cultures including for fungi and cytology of CSF, using markers to detect uniform populations of B and T lymphocytes and tumor cells, biochemical tests that are sensitive to neoplastic meningitis (such as β_2 -microglobulin, lactate dehydrogenase [LDH]), and PCR amplification of herpesviruses, serologic tests mainly for HIV, syphilis, coccidioidomycosis, *Brucella*, and Lyme disease. MRI of the brain and spinal cord with gadolinium should also be performed to detect parameningeal collections. If hydrocephalus develops, it should be managed along the lines described in Chap. 30.

A trial of antiviral agents and broad-spectrum antibiotics may be justified, although we have had limited success with them in our last several patients. We resort to a biopsy of the meninges over the frontal convexity or at a site that demonstrates infiltration or marked enhancement if the diagnosis has not been clarified in 6 to 12 months or if febrile meningitis persists for more than several weeks, but examination of this tissue has also proved to be of limited value. In Anderson's (1995) series, mentioned earlier, biopsy yielded a diagnosis in 5 of 25 patients. Finally, if bacterial infection has been reasonably excluded, corticosteroids are administered for several weeks and then tapered while observing the patient and resampling the CSF.

The CSF formula in a number of other *chronic or acutely recurring meningitides* corresponds to that of aseptic meningitis. These include (1) the Vogt-Koyanagi-Harada syndrome, which is characterized by combinations of iridocyclitis, depigmentation of a thick swath of hair (poliosis circumscripta) and of the skin, vitiligo, around the eyes, loss of eyelashes, dysacusis, and deafness (the pathologic basis of the syndrome is not known); and (2) Mollaret recurrent meningitis, many instances of which have been associated with HSV-1 (Steel) and others (perhaps most) with HSV-2 infection (Cohen et al). The syndrome is characterized by episodes of acute meningitis with severe headache and sometimes low-grade fever, lasting for about 2 weeks, and recurring over a period of several months or years. In a few patients of ours, in whom no virus could be identified in the CSF, antiviral therapy met with some success, although corticosteroids seemed to reduce the severity of acute episodes. A proportion of these cases follow bouts of genital herpes and individual cases have been reported with EBV, herpes-6 in children, and other viruses. A special syndrome that has been associated with HSV-2 is that

of aseptic meningitis and bladder failure and vaginal or vulvar pain after a bout of genital herpes (Elsberg syndrome as reviewed by Ellie and colleagues); (3) In some patients, the recurrent attacks are associated with encephalopathy and headache; this is probably identical to the illness called “pseudomigraine with temporary neurological symptoms” by Gomez-Aranda and described earlier by Bartleson. The entity, also known as HaNDL syndrome (“headache neurologic deficit and lymphocytic pleocytosis”) is allied more closely with the headache syndromes as discussed and cited in Chap. 10. (4) Allergic or hypersensitivity meningitis, in the past occurring in the course of serum sickness and now more commonly of autoimmune diseases such as lupus erythematosus, and in relation to certain medications such as nonsteroidal antiinflammatory drugs and intravenously administered immunoglobulin. (5) Behçet disease, which is an important acute, recurrent inflammatory CNS disease, particularly in individuals of Middle Eastern origin. It is essentially a diffuse inflammatory disease of small blood vessels that has several other characteristic features such as oral and genital ulcers and is more appropriately considered with the vasculitides in Chap. 34.

In summary, the temporal history of the illness, associated clinical findings, and laboratory tests usually provide clues to the diagnosis of nonviral and chronic forms of aseptic meningitis. It is useful to keep in mind the possibility of neoplasia, HIV, tuberculosis, cryptococcosis, sarcoidosis, syphilis, borreliosis, parameningeal collection, and inadequately treated bacterial meningitis—each of which presents an urgent diagnostic problem.

ACUTE ENCEPHALITIS

From the foregoing discussion it is evident that the separation of the clinical syndromes of aseptic meningitis and encephalitis is not always clear. In some patients with aseptic meningitis, mild drowsiness or confusion may be present, suggesting cerebral involvement. Conversely, in some patients with encephalitis, the cerebral symptoms may be mild and meningeal symptoms and CSF abnormalities predominate. The common practice is to assume that viral meningitis causes only fever, headache, stiff neck, and photophobia; if any other CNS symptoms are added, the condition is generally called meningoencephalitis. As has been emphasized, the same spectrum of viruses gives rise to both meningitis and encephalitis. It is our impression that many cases of enteroviral and practically all cases of mumps and LCM encephalopathy are little more than examples of intense meningitis in which the subpial surface of the brain is inflamed. Rarely have they caused demonstrable postmortem cerebral lesions, and surviving patients have no residual neurologic signs. Conversely, several agents, notably the arboviruses, may cause encephalitic lesions with only mild meningeal symptoms.

The core of the *encephalitis syndrome* consists of an acute febrile illness with evidence of various combinations of seizures, delirium, confusion, stupor or coma; aphasia, hemiparesis with asymmetry of tendon reflexes

and Babinski signs, involuntary movements, ataxia, and myoclonic jerks; and nystagmus, ocular palsies, and facial weakness. The meningitic component may be intense, have mild manifestations such as headache, or be entirely inapparent. The spinal fluid invariably shows a cellular reaction and the protein is slightly elevated. Imaging studies of the brain are most often normal but may show diffuse edema or enhancement of the cortex and, in certain infections, subcortical and deep nuclear involvement as well as, in the special case of HSV encephalitis, selective damage of the inferomedial temporal and frontal lobes.

Differentiation of Viral from Postinfectious Encephalitis (See also Chap. 36) The acute encephalitis syndrome described above may take two forms: the more common direct invasion of brain and meninges (true viral encephalitis) and a postinfectious encephalomyelitis that is presumably based on an autoimmune reaction to the systemic viral infection but in which virus is not present in neural tissue. The distinction between postinfectious encephalomyelitis and infectious encephalitis may be difficult, especially in younger patients who have a proclivity to develop the postinfectious variety with fever. The latter, termed acute disseminated encephalomyelitis (ADEM), occurs after a latency of several days, as the infectious illness is subsiding. It is expressed by a low-grade fever and cerebral symptoms such as confusion, seizures, coma, or ataxia. The spinal fluid shows slight inflammation and elevation of protein—sometimes a more intense reaction, and there are usually characteristic confluent, scattered, bilateral lesions in the white matter in imaging studies, findings that differ from those of viral encephalitis. When there is no coexistent epidemic of encephalitis to suggest the diagnosis, or the preceding systemic illness is absent or obscure, a differentiation between the two may not be possible on clinical grounds alone. The fever is generally higher in the infectious type but even this difference does not always hold in young children with ADEM. The encephalitis that follows certain childhood exanthems (postexanthematous) and vaccinations at any age (postvaccinal) are essentially forms of ADEM.

Because ADEM is predominantly an inflammatory and demyelinating process, we mention it here but discuss its clinical features and imaging more fully in Chap. 36, with the other demyelinating diseases such as multiple sclerosis, with which it shares some features. We also place in special categories further on the now rare Reye syndrome of postinfectious acute encephalopathy with hepatic failure that follows influenza, and other viral infections and postinfectious cerebellitis.

Etiology

Whereas numerous viral, bacterial, fungal, and parasitic agents are cited as causes of the encephalitis syndrome, only the viral ones are considered here, for they are the most common and it is to these that one usually refers when the term *encephalitis* is used. The nonviral forms (mycoplasmal, rickettsial, Lyme, etc.) are considered in Chap. 32, under “Encephalitis Caused by Bacterial Infections,” and should be reviewed with this section.

According to the Centers for Disease Control and Prevention, approximately 20,000 cases of acute viral encephalitis are reported annually in the United States. Death occurs in 5 to 20 percent of these patients and residual signs, such as mental deterioration, amnesic defect, personality change, recurrent seizures, and hemiparesis, are seen in approximately another 20 percent. However, these overall figures fail to reflect the widely varying incidence of mortality and residual neurologic abnormalities that follow infections by different viruses. In herpes simplex encephalitis, for example, approximately 50 percent of patients die or are left with some impairment, and in eastern equine encephalitis, the figures are even higher. On the other hand, death and serious neurologic sequelae have been observed in only 5 to 15 percent of those with western equine and West Nile infections and in even fewer patients with Venezuelan, St. Louis, and La Crosse encephalitis.

The types of viral encephalitis that occur with sufficient frequency to be of clinical importance are relatively few. HSV is by far the most common sporadic cause of encephalitis and has no seasonal or geographic predilections. Its age distribution is slightly skewed and biphasic, affecting persons mainly between ages 5 and 30 years and those older than age 50 years. Many other viruses, exemplified by the arboviral encephalitis, have a characteristic geographic and seasonal incidence. The most important of these is the Japanese encephalitis serogroup (Flaviviruses), of which the now common West Nile virus is a member. In recent outbreaks in the United States, the West Nile virus has been more frequent than any of the other arboviruses and has had a wide geographic distribution (Solomon). In the United States, eastern equine encephalitis, as the name implies, is observed mainly in the eastern states and on both the Atlantic and Gulf coasts. Western equine encephalitis is fairly uniformly distributed west of the Mississippi. St. Louis encephalitis, another arthropod-borne late-summer encephalitis, occurs nationwide but especially along the Mississippi River in the South; outbreaks occur in August through October, slightly later than is customary for the other arboviruses. Venezuelan equine encephalitis is common in South and Central America; in the United States it is practically confined to Florida and the southwestern states. California virus encephalitis predominates in the northern Midwest and northeastern states. After West Nile, the La Crosse variety is perhaps the most frequent identifiable arbovirus encephalitis in the United States.

Rabies infections occur worldwide, but in the United States they are seen mostly in the Midwest and along the West Coast. Japanese B encephalitis (the most common encephalitis outside of North America), Russian spring-summer encephalitis, Murray Valley encephalitis (Australian X disease), and several less common viral encephalitis are infrequent in the United States or, as in the case of West Nile fever, have appeared only recently. With the ease and rapidity of travel, many of these will undoubtedly increase in number in North America and parts of Europe where they have not been seen hitherto.

Infectious mononucleosis, which is a primary infection with EBV, is complicated by meningitis, encephalitis,

facial palsy, or polyneuritis of the Guillain-Barré type in a small proportion of cases. Each of these neurologic complications can occur in the absence of the characteristic fever, pharyngitis, and lymphadenopathy of infectious mononucleosis. The same is true of *M. pneumoniae*. In these two diseases there is still uncertainty as to whether they are true infectious encephalitis or postinfectious complications, as discussed in Chap. 32. Evidence from PCR testing of spinal fluid is consistent with a direct infection in some cases. Varicella zoster and CMV are other herpes-type viruses that may cause encephalitis. They are discussed in relation to the particular clinical settings in which they occur. Definite cases of "epidemic encephalitis" (encephalitis lethargica) have not been observed in acute form since 1930, although an occasional surviving patient with a residual parkinsonian syndrome is still seen in neurology clinics. However, various movement disorders, including parkinsonism, are being seen as a residua of encephalitis from the Flaviviruses. The latency from infection to these complications is brief, or may be present from the outset, quite unlike encephalitis lethargica. There may also be a postinfectious-immune variety of this midbrain encephalitis.

More recently, a sometimes overwhelming encephalitis has been recognized as a rare manifestation of influenza infection, particularly the H1N1 strain that has infected mainly children in Southeast Asian countries, but also other serotypes of influenza including mundane influenza viruses that cause yearly outbreaks. The disorder has been called an "encephalopathy" in research publications but convulsions, delirium, and coma suggest that the neurologic aspects are from encephalitis.

The relative frequency of the various viral infections of the nervous system can be appreciated from several studies. An early series from the Walter Reed Army Institute comprising 1,282 patients is particularly noteworthy in that a positive laboratory diagnosis was achieved in more than 60 percent of cases (Buescher et al)—a higher rate than in almost any subsequent study of comparable size. Aside from the poliovirus (some of the data were gathered before 1959) the common infective agents in cases of both aseptic meningitis and encephalitis were group B Coxsackie virus, echovirus, mumps virus, lymphocytic choriomeningitis virus, arboviruses, HSV, and *Leptospira*, in that order. In a later prospective virologic study of all children examined at the Mayo Clinic during the years 1974 to 1976, a diagnosis of aseptic meningitis, meningoencephalitis, or encephalitis was entertained in 42 cases and an infectious agent was identified in 30 of them (Donat et al). The California virus was isolated in 19 cases and one of the enteroviruses (echovirus types 19, 16, 21, or Coxsackie virus) in 8 cases; mumps, rubeola, HSV, adenovirus 3, and *M. pneumoniae* were detected in individual cases (several patients had evidence of combined infections). As mentioned, recent outbreaks of *West Nile virus*, close to 3,000 cases yearly in the United States, make it of more current import than some of the viral infections listed here. The related Japanese encephalitis virus is even more ubiquitous on a worldwide basis, causing 10,000 deaths in Asia each year.

In a more contemporary and impressively large series of viral infections of the nervous system from the United Kingdom involving more than 2,000 patients, viral identification in the CSF was attempted by means of PCR with positive results in only 7 percent, half of which were various enteroviruses (Jeffery et al). The other organisms commonly identified were HSV-1, followed by VZV, EBV, and other herpesviruses. In patients with AIDS, however, the relative frequencies of the organisms that cause meningoencephalitis are quite different and include special clinical presentations; this applies particularly to CMV infection of the nervous system, as discussed further on, under "Opportunistic Infections and Neoplasms of the CNS in AIDS." Our personal experience has been heavily biased toward HSV encephalitis, seasonal outbreaks of eastern equine or West Nile encephalitis, and AIDS-related cases.

Arboviral Encephalitis

The common arthropod-borne viruses (arboviruses) that cause encephalitis in the United States and their geographic range have been mentioned earlier. Most of the agents are in the category of Flaviviruses. There are alternating cycles of viral infection in mosquitoes and vertebrate hosts; the mosquito becomes infected by taking a blood meal from a viremic host (horse or bird) and injects virus into the host, including humans. The seasonal incidence of these infections is practically limited to the summer and early fall, when mosquitoes are biting. In the equine encephalitides, regional deaths in horses usually precede human epidemics. For St. Louis encephalitis, the urban bird or animal or possibly the human becomes the intermediate host. West Nile outbreaks are preceded by illness in common birds such as crows and jays. St. Louis, California, and La Crosse agents are endemic in the United States because of the cycle of infection in small rodents. Powassan virus from the deer tick has been added to the list of causes of Flavivirus encephalitis in North America as in the report by Tavakoli and coworkers.

The clinical manifestations of the arbovirus infections are almost indistinguishable from one another, although they do vary with the age of the patient. The incubation period after mosquito or tick bite transmission is 5 to 15 days. There may be a brief prodromal fever with arthralgia or rash (e.g., West Nile fever). In infants, there may be only an abrupt onset of fever and convulsions, whereas in older children and adults the onset is usually less abrupt, with complaints of headache, listlessness, nausea or vomiting, drowsiness, and fever for several days before medical attention is sought; convulsions, confusion, stupor, and varying degrees of stiff neck then become prominent. Photophobia, diffuse myalgia, and tremor (of either action or intention type) may be observed. Asymmetry of tendon reflexes, hemiparesis, extensor plantar signs, myoclonus, chorea, and sucking and grasping reflexes may also occur. McJunkin and colleagues described the clinical features of 127 patients with La Crosse infection seen at their medical center over a decade, and their descriptions are representative of other arboviral infec-

tions. In addition to the typical features of viral encephalitis they emphasize aspects that occur in a proportion of patients: hyponatremia, raised intracranial pressure with cerebral swelling, and, most notable to us, signal changes in the MRI that simulate herpes encephalitis.

A special syndrome of febrile, flaccid, paralytic poliomyelitis resulting from West Nile virus infection is now also well known. It evolves over several days and in a few cases is accompanied by facial paralysis (Jeha et al). A few cases have had an early extrapyramidal syndrome; any of these features may occur with the other Flaviviruses.

The fever and neurologic signs of arboviral encephalitis subside after 4 to 14 days unless death supervenes or destructive CNS changes have occurred. No antiviral agents are known to be effective; one must rely entirely on supportive measures. On occasion, brain swelling reaches a degree that requires specific therapy, as outlined in "Management of the Acutely Comatose Patient and Management of Raised Intracranial Pressure" in Chap. 17.

Of the arbovirus infections in the United States, eastern equine encephalitis (EEE) is among the most serious, as a large proportion of those infected develop encephalitis; approximately one-third die and a similar number, more often children, are left with disabling abnormalities—mental retardation, emotional disorders, recurrent seizures, blindness, deafness, hemiplegia, extrapyramidal motor abnormalities, and speech disorders. While only a small proportion of those exposed become infected, the poliomyelitis and parkinsonian syndromes of the Flaviviruses may be permanent residua as mentioned earlier (Solomon). On the other extreme, La Crosse encephalitis, which affects mostly children, has an almost uniformly benign outcome. The rate of progression from a nondescript febrile viral syndrome to encephalitis is similarly low in the arbovirus infections and mortality rate varies from 2 to 12 percent in different outbreaks.

Diagnosis The CSF findings are much the same as in aseptic meningitis (lymphocytic pleocytosis, mild protein elevation, normal glucose values). Recovery of virus from blood or CSF is usually not possible and PCR testing is routinely only applied during local epidemics. However, antiviral immunoglobulin (Ig) M antibody is present in the serum and CSF within the first days of symptomatic disease and can be detected and quantified by means of ELISA, making it preferable to other testing for specific diagnosis. Some patients have not developed antibodies by the time of admission to the hospital and the test may have to be repeated in several days. The MRI may be normal or show signal changes and edema in the cortex, basal ganglia, or thalamus (the latter is described particularly in the Japanese B virus group, West Nile, EEE, and rabies).

Pathology Perivascular cuffing by lymphocytes and other mononuclear leukocytes and plasma cells, as well as a patchy infiltration of the meninges with similar cells, are the usual histopathologic hallmarks of viral encephalitis. There is widespread degeneration of single nerve cells, with neuronophagia as well as scattered foci of inflammatory necrosis involving both the gray and white matter. The brainstem is relatively spared. In some cases

of eastern equine encephalitis, the destructive lesions may be massive, involving the major part of a lobe or hemisphere and are readily displayed by MRI, but in the other arbovirus infections the foci are microscopic in size (Deresiewicz et al). West Nile virus may produce a regional pattern of neuronal damage that affects the anterior horn cells of the spinal cord, a poliomyelitis, as mentioned earlier. Pathologic descriptions of this process have been provided by our colleagues and by others (see Anis et al).

Herpes Simplex Encephalitis

Of the common viral encephalitides, this is perhaps the gravest and is by far the most common. About 2,000 cases occur yearly in the United States, accounting for approximately 10 percent of all cases of encephalitis. Between 30 and 70 percent are fatal, and the majority of patients who survive are left with serious neurologic abnormalities. HSV encephalitis occurs sporadically throughout the year and in patients of all ages and in all parts of the world. It is almost always caused by HSV-1, which is also the cause of the common herpetic lesions of the oral mucosa; only rarely, however, are the oral and encephalitic lesions concurrent. The type 2 herpesvirus may also cause acute generalized encephalitis, usually in the neonate and in relation to genital herpetic infection in the mother. Type 2 infection in the adult more typically causes an aseptic meningitis and sometimes a polyradiculitis or myelitis, again in association with a recent genital herpes infection. Exceptionally, the localized adult type of encephalitis is caused by the type 2 virus and the diffuse neonatal encephalitis by type 1.

Clinical Features

The symptoms, which evolve over several days, are in most cases like those of any other acute encephalitis—namely, fever, headache, seizures, confusion, stupor, and coma. In some patients these manifestations are preceded by symptoms and findings that betray the predilection of this disease for the inferomedial or lateral portions of the frontal and temporal lobes and the insula. The symptoms and findings include olfactory or gustatory hallucinations, anosmia, temporal lobe seizures, personality change, bizarre or psychotic behavior or delirium, aphasia, and hemiparesis. Although several seizures at the onset of illness are not an uncommon presentation, status epilepticus is rare. Disturbed memory function can often be recognized, but usually this becomes evident only later in the convalescent stage as the patient awakens from stupor or coma. Hemorrhagic swelling and herniation of one or both temporal lobes through the tentorial opening may occur, leading to coma during the first few days of the illness, a very poor prognostic sign.

The CSF is typically under increased pressure and almost invariably shows a pleocytosis (range 10 to 200 cells/mm³; infrequently greater than 500 cells/mm³). The cells are mostly lymphocytes, but there may be a significant number of neutrophils early on. In a few cases, 3 to 5 percent in some large series, the spinal fluid was normal in the first days of the illness, only to become

abnormal when reexamined. The hemorrhagic nature of brain tissue destruction with this infection may be reflected in the spinal fluid. In fact, in only a minority of cases, red cells, sometimes numbering in the thousands but usually far fewer, and xanthochromia are found. The protein content is increased in most cases. Rarely, the CSF glucose levels may be reduced to slightly less than 40 mg/dL, creating confusion with tuberculous and fungal meningitides. The cerebral imaging appearance, giving highly characteristic features, is discussed later in the section on “Diagnosis.”

Pathology

The lesions take the form of an intense hemorrhagic necrosis of the inferior and medial temporal lobes and the mediobasal parts of the frontal lobes. The region of necrosis may extend upward along the cingulate gyri and sometimes to the insula or the lateral parts of the temporal lobes or caudally into the midbrain but always contiguous with areas of mediotemporal lobe necrosis. The temporal lobe lesions are usually bilateral but not symmetrical. This distribution of lesions is so characteristic that the diagnosis can be made by gross inspection or by their location and appearance on imaging studies. Cases described in past years as “acute necrotizing encephalitis” and “inclusion body encephalitis” were likely to have been instances of HSV encephalitis. In the acute stages, intranuclear eosinophilic inclusions are found in neurons and glia cells, in addition to the usual microscopic abnormalities of acute encephalitis and hemorrhagic necrosis. Specific intracellular staining with antibody to various portions of the virus is perhaps the most definitive demonstration of the disease.

The characteristic localization of the lesions in this disease has been putatively explained by the virus' route of entry into the CNS. Two such routes have been suggested (Davis and Johnson). The virus may, for example, be latent in the trigeminal ganglia and, with reactivation, infect the nose and then the olfactory tract. Alternatively, with reactivation in the trigeminal ganglia, the infection may spread along nerve fibers that innervate the leptomeninges of the anterior and middle fossae. The lack of lesions in the olfactory bulbs in as many as 40 percent of fatal cases (Esiri) is a point in favor of the second pathway.

Diagnosis

Acute herpes simplex encephalitis must be distinguished from other types of viral encephalitis, from acute hemorrhagic leukoencephalitis, and from paraneoplastic and other forms of limbic encephalitis, tumor, cerebral abscess, cerebral venous thrombosis, and septic embolism (see Chap. 32). When aphasia is the initial manifestation of the illness, it may be mistaken for a stroke. The CSF findings have been mentioned and are typical of a meningoencephalitis. Spinal fluid that contains a large number of red cells may be attributed to a ruptured saccular aneurysm. The electroencephalographic (EEG) changes, consisting of lateralized periodic high-voltage sharp waves in the temporal regions and slow-wave complexes at regular 2 to 3/s intervals, are highly suggestive in the appropriate clinical context, though they are not

Figure 33-1. Herpes simplex encephalitis. *Left panel:* T2-FLAIR coronal MRI, taken during the acute stage of the illness. There is increased signal in the inferior and medial temporal lobe and the insular cortex of the left hemisphere. *Right panel:* T1-weighted image after gadolinium infusion showing enhancement of the left insular and medial temporal cortices (arrows).

specific for the disease and their sensitivity has not been established with certainty.

CT shows hypodensity of the affected temporal lobe areas in perhaps two-thirds of cases and MRI shows signal changes in almost all (increased signal in T2-weighted images; Fig. 33-1). T1-weighted images demonstrate areas of low signal intensity with surrounding edema and sometimes with scattered areas of hemorrhage occupying the inferior parts of the frontal and temporal lobes. The lesions almost always enhance to some degree with contrast infusion or with gadolinium, indicating cortical and pial abnormalities of the blood-brain barrier. It should be noted that these destructive lesions, and certainly their degree, are almost unique among the viral encephalitides, being seen only occasionally in other viral infections of the brain.

A rising titer of neutralizing antibodies can be demonstrated from the acute to the convalescent stage, but this is not of diagnostic help in the acutely ill patient and may not be significant in patients with recurrent herpes infections of the oral mucosa. Tests for the detection of HSV antigen in the CSF by the application of PCR have been developed and are useful in diagnosis while the virus is replicating in the first few days of the illness (Rowley et al). A refinement in this technique (a nested PCR assay described by Aurelius and coworkers) reportedly has a sensitivity of 95 percent and gives very few false-positive tests in the first 3 weeks of illness. In the experience of Lakeman and colleagues, the test was 98 percent positive in cases proven by cultures of brain biopsy material and gave 6 percent false positives. Antiviral treatment did not appear to affect the results. False-negative tests are most likely to occur in the first 48 h of febrile infection. When the clinical features are consistent with the disease and the PCR test is negative, it is advisable to repeat it in several days, perhaps in another laboratory and to obtain PCR testing for HSV-2 as well.

The only alternative way to establish the diagnosis of acute HSV encephalitis is by fluorescent antibody study and by viral culture of cerebral tissue obtained from brain biopsy. The approach to biopsy as a diagnostic test is now

infrequently employed with the availability of the PCR test. We have now found it necessary to perform biopsy in only a very few cases, preferring to treat the patient with antiviral agents based on compatible clinical, radiologic, and CSF findings while awaiting serologic and PCR test results.

Treatment

Until the late 1970s, there was no specific treatment for HSV encephalitis. A collaborative study sponsored by the National Institutes of Health and also a Swedish trial indicated that the antiviral agent acyclovir significantly reduces both mortality and morbidity from the disease (Whitley et al; Sköldenberg et al). For this reason, it has become general practice to initiate treatment while confirmatory testing is being carried out. Acyclovir is given intravenously in a dosage of 30 mg/kg/d and continued for 10 to 14 days in order to prevent relapse. Acyclovir carries limited risk and can be discontinued if further clinical or laboratory features point to another diagnosis. The main problems that arise from the drug are local irritation of the veins used for infusion, mild elevation of hepatic enzymes, or transient impairment of renal function. Nausea, vomiting, tremor, or an encephalopathy that is difficult to distinguish from the encephalitis itself occurs in a very few patients.

The matter of *relapse after treatment* with acyclovir has been recognized, particularly in children. Several potential mechanisms have been suggested by Tiége and colleagues, including an immune-mediated inflammatory response, but treatment with too low a dose or for too brief a period is undoubtedly the main cause of the rare relapses that occur in adults. In children, a second course of acyclovir is usually successful.

When a large volume of brain tissue is involved, the hemorrhagic necrosis and surrounding edema act as an enlarging mass that requires separate attention. Coma and pupillary changes should not be attributed to the mass effect unless compression of the upper brainstem is evident on brain imaging, as the infection is capable of spreading to the mesencephalon from the contiguous deep temporal lobe, thereby causing coma by a direct

destructive effect. All measures used in the management of brain edema from mass lesions are applicable here, but there are insufficient data by which to judge their effectiveness. The concern that corticosteroids may aggravate the infection has not been borne out by clinical experience, but a detrimental effect cannot be discounted and their value is uncertain. Our experience (reported by Barnett et al) and that of Schwab and colleagues have been that the presence of raised intracranial pressure early in the illness presages a poor outcome. Seizures are usually brought under control by high doses of conventional antiepileptic drugs. The use of these medications prophylactically for seizures has not been resolved.

Prognosis The outcome of this disease, both mortality and morbidity, is governed to a large extent by the patient's age and state of consciousness, particularly at the time of institution of acyclovir therapy. If the patient is unconscious (except immediately after a convulsion), the outcome is usually poor. However, if treatment is begun within 4 days of onset of the illness in an awake patient, survival is greater than 90 percent (Whitley, 1990). Evaluation of patients 2 years after treatment showed 38 percent to be normal or nearly normal, whereas 53 percent were dead or severely impaired. The neurologic sequelae are often of the most serious type, consisting of a Korsakoff amnesic defect or a global dementia, seizures, and aphasia as described by Drachman and Adams in the era before treatment became available. If there were seizures during the acute illness, it is advisable to continue antiepileptic medications for a year or more and then judge the risk of discontinuing them on the basis of further seizures, the EEG, and the patient's exposure to situations that pose a danger, such as driving. With the exception of the rare relapsing cases mentioned earlier, the infection does not recur.

HHV-6 Encephalitis in Stem Cell Transplant

This agent, the cause of roseola (exanthema subitum), has had a controversial role in a number of acute febrile neurologic illnesses, including febrile seizures in infants and young children, subsequent temporal lobe epilepsy, cranial-nerve palsies, and other conditions. However, it is fairly firmly established as the cause of a medial temporal lobe (limbic) encephalitis in adult patients following allogeneic hematopoietic stem cell bone marrow transplantation, as summarized by Seeley and colleagues. All of their patients also developed a graft-versus-host reaction. The clinical and imaging features closely resemble the paraneoplastic and anti-voltage-gated potassium channel limbic encephalitis that is discussed in Chap. 31. The prognosis is far better than in herpetic encephalitis. It is mentioned here that mundane adenoviruses can also produce a severe medial temporal lobe encephalitis in bone marrow transplant cases, in one of our patients associated with gray matter damage in the spinal cord.

The other viral agents that appear as causes of encephalitis with some regularity in stem-cell and organ transplant patients include parvovirus, CMV, EBV, adenovirus, HSV, and varicella zoster virus. Quite often, these infections are but one component of multiorgan

viral infection. Some of these agents also cause manifestations of infection in peripheral and cranial nerves.

Rabies

This disease also stands apart from other acute viral infections by virtue of the latent period that follows inoculation with the virus and its stunningly distinctive clinical and pathologic features. Human examples of this disease are rare in the United States; between 1980 and 1997, only 34 instances were known to have occurred and since 1960, there have not been more than 5 or so cases in any 1 year. In some areas (Australia, Hawaii, Great Britain, and the Scandinavian peninsula), no indigenous cases have ever been reported. In contrast, in India there is a high incidence. The importance of this disease derives from the fact that it is almost invariably fatal once the characteristic clinical features appear, making survival of the infected individual dependent on the institution of specific therapeutic measures before the infection becomes clinically evident. Furthermore, each year 20,000 to 30,000 individuals are treated with rabies vaccine, having been bitten by animals that possibly were rabid, and although the incidence of complications with the newer rabies vaccination is much lower than before, a few serious reactions continue to be encountered (see further on and also Chap. 36).

Etiology

Practically all cases of rabies are the result of transdermal viral inoculation by an animal bite. In developing countries, where rabies is relatively common, the most frequent source is the rabid dog. In Western Europe and the United States, the most common rabid species are raccoons, skunks, foxes, and bats among wild animals and dogs and cats among domestic ones. Because rabid animals commonly bite without provocation, the nature of the attack should be determined. Also, the prevalence of animal rabies virus varies widely in the United States, and local presence of the disease is useful in assessing risk. Rare cases have been caused by inhalation of the virus shed by bats; a history of spelunking suggests this mode of acquiring the infection. In a few cases the source of the infection may not be identifiable. The epidemiology and public health aspects of rabies have been reviewed by Fishbein and Robinson.

Clinical Features

The incubation period is usually 20 to 60 days but may be as short as 14 days, especially in cases involving multiple deep bites around the face and neck. Tingling or numbness at the site of the bite, even after the wound has healed, is characteristic. This is thought to reflect an inflammatory response that is incited when the virus reaches the sensory ganglion.

The main neurologic symptoms, following a 2- to 4-day prodromal period of fever, headache, and malaise consist of apprehension, dysarthria, and psychomotor overactivity, followed by dysphagia (hence salivation and "frothing at the mouth"), spasms of throat muscles induced by attempts to swallow water or in rare cases

by the mere sight of water (“hydrophobia”), dysarthria, numbness of the face, diplopia, and spasms of facial muscles. These features indicate the involvement of the tegmental medullary nuclei. Generalized seizures, confusional psychosis, and a state of agitation may follow. A less common paralytic form (“dumb” rabies of older writings, in distinction to the above described “rabid” form) as a result of spinal cord infection may accompany or replace the state of excitement. The paralytic form is most likely to follow bat bites or, in the past, the administration of rabies vaccination. Coma gradually follows the acute encephalitic symptoms and, with rare exceptions as noted below, death ensues within 4 to 10 days, or longer in the paralytic form.

Pathologic Features

The disease is distinguished by the presence of cytoplasmic eosinophilic inclusions, the Negri bodies. They are most prominent in pyramidal cells of the hippocampus and Purkinje cells but have been seen in nerve cells throughout the brain and spinal cord. In addition there is widespread perivascular cuffing and meningeal infiltration with lymphocytes and mononuclear cells and small foci of inflammatory necrosis, such as those seen in other viral infections. The inflammatory reaction is most intense in the brainstem. The focal collections of microglia in this disease are referred to as *Babes nodules* (named for Victor Babes, a Romanian microbiologist).

Treatment

Bites and scratches from a potentially rabid animal should be thoroughly washed with soap and water and, after all soap has been removed, cleansed with benzyl ammonium chloride (Zephiran), which has been shown to inactivate the virus. Wounds that have broken the skin also require tetanus prophylaxis.

After a bite by a seemingly healthy animal, surveillance of the animal for a 10-day period is necessary. Should signs of illness appear in the animal, it should be killed and the brain sent, under refrigeration, to a government-designated laboratory for appropriate diagnostic tests. Wild animals, if captured, should be killed and the brain examined in the same way.

If the animal is found by fluorescent antibody or other tests to be rabid, or if the patient was bitten by a wild animal that escaped, *postexposure prophylaxis* should be given. Human rabies immune globulin (HRIG) is injected in a dose of 20 U/kg of body weight (one-half infiltrated around the wound and one-half intramuscularly). This provides passive immunization for 10 to 20 days, allowing time for active immunization. Duck embryo vaccine (DEV) was previously used for this purpose and greatly reduced the danger of serious allergic encephalomyelitis from about 1 in 1,000 cases (with the formerly used equine vaccine) to 1 in 25,000 cases; it is still used in many parts of the world. The more recently developed rabies vaccine grown on a human diploid cell line (human diploid cell vaccine [HDCV]) has reduced the doses needed to just 5 (from the 23 needed with DEV); these are given as 1-mL injections on the day of exposure and then on days 3, 7, 14, and 28 after the first dose.

The HDCV vaccine has increased the rate of antibody response and reduced even further the allergic reactions by practically eliminating foreign protein. A thorough trial of the new antiviral agents in patients already symptomatic has not been undertaken. Persons at risk for rabies, such as animal handlers and laboratory workers, should receive preexposure vaccination with HDCV. A preventative DNA rabies vaccine has been genetically engineered and is being tested for use in animal handlers and others at high risk.

With modern intensive-care techniques, there have been a number of survivors of the encephalitic illness, all of whom had received postexposure immunization. In addition to mechanical respiratory support, several secondary abnormalities must be addressed, including raised intracranial pressure, excessive release of antidiuretic hormone, diabetes insipidus, and extremes of autonomic dysfunction, especially hyper- and hypotension. Willoughby and colleagues were successful in treating a 15-year-old girl who had not received vaccine by using an empirical approach of induced coma with ketamine and midazolam supplemented by ribavirin and amantadine. The goal was to support the patient while her antibody response matured. At least two other cases treated in a similar manner, reported anecdotally, did not survive.

Acute Cerebellitis (Acute Ataxia of Childhood)

A comment is made here concerning a dramatic syndrome of acute ataxia that occurs in the context of an infectious illness, mainly in children. The syndrome was originally described by Westphal in 1872 following smallpox and typhoid fever in adults, but Batten is credited with drawing attention to the more common ataxic illness that occurs after common childhood infections such as measles, pertussis, and scarlet fever. Currently, acute ataxia of childhood is most often associated with chickenpox (about one-quarter of 73 consecutive cases reported by Connolly et al), but it can occur during or after any of the childhood exanthems, as well as in association with infections caused by enteroviruses (mainly Coxsackie virus), EBV, *Mycoplasma*, CMV, Q fever, vaccinia, a number of vaccinations, rarely following HSV, and also after nondescript respiratory infections (see Weiss and Guberman). The condition, as mentioned, is far less frequent in adults, but we encounter a case every few years in adolescents and individuals in their twenties; besides a case of varicella that we observed in a 25-year-old, the most common preceding organisms in these individuals have been EBV and *Mycoplasma*.

This illness, which is essentially a “meningocerebellitis,” appears relatively abruptly, over a day or so, and consists of limb and gait ataxia and often, but not uniformly, dysarthria and nystagmus. Additional signs include increased limb tone, Babinski signs, or confusion. The fever of the original infection may have abated, or it may persist through the early stages of the ataxic illness. As a rule, there is a mild pleocytosis; the CSF protein is elevated or may be normal. The MRI is normal in the majority of cases but some show enhancement with gadolinium of the cerebellar cortical ribbon. Most patients

make a slow recovery, but permanent residua are known to follow. Because the benign nature of the illness has precluded extensive pathologic study, there is uncertainty regarding the infectious or postinfectious nature of these ataxic illnesses. Some cases have shown an inflammatory pathology most suggestive of a postinfectious process (see Chap. 36), but the finding of fragments of VZV and *Mycoplasma* genomes in the spinal fluid by means of DNA amplification techniques favors a primary infectious encephalitis, at least in some instances.

SYNDROMES OF HERPES ZOSTER

Herpes zoster (“shingles,” “zona”) is a common viral infection of the nervous system occurring at an overall rate of 3 to 5 cases per 1,000 persons per year, with higher rates in the elderly. Shingles is distinctly rare in childhood. It is characterized clinically by radicular pain, a vesicular cutaneous eruption, and, less often, by segmental sensory and delayed motor loss. The pathologic changes consist of an acute inflammatory reaction in isolated spinal or cranial sensory ganglia and lesser degrees of reaction in the posterior and anterior roots, the posterior gray matter of the spinal cord, and the adjacent leptomeninges.

The neurologic implications of the segmental distribution of the rash were recognized by Richard Bright as long ago as 1831. Inflammatory changes in the corresponding ganglia and related portions of the spinal nerves were first described by von Bärensprung in 1862. The concept that varicella and zoster are caused by the same agent was introduced by von Bokay in 1909 and was subsequently established by Weller and his associates (1958). The common agent is varicella or VZV, a DNA virus that is similar in structure to the virus of herpes simplex. These and other historical features of herpes zoster were reviewed by Denny-Brown, Adams, and Fitzgerald and by Weller, Witton, and Bell.

Pathology and Pathogenesis

The pathologic changes in VZV infection consist of one or more of the following: (1) an inflammatory reaction in several unilateral adjacent sensory ganglia of the spinal or cranial nerves, frequently of such intensity as to cause necrosis of all or part of the ganglion, with or without hemorrhage; (2) an inflammatory reaction in the spinal roots and peripheral nerve contiguous with the involved ganglia; (3) a less-common poliomyelitis that closely resembles acute anterior poliomyelitis but is readily distinguished by its unilaterality, segmental localization, and greater involvement of the dorsal horn, root, and ganglion, sometimes with necrosis; and (4) a relatively mild leptomeningitis, largely limited to the involved spinal or cranial segments and nerve roots. These pathologic changes are the substrate of the neuralgic pains, the pleocytosis, and the local palsies that may attend and follow the VZV infection. There may also be a delayed cerebral vasculitis (see further on).

As to *pathogenesis*, herpes zoster represents a spontaneous reactivation of VZV infection, which becomes

latent in the neurons of sensory ganglia following a primary infection with chickenpox (Hope-Simpson). This mechanism is consistent with the differences in the clinical manifestations of chickenpox and herpes zoster, even though the same virus causes both. Chickenpox is highly contagious by respiratory aerosol, has a well-marked seasonal incidence (winter and spring), and tends to occur in epidemics. Zoster, on the other hand, is not communicable (except to a person who has not had chickenpox), occurs sporadically throughout the year, and shows no increase in incidence during epidemics of chickenpox. In patients with zoster, there is practically always a past history of chickenpox. Such a history may be lacking in rare instances of herpes zoster in infants, but in these cases there has usually been prenatal maternal contact with VZV.

VZV DNA is localized primarily in trigeminal and thoracic ganglion cells, corresponding to the dermatomes in which chickenpox lesions are maximal and that are most commonly involved by VZV (Mahalingam et al). The supposition is that the virus makes its way from the cutaneous vesicles of chickenpox along the sensory nerves to the ganglion, where it remains latent until activated, at which time it progresses down the axon to the skin. Multiplication of the virus in epidermal cells causes swelling, vacuolization, and lysis of cell boundaries, leading to the formation of vesicles and so-called Lipschütz inclusion bodies. Alternatively, the ganglia could be infected during the viremia of chickenpox, but then one would have to explain why only one or a few sensory ganglia become infected. Reactivation of virus is attributed to waning immunity, which would explain the increasing incidence of zoster with aging and with lymphomas, administration of immunosuppressive drugs, AIDS, and after radiation therapy.

The subject of pathogenesis of herpes zoster has been reviewed by Gildea and colleagues (2000) and in the monograph by Rentier, who describes the molecular and immune investigations pertaining to VZV.

Clinical Features

As indicated above, the incidence of herpes zoster rises with age. Hope-Simpson has estimated that if a cohort of 1,000 people lived to 85 years of age, half would have had one attack of zoster and 10 would have had two attacks. The notion that one attack of zoster provides lifelong immunity is incorrect, although recurrent attacks are rare and most localized repeated herpetic eruptions are caused by HSV. The sexes are equally affected, as is each side of the body. Herpes zoster occurs in up to 10 percent of patients with lymphoma and 25 percent of patients with Hodgkin disease—particularly in those who have undergone splenectomy or received radiotherapy. Conversely, approximately 5 percent of patients who present with herpes zoster are found to have a concurrent malignancy (about twice the number that would be expected), and the proportion appears to be even higher if more than two adjacent dermatomes are involved.

The vesicular eruption is usually preceded for several days by itching, tingling, or burning sensations in the involved dermatome, and sometimes by malaise and

fever. Or there is severe localized or radicular pain that may be mistaken for pleurisy, appendicitis, cholecystitis, muscle strain, or, quite often, ruptured intervertebral disc, until the diagnosis is clarified by the appearance of vesicles (nearly always within 72 to 96 h).

The rash consists of clusters of tense clear vesicles on an erythematous base, which become cloudy after a few days (as a result of accumulation of inflammatory cells), and dry, crusted, and scaly after 5 to 10 days. In a small number of patients, the vesicles are confluent and hemorrhagic, and healing is delayed for several weeks. In most cases, pain and dysesthesia last for 1 to 4 weeks; but in the others (7 to 33 percent in different series) the pain persists for months or, in different forms, for years, and presents a difficult problem in management. Impairment of superficial sensation in the affected dermatome(s) is common, and segmental weakness and atrophy are added in approximately 5 percent of patients. In the majority of patients the rash and sensorimotor signs are limited to the territory of a single dermatome, but in some, particularly those with cranial or limb involvement, two or more contiguous dermatomes are involved.

Rarely (and usually in association with malignancy) the rash is generalized, like that of chickenpox, or it is altogether absent (*zoster sine herpette*) in which case, the pain is often attributed to another more mundane process such as sciatica.

In more than half of the cases, the CSF shows a mild increase in cells, mainly lymphocytes, and a modest increase in protein content (although lumbar puncture is not performed to establish the diagnosis). The herpetic nature of the eruption can be confirmed by direct immunofluorescence of a biopsied skin lesion, using antibody to VZV, or inferred by finding multinucleated giant cells in scrapings from the base of an early vesicle (Tzanck smear). The spinal fluid also contains antibodies to the virus or evidence of the organism by PCR testing in 35 percent of cases according to a prospective study by Haanpää and colleagues.

Virtually any dermatome may be involved in zoster, but some regions are far more frequent than others. The thoracic dermatomes, particularly T5 to T10, are the most common sites, accounting for more than two-thirds of all cases, followed by the craniocervical regions. In the latter cases the disease tends to be more severe, with greater pain, more frequent meningeal signs, and involvement of the mucous membranes. Another rare complication of zoster, taking the form of a subacute amyotrophy (*zoster paresis*) of a portion of a limb or trunk, is probably linked to a restricted form of VZV myelitis.

There are two rather characteristic cranial herpetic syndromes—ophthalmic herpes and geniculate herpes. In *ophthalmic herpes*, which accounts for 10 to 15 percent of all cases of zoster, the pain and rash are in the distribution of the first division of the trigeminal nerve, and the pathologic changes are centered in the gasserian ganglion. The main hazard in this form of the disease is herpetic involvement of the cornea and conjunctiva, resulting in corneal anesthesia and residual scarring. Palsies of extraocular muscles, ptosis, and mydriasis are frequently associated, indicating that the third, fourth, and sixth

cranial nerves are affected in addition to the gasserian ganglion. The less common but also characteristic cranial nerve syndrome consists of a facial palsy in combination with a herpetic eruption of the external auditory meatus, sometimes with tinnitus, vertigo, and deafness. Ramsay Hunt (whose name has been attached to the syndrome) attributed this illness to herpes of the geniculate ganglion. Denny-Brown, Adams, and Fitzgerald found the geniculate ganglion to be only slightly affected in a man who died 64 days after the onset of a so-called *Ramsay Hunt syndrome* (during which time the patient had recovered from the facial palsy); there was, however, inflammation of the facial nerve.

Herpes zoster of the palate, pharynx, neck, and retroauricular region (*herpes occipitocollaris*) depends on herpetic infection of the upper cervical roots and the ganglia of the vagus and glossopharyngeal nerves. Herpes zoster in this distribution may also be associated with the Ramsay Hunt syndrome. The relative frequency of distribution of zoster in these truncal dermatomes and a proclivity for facial eruption, suggests to us that herpetic neurologic syndromes are more likely to occur if the distance of the ganglia from the skin is short.

Encephalitis and *cerebral angiitis* (see below) are rare but well-described complications of cervicocranial zoster, as discussed below, and a restricted but destructive myelitis is a similarly rare but often quite serious complication of thoracic zoster. Devinsky and colleagues reported their findings in 13 patients with zoster myelitis (all of them immunocompromised) and reviewed the literature on this subject. The signs of spinal cord involvement appeared 5 to 21 days after the rash and then progressed for a similar period of time. Asymmetrical paraparesis and sensory loss, sphincteric disturbances, and, less often, a Brown-Séquard syndrome were the usual clinical manifestations. The CSF findings were more abnormal than in uncomplicated zoster (pleocytosis and raised protein) but otherwise similar. The pathologic changes, which take the form of a necrotizing inflammatory myelopathy and vasculitis, involve not just the dorsal horn but also the contiguous white matter, predominantly on the same side and at the same segment(s) as the affected dorsal roots, ganglia, and posterior horns. Early therapeutic intervention with acyclovir appeared to be beneficial. Our experience with the problem includes an elderly man who was not immunosuppressed; he remained with an almost complete transverse myelopathy.

Many of the writings on *zoster encephalitis* give the impression of a severe illness that occurs temporally remote from the attack of shingles in an immunosuppressed patient. Indeed, such instances have been reported in patients with AIDS and may be concurrent with the small vessel vasculitis described below. However, our experience is more in keeping with that of Jemsek and colleagues and of Peterslund, who described a less severe form of encephalitis in patients with normal immune systems. Our several patients with this process, all elderly women, developed self-limited encephalitis during the latter stages of an attack of shingles. They were confused and drowsy, with low-grade fever but little meningismus, and a few had seizures. Recovery

was complete and the MRI was normal, in distinction to the vasculitic syndromes. In some reported cases, VZV has been isolated from the CSF and specific antibody to VZV membrane antigen (VAMA) has been found in the CSF and serum, although it is hardly needed for purposes of diagnosis. (The differential diagnosis in these elderly patients also includes a drowsy confusional state induced by narcotics given for the control of pain.) *Varicella cerebellitis*, a post- or parainfectious condition, was discussed earlier in the chapter.

Zoster Angiitis

A *cerebral angiitis* that occasionally complicates VZV infection is histologically similar to granulomatous angiitis and to Wegener granulomatosis. Typically, 2 to 10 weeks after the onset specifically of ophthalmic zoster, the patient develops an acute hemiparesis, hemianesthesia, aphasia, or other focal neurologic or retinal deficits associated with a mononuclear pleocytosis in the spinal fluid and elevated IgG indices in the CSF. Nagel and colleagues have found that specific antibodies in the CSF to the virus were more sensitive for the diagnosis of this condition than was detection of viral DNA. CT or MRI scans demonstrate small, deep infarcts in the hemisphere ipsilateral to the outbreak of shingles on the face. Angiograms show narrowing or occlusion of the internal carotid artery adjacent to the ganglia; but in some cases, vasculitis is more diffuse, even involving the contralateral hemisphere.

Whether the angiitis results from direct spread of the viral infection via neighboring nerves as postulated by Linnemann and Alvira, or represents an allergic reaction during convalescence from zoster, has not been settled. VZV-like particles have been found in the vessel walls, suggesting a direct infection and viral DNA has been extracted in a few cases from affected vessels. Because the exact pathogenetic mechanism is uncertain, treatment with both intravenous acyclovir and corticosteroids may be justified. There are occasional instances of a cerebral vasculitis following dermatomal zoster on the trunk.

An entirely different type of delayed *vasculitis that affects small vessels*, with which we have had limited experience, is being reported in patients with AIDS and other forms of immunosuppression. In this condition, weeks or months after one or more attacks of zoster, a subacute encephalitis ensues, including fever and focal signs. Some cases apparently arise without a rash, but viral DNA and antibodies to VZV are found in the CSF. The MRI shows multiple cortical and white matter lesions, the latter being smaller and less confluent than in progressive multifocal leukoencephalopathy. There is usually a mild pleocytosis. Almost all cases have ended fatally. The vasculitic and other neurologic complications of zoster have been reviewed by Gilden and colleagues (2002). Nagel and coworkers from Gilden's laboratory have also found cases in which the temporal arteries contain VZV particles and they have suggested that the vascular changes caused by the virus may simulate temporal arteritis.

Finally, as mentioned earlier, a facial palsy or pain in the distribution of a trigeminal or segmental nerve

(usually lumbar or intercostal) as a result of herpetic ganglionitis, may occur rarely without involvement of the skin (*zoster sine herpette*); lumbar disc herniation may be suspected. In a few such cases, an antibody response to VZV has been found (Mayo and Booss), and Dueland and associates have described an immunocompromised patient who developed a pathologically and virologically proved zoster infection in the absence of skin lesions. Similarly, Gilden and colleagues (2002) recovered VZV DNA from two otherwise healthy immunocompetent men who had experienced chronic radicular pain without a zoster rash. But practically no instances of Bell's palsy, tic douloureux, and intercostal neuralgia are associated with serologic evidence of activation of VZV (Bell's palsy has instead been associated with HSV, as indicated in Chap. 47).

Treatment

An important inception for shingles has been a live, attenuated vaccine that can be administered to adults over age 60. It has been shown to reduce the emergence of shingles and to decrease the incidence of postherpetic complications by two-thirds (Oxman et al).

During the acute stage of shingles, analgesics and drying and soothing lotions, such as calamine, help to blunt the pain. Nerve root blocks may provide temporary relief but are not often used. After the lesions have dried, the repeated application of capsaicin ointment (derived from hot peppers) may relieve the pain in some cases by inducing a cutaneous anesthesia. When applied too soon after the acute stage, however, capsaicin is highly irritating and should be used cautiously.

Acyclovir shortens the duration of acute pain and speeds the healing of vesicles, provided that treatment is begun within approximately 48 h (some authorities say 72 h) of the appearance of the rash (McKendrick et al, 1986). Several studies have suggested that the duration of postherpetic neuralgia is reduced by treatment during the acute phase with famciclovir or valacyclovir, but the incidence of this complication is not markedly affected. Famciclovir (500 mg tid for 7 d) or the better absorbed valacyclovir (2 g orally qid) are possibly better alternatives than the previously favored acyclovir (see below on the subject of postherpetic neuralgia). Other studies have shown favorable results in preventing postherpetic pain by starting a tricyclic antidepressant during the acute phase.

All patients with ophthalmic zoster should receive acyclovir or valacyclovir orally; in addition, acyclovir applied topically to the eye, in either a 0.1 percent solution every hour or a 0.5 percent ointment 4 or 5 times a day, is recommended by some ophthalmologists. Patients who are immunocompromised or have disseminated zoster (lesions in more than 3 dermatomes) should generally receive intravenous acyclovir for 10 days. There is now available (from state health agencies) a VZV immune globulin (VZIG) that may protect against dissemination in immunosuppressed patients but is not indicated for established disease. Although it may reduce the incidence of postherpetic neuralgia (Hugler et al), this is not its main purpose and it does not appear to prevent or ameliorate CNS complications.

Postherpetic Neuralgia

(See also Chaps. 8 and 10)

This severely painful syndrome follows shingles in 5 to 10 percent of patients but occurs almost three times more often among individuals older than age 60 years. The possible effect of acute treatment on the severity of postherpetic neuralgia is mentioned above but potential prevention with the vaccine is even more appealing.

The management of *postherpetic pain* and dysesthesia can be a trying matter for both the patient and the physician. It is likely that incomplete interruption of nerve impulses results in a hyperpathic state in which every stimulus excites pain. In a number of controlled studies, amitriptyline proved to be an effective therapeutic measure. Initially, it is given in doses of approximately 50 mg at bedtime; if needed, the dosage can be increased gradually to 125 mg daily. The addition of carbamazepine, gabapentin, pregabalin, or valproate may further moderate the pain, particularly if it is of lancinating type.

Capsaicin ointment can be applied to painful skin, as noted above. A salve of two aspirin tablets, crushed and mixed with cold cream or chloroform (15 mL) and spread on the painful skin, was reported to be successful in relieving the pain for several hours (King). The effect of nerve root blocks is inconsistent, but this procedure may afford temporary relief. In one randomized trial, the preemptive use of epidural steroids at the onset of the rash had minimal effects (van Wijck et al). It should be emphasized that postherpetic neuralgia eventually subsides even in the most severe and persistent cases but the short-term use of narcotics is appropriate when the pain is severe. Until the pain subsides, the physician must exercise skill and patience and avoid the temptation of subjecting the patient to one of the many surgical measures that have been advocated for this disorder (see Chap. 9 for further discussion of pain management). Some patients with the most persistent complaints, beyond a year, have symptoms of a depressive state and will be helped by antidepressive medications.

NEUROLOGIC DISEASES INDUCED BY RETROVIRUSES INCLUDING HIV AND SECONDARY OPPORTUNISTIC INFECTIONS

Retroviruses are a large group of RNA viruses, so called because they contain the enzyme reverse transcriptase, which permits the reverse flow of genetic information from RNA to DNA. Two families of retroviruses are known to infect humans: (1) the *lentiviruses*, the most important of which is the HIV, the cause of AIDS, and (2) the *oncornaviruses*, which include the human T-cell lymphotropic viruses (HTLV-I), the agents that induce chronic T-cell leukemias and lymphomas (HTLV-II) and tropical spastic paraparesis (HTLV-I). A comprehensive account of the neurobiology, pathology, and clinical features of these infections can be found in the appropriate sections of *Harrison's Principles of Internal Medicine* and authoritative information regarding treatment is given in the text by Rubin and Young.

The Acquired Immunodeficiency Syndrome

In 1981, physicians became aware of the frequent occurrence of otherwise rare opportunistic infections and neoplasms—notably *Pneumocystis carinii* pneumonia and Kaposi sarcoma—in otherwise healthy young homosexual men. The study of these patients led to the recognition of a new viral disease, AIDS.

HIV infection is characterized by an acquired and usually profound depression of cell-mediated immunity as manifest by cutaneous anergy, lymphopenia, reversal of the T-helper-to-T-suppressor cell ratio—more accurately, CD4+/CD8+ lymphocytes, as a result of reduction in CD4+ cells—and depressed in vitro lymphoproliferative response to various antigens and mitogens. It is this failure of immune function that explains the development of a wide range of opportunistic infections and unusual neoplasms. Virtually all organ systems are vulnerable, including all parts of the CNS, the peripheral nerves and roots, and muscle. Moreover, the nervous system is susceptible to a number of unusual syndromes that are the direct result of the AIDS virus infection.

Epidemiology

In a span of 25 years, HIV infection and AIDS have attained pandemic proportions. At the time of this writing it was estimated by the World Health Organization (WHO) that approximately 34 million persons are infected worldwide and that approximately 1 million adults in the United States are seropositive for the virus with 50,000 new cases yearly. The CDC furthermore estimates that 18 percent of infections have not been diagnosed. Though the incidence is decreasing, particularly startling are the statistics from sub-Saharan Africa and Southeast Asia, where the WHO estimated that approximately 25,000,000 adults—or almost 9 percent of the adult population—were infected. In some areas of East Africa, 30 percent of adults are infected with the virus.

In the United States, AIDS affects mainly homosexual and bisexual males (two-thirds of all cases) and male and female drug users (almost one-third of cases). Somewhat less than 2 percent of patients who are at risk are hemophiliacs and others who receive infected blood or blood products, and the disease has occurred in infants born of mothers with AIDS. Moreover, the virus may be transmitted by asymptomatic and still immunologically competent mothers to their offspring. Spread of the disease by heterosexual contact accounts for approximately 5 percent of cases, but this number is gradually increasing, partly through the activities of intravenous drug users. By contrast, an estimated 80 percent of African AIDS patients acquire their disease through heterosexual contact.

The related but less common entity of HIV-2 infection causes a generally less severe illness than HIV-1 but may include almost any of the features described below, including dementia. The virus is currently most prolific in Brazil, Cape Verde, and West African countries. The diagnosis is made complicated by the usual findings of a positive ELISA test but a negative or indeterminate Western blot results when conventional methods are used. A specific Western blot is available for HIV-2.

Clinical Features

Infection with HIV produces a spectrum of disorders, ranging from *clinically inapparent seroconversion* to widespread lymphadenopathy and other systemic manifestations such as diarrhea, malaise, and weight loss, which comprises the direct effects of the virus on all organ systems as well as the complicating effects of a multiplicity of secondary parasitic, fungal, viral, and bacterial infections and a number of neoplasms, all of which require cell-mediated immunity for containment. Until the recent advent of multiple antiviral drug therapy, once the manifestations of AIDS had become established, half of patients died by 1 year and most by 3 years. Neurologic abnormalities had been found in about one-third of untreated patients with AIDS, but at autopsy the nervous system is affected in nearly all of them. Table 33-2 lists the main infections and neoplastic lesions of the nervous system that complicate AIDS.

It has already been mentioned that HIV infection may present as an acute *asymptomatic meningitis* with a mild lymphocytic pleocytosis and modest elevation of

CSF protein. The acute illness may also take the form of a *meningoencephalitis* or even a *myelopathy* or *neuropathy* (see further on). Most patients recover from the initial acute neurologic illnesses; the relationship to AIDS may pass unrecognized, as these illnesses are quite nonspecific clinically and may precede or coincide with seroconversion. Once seroconversion has occurred, the patient becomes vulnerable to all the late complications of HIV infection. In adults, the interval between infection and the development of AIDS ranges from several months to 15 years or even longer; the mean latency is 8 to 10 years and 1 year or less in infants.

HIV-2 may display special features of a subacute confusional-dementing illness with deep white matter and basal ganglionic damage.

HIV-Associated Neurocognitive Disorders (AIDS Dementia Complex)

In the later stages of HIV infection, the most common neurologic complication is a subacute or chronic HIV encephalitis presenting as a form of dementia; formerly it was called AIDS encephalopathy or encephalitis, but it is now generally referred to as AIDS dementia complex (ADC; Navia, Jordan, and Price). It has been estimated that only 3 percent of AIDS cases present in this manner, but the frequency is far higher, close to two-thirds, after the constitutional symptoms and opportunistic infections of AIDS have become established. In children with AIDS, dementia is more common than all opportunistic infections, more than 60 percent of children eventually being affected.

The disorder in adults takes the form of a slowly or subacutely progressive dementia (loss of retentive memory, inattentiveness, language disorder, and apathy) accompanied variably by abnormalities of motor function. Patients complain of being unable to follow conversations, taking longer to complete daily tasks, and becoming forgetful. Incoordination of the limbs, ataxia of gait, and impairment of smooth pursuit and saccadic eye movements may be early accompaniments of the dementia. Heightened tendon reflexes, Babinski signs, grasp and suck reflexes, weakness of the legs progressing to paraplegia, bladder and bowel incontinence reflecting spinal cord or cerebral involvement, and abulia or mutism are prominent in the later stages of the disease. In the untreated case, the dementia evolves, over a period of weeks or months; survival after the onset of dementia is generally 3 to 6 months but may be considerably longer if treatment is instituted. Treatment with antiretroviral drugs can result in cognitive improvement. There is an interest in rare cases of poor penetration of antiretroviral drugs into the central nervous system, allowing for viral replication and reemergence despite elimination of HIV from the peripheral blood.

Tests of psychomotor speed seem to be most sensitive in the early stages of dementia (e.g., trail making, pegboard, and symbol-digit testing). Epstein and colleagues have described a similar disorder in children, who develop a progressive encephalopathy as the primary manifestation of AIDS. The disease in children is characterized by an impairment of cognitive functions

Table 33-2

NEUROLOGIC COMPLICATIONS OF HIV-AIDS

Brain

Encephalitis

- HIV encephalitis
- Cytomegalovirus encephalitis
- Varicella zoster virus encephalitis
- Herpes simplex virus encephalitis

Focal lesion

- Cerebral toxoplasmosis
- Brain lymphoma
- Progressive multifocal leukoencephalopathy
- Cryptococcoma
- Bacterial brain abscess
- Tuberculoma

Cerebrovascular disorders—nonbacterial endocarditis, cerebral hemorrhages associated with thrombocytopenia, and vasculitis

HIV dementia

Spinal cord

- Vacuolar myelopathy
- Herpes simplex or zoster myelitis

Meningitis

- Acute and chronic lymphocytic meningitis
- Cryptococcal and other fungal types
- Tuberculous
- Syphilitic
- Herpes zoster

Peripheral nerve and root

- Distal sensory polyneuropathy
- Herpes zoster
- Cytomegalovirus lumbar polyradiculopathy
- Acute and chronic inflammatory polyneuritis
- Mononeuritis multiplex
- Sensorimotor demyelinating polyneuropathy
- Diffuse infiltrative lymphocytic syndrome (DILS)
- Leprosy

Muscle

- Polymyositis and other myopathies (including drug induced)

Figure 33-2. MRI of HIV leukoencephalopathy. There are large areas of white matter change that underlie one form of AIDS dementia; cortical atrophy and ventricular enlargement are evident.

and spastic weakness and secondarily by impairment of brain growth.

The CSF (including those lacking other manifestations of AIDS) may be normal or show only a slight elevation of protein content and, less frequently, a mild lymphocytosis. HIV can be isolated from the CSF. In the CT scan there is widening of the sulci and enlargement of the ventricles; MRI may show patchy but confluent or diffuse white matter changes with ill-defined margins (Fig. 33-2). These findings are useful in diagnosis, although CMV infection of the brain in AIDS produces a similar MRI appearance, as described further on.

The pathologic basis of the dementia appears to be a diffuse and multifocal rarefaction of the cerebral white matter accompanied by scanty perivascular infiltrates of lymphocytes and clusters of a few foamy macrophages, microglial nodules, and multinucleated giant cells (Navia, Chos, Petito et al). Evidence of CMV infection may be added, but accumulating virologic evidence indicates that the AIDS dementia complex is a result of direct infection with HIV. Which of these changes corresponds most closely to the presence and severity of dementia has not been settled. The pathologic changes in AIDS dementia are actually not as uniform as portrayed here. In one group of patients, there is a diffuse pallor of the cerebral white matter, most obvious with myelin stains, accompanied by reactive astrocytes and macrophages; the myelin pallor seems to reflect a breakdown of the blood-brain barrier.

In another form of this process, referred to as “diffuse poliodystrophy,” there is widespread astrogliosis and microglial activation in the cerebral cortex, with little recognizable neuronal loss. In yet other patients, small or large perivascular foci of demyelination, like those of postinfectious encephalomyelitis, are observed; the nature of this diffuse white matter lesion is not understood. These forms of pathologic change may occur singly or together and all correlate

poorly with the severity of the dementia. Progressive multifocal leukoencephalopathy also occurs in patients with AIDS and is simulated by the primary white matter encephalopathy.

HIV Myelopathy, Peripheral Neuropathy, and Myopathy

A *myelopathy*, taking the form of a vacuolar degeneration that bears a marked pathologic resemblance to subacute combined degeneration because of vitamin B₁₂ deficiency, is sometimes associated with the AIDS dementia complex; or the myelopathy may occur in isolation, as the leading manifestation of the disease (Petito et al). This disorder of the spinal cord is discussed further in Chap 47.

AIDS may also be complicated by several forms of *peripheral neuropathy*, as discussed in Chap 46. A distal, symmetrical, axonal polyneuropathy, predominantly sensory and dysesthetic in type has been the most common neuropathic pattern. The HIV virus has been isolated from the peripheral nerves and ganglia. In fact, this stands as the first proven viral polyneuritis in humans (zoster being more a ganglionopathy). In other patients, a painful *mononeuropathy multiplex* occurs, seemingly related to a focal vasculitis, or there may be a subacute inflammatory cauda equina syndrome (a *polyradiculitis*) that is usually caused by an accompanying CMV infection (Eidelberg et al). Cornblath and colleagues have documented the occurrence of an *inflammatory demyelinating peripheral neuropathy*, of both the acute (Guillain-Barré) and chronic types, in otherwise asymptomatic patients with HIV infection. Most of these patients had a mild pleocytosis in addition to an elevated CSF protein content. Most patients with inflammatory demyelinating neuropathy have recovered—either spontaneously or in response to plasma exchange—suggesting an immunopathogenesis similar to that of the Guillain-Barré syndrome. Cornblath and associates suggest that all patients with inflammatory demyelinating polyneuropathies should now be tested for the presence of HIV infection. *Facial palsy* is being reported with increasing frequency as a feature of AIDS; its relationship to the generalized polyneuritis of AIDS is uncertain.

In a rare peripheral neuropathy of AIDS termed *diffuse infiltrative lymphocytosis syndrome* (DILS), a variety of clinical syndromes have been described including all patterns of the usual AIDS polyneuropathies. Some instances of polyneuropathy in AIDS patients are probably caused by the nutritional depletion that characterizes advanced stages of the disease and to the effects of therapeutic agents. These AIDS-related neuropathies are discussed in Chap. 46 and are summarized by Wulff and Simpson.

A primary *myopathy*, taking the form of an inflammatory polymyositis, has been described in HIV patients at any stage of the disease (Simpson and Bender). In some of these cases, the myopathy has improved with corticosteroid therapy. The original anti-AIDS drug, zidovudine (AZT), has caused a myopathy, probably because of its effect on mitochondria, but some investigators have attributed almost all such cases to be attributable to the

AIDS virus itself (see “HIV and HTLV-I Myositis” in Chap. 49). It is apparent that this remains an area of some controversy.

Opportunistic Infections and Neoplasms of the CNS in AIDS

In addition to the direct neurologic effects of HIV infection, a variety of opportunistic disorders, both focal and generalized, occur in such patients as outlined in Table 33-2. Interestingly, there appears to be a predilection for certain ones—toxoplasmosis, CMV infection, primary B-cell lymphoma, cryptococcosis, and progressive multifocal leukoencephalopathy, in approximately this order of frequency (Johnson). The focal encephalitis and vasculitis of VZV infection, considered earlier in this chapter, and unusual types of tuberculosis and syphilis are other common opportunistic infections of AIDS. Usually *P. carinii* infection and Kaposi sarcoma do not spread to the nervous system. In almost of these categories, the infectious process is accelerated or intensified by the presence of the HIV infection.

Toxoplasmosis Of the focal infectious complications, cerebral toxoplasmosis is the most frequent (and treatable; see Chap 32). In the autopsy series of AIDS reported by Navia, Petito, Gold, and colleagues, areas of inflammatory necrosis caused by *Toxoplasma* were found in approximately 13 percent (see Fig. 32-6). Lumbar puncture, contrast-enhanced CT scanning, and MRI are useful in diagnosis. The spinal fluid usually shows an elevation of protein in the range of 50 to 200 mg/dL, and one-third of patients have a lymphocytic pleocytosis. Because the disease usually represents reactivation of a prior *Toxoplasma* infection, it is important to identify *Toxoplasma*-seropositive patients early in the course of AIDS and to treat them with oral pyrimethamine (100 mg initially and then 25 mg daily) and a sulfonamide (4 to 6 g daily in four divided doses). Curiously, the toxoplasmosis, so common in the brains of AIDS patients, is not a frequent cause of one of its more typical manifestations, myositis. The main clinical problem in reference to toxoplasmosis in AIDS is its differentiation from cerebral lymphoma as discussed below and in Chap. 31.

In a series from Johns Hopkins (see Johnson, 1998), approximately 11 percent of AIDS patients developed a *primary CNS lymphoma*, which may, in some cases, be difficult to distinguish from toxoplasmosis clinically and radiologically. If the cytologic study of the CSF is negative and there has been no response to antibiotics (see below), stereotaxic brain biopsy may be necessary for diagnosis. The prognosis in such patients is considerably less favorable than in non-AIDS patients; the response to radiation therapy, methotrexate, and corticosteroids is short-lived, and survival is usually measured in months.

In the face of enhancing focal brain lesions in AIDS, the current approach is to initially assume the presence of toxoplasmosis, which is treatable. Antibody tests for toxoplasmosis should be obtained; the absence of IgG antibodies mandates that treatment be changed in order to address the problem of brain lymphoma. Also,

if antitoxoplasmal therapy with pyrimethamine and sulfadiazine fails to reduce the size of the lesions within several weeks, another cause should be sought, again mainly lymphoma. In those patients who cannot tolerate the frequent side effects of pyrimethamine or sulfonamides (rash or thrombocytopenia), clindamycin may be of value. Recently, it has been suggested that positron emission tomography (PET) and other metabolic imaging techniques can identify lymphoma as the cause of a mass lesion in the HIV patient. The less frequent possibilities of tuberculous or bacterial brain abscess should be kept in mind if none of these avenues allow a confident diagnosis.

Cytomegalovirus Among the nonfocal neurologic complications of AIDS, the most common are CMV and *cryptococcal* infections. At autopsy, about one-third of AIDS patients are found to be infected with CMV. However, the contribution of this infection to the total clinical picture is often uncertain. Despite this ambiguity, certain features have emerged as typical of CMV encephalitis in the AIDS patient. According to Holland and colleagues, late in the course of AIDS and usually concurrent with CMV retinitis, the encephalopathy evolves over 3 to 4 weeks. Its clinical features include an acute confusional state or delirium combined in a small proportion of cases with cranial nerve signs including ophthalmoparesis, nystagmus, ptosis, facial nerve palsy, or deafness. In one of our patients, there were progressive oculomotor palsies that began with light-fixed pupils.

Pathologic specimens and MRI show the process to be concentrated in the ventricular borders, especially evident as T2 signal hyperintensity in these regions. The lesions may extend more diffusely through the adjacent white matter and be accompanied by meningeal enhancement by gadolinium in a few cases. Extensive destructive lesions have also been reported; this has been true in two of our own cases. Such lesions may be associated with hemorrhagic changes in the CSF in addition to showing an inflammatory response. CMV may also produce a painful lumbosacral polyradiculitis in AIDS (Chap. 44).

The diagnosis of CMV infection during life is often difficult. Cultures of the CSF are usually negative and IgG antibody titers are nonspecifically elevated. Newer PCR methods prove useful here. Where the diagnosis is ganciclovir and foscarnet has been recommended, but, as pointed out by Kalayjian and colleagues, the CMV disease may develop and progress while patients are taking these medications as maintenance therapy.

Cryptococcal Infection Meningitis with this fungus and less often, *solitary cryptococcoma* are the most frequent fungal complications of HIV infection. Flagrant symptoms of meningitis or meningoencephalitis may be lacking and the CSF may show little abnormality with respect to cells, protein, and glucose. For these reasons, evidence of cryptococcal infection of the spinal fluid should be actively sought with antigen testing, and fungal cultures. India ink preparations are still valuable and rapid but are not currently performed consistently and well enough in many hospitals to be entirely dependable. Treatment is along the lines outlined in Chap. 32.

Varicella Zoster Cerebral infections with this virus are less common complications of AIDS, but when they do occur, they tend to be severe. They take the form of multifocal lesions of the cerebral white matter, somewhat like those of progressive multifocal leukoencephalopathy, a cerebral vasculitis with hemiplegia (usually in association with ophthalmic zoster), or, rarely, a myelitis. Encephalitis caused by HSV-1 and HSV-2 has also been identified in the brains of AIDS patients, but the clinical correlates are unclear. Shingles involving several contiguous dermatomes is known to occur in AIDS with CD4 counts below 500, as in other immunosuppressed conditions.

Tuberculosis Two particular types of mycobacterial infection tend to complicate AIDS—*Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare*. Tuberculosis predominates among drug abusers and HIV patients in developing countries, and a higher-than-usual proportion of these immunosuppressed individuals develop tuberculous meningitis. Diagnosis and treatment are along the same lines as in non-AIDS patients.

Neurosyphilis Syphilitic meningitis and meningo-vascular syphilis appear to have an increased incidence in AIDS patients. Cell counts in the CSF are unreliable as signs of activity; diagnosis depends entirely upon serologic tests. It is possible that AIDS causes false-positive tests for syphilis. It appears that the presence of HIV infection accelerates the transition of syphilis to later stages, including infection of the nervous system. Indeed, a category of quaternary syphilis has emerged that consists of an aggressive and rapidly progressive necrotizing process that causes strokes and dementia as a result of involvement of brain parenchyma and vessels. The incidence of relapse of syphilis and resistance to conventional doses of antisyphilitic medication are probably increased with HIV coinfection. It is unclear, however, if the tertiary forms of syphilis, general paresis and tabes dorsalis, are increased in incidence because of AIDS; they may require the chronicity of meningovascular syphilis to evolve. Readers are referred to the review by Marra.

Other rare organisms, such as *Bartonella henselae*, the cause of cat scratch fever, are found rarely in AIDS patients and have been implicated in an encephalitis. Progressive multifocal leukoencephalopathy, a viral disease now closely linked with the immunosuppressed state of AIDS and seen in high numbers, is discussed further on in this chapter.

Treatment

The treatment of HIV infection/AIDS, as is true for any chronic, life-threatening disease, is difficult. Treatment with several antiretroviral drugs is required not just for control of the neurologic manifestations of retroviral infection but also to control secondary infections. Recommendations regarding drug therapy for HIV infection change rapidly (Rubin and Young) and the reader is referred to any of the modern sources for the details of treatment, including *Harrison's Principles of Internal Medicine*. It is believed that these approaches will prolong survival but it might be expected also to

increase the prevalence of neurologic complications of AIDS, each of which needs to be treated as it is recognized. A special result of HIV antiretroviral treatment may induce an intense inflammatory response to a coexistent infection. This complication, immune reconstitution inflammatory syndrome, or *IRIS*, is perhaps most pertinent to progressive multifocal leukoencephalopathy discussed later.

Tropical Spastic Paraparesis, HTLV-I Infection

This is an endemic neurologic disorder in many tropical and subtropical countries. Its cause was overlooked until 1985, when Gessain and coworkers found IgG antibodies to HTLV-I in the sera of 68 percent of tropical spastic paraparesis (TSP) patients in Martinique. The same antibodies were then identified in the CSF of Jamaican and Colombian patients with TSP, and in patients with a similar neurologic disorder in the temperate zones of southern Japan. The latter disorder was originally called HTLV-I-associated myelopathy (HAM), but it is now considered to be identical to HTLV-I-positive TSP (Roman and Osame). It is a curious feature of this disorder that only a small proportion of HTLV-I-infected persons (estimated at 2 percent) develop a myelopathy. Sporadic instances have now been reported from many parts of the Western world. The virus is transmitted in one of several ways—from mother to child, across the placenta or in breast milk; by intravenous drug use or blood transfusions; or by sexual contact. The age of onset is in mid adult life, and it is more common in females than in males, in a ratio of 3:1.

The clinical and pathologic features of the disease are described in Chap. 44 and in several recommended reviews (Rodgers-Johnson et al); the differentiation from the progressive spinal form of multiple sclerosis and with subacute combined degeneration, with which it is most likely to be confused, is discussed further on under "Differential Diagnosis." There are also clinical and pathologic differences from the myelopathy caused directly by HIV infection. No form of treatment has proved effective in reversing this disorder, although there are anecdotal reports that the intravenous administration of immune globulin may halt its progress.

The retrovirus HTLV-II is less common than HTLV-I but the two are virologically very similar. There is a high rate of infection with HTLV-II among drug users who are coinfecting with HIV. A few cases of myelopathy have been reported in HTLV-II-infected patients, similar in all respects to HTLV-I-associated myelopathy (Lehky et al).

VIRAL INFECTIONS OF THE DEVELOPING NERVOUS SYSTEM (See Chap. 38)

Viral infections of the fetus, notably rubella, CMV, HIV, herpes zoster, Epstein-Barr, and HSV infection of the newborn are important causes of CNS abnormalities. This subject is covered in detail in "Intrauterine and Neonatal Infections" in Chap. 38.

ACUTE ANTERIOR POLIOMYELITIS

In the past, this syndrome was almost invariably the result of infection by one of the three types of poliovirus. However, illnesses that clinically resemble poliovirus infections can be caused by other enteroviruses such as the Coxsackie groups A and B and Japanese encephalitis, as well as by West Nile virus. Epidemics of hemorrhagic conjunctivitis (caused by enterovirus 70 and formerly common in Asia and Africa) can also be associated with a lower motor neuron paralysis resembling poliomyelitis (Wadia et al). In countries with successful poliomyelitis vaccination programs, these other viruses are now the most common causes of the anterior poliomyelitis syndrome. In some cases, the illnesses induced by these viruses are benign and the associated paralysis is insignificant. West Nile virus is an exception that has been associated with a severe and persistent asymmetrical flaccid poliomyelitis.

The important (paralytic) disease in this category nonetheless remains poliomyelitis. Although no longer a scourge in areas where vaccination is routine, its lethal and crippling effects are still fresh in the memory of physicians who practiced in the 1950s. In the summer of 1955, when New England experienced its last epidemic, 3,950 cases of acute poliomyelitis were reported in Massachusetts alone, and 2,771 were paralytic. The details of this epidemic described by Pope and colleagues are worth reviewing by any student of the disease. Polio has essentially from the Americas, the only cases currently being imported ones. Live polio vaccine, which had been the source of approximately 150 cases in previous decades, is no longer used in the United States.

Of course, because it is highly communicable, acute poliomyelitis still occurs in regions of the world where large-scale and recurrent vaccination is not practiced. In a recent year, there were fewer than 2,000 cases in the world but there are periodic small outbreaks. For these reasons and also because it stands as a prototype of a neurotropic viral infection, the main features of the disease should be known to neurologists.

The paralytic residua of previous epidemics can still be seen. In these cases, a delayed progression of muscle weakness may appear many years after the acute paralytic illness—a condition termed postpolio syndrome (see discussion of amyotrophic lateral sclerosis [ALS] in Chap. 39).

Etiology

The poliomyelitis agent is a small RNA virus that is a member of the enterovirus group of the picornavirus family. Three antigenically distinct types have been defined and infection with one does not protect against the others. Poliomyelitis is a highly communicable disease. The main reservoir of infection is the human intestinal tract (humans are the only known natural hosts), and the main route of infection is fecal-oral, i.e., hand to mouth, as with other enteric pathogens. The virus multiplies in the pharynx and intestinal tract. During the incubation period, which is from 1 to 3 weeks, the virus can be

recovered from both of these sites. In only a small fraction of infected patients is the nervous system invaded. Between 95 and 99 percent of infected patients are asymptomatic or experience only a nonspecific febrile illness. It is the latter type of patient—the carrier with inapparent infection—who is most important in the spread of the virus from one person to another.

Clinical Manifestations

In the *inapparent infections*, and those in which there are only mild systemic symptoms with pharyngitis or gastroenteritis had been called *abortive poliomyelitis*. The mild symptoms correspond to the period of viremia and dissemination of the virus; they give rise in most cases to an effective immune response—a feature that accounts for the failure to cause meningitis or poliomyelitis. In the relatively small proportion of patients in whom the nervous system is invaded, the illness still has a wide range of severity from mild aseptic meningitis (*nonparalytic* or *preparalytic poliomyelitis*) to the most severe forms of paralytic poliomyelitis.

Nonparalytic Poliomyelitis The prodromal symptoms consist of listlessness, generalized, nonthrobbing headache, fever of 38 to 40°C (100.4 to 104°F), stiffness and aching in the muscles, sore throat in the absence of upper respiratory infection, anorexia, nausea, and vomiting. These symptoms may subside to a varying extent, to be followed after 3 to 4 days by recrudescence of headache and fever and by symptoms of nervous system involvement; more often the second phase of the illness blends with the first. Tenderness and pain in the muscles, tightness of the hamstrings (spasm), and pain in the neck and back become increasingly prominent. Other early manifestations of nervous system involvement include irritability, restlessness, and emotional instability; these are frequently a prelude to paralysis. Added to these symptoms are stiffness of the neck on forward flexion and the characteristic CSF findings of aseptic meningitis. This may constitute the entire illness; alternatively, paralysis may follow the preparalytic symptoms.

Paralytic Poliomyelitis Weakness becomes manifest while the fever is at its height, or, just as frequently, as the temperature falls and the general clinical picture seems to be improving. Muscle weakness may develop rapidly, attaining its maximum severity in 48 h or even less; or it may develop more slowly or in stuttering fashion over a week, rarely even longer. As a general rule, there is no progression of weakness after the temperature has been normal for 48 h. The distribution of spinal paralysis is quite variable; rarely there may be an acute symmetrical paralysis of the muscles of the trunk and limbs as occurs in the Guillain-Barré syndrome. Excessive physical activity and local injections during the period of asymptomatic infection were thought to favor the development of paralysis of the exercised or injected limbs.

Coarse fasciculations are seen as the muscles weaken; they are transient as a rule, but occasionally they persist. Tendon reflexes are diminished and lost as the weakness evolves and paralyzed muscles become flaccid. Patients frequently complain of paresthesias in the affected limbs but objective sensory loss is seldom demonstrable.

Retention of urine is a common occurrence during the early phase in adult patients, rarely persisting. Atrophy of muscle can be detected within 3 weeks of onset of paralysis, is maximal at 12 to 15 weeks, and is permanent.

Bulbar paralysis is more common in young adults, but usually such patients have spinal involvement as well. The most frequently involved cranial muscles are those of deglutition, reflecting involvement of the nucleus ambiguus. The other great hazards of medullary disease are disturbances of respiration and vasomotor control—hiccough, shallowness and progressive slowing of respiration, cyanosis, restlessness and anxiety from air hunger, hypertension, and, ultimately, hypotension and shock. When these disturbances are added to paralysis of diaphragmatic and intercostal musculature, the patient's survival is threatened and the institution of respiratory assistance and intensive care becomes urgent.

Pathologic Changes and Clinicopathologic Correlations

In fatal infections, lesions are found in the precentral (motor) gyrus of the brain (usually of insufficient severity to cause symptoms), brainstem, and spinal cord. The brunt of the disease in these cases is borne by the hypothalamus, thalamus, motor nuclei of the brainstem and surrounding reticular formation, vestibular nuclei and roof nuclei of the cerebellum, and mainly the neurons of the anterior and intermediate gray matter of the spinal cord. In these areas, nerve cells are destroyed and phagocytosed by microglia (neuronophagia). A local leukocytic reaction is present for only a few days, but mononuclear cells persist as perivascular accumulations for many months. Inclusion bodies are not seen. The earliest histopathologic changes in the anterior horns of the cord are central chromatolysis of the nerve cells, along with an inflammatory reaction. These changes correlate with a multiplication of virus in the CNS and, in the infected monkey, precede the onset of paralysis by one or several days.

In Bodian's experimental material, the infected motor neurons continued to function until a stage of severe chromatolysis was reached. Moreover, if damage to the cell had attained only the stage of central chromatolysis, complete morphologic recovery could be expected—a process that took a month or longer. After this time, the degrees of paralysis and atrophy were closely correlated with the number of motor nerve cells that had been destroyed; where limbs remain atrophic and paralyzed, less than 10 percent of neurons survived in corresponding cord segments. Lesions in the motor nuclei of the brainstem are associated with paralysis in corresponding muscles. Disturbances of swallowing, respiration, and vasomotor control are related to neuronal lesions in the medullary reticular formation, centered in the region of the nucleus ambiguus, as mentioned earlier.

Atrophic, areflexic paralysis of muscles of the trunk and limbs relates, of course, to destruction of neurons in the anterior and intermediate horns of the corresponding segments of the spinal cord gray matter. The affected regions can be quite focal or scattered, giving rise, for instance, to permanent paralysis of only one limb. Stiffness

and pain in the neck and back, attributed to "meningeal irritation," are probably related to the mild inflammatory exudate in the meninges and to the generally mild lesions in the dorsal root ganglia and dorsal horns. These lesions also account for the muscle pain and paresthesia in parts that later become paralyzed. Abnormalities of autonomic function are attributable to lesions of autonomic pathways in the reticular substance of the brainstem and in the lateral horn cells in the spinal cord.

It is of interest that poliovirus has been readily isolated from CNS tissue of fatal cases but can rarely be recovered from the CSF during clinical disease. This is in contrast to the closely related Coxsackie and echo picornaviruses, which have been isolated frequently from the CSF during the neurologic illness.

Treatment

Patients in whom acute poliomyelitis is suspected require careful observation of swallowing function, vital capacity, heart rate, and blood pressure in anticipation of respiratory and circulatory complications. With paralysis of limb muscles, footboards, hand and arm splints, and knee and trochanter rolls prevent foot-drop and other deformities. Frequent passive movement prevents contractures, ankylosis, and pressure sores.

Respiratory failure as a result of paralysis of the intercostal and diaphragmatic muscles or of depression of the respiratory centers in the brainstem calls for the use of a positive-pressure respirator and in most patients, for a tracheostomy as well. It was during the epidemics of the mid-twentieth century that the use of Drinker's "iron lung" attained widespread use. The management of the pulmonary and circulatory complications does not differ from their management in diseases such as myasthenia gravis and Guillain-Barré syndrome and is best carried out in special respiratory or neurologic intensive care units.

The authors know of no systematic study of the potency of antiviral agents in this disease.

Prevention

Prevention, of course, has proved to be one of the outstanding accomplishments of modern medicine. The cultivation of poliovirus in cultures of human embryonic tissues and monkey kidney cells—the achievement of Enders and associates—made possible the development of effective vaccines. The first of these was the injectable Salk vaccine, containing formalin-inactivated virulent strains of the three viral serotypes. This was followed by the Sabin vaccine, which consists of attenuated live virus, administered orally in two doses 8 weeks apart; boosters are required at 1 year of age and again before starting school. Since 1965, the reported annual incidence rate of poliomyelitis in the United States has been less than 0.01 per 100,000 (compared to a rate of 24 cases per 100,000 during the years 1951 to 1955). Very rarely in the past, poliomyelitis followed vaccination with the attenuated live virus (0.02 to 0.04 cases per 1 million doses). The virus is not used in the United States and polio is essentially eradicated in the Americas. The only obstacle to eradication of the disease elsewhere is inadequate utilization of the vaccine. Conceivably, with an increasing lack of immunity

in underdeveloped nations (so-called herd immunity), outbreaks of poliomyelitis could occur once again.

Prognosis

Mortality from acute paralytic poliomyelitis is between 5 and 10 percent—higher in the elderly and very young. If the patient survives the acute stage, paralysis of respiration and deglutition usually recovers completely; in only a small fraction of such patients is chronic respiratory care necessary. Many patients also recover completely from early muscular weakness, and even the most severely paralyzed often improve to some extent. The return of muscle strength occurs mainly in the first 3 to 4 months and is probably the result of morphologic restitution of partially damaged nerve cells. Branching of axons of intact motor cells with collateral reinnervation of muscle fibers of denervated motor units may also play a part. Slow recovery of slight degree may then continue for a year or more. The postpolio syndrome is discussed in “Differential Diagnosis of ALS” in Chap. 39 and in Chap. 48.

Nonpoliovirus Poliomyelitis

As indicated earlier, a number of RNA viruses that normally cause mundane upper respiratory or enteric infections are now the main causes of a sporadic poliomyelitic syndrome. Fifty-two such cases were recorded by the Centers for Disease Control over a 4-year period. Most of them were caused by one of the echoviruses and a smaller number to Coxsackie enteroviruses, particularly strains 70 and 71. The former illness leaves little residual paralysis, but the Coxsackie viruses, which have been studied in several outbreaks in the United States, Bulgaria, and Hungary, have had more variable effects. Enterovirus 70 causes acute hemorrhagic conjunctivitis in limited epidemics and is followed by a poliomyelitis in 1 of every 10,000 cases. European outbreaks of enterovirus 71, known in the United States as a cause of hand-foot-and-mouth disease and of aseptic meningitis, have resulted in poliovirus-type paralysis, including a few fatal bulbar cases (Chumakov et al). In a recent outbreak of enterovirus 71 in Taiwan, Huang and associates described brainstem encephalitis with myoclonus and cranial nerve involvement in a high proportion of the patients. The tendency of West Nile virus to cause a poliomyelitis has already been mentioned.

Our own experience with this form of poliomyelitis has consisted of several patients who were referred over the years for paralyzing illnesses initially thought to be Guillain-Barré syndrome (Gorson and Ropper). In each case, the illness began with fever and aseptic meningitis (50 to 150 lymphocytes/mm³ in the CSF), followed by backache and widespread, relatively symmetrical paralysis, including the oropharyngeal muscles in two cases and asymmetrical weakness limited to the arms in two patients. There were no sensory changes. One patient had a mild concurrent encephalitic illness and died months later. The evolving electromyographic changes indicated that the paralysis was caused by a loss of anterior horn cells rather than by a motor neuropathy or a purely motor radiculopathy, but this distinction was not always certain. MRI was remarkable in showing distinct changes in the

Figure 33-3. MRI of the cervical cord in a patient with nonpoliovirus poliomyelitis and an asymmetrical, flaccid, bibrachial paralysis. There is T2 signal change in the anterior regions of the gray matter.

gray matter of the cord, mainly ventrally (Fig. 33-3). No virus could be isolated from the CSF and serologic tests in our patients failed to implicate any of the usual encephalitic RNA viruses, including poliovirus. The patients had been immunized against the poliomyelitis viruses.

SUBACUTE AND CHRONIC VIRAL INFECTIONS

The concept that viral infections may lead to chronic disease, especially of the nervous system, had been entertained since the 1920s, but only many decades later was it firmly established. Indirect and direct evidence supported this view: (1) the demonstration of a slowly progressive noninflammatory degeneration of nigral neurons long after an attack of encephalitis lethargica; (2) the finding of inclusion bodies in cases of subacute and chronic sclerosing encephalitis; (3) the discovery of chronic neurologic disease in sheep caused by a conventional RNA virus (*visna*)—it was in relation to this disease in sheep that Sigurdsson first used the term *slow virus infection* to describe long incubation periods during which the animals appeared well; and (4) the demonstration by electron microscopy of viral particles in the lesions of progressive multifocal leukoencephalopathy and, later, isolation of virus from the lesions. The suggestion that the late onset of progressive weakness after poliomyelitis (“postpolio syndrome”) might represent a slow infection has never been verified. Claims have also been made numerous times over the years for a viral causation of multiple sclerosis, amyotrophic lateral sclerosis, and other degenerative diseases, but the evidence in all instances has been questionable.

The established human slow infections of the nervous system caused by conventional viruses include subacute sclerosing panencephalitis (measles virus), progressive rubella panencephalitis, and progressive multifocal leukoencephalopathy (JC virus). These diseases, except for PML, are decidedly rare. They are caused by conventional viruses and are not to be confused with a group of subacute and chronic neurologic diseases that are instead

the result of *prions*, entirely distinct unconventional transmissible agents. These are accorded a separate section later in this chapter.

Subacute Sclerosing Panencephalitis

This disease was first described by Dawson in 1934 under the name "inclusion body encephalitis" and extensively studied by Van Bogaert, who renamed it *subacute sclerosing panencephalitis*. It is now recognized to be the result of chronic measles virus infection. Never a common disease, the condition occurred until recently at a rate of about 1 case per 1 million children per year and now, with the introduction and widespread use of measles vaccine, it has practically disappeared.

Children and adolescents were affected for the most part, the disease rarely appearing beyond the age of 10 years. Typically there is a history of primary measles infection at a very early age, often before 2 years, followed by a 6- to 8-year asymptomatic period. The illness evolved in several stages. Initially there was a decline in proficiency at school, temper outbursts and other changes in personality, difficulty with language, and loss of interest in usual activities. These soon give way to a severe and progressive intellectual deterioration in association with focal or generalized seizures, widespread myoclonus, ataxia, and sometimes visual disturbances caused by progressive chorioretinitis. As the disease advances, rigidity, hyperactive reflexes, Babinski signs, progressive unresponsiveness, and signs of autonomic dysfunction appear. In the final stage, the child lies insensate, virtually "decorticated."

The course is usually steadily progressive, death occurring within 1 to 3 years. A series of 39 such adult cases from India with mean age of 21 years was reported by Prashanth and coworkers, the oldest patient a 43-year old. The main features were similar in most ways to childhood cases, except that several had visual disturbances and two had extrapyramidal features, raising the possibility of prion disease. Myoclonus was present early in the illness in 26 and developed later in all cases; the movements were described as "slow," a characteristic alluded to in other series. In two cases that occurred in pregnant women, blurred vision and weakness of limbs was followed by akinetic mutism, without a trace of myoclonus or cerebellar ataxia. Nevertheless, the progressive ataxic-myoclonic chronic dementia in a child is so typical that bedside diagnosis was usually possible.

The EEG shows a characteristic abnormality consisting of periodic (every 5 to 8 s) bursts of 2 to 3/s high-voltage waves, followed by a relatively flat pattern. The CSF contains few or no cells, but the protein content is increased, particularly the gamma globulin fraction, and agarose gel electrophoresis discloses oligoclonal bands of IgG. These proteins have been shown to represent measles-virus-specific antibody (Mehta et al). MRI changes begin in the subcortical white matter and spread to the periventricular region (Anlar et al).

Histologically, the lesions involve the cerebral cortex and white matter of both hemispheres and the brainstem. The cerebellum is usually spared. Destruction of nerve cells, neuronophagia, and perivenous cuffing

by lymphocytes and mononuclear cells indicate the viral nature of the infection. In the white matter there is degeneration of medullated fibers (both myelin and axons), accompanied by perivascular cuffing with mononuclear cells and fibrous gliosis (hence the term *sclerosing encephalitis*). Eosinophilic inclusions, the histopathologic hallmark of the disease, are found in the cytoplasm and nuclei of neurons and glia cells. Virions, thought to be measles nucleocapsids, have been observed in the inclusion-bearing cells examined electron microscopically.

How a ubiquitous and transient viral infection in a seemingly normal young child allows the development, many years later, of a rare encephalitis is a matter of speculation. Sever believes that there is a delay in the development of immune responses during the initial infection and a later inadequate immune response that is incapable of clearing the suppressed infection.

The differential diagnosis of SSPE includes the childhood and adolescent dementing diseases such as lipid storage diseases (see Chap. 37), prion disease (Creutzfeldt-Jakob), and Schilder-type demyelinating disease (see Chap. 36). In presumptive clinical cases of SSPE, the findings of periodic complexes in the EEG, elevated gamma globulin and oligoclonal bands in the CSF, and elevated measles antibody titers in the serum and CSF are sufficient to make the diagnosis.

No effective treatment is available. The administration of amantadine and inosine pranobex (formerly inosiplex) was found by some investigators to lead to improvement and prolonged survival, but these effects have not been corroborated.

Subacute Measles Encephalitis with Immunosuppression

Whereas SSPE occurs in children who were previously normal, another rare type of measles encephalitis has been described that affects both children and adults with defective cell-mediated immune responses (Wolinsky et al). In this type, measles or exposure to measles precedes the encephalitis by 1 to 6 months. Seizures (often epilepsy partialis continua), focal neurologic signs, stupor, and coma are the main features of the neurologic illness and lead to death within a few days to a few weeks. The CSF may be normal, and levels of measles antibodies do not increase. Aicardi and colleagues have isolated measles virus from the brain of such a patient. The lesions are similar to those of SSPE (eosinophilic inclusions in neurons and glia, with varying degrees of necrosis) except that inflammatory changes are lacking. In a sense, this subacute measles encephalitis is an opportunistic infection of the brain in an immunodeficient patient. The relatively short interval between exposure and onset of neurologic disease, the rapid course, and lack of antibodies distinguish this form of subacute measles encephalitis from both SSPE and post-measles (postinfectious) encephalomyelitis (see Chap. 36).

Progressive Rubella Panencephalitis

The deficits associated with congenital rubella infection of the brain are nonprogressive at least after the second

or third year of life. There are, however, descriptions of children with the congenital rubella syndrome in whom a progressive neurologic deterioration occurred after a stable period of 8 to 19 years (Townsend et al; Weil et al). In 1978, Wolinsky described 10 instances, a few of them apparently related to acquired rather than to congenital rubella. Since then, this late-appearing progressive syndrome seems to have disappeared, no definite new cases having been reported in the past 30 years but it nonetheless remains of biological interest.

The clinical syndrome was quite uniform. On a background of the features of congenital rubella, a decade later there occurred a deterioration in behavior and school performance, often associated with seizures, and, soon thereafter, a progressive impairment of mental function (dementia). Clumsiness of gait was an early symptom, followed by a frank ataxia of gait and then of the limbs. Spasticity and other corticospinal tract signs, dysarthria, and dysphagia ensue.

Progressive Multifocal Leukoencephalopathy

This disorder, first observed clinically by Adams and colleagues in 1952, was described morphologically in 1958 by Åstrom and coworkers, and then with a larger body of material by Richardson in 1961. It is characterized by widespread demyelinating lesions, mainly of the cerebral hemispheres but sometimes of the brainstem and cerebellum, and, rarely, of the spinal cord. The lesions vary greatly in size and severity—from microscopic foci of demyelination to massive multifocal zones of destruction of both myelin and axons involving large parts of a cerebral or cerebellar hemisphere. The abnormalities of the glia cells are distinctive. Many of the reactive astrocytes in the lesions are gigantic and contain deformed and bizarre-shaped nuclei and mitotic figures, changes that are seen otherwise only in malignant glial tumors. Also, at the periphery of the lesions, the nuclei of oligodendrocytes are greatly enlarged and contain abnormal inclusions. Many of these cells are destroyed, accounting for the demyelination. Vascular changes are lacking, and inflammatory changes are present but usually insignificant, except in a small number of interesting cases in which immune reconstitution by retroviral drugs for AIDS allows the emergence of intense inflammation.

Clinical Features

An uncommon disease of late adult life, PML usually develops in a patient with a neoplasm or chronic immunodeficiency state. The large majority of cases are now observed in patients with AIDS in whom the incidence of PML approaches 5 percent. Viewed from another perspective, more than 75 percent of cases of PML in the current era are associated with HIV. Indeed, the incidence is so much higher than in any other form of immunosuppression that an interaction between HIV and the causative virus of PML has been suggested. Other important associations are with chronic neoplastic disease (mainly chronic lymphocytic leukemia, Hodgkin disease, lymphosarcoma, and myeloproliferative disease) and less often, with nonneoplastic granulomatosis, such

as tuberculosis or sarcoidosis. A number of cases occur in patients receiving immunosuppressive drugs for renal transplantation, multiple sclerosis (see Chap. 36), or for other reasons.

Personality changes and intellectual impairment may introduce the neurologic syndrome, which then evolves over a period of several days to weeks. Any one or some combination of hemiparesis progressing to quadriplegia, visual field defects, cortical blindness, aphasia, ataxia, dysarthria, dementia, confusional states, and coma are manifestations. Some of the cases under our observation had a predominantly cerebellar syndrome. Seizures are infrequent, occurring in only about 10 percent of cases. In most cases, death occurs in 3 to 6 months from the onset of neurologic symptoms and even more rapidly in patients with AIDS unless aggressive antiretroviral treatment is undertaken. The CSF is usually normal. CT and MRI localize the nonenhancing demyelinating lesions with clarity (Fig. 33-4) but the variability in size, location, and multiplicity make the diagnosis more dependent on viral DNA isolation from CSF and on the context of immunosuppression.

Pathogenesis

Waksman's original suggestion (quoted by Richardson) that PML could be caused by viral infection of the CNS in patients with impaired immunologic responses proved to be correct. ZuRhein and Chou, in an electron microscopic study of cerebral lesions from a patient with PML later demonstrated crystalline arrays of particles resembling papovaviruses in the inclusion-bearing oligodendrocytes. Since then a human polyomavirus, designated "JC virus" or JCV (initials of the patient from whom the virus was originally isolated), has definitively been shown to be the causative agent. JCV is ubiquitous, as judged by the presence of antibodies to the virus in approximately 70 percent of the normal adult population. It is thought to be dormant in the kidney or bone marrow until an immunosuppressed state permits its active replication. The virus has been isolated from the urine, blood lymphocytes, bone marrow, and kidney, but there is no clinical evidence of damage to extraneural structures.

Treatment

The disease is generally believed to be untreatable in the non-AIDS patient. Anecdotal reports of the efficacy of various medications such as cytosine arabinoside, zidovudine, mirtazapine, interferon, and topotecan, either have not been tested in, or have failed to be sustained in larger trials. In AIDS patients, aggressive treatment using antiretroviral drug combinations, including protease inhibitors, greatly slows the progression of PML and has led to remission in almost half of cases for a year, as in the large series reported by Antinori and colleagues. Several retrospective series found that a CD4 count below 100 cells/ μ L is a poor prognostic sign for recovery from PML. A review of these issues, particularly relating to AIDS and PML, is in the report by Mangi and Miller.

A special comment should be made regarding the transient but sometimes severe clinical worsening of PML that may occur during the initial treatment of HIV

Figure 33-4. Progressive multifocal leukoencephalopathy (PML). MRI, T2-FLAIR, demonstrates multiple subcortical white matter lesions in both hemispheres (*left panel*) and in the left pons (*right panel*) in a 31-year-old male with AIDS. The lesions did not enhance.

infection with antiretroviral drugs. This syndrome has been attributed to the emergence of acute inflammation surrounding the demyelinating lesions as a result of reconstitution of the immune system (immune reconstitution syndrome or *IRIS* that has been mentioned in the section on the treatment of HIV). In support of this mechanism, there is a parallel blossoming of the lesions with gadolinium enhancement on MRI. Treatment with corticosteroids has been suggested and is said to allow survival and temporary remission of PML, although we have seen at least one dramatic exception. Judicious use of corticosteroids is implemented to mute this reaction.

Encephalitis Lethargica (von Economo Disease, Sleeping Sickness)

Although examples of a somnolent-ophthalmoplegic encephalitis dot the early medical literature (e.g., *nona*, *fébre lethargica*, *Schlafrkrankheit*), it was in the wake of the influenza pandemic of World War I that this disease appeared prominently and continued to reappear for about 10 years. The viral agent was never identified, but the clinical and pathologic features were typical of viral infection. Nonetheless recent testing of archived brain material has failed to reveal influenzal RNA, so that encephalitis lethargica may be considered a putative viral disease. An alternative view of an immune pathogenesis is presented below.

The importance of encephalitis lethargica relates to its unique clinical syndromes and sequelae and to its place as the first recognized “slow virus infection” (ironically,

without identification of the agent) of the nervous system in humans. The unique symptoms were ophthalmoplegia and pronounced somnolence, from which the disease took its name. Some patients were overly active, and a third group manifested a disorder of movement in the form of bradykinesia, catalepsy, mutism, chorea, or myoclonus. Lymphocytic pleocytosis was found in the spinal fluid of half the patients, together with variable elevation of the CSF protein content. More than 20 percent of the victims died within a few weeks, and many survivors were left with varying degrees of impairment of mental function. However, the most extraordinary feature was the appearance of a parkinsonian syndrome, after an interval of weeks or months (occasionally years), in a high proportion of survivors. Myoclonus, dystonia, oculogyric crises (Chap. 14) and other muscle spasms, bulimia, obesity, reversal of the sleep pattern, and, in children, a change in personality with compulsive behavior (“organic drive-ness”) were other distressing sequelae. This is not the only form of encephalitis known to cause a delayed extrapyramidal syndrome of this type (a similar though not identical syndrome with a much shorter latency may follow Japanese B encephalitis and other arboviral encephalitis).

The pathology was typical of a viral infection, localized principally to the midbrain, subthalamus, and hypothalamus. In the patients who died years later with Parkinson syndrome, the main findings were depigmentation of the substantia nigra and locus ceruleus because of nerve cell destruction. Neurofibrillary changes in the surviving nerve cells of the substantia nigra and the oculomotor

and adjacent nuclei were also described, indistinguishable from those of progressive supranuclear palsy. Lewy bodies were not seen, in contrast to idiopathic Parkinson disease, where they are consistently present. Only a few new cases of postencephalitic type have been seen in the United States and western Europe since 1930. Sporadic cases, such as the four reported by Howard and Lees, may be examples of this disease, but there is no way of proving their identity.

More often currently, a postinfectious extrapyramidal syndrome is putatively the result of circulating autoantibodies. While not necessarily viral in origin, this is an appropriate place to summarize the recent findings of Dale and colleagues, who have studied the problem carefully and presented 20 cases that were remarkably similar to the ones described by von Economo. Half of their patients had a preceding pharyngitis that was followed by somnolence or pathologic insomnia, parkinsonism, dyskinesias, and psychiatric symptoms. Many had oligoclonal bands in the cerebrospinal fluid and some had changes on MRI in the basal ganglia. Their singular finding was that 95 percent had serum autoantibodies against basal ganglia neural antigens (two-thirds also had antibodies to anti-streptolysin O). Pathologic examination in one case showed perivascular inflammation. Thus, the long-held notion that this form of encephalitis was, and is, a viral illness might be challenged. Dale and colleagues comment that von Economo and his contemporaries in fact doubted that there was a connection to influenza.

Other Forms of Subacute Encephalitis

A number of uncommon conditions not covered above are characterized by regional inflammation in the cerebrum. Among these, *Rasmussen encephalitis*, which causes intractable focal seizures and progressive hemiparesis (see Chap. 16), has been tentatively connected to infections by CMV and HSV-I in various studies that used PCR techniques but the presence of autoantibodies to glutamate receptors suggest this is an immune process. However, a specific immune reaction consisting of antibodies to glutamate receptors has been implicated more consistently and immunosuppressive treatments may be effective. It is not clear whether this process can be classed with the infectious encephalitides; it is discussed in detail with other epileptic diseases in Chap. 16. Similarly, the restricted inflammatory conditions called *limbic encephalitis* and “brainstem encephalitis”—most often a distant effect of lung cancer—have some characteristics of a subacute viral encephalitis, but no agent has been consistently isolated and they are also best considered immunologic reactions. They are included in the discussion of paraneoplastic illnesses in Chap 31.

PRION DISEASES

This category of infections includes a quartet of human diseases—Creutzfeldt-Jakob disease (and a variant that infects cows and may be rarely transmitted to humans),

the Gerstmann-Sträussler-Scheinker syndrome, kuru, and fatal familial insomnia.

Although this group of diseases has been included for discussion in the chapter on viruses that affect the nervous system, it has been evident for some time that the cause of these diseases is neither a virus nor a viroid (nucleic acid alone, without a capsid structure). The transmissible, or “infectious” nature of prions was discovered by Gadjusek and Gibbs in the Fore tribes of New Guinea, who practiced ritual cannibalism and ate the brains of the deceased. The resulting disease, kuru, is described further on but the important point is that the aforementioned workers were able to transmit the disease to chimpanzees after a long latent period of years. Prusiner is credited with doggedly pursuing this problem, for which he was awarded the Nobel Prize. He (1993, 1994, 2001) has presented evidence that the transmissible pathogen is a proteinaceous infectious particle that is devoid of nucleic acid, resists the action of enzymes that destroy RNA and DNA, fails to produce an immune response, and electron microscopically does not have the structure of a virus. To distinguish this pathogen from viruses and viroids, Prusiner introduced the term *prion*.

The very same prion protein (PrP) is normally encoded by a gene on the short arm of chromosome 20 in humans. The discovery of mutations in the PrP genes of patients with familial Creutzfeldt-Jakob disease and Gerstmann-Sträussler-Scheinker syndrome (described below) attests to the fact that prion diseases may be both genetic and infectious. This is another way in which prions are unique among all pathogens. It is now possible to detect inherited types of prion diseases during life, using DNA extracted from leukocytes. How prions arise in sporadic forms of spongiform encephalopathy is not fully understood. The conversion of the normal cellular protein to the infectious form involves a conformational change in the protein structure as described in Prusiner’s review in 2001. Remarkably, as discussed below, the current theory holds that an abnormally folded prion protein can act as a template for the conversion of normal PrP to PrP^{sc} (the latter denoting the scrapie prion; see further on). A description of the human prion diseases is given here, the most important by far being Creutzfeldt-Jakob disease.

Creutzfeldt-Jakob Disease (Subacute Spongiform Encephalopathy)

These terms refer to a distinctive cerebral disease in which a rapidly or subacutely progressive and profound dementia is associated with diffuse myoclonic jerks and a variety of other neurologic abnormalities, mainly visual or cerebellar. The major neuropathologic changes are found in the cerebral and cerebellar cortices, and the outstanding features are widespread neuronal loss and gliosis accompanied by a striking vacuolation or spongy state of the affected regions—hence the designation *subacute spongiform encephalopathy (SSE)*. Less severe changes in a patchy distribution are found in cases with a briefer clinical course.

The widely used term Creutzfeldt-Jakob disease (CJD) may be an inappropriate eponym as it is most unlikely that the patient described by Creutzfeldt and at least three of the five patients described by Jakob did not have the same disease that we now recognize as subacute spongiform encephalopathy. However, decades of use make it virtually impossible to displace.

One of the more interesting aspects of the development of the prion concept has been the hypothesis that many conditions, most in the category of degenerative neurologic disease and characterized by the accumulation of specific proteins such as amyloid, tau, synuclein, and ubiquitin may have a similar mechanism in sequential, contiguous conformational change in protein aggregation.

Epidemiology and Pathogenesis

The disease appears in all parts of the world and in all seasons, with an annual incidence of 1 to 2 cases per million of population. The incidence is higher in Israelis of Libyan origin, in immigrants to France from North Africa, and perhaps in Slovakia. The incidence of spongiform encephalopathy is somewhat higher in urban than in rural areas, but a consistent temporal or spatial clustering of cases has not been observed, at least in the United States. A small proportion of all series is familial—varying from 5 percent reported by Cathala and associates to 15 percent of 1,435 cases analyzed by Masters and coworkers (1979). The occurrence of familial cases that are not in the same household probably indicates a genetic susceptibility to infection, although the possibility of common early exposure to the transmissible agent cannot be excluded. A small number of conjugal cases have also been reported. The only clearly demonstrated mechanism of spread of the usual type of CJD is iatrogenic, having occurred in a few cases after transplantation of corneas or dural grafts from infected individuals, after implantation of infected electroencephalographic depth electrodes, and after the injection of human growth hormone or gonadotropins that had been prepared from pooled cadaveric sources. At least one neurosurgeon is known to have acquired the disease. Of some interest is the finding by Zanusso and colleagues of the infectious prion protein in the nasal mucosa of all nine patients studied with the sporadic disease. This suggests a route for entry into the nervous system of the aberrant prion and also a potential diagnostic test. As noted further on, the tonsils of patients affected with variant CJD may also show immunostaining for prions.

Attention has been drawn to an outbreak of prion disease among cows in the British Isles (“mad cow disease,” bovine spongiform encephalopathy, BSE). Cows elsewhere have sporadically been found to be infected. The mini-epidemic began in 1986, with putative transmission of the disease to some 24 humans. These patients were younger (average age of onset 27 years) than those with typical CJD (average age of onset 65 years) and manifested psychiatric and sensory symptoms as the first sign of illness; they did not exhibit the usual EEG findings even as the illness advanced to its later stages (Will et al). This has been called “new variant Creutzfeldt-Jakob

disease (vCJD).” One reason for including a lengthy explanation of this illness is the potential for cases to appear in future years. It was shown that the prion strain in affected patients is identical to the one from affected cattle and different from the prion agent that causes sporadic CJD. The mode of transmission, presumed to be the ingestion of infected meat, is reminiscent of the propagation of kuru in New Guinea by ceremonial ingestion of brain tissue from infected individuals that opened the era of understanding of prion disease.

Prion (spongiform) encephalopathy or all types has now been firmly associated with the conversion of a normal cellular protein, PrP^c to an abnormal isoform, PrP^{sc}. The transformation involves a change in the physical conformation of the protein in which its helical proportion diminishes and the proportion of the β pleated sheet increases (see reviews by Prusiner). The current understanding is that the “infectivity” of prions and their propagation in brain tissue result from the susceptibility of the native PrP to alter its shape as a result of physical exposure to the abnormal protein, a so-called conformational disease. Conformationally altered prions have a tendency to aggregate, and this may be the mode of cellular destruction that leads to neuronal disease. In contrast, familial cases of prion disease are thought to be the result of one of several gene aberrations residing in the region that code for PrP^c.

As the isoforms of the prions that causes the sporadic disease have been characterized, clinical patterns have emerged as more or less typical of certain protein configurations and their underlying genotypes. Several competing classification systems have been devised that are based on both the presence of methionine (M) or valine (V) at codon 129 of the prion protein and on which of two physicochemical properties it displays (termed types 1 or 2; see Parchi et al). The most common variant in most studies has been MM and the least common, VV, and type 1 is more frequent than type 2 (hence MM1 is the most common type overall, present in approximately two-thirds of sporadic cases). However, classification is complicated by the fact that some brain samples show more than one type of protein. Although several studies conflict on these points, a typical EEG pattern was most common in type 1 cases with at least one methionine, whereas MV2 cases were most likely to have MRI changes (see further on). Some studies have suggested that the MV2 subtype, comprising a small proportion of cases, was likely to present with ataxia, psychiatric changes, a lack of positive sharp waves on EEG, and a prolonged duration of disease, but none of the distinctions has been even close to absolute. There has also been controversy regarding the relationship of the genotype to the sensitivity of diagnostic tests discussed below. Details of these putative associations can be found in an extensive international study of 2,541 pathologically confirmed cases of CJD reported by Collins and colleagues.

Clinical Features

Prion encephalopathy is in most cases a spontaneously occurring disease of late middle age, although it occurs

in young adults. The sexes are affected equally. In the large series of pathologically verified cases reported by Brown and coworkers, prodromal symptoms—consisting of fatigue, depression, weight loss, and disorders of sleep and appetite lasting for several weeks—were observed in about one-third of the patients.

The early stages of the neurologic disease are characterized by a great variety of clinical manifestations, but the most frequent are changes in behavior, emotional response, and intellectual function, often followed by ataxia and abnormalities of vision, such as distortions of the shape and alignment of objects or impairment of visual acuity. Typically, the early phase of the disease is dominated by symptoms of confusion, with hallucinations, delusions, and agitation. In other instances, cerebellar ataxia (Brownell-Oppenheimer variant) or visual disturbances (Heidenhain variant) precede the mental changes and may be the most prominent features for several months. Headache, vertigo, and sensory symptoms are complaints in some patients but become quickly obscured by dementia and muteness.

As a rule, the disease progresses rapidly, so that obvious deterioration is seen from week to week and even day to day. Sooner or later, in almost all cases, myoclonic contractions of various muscle groups appear, perhaps unilaterally at first but later becoming generalized. Or, infrequently, the myoclonus may not appear for weeks or months after the initial mental changes. In a few patients, a startle response, that is elicitable for a brief period of time, is the only manifestation of myoclonus. In general, the myoclonic jerks are evocable by sudden sensory stimuli of all sorts, a startle response (to noise, bright light, touch) but they occur spontaneously as well. Twitches of individual fingers are typical but it should be emphasized that well-formed seizures are not a component of the illness. These changes gradually give way to a mute state, stupor, and coma, but the myoclonic contractions may continue to the end. Signs of degeneration of the pyramidal tracts or anterior horn cells, palsies of convergence and upgaze, and extrapyramidal signs occur in a small number of patients as the disease advances.

The clinical diagnosis during life rests mostly on the recognition of one of the clusters of typical clinical features, particularly the special rate of rapid progression of dementia—much more quickly than that of common degenerative diseases—coupled with stimulus-sensitive myoclonus and the characteristic MRI and EEG changes that occur in most patients (see below).

The disease is invariably fatal, usually in a few months and almost always less than a year from the onset. In approximately 10 percent of patients, the illness begins with almost stroke-like suddenness and runs its course rapidly, in a matter of a few weeks. At the other extreme, a small number of patients have reportedly survived for 2 to 10 years, but these reports should be accepted with caution; in some of them, the illness appears to have been superimposed on Alzheimer or Parkinson disease or some other chronic condition that predated the prion illness.

Laboratory Diagnosis

The routine CSF and other laboratory tests are normal—useful findings in that they exclude a number of chronic inflammatory causes of dementia such as neurosyphilis. In most patients, the EEG pattern is distinctive, changing over the course of the disease from one of diffuse and nonspecific slowing to one of stereotyped high-voltage slow- (1- to 2-Hz) and sharp-wave complexes on an increasingly slow and low-voltage background (see Fig. 2-5G). The high-voltage sharp waves, which give the appearance of periodicity (they have been called pseudo-periodic), are synchronous with the myoclonus, but may persist in its absence.

MRI of the brain has now been appreciated to show hyperintensity of the lenticular nuclei on T2-weighted and diffusion-weighted images in the basal ganglia and cortex when the disease is fully established (Fig. 33-5). Long contiguous segments of the cortex, as well as various parts of the basal ganglia, show these alterations in a pattern that is characteristic and mistakable only perhaps for the appearance of diffuse cerebral anoxia. According to Shiga and colleagues, these changes occur in 90 percent of cases (cortex more often than caudate or lenticular nuclei and sometimes both), making them potentially the most sensitive test for the disease but the proportion has been lower in our patients. Complicating the interpretation of the MRI findings in this disease have been reports from Japan of extensive white matter lesions in several autopsy-proven cases (Matsusue et al).

There are helpful confirmatory diagnostic tests but they are not always necessary. Hsich and colleagues described a now widely used test of CSF—the finding by immunoassay of peptide fragments of normal brain proteins, termed “14-3-3.” This test is particularly useful in separating CJD from other chronic noninflammatory dementing diseases but it has been sometimes disappointing on our wards, giving both false-positive and false-negative results. Several studies have given conflicting information on the sensitivity of the 14-3-3 test in relation to the various forms of prions and differing clinical presentations, but all seem to converge on the fact that repeated testing, up to three times is more likely to give positive results. A summary publication has indicated an overall sensitivity from pooled reports of 92 percent and specificity of 80 percent (report of the Guidelines Development Committee of the American Academy of Neurology). Also, enolase and neopterin concentrations in CSF are elevated in most cases, but the release of these substances is found with other types of brain lesions, particularly infarction. A number of other tests are emerging from specialized laboratories that are able to detect the specific abnormal PrP^{Sc} isoform of the prion protein in the spinal fluid. Prusiner’s laboratory has been able to detect eight prion strains but it is not yet clear if this scientific advance can be put to clinical use.

Tonsillar material from patients with new variant Creutzfeldt-Jakob disease (“mad cow disease”) stains

Figure 33-5. MRI showing T2 signal changes in the striatum in a patient with sporadic CJD (*left*) of 1 month's duration. DWI sequence showing restriction of diffusion in contiguous bands of cortex and in the striatum (*right*) in the same case.

with antibodies against abnormal prion protein, but this technique does not appear to be applicable to the early diagnosis of the sporadic disease (Hill). Whether the earlier-mentioned finding of infectious prion material in the nasal mucosa in the sporadic form will prove to have practical value in diagnosis is yet to be determined.

The National Prion Disease Pathology Surveillance Center, which was established at Case Western Reserve University, is available to assist clinicians by performing, free of charge, a variety of specific diagnostic tests (accessible through <http://www.cjdsurveillance.com>).

Pathology The disease affects principally the cerebral and cerebellar cortices, generally in a diffuse fashion, although in some cases the occipitoparietal regions are almost exclusively involved, as in those described by Heidenhain. In others, such as the cases of Brownell and Oppenheimer alluded to earlier, the cerebellum has been most extensively affected, with early and prominent ataxia. The degeneration and disappearance of nerve cells are associated with extensive astroglial proliferation; ultrastructural studies have shown that the microscopic vacuoles, which give the tissue its typically spongy appearance, are located within the cytoplasmic processes of glia cells and dendrites of nerve cells. The loss in particular of certain inhibitory neurons in the thalamic reticular nuclei seems to correspond to the presence of myoclonus and positive sharp waves in the EEG according to Tschampa and colleagues. Despite the fact that the disease is caused by a transmissible agent, the lesions

show no evidence of an inflammatory reaction and no viral particles are seen.

Differential Diagnosis The diagnosis of most cases presents no difficulty if the rapidity of progression and the myoclonus are recognized. Not infrequently, however, we have been surprised by a "typical" case that proves to be some other disease. Lithium intoxication, Hashimoto encephalopathy (as emphasized by Seipelt and colleagues who found a number of these cases in an epidemiologic survey of SSE; Chap. 40), Whipple disease (see Chap. 32), intravascular lymphoma, and carcinomatous meningitis—all of them characterized by myoclonus and dementia—may mimic CJD in the early weeks of illness. Contrariwise, the early mental changes of SSE may be misinterpreted as an atypical or unusually intense emotional reaction, as one of the major psychoses, as an unusual form of Alzheimer disease with myoclonus, corticobasal degeneration (see Chap. 39), or as Lewy-body disease. Despite the designation of CJD as a progressive dementia, the similarities to even rapidly developing Alzheimer disease are superficial. Also, diagnosis may be difficult in patients who present with dizziness, gait disturbance, diplopia, or visual disturbances until the rapidly evolving clinical picture clarifies the issue. Subacute sclerosing panencephalitis (see earlier in this chapter) in its fully developed form may resemble CJD, but the former is chiefly a disease of children or young adults, and the CSF shows elevation of gamma globulin (IgG), whereas

the latter is essentially a disease of middle age and the presenile period and the CSF is normal. Limbic-brainstem-cerebellar encephalitis in patients with an occult tumor and AIDS dementia (discussed earlier) also figure in the differential diagnosis. Cerebral lipodosis in children or young adults can result in a similar combination of myoclonus and dementia, but the clinical course in such cases is extremely chronic and there are retinal changes that do not occur in spongiform encephalopathy. Well-formed convulsions should direct attention to another diagnosis.

Management No specific treatment is known. Antiviral agents have been ineffective. In view of the transmissibility of the disease from humans to primates and iatrogenically from person to person with infected materials, certain precautions should be taken in the medical care and handling of materials from affected patients. Special isolation rooms are unnecessary, and the families of affected patients and nursing staff can be reassured that casual contact poses no risk. Needle punctures and cuts are not thought to pose a risk, but some uncertainty remains. The transmissible agent is resistant to boiling, treatment with formalin and alcohol, and ultraviolet radiation but can be inactivated by autoclaving at 132°C (269.6°F) at 15 lb/in² for 1 h or by immersion for 1 h in 5 percent sodium hypochlorite (bleach). Workers exposed to infected materials (butchers, abattoir workers, healthcare workers) should wash thoroughly with ordinary soap. Needles, glassware, needle electrodes, and other instruments should be handled with great care and immersed in appropriate disinfectants and autoclaved or incinerated. The performance of a brain biopsy or autopsy requires that a set of special precautions be followed, as outlined by Brown but this surgical procedure is not necessary as more diagnostic tools have become available. Obviously such patients or any others known to have been demented should not be donors of organs or corneas for transplantation or blood for transfusion.

Gerstmann-Sträussler-Scheinker Syndrome

This is a rare, strongly familial disease inherited as an autosomal dominant trait. It begins insidiously in midlife and runs a chronic course (mean duration 5 years). The main characteristics are progressive cerebellar ataxia, corticospinal tract signs, dysarthria, and nystagmus. Dementia is often associated but is relatively mild.

Dyesthesias and proximal weakness of the legs have been emphasized as an early feature by Arata and colleagues. Their report may be consulted for details of 11 well-studied cases. The MRI is usually normal; with progression, generalized atrophy is found.

There are characteristic spongiform changes in brain tissue, as in CJD. Brain tissue from patients with this disease, when inoculated into chimpanzees, has produced a spongiform encephalopathy (Masters et al, 1981). Molecular genetic studies of affected family members demonstrate a mutation of the prion protein gene. This syndrome should be considered as a small familial subset of SSE, of slowly progressive type.

Fatal Insomnia (Familial and Sporadic)

This is another rare and usually familial disease in the spongiform encephalopathy group. It is characterized by intractable insomnia, sympathetic overactivity, and dementia, leading to death in 7 to 15 months (see also Chap. 16). The pathologic changes, consisting of neuronal loss and gliosis, are found mainly in the medial thalamic nuclei. Studies of a few families have shown a mutation of the prion protein gene and brain material was found to contain a protease-resistant form of the gene that is characterized by a mutation in the prion gene at codon 178 in conjunction with the presence of methionine at codon 129 on chromosome 20, the latter being a feature of sporadic CJD. Transmission of the disease by inoculation of infected brain material has not been accomplished (Medori et al). There is also a rare sporadic form of this disease and the configuration of the prion alteration is different from the familial variety.

Kuru

This disease occurs exclusively among the Fore linguistic group of natives of the New Guinea highlands and is included here because of its historical interest as the first slow infection caused by an unconventional transmissible agent to be documented in human beings. Clinically the disease takes the form of an afebrile, progressive cerebellar ataxia, with abnormalities of extraocular movements, weakness progressing to immobility, incontinence in the late stages, and death within 3 to 6 months of onset. In some ways it is similar to the ataxic (Brownell-Oppenheimer) variant of CJD. The remarkable epidemiologic and pathologic similarities between kuru and scrapie in sheep were pointed out in 1959 by Hadlow, who suggested that it might be possible to transmit kuru to subhuman primates. This was accomplished in 1966 by Gajdusek and coworkers; inoculation of chimpanzees with brain material from affected humans produced a kuru-like syndrome in chimpanzees after a latency of 18 to 36 months. Since then the disease has been transmitted from one chimpanzee to another and to other primates by using both neural and nonneural tissues. The pioneering work in this field led to the awarding of a Nobel Prize to these workers and the same prize was awarded to Prusiner 23 years later, representing a landmark in which the Nobel was awarded twice for work regarding the same disease. Histologically there is a noninflammatory loss of neurons and spongiform change throughout the brain, but predominantly in the cerebellar cortex, with astroglial proliferation and periodic acid-Schiff-positive stellate plaques of amyloid-like material ("kuru plaques"). The transmissible agent has not been visualized, however.

Kuru has gradually disappeared because of the cessation of ritual cannibalism by which the disease had been transmitted. In this ritual, infected brain tissue was ingested and rubbed over the body of the victim's kin (women and young children of either sex), permitting absorption of the infective agent through conjunctivae, mucous membranes, and abrasions in the skin.

Cerebrovascular Diseases

Among all the neurologic diseases of adult life, stroke ranks first in frequency and importance. The common mode of expression of *stroke* is a relatively sudden occurrence of a focal neurologic deficit. Strokes are broadly categorized as ischemic or hemorrhagic. *Ischemic stroke* is due to occlusion of a cerebral blood vessel and causes cerebral infarction. The resultant neurologic syndrome corresponds to a portion of the brain that is supplied by one or more cerebral vessels. Knowledge of the stroke syndromes, the signs and symptoms that correspond to the region of brain that is supplied by each vessel, allows a degree of precision in determining the particular vessel that is occluded and from the temporal evolution of the syndrome, the underlying cause of vascular occlusion can be deduced.

Ischemic strokes are classified by the underlying cause of the vascular occlusion. One of three main processes is usually operative: (i) atherosclerosis with superimposed thrombosis affecting large cerebral or extracerebral blood vessels, (ii) cerebral embolism, and (iii) occlusion of small cerebral vessels within the parenchyma of the brain. There are many other pathologic processes that lead to ischemic brain damage, not all associated with occlusion of cerebral vessels, including arterial dissection, inflammatory conditions such as vasculitis, thrombosis of cerebral veins and dural sinuses, in situ thrombosis of large or small cerebral vessels due to hypercoagulable conditions, vasospasm from any of several mechanisms, unusual types of embolic materials such as fat, tumor, cholesterol, and several unique diseases that involve the cerebral vasculature (see further on). Closely allied with ischemic strokes is the transient ischemic attack (TIA), a temporary neurologic deficit caused by a cerebrovascular disease that leaves no clinical or imaging trace. The causes of stroke are so numerous that the listing given in Table 34-1 offers only a guide to the remainder of this chapter. As helpful is knowledge of the major causes of stroke by each epoch of age, particularly in childhood and young adults, a subject taken up in a later section and summarized in Table 34-2.

The second broad category consists of *hemorrhage*, which occurs either within the substance of the brain, intracerebral hemorrhage, or contained within the subarachnoid spaces and ventricular system, subarachnoid hemorrhage. The causes of the first category are numerous and

include chronic hypertension, coagulopathies that arise endogenously or as a result of anticoagulant medications, vascular malformations of the brain, cranial trauma, and hemorrhage that occurs within the area of an ischemic stroke. Subarachnoid hemorrhage has fewer fundamental causes, the most common being the rupture of a developmental aneurysm arising from the vessels of the circle of Willis, but also includes cerebral trauma and arteriovenous malformations, and rarer processes.

THE CLINICAL STROKE SYNDROME

There are all gradations of severity, but in all forms of stroke the essential feature is abruptness with which the neurologic deficit develops—usually a matter of seconds that stamps the disorder as vascular. In its most severe form, the patient with a stroke becomes hemiplegic or even comatose—an event so dramatic that it had in the past been given vivid designations: *apoplexy*, *cerebrovascular accident (CVA)*, or shock (colloquial). However, *stroke* is the preferred term.

In its mildest form, a stroke may consist of a trivial and transient neurologic disorder insufficient for the patient even to seek medical attention. Most embolic strokes occur suddenly and the deficit reaches its peak almost at once. Thrombotic strokes tend to evolve somewhat more slowly over a period of minutes or hours and occasionally days; in the latter case, the stroke usually progresses in a saltatory fashion, i.e., in a series of steps rather than smoothly. In cerebral hemorrhage, also abrupt in onset, the deficit may be virtually static or steadily progressive over a period of minutes or hours, while subarachnoid hemorrhage is almost instantaneous. It follows that gradual downhill course over a period of several days or weeks will usually be traced to a nonvascular disease. There are, however, many exceptions, such as the additive effects of multiple vascular occlusions and the progression that is caused by secondary brain edema surrounding large infarctions and cerebral hemorrhages. At the other extreme is rapid regression of a focal stroke syndrome that reverses itself entirely and dramatically over a period of minutes or up to an hour; this defines the TIA.

The second essential feature of stroke is its focal signature. The neurologic deficit reflects both the location

Table 34-1

CAUSES OF ISCHEMIC AND HEMORRHAGIC STROKE

1. Atherosclerotic thrombosis
2. Transient ischemic attacks
3. Embolism
4. Hypertensive hemorrhage
5. Ruptured or unruptured saccular aneurysm or arteriovenous malformation
6. Arteritis
 - a. Meningovascular syphilis, arteritis secondary to pyogenic and tuberculous meningitis, rare infective types (typhus, schistosomiasis, malaria, mucormycosis, etc.)
 - b. Autoimmune vasculopathies (polyarteritis nodosa, lupus erythematosus), necrotizing arteritis. Wegener arteritis, temporal arteritis, Takayasu disease, granulomatous or giant cell arteritis of the aorta, and giant cell granulomatous angiitis of cerebral arteries
7. Cerebral thrombophlebitis: secondary to infection of ear, paranasal sinus, face, etc.; with meningitis and subdural empyema; debilitating states, postpartum, postoperative, cardiac failure, hematologic disease (polycythemia, sickle cell disease), and of undetermined cause
8. Hematologic disorders: anticoagulants and thrombolytics, clotting factor disorders, polycythemia, sickle cell disease, thrombotic thrombocytopenic purpura, thrombocytosis, intravascular lymphoma, etc.
9. Trauma and dissection of carotid and basilar arteries
10. Amyloid angiopathy
11. Dissecting aortic aneurysm
12. Complications of arteriography
13. Complex migraine with persistent deficit
14. With tentorial, foramen magnum, and subfalcial herniations
15. Miscellaneous types: fibromuscular dysplasia, with local dissection of carotid, middle cerebral, or vertebrobasilar artery, x-irradiation, unexplained middle cerebral infarction in closed head injury, pressure of unruptured saccular aneurysm, complication of oral contraceptives, moyamoya disease
16. Genetic causes in children and young adults and others

and the size of the infarct or hemorrhage. Hemiplegia stands as the most typical sign of cerebrovascular diseases, whether in the cerebral hemisphere or brainstem, but there are many other manifestations, occurring in recognizable combinations. These include paralysis, numbness, and sensory deficits of many types on one side of the body, aphasia, visual field defects, diplopia, dizziness, dysarthria, and so forth. The neurovascular syndromes enable the physician to localize the lesion—sometimes so precisely that even the affected arterial branch can be specified—and to indicate whether the lesion is an infarct or a hemorrhage. These syndromes are described in the sections that follow. This group of diseases has also provided the most instructive approach to localization in neurology. As our colleague C.M. Fisher aptly remarked, neurology is learned “stroke by stroke.” Also, the focal ischemic lesion has divulged some of our most important ideas about the function of the human brain.

The analysis of a stroke involves several steps. First, the clinician must determine whether the event is a stroke rather than some other process that may have a similar sudden onset, such as migraine, seizure, or syncope. Second, if the event is considered likely to be a stroke

Table 34-2

CEREBROVASCULAR DISEASES CHARACTERISTIC OF EACH AGE PERIOD

1. Prenatal circulatory diseases leading to
 - a. Porencephaly
 - b. Hydranencephaly
 - c. Hypoxic-ischemic damage
 - d. Unilateral cerebral infarction
2. Perinatal and postnatal circulatory disorders resulting in
 - a. Cardiorespiratory failure and generalized ischemia—*état marbré*
 - b. Periventricular infarcts
 - c. Matrix hemorrhages and ischemic foci in premature infants
 - d. Hemorrhagic disease of the newborn
3. Infancy and childhood: vascular diseases associated with
 - a. Ischemic infarction
 - b. Congenital heart disease and paradoxical embolism
 - c. Moyamoya disease
 - d. Bacterial endocarditis, rheumatic fever, lupus erythematosus
 - e. Sickle cell anemia
 - f. Mitochondrial disorders (MELAS)
 - g. Homocystinuria and Fabry angiokeratosis
4. Adolescence and early adult life: vascular occlusion or hemorrhage with
 - a. Pregnancy and puerperium
 - b. Estrogen-related stroke
 - c. Migraine
 - d. Vascular malformations
 - e. Premature atherosclerosis
 - f. Arteritis
 - g. Valvular heart disease
 - h. Sickle cell anemia
 - i. Antiphospholipid arteriopathy, plasma C-protein deficiency, and other coagulopathies
 - j. Moyamoya, Takayasu diseases
 - k. Arterial dissections
 - l. Amyloid angiopathy
5. Middle age
 - a. Atherosclerotic thrombosis and embolism
 - b. Cardiogenic embolism
 - c. Primary (hypertensive) cerebral hemorrhage
 - d. Ruptured saccular aneurysm
 - e. Arterial dissection
 - f. Fibromuscular dysplasia
6. Late adult life
 - a. Atherosclerotic thrombotic occlusive disease
 - b. Embolic disease
 - c. Lacunar stroke
 - d. Brain hemorrhage (multiple causes)
 - e. Multiinfarct dementia
 - f. Binswanger disease

MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke.

or TIA, then the pathophysiology must be ascertained (e.g., cerebral embolism from the heart or a proximal artery, large vessel atherothrombotic occlusion, venous occlusive disease). Third, acute treatment (e.g., tissue plasminogen activator) is initiated, if appropriate. Fourth, a plan for the prevention of future strokes is undertaken.

In the last decades, extraordinary imaging technology has been introduced that allow the physician to make physiologic distinctions among normal, ischemic, and infarcted brain tissue. This approach to stroke will likely

guide the next generation of treatments and has already had a pronounced impact on the direction of research in the field. Salvageable brain tissue in the acute phase of stroke can be delineated by these methods. To identify such ischemic but not yet infarcted tissue is a major goal of modern acute stroke medicine. In particular, diffusion-weighted magnetic resonance imaging has already altered the understanding and management of stroke patients.

The introduction of effective treatments for acute stroke has led to greater dependence on these sophisticated imaging techniques, but the authors believe it remains essential for the neurologist to understand the details of the cerebral vascular anatomy and the corresponding stroke syndromes for several reasons. Imaging techniques, though increasingly accurate, are not perfect. In cases in which the imaging does not reveal a stroke, the clinician remains dependent on careful history and neurologic examination. Furthermore, in many parts of the world, imaging techniques are unavailable at the pace necessary to initiate acute treatment. Finally, understanding the detailed anatomy helps the neurologist understand how the nervous system functions, lessons which are applicable to many other categories of illness other than stroke.

Despite these valuable imaging and therapeutic advances in stroke neurology, three points should be made. First, all physicians have a role to play in the prevention of stroke by encouraging the reduction of risk factors, such as hypertension, smoking, and hyperlipidemia and the identification of signs of potential impending stroke, such as transient ischemic attacks, atrial fibrillation, and carotid artery stenosis. Second, careful clinical evaluation integrated with the newer testing methods still provides the most powerful approach to this category of disease. Finally, there has been a departure from the methodical clinicopathologic studies that have been the foundation of our understanding of cerebrovascular disease. Increasingly, randomized trials involving several hundred and even thousands of patients and conducted simultaneously in dozens of institutions have come to dominate investigative activity in this field. These multicenter trials have yielded highly valuable information about the treatment of a variety of cerebrovascular disorders, both symptomatic and asymptomatic. However, this approach suffers from a number of inherent limitations, the most important of which is that the homogenized data derived from an aggregate of patients is difficult to apply to a specific case at hand or the data is not available to resolve each patient's particular problem. Most large studies show only modest or marginal differences between treated and control groups and correspondingly give guidance in large populations. These multicenter studies will be critically appraised at appropriate points in the ensuing discussion.

Differentiation of Stroke from Other Neurologic Illnesses

The diagnosis of a vascular lesion therefore rests essentially on recognition of the stroke syndrome; without

evidence of this, the diagnosis must always be in doubt. The three criteria by which the stroke is identified should be reemphasized: (1) the temporal profile of the clinical syndrome, (2) evidence of focal brain disease, and (3) the clinical setting. Definition of the temporal profile requires a clear history of the premonitory phenomena, the mode of onset, and the evolution of the neurologic disturbance in relation to the patient's medical status. Here, an inadequate history is the most frequent cause of diagnostic error. If these data are lacking, the stroke profile may still be determined by extending the period of observation for a few days or weeks, thus invoking the clinical rule that the physician's best diagnostic tool is a second and third examination. The first distinction is to separate ischemic from hemorrhagic stroke; features that are characteristic of the latter such as headache and vomiting at the onset, rapid progression to coma, and severe hypertension are emphasized in the later section on cerebral hemorrhage. Often, however, the distinction is not so clear because sudden onset of a focal neurologic problem is the core syndrome of both processes.

There are few categories of neurologic disease whose temporal profile mimics that of the cerebrovascular disorders. Migraine may do so, but the history usually provides the diagnosis. A seizure may be followed by a prolonged focal deficit (Todd paralysis) but is rarely the initial event in a stroke; the setting in which these symptoms occur and their subsequent course clarify the clinical situation. Tumor, infection, inflammation, degeneration, and nutritional deficiency are unlikely to manifest themselves precipitously, although rarely a primary or metastatic brain tumor produces a focal deficit of abrupt onset (see later). Trauma, of course, occurs abruptly but usually offers no problem in diagnosis. In multiple sclerosis and other demyelinating diseases, there may be an abrupt onset or exacerbation of symptoms, but for the most part they occur in a different age group and clinical setting. Conversely, a stroke-like onset of cerebral symptoms in a young adult should always raise a suspicion of demyelinating disease. A stroke developing over a period of several days usually progresses in a stepwise fashion, increments of deficit being added abruptly from time to time. A slow, gradual, downhill course over a period of 2 weeks or more indicates that the lesion is probably not vascular but rather neoplastic, demyelinating, infectious (abscess) or granulomatous, or a subdural hematoma.

In regard to the *focal neurologic deficits* of cerebrovascular disease, many of the nonvascular diseases may produce symptoms that are much the same, and the diagnosis cannot rest solely on this aspect of the clinical picture. Nonetheless, specific patterns of neurologic signs are so highly characteristic of vascular occlusion—e.g., the lateral medullary syndrome—that they mark the disease as a stroke. Conversely, certain disturbances are hardly ever attributable to ischemic stroke—e.g., diabetes insipidus, fever, bitemporal hemianopia, parkinsonism, generalized myoclonus, repeated falls, and isolated cranial-nerve palsies—and their presence may be of help in excluding vascular disease. Finally, the diagnosis of cerebrovascular disease should always be made on positive data, not by exclusion.

A few conditions are so often confused with cerebrovascular diseases that they merit further comment. Miscellaneous conditions occasionally taken to be a stroke are migraine; Bell's palsy; Stokes-Adams syncopal attacks; a severe attack of labyrinthine vertigo; diabetic ophthalmoplegia; acute ulnar, radial, or peroneal palsy; embolism to a limb; and temporal arteritis associated with blindness all of which are discussed in later parts of this chapter.

A brain tumor, especially a rapidly growing glioblastoma or lymphoma, may produce a severe hemiplegia rapidly. Also, the neurologic deficit caused by cancer metastatic to the cerebrum may evolve rapidly, almost at a stroke-like pace. Moreover, in rare cases of brain tumor, a hemiplegia may be preceded by transitory episodes of neurologic deficit, indistinguishable from TIAs. The presence of the tumor and its effects on the cerebrum may make it difficult for the patient to articulate a clear history. A lack of detailed history may also be responsible for the opposite diagnostic error, i.e., mistaking a relatively slowly evolving stroke (usually caused by internal carotid artery or basilar occlusion) for a tumor. CT and MRI usually settle the problem. A brain abscess or inflammatory necrotic lesion—e.g., herpes encephalitis or toxoplasmosis—may also develop rapidly.

Contrariwise, certain manifestations of stroke may be incorrectly interpreted as evidence of some other neurologic disorder. *Headache*, at times severe, often occurs as a prodrome of a thrombotic stroke or subarachnoid hemorrhage; unless this is appreciated, a diagnosis of migraine may be made. *Dizzy spells, vertigo, vomiting, or brief intermittent lapses of equilibrium* as a result of vascular disease of the brainstem may be ascribed to vestibular neuritis, Ménière disease, Stokes-Adams syncope, or gastroenteritis. A detailed account of the attack will usually avert this error. A strikingly focal monoplegia of cerebral origin, causing only weakness of the hand or arm or foot-drop, is not infrequently misdiagnosed as a peripheral neuropathy or plexopathy.

Epidemiology of Cerebrovascular Diseases

Stroke, after heart disease and cancer, is the third most common cause of death in the United States. Every year there are in the United States approximately 700,000 cases of stroke—roughly 600,000 ischemic lesions and 100,000 hemorrhages, intracerebral or subarachnoid—with 175,000 fatalities from these causes combined. Since 1950, coincident with the introduction of effective treatment for hypertension, there has been a substantial reduction in the frequency of stroke. Both sexes have shared in the reduced incidence. During this period, the incidence of coronary artery disease and uncontrolled hypertension also fell significantly. By contrast, there has been no change in the frequency of aneurysmal rupture. In the last two decades, according to the American Heart Association, the mortality rate from stroke has declined by 12 percent, but the total number of strokes may again be rising. Stroke assumes importance both because of its high rate of mortality and the residual disability that it causes.

The burden of stroke has far wider implications when viewed from an international perspective. Cerebrovascular disease is estimated to account for 7.8 million deaths yearly throughout the world and represents about 13 percent of all causes of death. In developed countries, stroke mortality is only surpassed by cardiac ischemic diseases and close to equivalent to the cancers collectively (mainly lung cancer) in the most recent Global Burden of Disease study undertaken in 2004. Stroke remains among the five leading causes of death across every income group in most countries in the last comprehensive review by the World Health Organization in 2004. They cause significant physical, emotional, and cognitive disabilities among survivors, accounting for 3.6 percent of the total disability-adjusted life years (DALYs) and thus placing stroke within the 10 leading causes of disability irrespective of the development status of countries (see http://www.who.int/healthinfo/global_burden_disease/GBD_report_2004update_part2.pdf).

Risk Factors for Stroke

This is an area of major public health importance in that several modifiable factors are known to increase the liability to stroke. The most important of these are hypertension, atrial fibrillation, diabetes mellitus, cigarette smoking, and hyperlipidemia. Others, such as systemic diseases associated with a hypercoagulable state and the use of contraceptives, also contribute, but only in special circumstances. Hypertension is also the most readily recognized factor in the genesis of primary intracerebral hemorrhage. It appears that the stroke-producing potential of hypertension is as much the product of heightened systolic pressure, as of diastolic pressure (Rabkin et al). The cooperative studies of the Veterans Administration (see Freis et al) and the report by Collins and associates (collating 14 randomized trials of antihypertensive drugs) convincingly demonstrated that the long-term control of hypertension decreased the incidence of both ischemic infarction and intracerebral hemorrhage. It has been found that simple measures such as the use of hydrochlorothiazide for blood pressure control may be, overall, the most effective. The presence of congestive heart failure and coronary atherosclerosis also increases the probability of stroke. As for embolic strokes, the most important risk factors are structural cardiac disease and arrhythmias, mostly atrial fibrillation, which increases the incidence of stroke about 6-fold, and by 18-fold if, as was common in the past, there is also rheumatic valvular disease.

Diabetes hastens the atherosclerotic process in both large and small arteries. Weinberger and colleagues and Roehmholdt and coworkers found diabetic patients to be twice as liable to stroke as age-matched nondiabetic groups. The importance of long-duration cigarette smoking in the development of carotid atherosclerosis has long been known and was quantitated by Ingall and colleagues. The interactions between diabetes and hypertension on the one hand, and intracerebral hemorrhage and atherothrombotic infarction on the other, as well as the association of cardiac disease and cerebral embolism,

are considered further on in this chapter in relation to each of these categories of cerebrovascular disease. Numerous clinical trials have also shown a marked reduction in stroke incidence with the use of cholesterol-lowering drugs. As in the case of coronary artery disease, the level of low-density lipoprotein (LDL) cholesterol has the most impact on the incidence of stroke but elevated triglycerides may also confer risk. Subsidiary factors, such as low potassium intake and reduced serum levels of potassium, are associated with an increased stroke rate in several studies, including one in which we participated, but the mechanism of this effect is obscure (Green et al); a detrimental effect on blood pressure is possible. Public health measures designed to detect and reduce the aforementioned risk factors offer the most intelligent long-range approach to the prevention of cerebrovascular disease.

Finally, in keeping with the emerging field of genetic risk factors in human disease, several genetic loci have been found that putatively impart a risk of stroke in various populations. The largest of these, reported by Ikram and associates, has implicated a polymorphism on chromosome 12, encompassing several genes that have putative connections to vascular disease. However, other groups, such as the International Stroke Genetics Consortium, were unable to confirm this. It seems likely that more refined definitions of stroke subtypes and careful genotyping of circumscribed populations will be necessary if genetic risk factors for stroke are to be found that are not simply markers for vasculopathy, inducing diseases such as diabetes, hyperlipidemia, and hypertension.

The Major Causes of Cerebral Vascular Occlusion and Ischemic Stroke

Two causes of ischemic stroke stand out: atherosclerotic-thrombotic disease of the cerebral or extracerebral vessels, and cerebral embolism. An understanding of the biology of these two processes is essential for the analysis of the clinical, laboratory, and imaging features of stroke and its treatment. All other causes of vascular occlusion taken together, account for far fewer strokes. These are also important and they are accorded their own sections later in the chapter.

Atherothrombosis

The evolution of clinical phenomena in cerebral thrombosis, both of large intracranial (basilar, carotid) or extracranial (carotid, vertebral) and small vessels (lacunes), is more variable than that of embolism and hemorrhage. In approximately half of patients the stroke is preceded by minor signs or one or more transient attacks of focal neurologic dysfunction, TIAs, discussed further on. These transient *prodromal episodes* may herald the oncoming vascular event caused by atherothrombotic stroke. Occasionally embolism is preceded by a transient neurologic disorder but TIAs are generally considered as more closely aligned with atherothrombotic stroke.

The thrombotic stroke syndrome develops in one of several ways. There may be a single episode, but typically the whole stroke evolves over a few minutes or hours or less. Characteristic is a “stuttering” or intermittent progression

of neurologic deficits extending over several hours or a day or longer. This is a starkly different profile from the abrupt onset of stroke that characterizes the embolic mechanism discussed further on. In thrombosis, a partial stroke may occur and even recede temporarily for several hours, after which there is rapid progression to the completed deficit—or several fleeting episodes may be followed by a longer one and, hours or a day or two later, by a major stroke. Several parts of the body may be affected at once or only one part, such as a limb or one side of the face, the other parts becoming involved serially in step-like fashion until the stroke is fully developed. Sometimes the deficit is episodic; spells of weakness or involuntary movement of a hand or arm or dimness of vision, lasting 5 to 10 min, occur spontaneously or are brought on by standing or walking. Each of the partial attacks may reproduce the profile of the stroke in miniature. In other words, the principle of intermittency seems to characterize the thrombotic process from beginning to end.

Also characteristic of atherothrombotic events in many, but not all cases, is the occurrence of the stroke during sleep; the patient awakens paralyzed, either during the night or in the morning. Unaware of any difficulty, he may arise and fall helplessly to the floor with the first step. This is the story given by half of our patients with thrombotic strokes, as well as by a smaller number with embolic strokes.

Most deceptive are the few instances, in which the neurologic disorder evolves very gradually, over several days or longer (“slow stroke”). One’s first impulse is to make a diagnosis of brain tumor, abscess, or subdural hematoma. This error can usually be avoided by a careful analysis of the course of the illness, which will disclose an uneven, saltatory progression. There are also cases—and these are usually instances of pure motor hemiplegia—in which the evolution of a thrombotic stroke is evenly progressive over a period of days. It is likely also that the abrupt development of a thrombus on an atherosclerotic plaque in a distal cerebral vessel (beyond the circle of Willis) can also cause a fairly sudden or at least rapid evolution of stroke, but this is not characteristic.

Atheromatous plaques preferentially form at branching points and curves of the cerebral arteries. *The most frequent sites are* (1) in the *internal carotid artery* at its origin from the common carotid; (2) in the *cervical part of the vertebral arteries and at their junction to form the basilar artery*; (3) in the *stem or at the main bifurcation of the middle cerebral arteries*; (4) in the *proximal posterior cerebral arteries* as they wind around the midbrain; and (5) in the *proximal anterior cerebral arteries* as they pass anteriorly and curve over the corpus callosum. The last two sites are far less frequent than the first three. It is infrequent for the cerebral arteries to develop significant plaques beyond their first major branching after the circle of Willis. Also, it is unusual for the cerebellar and ophthalmic arteries to show atheromatous involvement. The common carotid and vertebral arteries at their origins from the aorta are additional frequent sites of atheromatous deposits, but because of abundant collateral arterial pathways, occlusions at these sites are less commonly associated with cerebral ischemia as discussed further on.

Atherothrombosis may cause cerebral infarction in several ways. The most obvious is that an occlusive plaque or a thrombus formed on a plaque occupies the lumen of a major intracerebral vessel, such as the middle cerebral artery, and stops flow to the areas of the brain supplied by the vessel. A variation of this mechanism is one of occlusion by atherosclerosis of a more proximal vessel, such as the distal carotid artery. This leads to infarction in the territory between major branches of the internal carotid circulation that are most susceptible to reduced blood flow—termed “watershed infarction.” Or, an atherothrombotic lesion in a proximal vessel may serve as the nidus for the formation of an embolus that manifests itself as a stroke in one of the territories of that vessel—called “artery-to-artery” embolism. The essential issue here is that it is almost always severe stenosis of a proximal internal carotid artery that produces either ischemic or embolic stroke; milder degrees are usually not implicated. A separate mechanism pertains when an atherosclerotic plaque in a large vessel of the circle of Willis occludes the orifices of small penetrating vessels, most often the lenticulostriate branches of the middle cerebral artery or the thalamostriate vessels of the posterior cerebral artery, and cause small, or more confluent, strokes deep in the brain.

Whether plaque rupture plays a role in vessel occlusion or thrombus formation, as it does in the coronary artery, is not clear. In the carotid artery, Hosseini and coworkers found evidence of intraplaque hemorrhage using special MRI techniques and found these changes to be predictive of stroke in the distal distribution of the artery. Previous work by Fisher and Ojemann, cited in the references, involving the serial sectioning of carotid plaques removed at surgery, suggested otherwise. It is clear that the more severe the focal atheromata, the more likely a thrombotic complication will occur. Whether the complexity of a carotid artery plaque with ulcerations is an important component of stroke risk, for example, by originating small emboli, is not entirely settled. Again, it is the high degree of stenosis, usually above 90 percent of the original lumen compromised, or a residual lumen of less than approximately 2 mm, of the carotid artery that is most likely to be associated with strokes in the distal territory of the vessel.

Atheromatous lesions may regress to some extent under the influence of diet and lipid-lowering drugs. Hennerici and colleagues followed a series of patients with carotid stenosis for a period of 18 months and observed spontaneous regression in nearly 20 percent of the lesions. In the large majority of cases, however, atherosclerosis is a progressive disease.

The hemostatic elements, both clotting factors and platelets, which produce a thrombus within a vessel are complex and have been the object of intense study (see Furie and Furie for a discussion of this field). However, just as in the case of coronary artery disease, it is often the development and enlargement of the thrombus that acts as the final element in cerebral vascular occlusion and an ischemic stroke. It seems plausible, although not adequately studied, that the temporal profile of atherothrombotic stroke reflects this accretion of clot in a vessel.

These biologic mechanisms have bearing on the treatment and prevention of stroke.

Cerebral Embolism

This is the most common cause of ischemic strokes and of all the types of stroke, cerebral embolism develops most rapidly, “like a bolt out of the blue.” As a rule, the full-blown picture evolves within seconds, exemplifying most perfectly the idealized temporal profile of a stroke. Although the abruptness with which the stroke develops and the lack of prodromal symptoms point strongly to embolism, the diagnosis is based on the total clinical circumstances. Embolism always merits careful consideration in young persons, in whom atherosclerosis is less common. Only occasionally does the problem unfold more gradually, over many hours, with some fluctuation of symptoms. Possibly, in these cases the embolus initiates a propagating thrombotic process in the occluded vessel.

In most cases, the embolic material consists of a fragment that has broken away from a thrombus within the heart (“cardioembolic”). Somewhat less frequently, the source is intraarterial from the distal end of a thrombus within the lumen of an occluded or severely stenotic carotid or vertebral artery, or a clot that originates in the systemic venous system and passes through an aperture in the heart walls, or the origin of an embolus may be from large atheromatous plaques in the aorta. Thrombotic or infected material (endocarditis) that adheres to the aortic or mitral heart valves and breaks free are also well-appreciated sources of embolism, as are clots originating on prosthetic heart valves. Embolism caused by fat, tumor cells (atrial myxoma), fibrocartilage, amniotic fluid, or air enters into the differential diagnosis of stroke only in special circumstances.

The embolus usually becomes arrested at a bifurcation or other site of natural narrowing of the lumen of an intracranial vessel. The resultant infarction is pale, hemorrhagic, or mixed; hemorrhagic infarction nearly always indicates embolism (although venous occlusion can do the same). Any region of the brain may be affected, the territories of the middle cerebral artery, particularly the superior division, being most frequently involved. The two cerebral hemispheres are approximately equally affected. Large embolic clots can block large vessels (e.g., the carotid arteries in the neck or at their termination intracranially), while tiny fragments may reach vessels as small as 0.2 mm in diameter, usually with inconsequential effects. The embolic material may remain arrested and plug the lumen solidly, but more often it breaks into fragments that enter smaller vessels so that even careful pathologic examination fails to reveal their final location. In this instance, the clinical effects may abate. Because of the rapidity with which embolic occlusion develops, useful collateral influx does not become established. Thus, sparing of the brain territory distal to the site of occlusion is usually not as evident as in thrombosis that develops more slowly.

According to the Framingham Heart Study, patients with chronic atrial fibrillation are approximately six times more liable to stroke than an age-matched population with normal cardiac rhythm (Wolf et al, 1983) and the

risk is considerably higher if there is also rheumatic valvular disease, now far less prevalent than in the past. Furthermore, the risk for stroke conferred by the presence of atrial fibrillation varies with age, being 1 percent per year in persons younger than age 65 years, and as high as 8 percent per year in those older than age 75 years with additional risk factors. These levels of risk are of prime importance in determining the potential benefit of chronic anticoagulation, as discussed later. Embolism may also occur in cases of paroxysmal atrial fibrillation or flutter and various studies have suggested that the risk of stroke is even greater than for the chronic arrhythmia. Even more vexing, intermittent and asymptomatic atrial fibrillation is difficult to detect except with long periods of rhythm monitoring. For example, in a study of patients with implanted pacemakers or defibrillators but not known to have atrial fibrillation by Healy and colleagues, a substantial number of atrial arrhythmias were uncovered and raised the risk of stroke fivefold. In related studies by Gladstone and coworkers and by Gaillard and colleagues, suggest that recording heart rhythm for longer periods with a loop monitor increases the rate of detection of episodic atrial fibrillation to approximately 15 percent, from approximately 3 percent with conventional Holter monitoring. Whether such long-term monitoring should be adopted in routine practice is not yet certain, but it is being increasingly added in the evaluation of "cryptogenic" stroke.

Several scoring systems have been developed to gauge the future likelihood of stroke from atrial fibrillation. The CHADS₂ and related systems are shorthand methods to quantitate the risk factors that modulate risk for stroke in a patient with atrial fibrillation. A refinement of this system, CHA₂DA₂-VASC is purported to improve these predictions but the confidence intervals around the point estimates of predictive values in both scales are considerable and clinical judgment must be exercised in their use. This is reflected in part by the observation that the second score does not confer increased risk of stroke in a continuous fashion with each increase in score. The scores, subject to replacement by future ones, are given in Table 34-3. Furthermore, the goal of most of these systems is to make choices regarding warfarin or similar anticoagulation for the prevention of embolic stroke from the arrhythmia as discussed later in the chapter, or as pertinently to identify patients who have such a low risk of stroke that the risks of anticoagulation may not be justified. Epidemiologic and clinical aspects of the protective effects of anticoagulation have their own imprecisions.

Mural thrombus deposited on the damaged endocardium overlying a myocardial infarct in the left ventricle, particularly if there is an aneurysmal sac, is an important source of cerebral emboli, as is a thrombus associated with severe mitral stenosis without atrial fibrillation, now a far less common circumstance than when rheumatic fever was prevalent. Emboli may occur in the first few weeks after an acute myocardial infarction but Loh and colleagues found that a lesser degree of risk persists for up to 5 years. Cardiac catheterization or surgery, especially valvuloplasty, may disseminate fragments from a thrombus or a calcified valve. Mitral and aortic

Table 34-3

SCORING SYSTEMS TO PREDICT THE RISK OF STROKE IN PATIENTS WITH ATRIAL FIBRILLATION (CHADS₂ AND CHA₂DA₂-VASC)

CHADS ₂	POINTS ASSIGNED FOR EACH ITEM	PREDICTED YEARLY STROKE RISK BY TOTAL SCORE
Congestive heart failure	1	0.... 1.9%
Hypertension	1	1..... 2.8%
Stroke, TIA in past	2	2..... 4.0%
Vascular disease	1	3... 5.9%
Diabetes	1	4... 8.5%
Female	1	5.. 12.5%
Age		
<65 years	0	4.... 8.5%
65-74 years	1	5.....12.5%
>75 years	2	6....18.2%

CHA ₂ DA ₂ -VASC	POINTS ASSIGNED FOR EACH ITEM	0.... 0%
Heart failure or ejection fraction <35%	1	1..... 1.3%
Hypertension	1	2..... 2.2%
Age <65 years	0	3..... 3.2%
66-74 years	1	
>75 years	2	
Previous stroke or TIA	2	4..... 4.0%
Diabetes	1	5.....6.7%
Coronary or peripheral vascular disease	1	6..... 9.8%
Female	1	7..... 6.9%
		8..... 6.7%
		9..... 15.5%

valve prostheses are, as mentioned, additional important sources of embolism.

Another source of embolism is the carotid or vertebral artery, where clot forming on an ulcerated atheromatous plaque may be detached and carried to an intracranial branch (artery-to-artery embolism). A similar phenomenon occurs with arterial dissections, discussed in a later section, "Less Common Causes of Ischemic Cerebrovascular Disease," and sometimes with fibromuscular disease of the carotid or vertebral arteries.

Atheromatous plaques in the ascending aorta have been recognized to be a more frequent source of embolism than had been previously appreciated. Amarenco and colleagues reported that as many as 38 percent of a group of patients with no discernible cause for embolic stroke had echogenic atherosclerotic plaques in the aortic arch that were greater than 4 mm in thickness, a size found to be associated on a statistical basis with strokes. Disseminated cholesterol emboli from the aorta are known to occur in the cerebral circulation and may be dispersed to other organs as well; rarely, this is sufficiently severe to cause an encephalopathy and pleocytosis in the spinal fluid.

Also of interest are the symptoms caused by an embolus as it traverses a large vessel. This *migrating or traveling embolus syndrome* is most evident in cases of

posterior cerebral artery occlusion, either from a cardiogenic source or from a thrombus in the proximal vertebral artery ("artery-to-artery" embolism; see Koroshetz and Ropper). Minutes or more before the hemianopia develops, the patient reports fleeting dizziness or vertigo, diplopia, or dysarthria, the result of transient occlusion of the origins of penetrating vessels as the clot material traverses the basilar artery. Small residual areas of infarction within the brainstem or cerebellum can be seen on MRI or found at autopsy, and some of the signs of brainstem infarction may persist. The basilar artery is singularly susceptible to this syndrome because the vertebral arteries are smaller in caliber than the basilar, allowing a clot to slowly traverse the larger vessel; furthermore, a clot in the basilar artery is prone to occlude the small orifices of arteries that supply blood to the brainstem.

Paradoxical embolism occurs when an abnormal communication exists between the right and left sides of the heart (particularly a patent foramen ovale [PFO]) or the alternative route of connection via a pulmonary arteriovenous fistula. Embolic material arising in the veins of the lower extremities or pelvis or elsewhere in the systemic venous circulation bypasses the pulmonary circulation and reaches the cerebral vessels. Pulmonary hypertension (often from previous pulmonary embolism) favors the occurrence of paradoxical embolism, but these strokes occur even in the absence of pulmonary hypertension. Several studies indicate that the presence of a small atrial septal aneurysm adjacent to the patent foramen increases the likelihood of stroke. In the series reported by Mas and colleagues (2001), patients ages 18 to 55 years who had a stroke were followed for 4 years; the risk of second stroke was 2 percent in those with a PFO alone and 15 percent among those with both a PFO and an atrial septal aneurysm (curiously, the risk among those with neither congenital abnormality was 4 percent—higher than for those with a PFO alone). This mechanism comes into play mainly in considering the causes of stroke in the younger patient, but Handke and colleagues published a series in which there was a slightly increased risk of stroke in patients who were older than age 55 and had PFO. It must be emphasized, however, that about one-third of patients in all age groups will be found to have a PFO, and anticoagulation or repair of these lesions in older patients with embolic stroke has not been shown to be beneficial (see further on for discussion of treatment of PFO). Subendocardial fibroelastosis, idiopathic myocardial hypertrophy, cardiac myxomas, and myocardial lesions of trichinosis are additional rare causes of embolism from a cardiac source. The vegetations of infective and noninfective (marantic) endocarditis give rise to several different lesions in the brain as described in Chap. 32.

Mitral valve prolapse, in the past considered a common source of emboli, especially in young patients, is no longer currently thought to be an important origin. The initial impetus for considering this abnormality as a source of embolus came from the study of Barnett and colleagues (1980) of a group of 60 patients who had TIAs or small strokes and were younger than 45 years of age; mitral prolapse was detected (by echocardiography and

a characteristic midsystolic click) in 24 patients, but in only 5 of 60 age-matched controls. However, several subsequent large studies (Sandok and Giuliani; Jones et al) found that only a very small proportion of strokes in young patients could be attributed to prolapse; even then, the connection was inferred by the exclusion of other causes of stroke. Indeed, in a study using stringent criteria for the echocardiographic diagnosis of prolapse, Gilon and colleagues were unable to establish a relation to stroke. Usually, when valvular prolapse is associated with stroke, it is usually severe with ballooning of the valve and a propensity to accumulate clot behind the valve. Of interest, Rice and colleagues described a family with premature stroke in association with valve prolapse and a similar relationship has been reported in twins; the same may occur in Ehlers-Danlos disease.

The *pulmonary veins* are a potential, if infrequent, source of cerebral emboli, as reflected by the occurrence of cerebral abscesses in association with pulmonary infectious disease (and by the high incidence of cerebral deposits secondary to pulmonary carcinoma). In Osler-Weber-Rendu disease, pulmonary shunts serve as a conduit for emboli. A rare type of embolism follows thyroidectomy, where thrombosis in the stump of the superior thyroid artery extends proximally until a section of the clot, protruding into the lumen of the carotid artery, is carried into the cerebral circulation.

During *cerebral arteriography*, emboli may arise from the tip of the catheter, or manipulation of the catheter may dislodge atheromatous material from the aorta or carotid or vertebral arteries and account for some of the strokes during this procedure. Monitoring of the cerebral arteries by transcranial Doppler insonation has suggested that small emboli frequently arise during angiographic procedures. For example, a study by Bendszus and colleagues found that 23 of 100 consecutive patients had new cortical lesions shown on diffusion-weighted MRI just after cerebral arteriography. However, none of these patients was symptomatic, and with good technique, emboli from vascular catheters are infrequent.

Cerebral embolism of special type must always have occurred when secondary metastatic tumor is deposited in the brain but a mass of tumor cells is seldom large enough to occlude a cerebral artery and produce the picture of a stroke. Nevertheless, tumor embolism with stroke is known from cardiac myxoma and fibroelastoma, and occasionally with other tumors, even systemic ones; in some of these cases it is a thrombus in the primary lesion that offers a source of embolism. This syndrome must be distinguished from embolism caused by nonbacterial endocarditis that complicates malignant neoplasms (nonbacterial thrombotic endocarditis is discussed further on). This special source of cerebral embolism is a component of a hypercoagulable state that especially accompanies adenocarcinoma and cachexia.

Diffuse cerebral *fat embolism* is related to severe bone trauma. As a rule, the emboli are minute and widely dispersed, giving rise first to pulmonary symptoms and then to multiple dermal (anterior axillary fold and elsewhere) and cerebral petechial hemorrhages. Accordingly, the clinical picture is more of an encephalopathy and

not strictly focal as it is in a stroke, although in some instances there may be focal features. Cerebral *air embolism* is a rare complication of abortion, scuba diving, or cranial, cervical, or thoracic operations involving large venous structures or venous catheter insertion; it was formerly encountered as a complication of pneumothorax therapy. Clinically, cerebral air embolism may be difficult to separate from the deficits following hypotension or hypoxia with which it frequently coexists. Hyperbaric treatment may be effective if instituted early.

Despite the large number of established sources of emboli, the point of origin cannot be determined in 20 to 30 percent or more of presumed embolic strokes. In such cases, emboli likely have originated from thrombi in the cardiac chambers but have left behind no residual clot and may be undetectable even by sophisticated methods, such as transesophageal echocardiography and newer MR techniques. Other cases may be a result of atheromatous material arising from the aorta or paradoxical embolism. If extensive evaluation fails to disclose the origin, the odds still favor a source in the left heart. Often, the diagnosis of cerebral embolism is made at autopsy without finding a source. In these cases, one presumes that the search for a thrombotic nidus may not have been sufficiently thorough and small thrombi in the atrial appendage, endocardium (between the papillary muscles of the heart), the aorta and its branches, or pulmonary veins may have been overlooked. Nevertheless, the source of embolic material is not revealed in a number of cases.

Transient Ischemic Attacks (TIAs)

When brief ischemic attacks precede a stroke but disappear entirely, leaving no clinical or imaging trace of cerebral infarction, they almost always stamp the underlying process as atherothrombotic involving a large or small blood vessel. Transient ischemic attacks can reflect the involvement of virtually any cerebral artery: common or internal carotid; middle, posterior, or anterior cerebral; ophthalmic; vertebral, basilar, or cerebellar; or a penetrating branch to the internal capsule, thalamus, or brainstem (lacunar TIAs). Thus, they may present themselves as transient spells of hemiparesis, aphasia, numbness or tingling on one side of the body, dysarthria, diplopia, ataxia, obscuration of a visual field, or combinations thereof that replicate the stroke syndromes. TIAs may precede, accompany, or infrequently follow the development of a stroke, or they can occur by themselves without leading to a stroke—a fact that makes any form of therapy difficult to evaluate. Transient ischemic episodes must be distinguished from other brief neurologic attacks that are from seizures, migraine and its variants, transient global amnesia, syncope, vertigo from labyrinthine disease, and psychogenic episodes as emphasized further on. The differentiation of TIAs from other similar transient spells is not always straightforward and occupies considerable attention from neurologists; the implications of these distinctions have serious implications with regard to evaluation and treatment.

Although there is little doubt that TIAs are caused by transient focal ischemia, their mechanism is not

fully understood. Current opinion holds that TIAs are brief, reversible episodes of focal ischemic brain disturbance without evidence of cerebral infarction. The consensus had in the past been that their duration should be less than 24 h, an idea introduced 40 years ago by a committee assigned to study the problem. It is more useful clinically to separate attacks that last only a few minutes (up to 1 h) and leave no permanent signs, from those of longer duration, which are almost invariably a result of embolism that shows evidence of infarction on imaging studies and therefore carry an entirely different connotation than briefer TIAs. Whether to redefine TIAs by the presence or absence of imaging abnormalities after a transient focal neurologic episode may be semantic because, in either case, embolus or atherosclerosis may be responsible for the following stroke and the evaluation for the source of the difficulty is essentially the same in both circumstances.

In the clinical analysis of TIAs, it is also useful to separate a single transient episode from repeated ones that are all of uniform type. The latter are more a warning of impending vascular occlusion, particularly of the internal carotid artery, whereas the former, especially when prolonged, are again often caused by an embolus that leaves no lasting clinical effect. Prolonged, fluctuating TIAs are the most ominous. Approximately 20 percent of infarcts that follow TIAs occur within a month after the first attack, and approximately 50 percent within a year (Whisnant et al). In an attempt to provide a predictive tool, various scales have been devised, among them the “ABCD” system devised by Rothwell and colleagues (2005) and derivatives of this scale. Blood pressure, unilateral weakness, speech disturbance, and the duration of symptoms (all less than 1 h) are added to produce a predictive score for stroke within 1 week. Studies subsequent to the original one have given variable sensitivities, for which reason this interesting approach must be considered in clinical context. In the original study, unilateral weakness and duration lasting over an hour were most predictive of stroke. The problem of determining the cause of a prolonged TIA has been alluded to—many of these cases are a result of emboli.

In a prospective study of a large group of patients with TIAs caused by atherosclerotic vascular disease, the 5-year cumulative rate of fatal or nonfatal cerebral infarction was 23 percent (Heyman et al). Interestingly, the rate of myocardial infarction in this group of patients, particularly in those with carotid lesions, was almost as high (21 percent), and in other series it has exceeded the risk of stroke. Thus the occurrence of carotid TIAs is a predictor not only of cerebral infarction but also of myocardial infarction. About two-thirds of all patients with TIAs are men with hypertension, reflecting the higher incidence of atherosclerosis in this group. Occasionally, in younger adults, TIAs may occur as relatively benign phenomena, without recognizable features of atherosclerosis or risk factors for it. Migraine is suspected in such patients (see further on); other such instances are a result of special hematologic disorders such as the antiphospholipid antibody discussed later in the chapter.

It should also be pointed out that blood diseases that cause excessive viscosity or sludging of blood (polycythemia vera, sickle cell disease, thrombocytosis, leukemia, and hyperglobulinemic states) may also cause TIAs prior to a stroke.

Transient Monocular Blindness

In the transient ischemic attack of the eye, *transient monocular blindness* (also called *amaurosis fugax* or *TMB*) is the usual symptom. Most of the visual episodes evolve swiftly, over 5 to 30 s, and are described as a horizontal shade falling (or rising) smoothly over the visual field until the eye is completely but painlessly blind. The attack clears slowly and uniformly. Sometimes the attack takes the form of a wedge of visual loss, sudden generalized blurring, or, a gray or bright light obscuring vision. Transient attacks of monocular blindness are usually more stereotyped with repeated episodes than are hemispheric attacks. TIAs consisting of a homonymous hemianopia should suggest a stenosis of the posterior cerebral artery but it is often difficult for the patient to make the distinction from monocular blindness.

The implications of amaurosis fugax have been evaluated by several investigators and found not to be quite as ominous as those of hemispheric TIAs, particularly in younger patients. Poole and Ross Russell observed a group of 110 patients for periods of 6 to 19 years following an episode of amaurosis fugax (exclusive of the type caused by cholesterol emboli). At the end of 6 years, the mortality rate (mainly because of heart disease) was 21 percent, but the incidence of stroke was 13 percent (compared to expected figures of 15 and 3, respectively, percent in an age-matched population). Of the patients who were alive at the end of the observation period, 43 percent had had no further attacks of amaurosis fugax following the initial episode. Noteworthy also was the finding that among patients with normal carotid arteriograms, only 1 of 35 had had a stroke during the followup period, whereas stroke had occurred in 8 of 21 patients in whom the internal carotid artery was occluded or stenotic. As pointed out by Benavente and colleagues, the risk of stroke over the 3 years following an attack is as low as 2 percent if there are no other issues such as diabetes, but it may be as high as 24 percent in older patients with risk factors for atherosclerosis. Tippin and coworkers reviewed the records of 83 patients with onset of amaurosis fugax before the age of 45 years and found evidence of stroke in none; moreover, 42 of these patients were examined after a mean period of 5.8 years during which no stroke had occurred. It is evident that in this younger group a mechanism other than atherosclerosis was operative, such as migraine or an antiphospholipid antibody (discussed further on).

It is perhaps not surprising that the risk of stroke after transient monocular blindness is lower than for cerebral TIAs from carotid atherosclerotic disease. The size of particulate material that occludes the ophthalmic and its branches' vessels is so small that a similar event in the cerebral hemispheres would be less likely to produce symptoms. Furthermore, ischemia of the retina produces symptoms that are hard for the patient

to ignore. While there are other underlying causes of TMB, these notions taken together could explain a large part of the difference in risk between conventional TIA and TMB.

Lacunar Transient Ischemic Attacks

It has been recognized that strokes caused by occlusion of small penetrating vessels of the brain have a propensity to be intermittent ("stuttering") at their onset and occasionally to allow virtually complete restitution of function between discrete episodes. Whether this constitutes a "lacunar TIA" has been debated, but it seems to us that the more important problem is our inability to distinguish a transitory occlusion of a small vessel from that of a larger vessel. Donnan and colleagues (1993) speak of a "capsular warning syndrome," which we have seen a number of times, consisting of escalating episodes of weakness in the face, arm, and leg and culminating in a capsular lacunar stroke. We conclude that lacunar symptoms at their onset may stutter or remit for hours or days, and there is no doubt that one or many of them may precede a lacunar stroke. Nevertheless, the basic pattern of a small deep stroke remains identifiable in mild form; partial syndromes that simulate cortical TIA are less common. Lacunar stroke is discussed extensively further on.

Mechanism of Transient Ischemic Attacks

The question here, so far not satisfactorily answered, is whether reduced blood flow or embolic particles are responsible for TIAs. Whatever the cause of the attacks, they are in most cases intimately related to vascular stenosis and, usually, to ulceration as a result of atherosclerosis and thrombus formation. Embolization of fibrin-platelet material from atherosclerotic sites indeed may be the cause of attacks in some cases, but it is difficult to understand how attacks of identical pattern could be caused by successive emboli from a distance that enter the same arterial branch each time. Moreover, one would expect the involved cerebral tissue to be at least partially damaged by embolism, leaving some residual signs. When a single transient episode has occurred, particularly if prolonged, the factor of recurrence does not enter into the diagnosis, and cerebral embolism must, of course, then be considered. In some cases of documented embolism, the neurologic state fluctuates from normal to abnormal repeatedly for as long as 36 h, giving the appearance of TIAs ("accelerated TIAs"); in others, a deficit of several hours' duration occurs, fulfilling the traditional (now largely discarded) criterion for TIAs. As already noted, the same sequence of events can precede lacunar infarction and seem far more likely to be the result of locally reduced blood flow than to recurrent emboli. *Restated, a single transitory episode, especially if it lasts longer than 1 h, and multiple episodes of different pattern, suggest embolism and must be distinguished from brief (2- to 10-min) recurrent attacks of the same clinical pattern, which suggest TIAs from atherosclerosis and thrombosis in a large vessel.*

Ophthalmoscopic observations of the retinal vessels made during episodes of transient monocular blindness may infrequently show either an arrest of blood flow

in the retinal arteries and breaking up of the venous columns to form a "boxcar" pattern or scattered bits of white material temporarily blocking the retinal arteries. These observations indicate that in some cases of ischemic attacks involving the retinal vessels, a temporary, complete, or relatively complete cessation of blood flow occurs locally. Whether this is a result of platelet or fibrin emboli or of platelet aggregation in situ because of decreased perfusion pressure remains unsettled.

On the other hand, exercise and postural TIAs, when they do occur, are particularly suggestive of stenosis of aortic branches, as occurs in Takayasu disease (see further on) and in dissection of the aortic arch and, occasionally, in a fixed atherosclerotic carotid stenosis. TIAs induced by hyperventilation are said to be characteristic of moyamoya disease, a progressive stenosis of intracranial vessels discussed in a later section.

In states of anemia, polycythemia, thrombocythemia, extreme hyperlipidemia, hyperviscosity from macroglobulinemia, sickle cell anemia, and extreme hyper- or hypoglycemia, there may be transient neurologic deficits related to rheologic or other changes in blood, as already mentioned. In some of these cases, the metabolic or rheologic change appears to have brought out symptoms of stenosis in a large or small vessel, but just as often the vasculature is normal. Patients with antiphospholipid antibodies may have TIAs, the mechanism of which is undefined.

In some instances the TIAs begin after the artery has already been occluded by thrombus. As shown by Barnett, emboli may arise from the distal end of the thrombus or enter the upper part of the occluded vessel through a collateral artery. However, almost one-fifth of "carotid TIAs" in the series of Pessin and colleagues (1977), and a somewhat larger proportion of cases reported by Ueda and coworkers, had neither stenosis nor ulceration of the carotid arteries. In most of the cases with normal carotid arteries, the ischemic attacks exceeded 1 h in duration, suggesting embolism from the heart or great vessels including the aortic arch; but there were also a small number of brief ischemic attacks that were unexplained even after arteriography.

In general, hemodynamic changes in the retinal or cerebral circulation make their appearance when the lumen of the internal carotid artery is reduced to 2.0 mm or less (normal diameter, 7.0 mm; range, 5 to 10 mm, lower part of this range in women). This corresponds to a reduction in cross-sectional area of the vessel of more than 95 percent. The exact degree of stenosis that may cause TIAs and the risk of stroke with mild and moderate degrees of stenosis are controversial and are addressed further on.

Differential Diagnosis of TIA

Transient focal neurologic symptoms are ubiquitous in neurologic practice. They may be a result of seizures, migraine, syncope, or other conditions such as transient global amnesia (see Chap. 21), and they occur occasionally in patients with multiple sclerosis. The clinical setting in which they occur assists in making clear the nature

of the attack. Furthermore, transient and reversible episodes of focal cerebral symptoms, indistinguishable from TIAs, are known to occur in patients with meningioma, glioblastoma, metastatic brain tumors situated in or near the cortex, and even with subdural hematoma. Although infrequent, these attacks are important mainly because the use of anticoagulants is relatively contraindicated in some of these circumstances. We have seen these episodes mainly with meningiomas and subdural hematomas; they have consisted of transient aphasia or speech arrest lasting from 2 min to several hours, but sensory symptoms with or without spread over the body, arm weakness, and hemiparesis have also been reported. Some remarkable cases of meningioma have involved repeated transient attacks for decades. Seizures are always suspected in these cases but are rarely proved. It has been speculated that a local vascular disturbance of some kind is operative, but the mechanism is not understood. As far as we can determine, mass lesions have not caused episodes that simulate posterior circulation TIAs.

The issue of the uncertainty regarding vertigo alone as a manifestation of a TIA referable to the basilar or vertebral artery was addressed in Chap. 15. There are occasional cases in which multiple brief episodes of vertigo, lasting perhaps a minute or less and fluctuating in intensity, may be interspersed with additional signs of brainstem ischemia. Careful questioning of the patient usually settles the question but imaging may be necessary in cases where uncertainty remains. Even then, more instances of vertigo than are justified are attributed to atherosclerotic disease in the posterior vessels. In some patients, the complaint of "dizziness" will prove, however infrequently, to be part of a carotid TIA; hence this symptom, in our experience and that of Ueda and associates, is not a totally reliable indicator of the vascular territory involved. According to Ross Russell, so-called drop attacks (see Chap. 7) have been recorded in 10 to 15 percent of patients with vertebrobasilar insufficiency but we have never observed such attacks as a recurrent ischemic phenomenon or a manifestation of other forms of cerebrovascular disease and the syndrome has usually been due to syncope, seizure, or has been of obscure origin.

Pathophysiology of Ischemic Infarction

Cerebral infarction basically comprises two pathophysiologic processes: one, a loss of the supply of oxygen and glucose secondary to vascular occlusion, and the other, an array of changes in cellular metabolism consequent to the collapse of energy-producing processes, ultimately with disintegration of cell structures and their membranes, a process subsumed under the term necrosis. Of potential therapeutic importance are the observations that some of the cellular processes leading to neuronal death are not irrevocable and may be reversed by early intervention, either through restoration of blood flow, by prevention of the influx of calcium into cells, or by interdicting intermediary processes involved in cell death.

At the center of an ischemic stroke is a zone of infarction. The necrotic tissue swells rapidly, mainly because of excessive intracellular water content (cytotoxic edema). Because anoxia also causes necrosis and swelling of cerebral tissue, oxygen lack must be a factor common to both infarction and anoxic encephalopathy. The effects of ischemia, whether functional and reversible or structural and irreversible, depend on its degree and duration. The margins of the infarct are hyperemic, being supplied by meningeal collaterals, and here there is only minimal or no parenchymal damage.

Implicit in discussions of ischemic stroke and its treatment is the existence of a “penumbra” zone that is marginally perfused and contains at-risk but viable neurons. Presumably this zone exists at the margins of an infarction, which at its core has irrevocably damaged tissue that is destined to become necrotic. Using various methods, such a penumbra can be demonstrated in association with some infarctions but not all, and the degree of reversible tissue damage is difficult to determine. The neurons in the penumbra are considered to be physiologically “stunned” by moderate ischemia and subject to salvage if blood flow is restored in a certain period of time. Olsen and colleagues demonstrated hypoperfused penumbral zones but, interestingly, found that regions just adjacent to them are hyperperfused. These concepts find a parallel in attempts to demonstrate by imaging matching of perfusion and infarction (detected by diffusion-weighted images on MRI) in patterns with acute stroke as discussed in the section on treatment. Elevating the systemic blood pressure or improving the rheologic flow properties of blood in small vessels by hemodilution improves flow in the penumbra; however, attempts to use these techniques in clinical work have met with mixed success.

Vascular Factors

The effects of a focal arterial occlusion on brain tissue vary depending on the location of the occlusion and on available collateral and anastomotic channels. In occlusion of the internal carotid artery in the neck, there may be anastomotic flow through the anterior and posterior communicating arteries of the circle of Willis from the external carotid artery through the ophthalmic artery or via other smaller external-internal connections (Fig. 34-1). With blockage of the vertebral artery, the anastomotic flow may be via the deep cervical, thyrocervical, or occipital arteries or retrograde from the other vertebral artery and again through the posterior communicating arteries. If the occlusion is in the stem portion of one of the cerebral arteries, i.e., distal to the circle of Willis, a series of meningeal interarterial anastomoses may carry sufficient blood into the compromised territory to lessen ischemic damage (Fig. 34-2). There is also a capillary anastomotic system between adjacent arterial branches, and although it may reduce the size of an ischemic territory, it is usually not adequate to prevent infarction. Thus, in the event of occlusion of a major arterial trunk, the extent of infarction ranges from none at all to the entire vascular territory of that vessel. Between these two extremes are all degrees of variation in the extent of infarction and its degree of completeness.

The phenomenon of cerebrovascular *autoregulation* is appropriately introduced here. Over a range of mean blood pressures of approximately 50 to 150 mm Hg, the small pial vessels are able to dilate and to constrict in order to maintain cerebral blood flow (CBF) in a relatively narrow range. This accommodation eventually fails at the extremes of blood pressure, after which CBF follows systemic pressure passively, either falling precipitously or rising to levels that damage the walls of small vessels. The conditions in which the limits of autoregulation are exceeded are at the extremes of hypertensive encephalopathy at one end and circulatory failure at the other, both of which are discussed in later sections of the chapter.

If brain tissue is observed in experimental circumstances at the time of arterial occlusion, the venous blood is first seen to darken, owing to an increase in deoxygenated hemoglobin. The viscosity of the blood and resistance to flow both increase, and there is sludging of formed blood elements within vessels. The tissue becomes pale. Arteries and arterioles become narrowed. Upon reestablishing flow in the occluded artery, the sequence is reversed and there may be a slight hyperemia.

Metabolic and Physiologic Factors

Many of these factors relating to cerebral blood flow have been studied by Heiss and by Siesjo and others and are reviewed in detail by Hossman. They have determined the critical threshold of CBF, measured by xenon clearance, below which functional impairment occurs. In several animal species, including macaque monkeys and gerbils, the critical level was 23 mL/100 g/min (normal is 55); if, after a short period of time, CBF is restored to higher levels, the impairment of function can be reversed. Reduction of CBF below 10 to 12 mL/100 g/min causes infarction, almost regardless of its duration. The critical level of hypoperfusion that abolishes function and leads to tissue damage is therefore a CBF between 12 and 23 mL/100 g/min. At these levels of blood flow the electroencephalogram (EEG) is slowed, and below this level it becomes isoelectric. In the region of marginal perfusion, the K level increases (as a result of efflux from injured depolarized cells) and adenosine triphosphate (ATP) and creatine phosphate are depleted. These biochemical abnormalities are reversible if the circulation is quickly restored to normal. Disturbance of calcium ion homeostasis and accumulation of free fatty acids interfere with full recovery of cells. A CBF of 6 to 8 mL/100 g/min causes marked ATP depletion, increase in extracellular K, increase in intracellular Ca, and cellular acidosis, invariably leading to histologic signs of necrosis. These changes do not become apparent for several hours. Free fatty acids (appearing as phospholipases) are activated and destroy the phospholipids of neuronal membranes. Prostaglandins, leukotrienes, and free radicals accumulate, and intracellular proteins and enzymes are denatured. Cells then swell, a process called *cellular*, or *cytotoxic*, *edema* (see “Brain Edema” in Chap. 31). Similar abnormalities affect mitochondria even before other cellular changes are evident.

Regarding anoxic damage of the brain, Ames and Nesbett, in a series of articles, studied the rabbit retina

Figure 34-1. Arrangement of the major arteries on the right side carrying blood from the heart to the brain. Also shown are collateral vessels that may modify the effects of cerebral ischemia. For example, the posterior communicating artery connects the internal carotid and the posterior cerebral arteries and may provide anastomosis between the carotid and basilar systems. Over the convexity, the subarachnoid interarterial anastomoses linking the middle, anterior, and posterior cerebral arteries are shown, with inset A illustrating that these anastomoses are a continuous network of tiny arteries forming a border zone between the major cerebral arterial territories. Occasionally a persistent trigeminal artery connects the internal carotid and basilar arteries proximal to the circle of Willis, as shown in inset B. Anastomoses between the internal and external carotid arteries via the orbit are illustrated in inset C. Wholly extracranial anastomoses from muscular branches of the cervical arteries to vertebral and external carotid arteries are indicated in inset D.

Figure 34-2. Diagram of the base of the brain showing the principal vessels of the vertebrobasilar system (the circle of Willis and its main branches). The term *M1* is used to refer to the initial (stem) segment of the middle cerebral artery; *A1* to the initial segment of the anterior cerebral artery proximal to the anterior communicating artery; *A2* to the postcommunal segment of the anterior cerebral artery; and *P1* and *P2* to the corresponding pre- and post-communicating segments of the posterior cerebral artery. The letters and arrows on the right indicate the levels of the four cross-sections following: *A* = Fig. 34-15; *B* = Fig. 34-14; *C* = Fig. 34-13; *D* = Fig. 34-12. Although vascular syndromes of the pons and medulla have been designated by sharply outlined shaded areas, one must appreciate that because satisfactory clinicopathologic studies are scarce, the diagrams do not always represent established fact. The frequency with which infarcts fail to produce a well-recognized syndrome and the special tendency for syndromes to merge with one another must be emphasized.

in an immersion chamber in which O_2 and various substrates could be altered directly rather than through the vasculature. They found that cells could withstand complete absence of O_2 for 20 min. After 30 min of anoxia, there was irreversible damage, reflected by an inability of the tissue to utilize glucose and to synthesize protein. Hypoglycemia further reduced the tolerance to hypoxia, whereas the tolerance could be prolonged by reducing the energy requirements of cells (increasing magnesium in the medium). Ames and colleagues (1968) postulated that the long period of tolerance of retinal neurons to complete anoxia *in vitro*, in comparison to that *in vivo*, is related to what he called the no-reflow phenomenon (swelling of capillary endothelial cells, which prevents the restoration of circulation), as mentioned earlier. Body temperature is yet another important factor in determining the extent of infarction. A reduction of even 2 to 3°C (3.6 to 5.4°F) reduces the metabolic requirements of neurons and increases their tolerance to hypoxia by 25 to 30 percent.

One area of interest has focused on the role of excitatory neurotransmitters in stroke, particularly glutamate

and aspartate, which are formed from glycolytic intermediates of the Krebs cycle. These neurotransmitters, released by ischemic cells, excite neurons and produce an intracellular influx of Na and Ca. These changes are in part responsible for irreversible cell injury, but this must be an oversimplification. Some current attempts at therapy, for example, are directed at limiting the extent of infarction by blocking the glutamate receptor, particularly the NMDA (*N*-methyl-D-aspartate) channel—one of several calcium channels that open under conditions of ischemia and set in motion a cascade of cellular events eventuating in neuronal death (*apoptosis*). However, even complete blockade of the NMDA channels has not prevented cellular death, presumably because dysfunction of several other types of calcium channels continues and allows calcium entry to cells. Additional biochemical events must be induced by ischemia, including the production of free radicals, which leads to peroxidation and disruption of the outer cell and mitochondrial membranes. Clearly, the cascade of intracellular events that lead to neuronal death is likely to be more complex than is currently envisioned.

The extent of neural tissue dysfunction is not dictated solely by the activation of these mechanisms in neurons. It is now clear that toxic influences are exerted on oligodendroglial cells in white matter during ischemia and on astrocytic cells that support neurons. Moreover, injury to both neurons and astrocytes is augmented by an inflammatory response that activates endothelial cells to express cell adhesion molecules that attract additional inflammatory cells and upregulate levels of inflammatory proteases (e.g., metalloproteases) and cytokines (e.g., interleukins and chemokines). These events are summarized in the review by Lo and coworkers and are areas of active research.

It is also clear that as ATP production fails, there is significant accumulation of lactic acid in cerebral tissue, and all the biochemical changes consequent to the cellular acidosis occur. These may also be of importance in determining the extent of cell damage (see reviews of Raichle and of Plum). Myers and Yamaguchi showed that monkeys infused with glucose before the induction of cardiac arrest suffered more brain damage than did either fasted or saline-infused animals. They suggested that the high cerebral glucose level under anaerobic conditions led to increased glycolysis during the ischemic episode and that the accumulated lactate was neurotoxic. On the basis of such observations, Plum suggested that scrupulous control of the blood glucose might reduce the risk of cerebral infarction in diabetic and other stroke-prone patients, and during conditions of potential hyperglycemia. Clinical implementation of this idea is difficult and its advantages remain to be established. Nonetheless, these multiple molecular pathways for neuronal damage provide opportune points for therapeutic intervention.

Hematologic Factors

Involved in the process of thrombosis are changes in a number of natural anticoagulant factors such as heparin cofactor 2, antithrombin III, protein C, and protein S. Some of these are extrinsic to the blood vessels and hence may result in thrombosis in one or in multiple sites even without prior vascular injury. These are discussed by Furie and Furie. Protein C is a vitamin K-dependent protease that, in combination with its cofactors protein S and antithrombin III, inhibits coagulation. A deficiency of any of these factors may predispose to *in situ* thrombosis within either the arterial or venous systems and is a cause of otherwise unexplained strokes in young persons. For example, protein C deficiency (heterozygous in one of every 16,000 individuals) is a cause of thrombosis of both veins and arteries; a resistance to activated protein C has also been described (causing venous thrombosis almost exclusively). Antiphospholipid antibody is yet another cause of vascular occlusion that is not incited by damage to the vessel wall (see later in chapter). The metabolic disturbances in a number of metabolic diseases such as Fabry disease also favor cerebrovascular clotting. Persons with inflammatory bowel diseases (ulcerative colitis, Crohn disease) are known to be prone to thrombotic strokes. Whether inflammation elsewhere in the body predisposes to cerebral vascular occlusions is an open question. Curiously, the hypercoagulable state induced

by certain adenocarcinomas (Trousseau's syndrome) does not often produce *in situ* arterial occlusion but it does lead to thrombotic vegetations on heart valves that precipitate strokes and it predisposes to cerebral venous thrombosis as discussed further on.

These hematologic factors should be sought when unexplained strokes occur in children or young adults, in families whose members have had frequent strokes, in pregnant or parturient women, and in women who are migraineurs or taking birth control pills. According to Markus and Hambley, whose review of this subject is recommended, screening for lupus anticoagulant, anti-cardiolipin antibodies, deficiency of proteins C and S, and antithrombin III is probably justified, but mainly in these special circumstances. This special category of vascular thrombosis is taken up in later sections.

IMAGING TECHNIQUES IN STROKE

Technologic advances continue to enhance the clinical study of stroke patients; they allow the demonstration of both the cerebral lesion and the affected blood vessel. CT demonstrates and accurately localizes even small hemorrhages, hemorrhagic infarcts, subarachnoid blood, clots in and around aneurysms, arteriovenous malformations, and established regions of infarction.

Magnetic resonance imaging is able to reveal flow voids in vessels, hemosiderin and iron pigment, and the alterations resulting from ischemic necrosis and gliosis. MRI is particularly advantageous in demonstrating small lacunar lesions deep in the hemispheres and abnormalities in the brainstem (a region obscured by adjacent bone in CT). However, the main advance has been the introduction of diffusion-weighted magnetic resonance techniques, which allow the detection of an infarctive lesion within minutes of the stroke, *i.e.*, considerably earlier than CT and other MRI sequences (Fig. 34-3). The various MRI imaging sequences used in the diagnosis and dating of stroke are discussed below and in Chap. 2 and in Table 34-4.

Arteriography, enhanced by digital processing of images, accurately demonstrates stenoses and occlusions of the intracranial and extracranial vessels as well as aneurysms, vascular malformations, and other blood vessel diseases such as arteritis and vasospasm. To a large extent, conventional contrast angiography has been supplanted by magnetic resonance angiography (MRA), venography (MRV), and CT angiography for the visualization of large intracranial arteries and veins (see Fig. 2-2J and K). These techniques have the advantage of relative safety (injection of contrast media is required for CT angiography) but do not give refined images of the smaller blood vessels. MRA depicts the "time of flight" of blood through vessels and is not as accurate as CT angiography in measuring the degree and morphology of changes within a cerebral or intracranial vessel. Vascular imaging by MRI has the advantage that areas of restricted diffusion can be detected during the same imaging session, while the CT technique, in addition to better resolution of vascular

Figure 34-3. MRI showing acute infarctions. The upper images show a right middle cerebral artery infarction that appears bright on diffusion-weighted imaging (DWI) (*upper left*). There is subtle hyperintensity representing early vasogenic edema on T2-FLAIR sequence (*upper right*). The lower images show an acute cerebellar infarction in the territory of the posterior inferior cerebellar artery (PICA) that is bright on DWI (*lower left*) and faintly bright on T2-FLAIR (*arrow, lower right*). There is also a previous infarction just anterior to the acute cerebellar stroke that is dark on DWI and bright on T2 due to gliosis.

lumens, is preferable in circumstances requiring the demonstration of soft tissues and bone adjacent to blood vessels, thereby providing the surgeon with important anatomic information (see Chap. 2).

Other procedures for the investigation of cerebrovascular disease include Doppler ultrasound flow studies, which demonstrate atheromatous plaques and stenoses of large vessels, particularly of the carotid but also of the vertebrobasilar arteries. The transcranial Doppler technique has reached a degree of precision whereby occlusion or spasm of the main vessels of the circle of Willis can be detected and roughly quantitated. Various methods of measuring regional blood flow with positron

emission tomography (PET) and radionuclide imaging find use in special instances discussed in appropriate sections of the chapter.

The EEG and lumbar puncture have lost favor in stroke diagnosis but the former is possibly underused as a readily available means of detecting cortical infarction in the wake of ischemia of a region of one hemisphere. It allows a distinction to be made between occlusion of a small and a large vessel, because focal EEG abnormalities are sparse or absent with a deep lacunar stroke. The technique finds more use in distinguishing between transient alterations in nervous function that are a result of seizures and episodes caused by focal ischemia.

Table 34-4

MRI SEQUENCES IN THE DIAGNOSIS OF STROKE

SEQUENCE	TE	TR	GOOD FOR	BRIGHT	DARK
T1-weighted	<50	<1,000	Subacute blood, contusions, CSF disorders	CSF, bone, edema, deoxyhemoglobin mineralization	
T2-weighted	>80	>2,000	Infarcts, inflammation, tumors	CSF, liquids, edema	Solids, calcium
Proton (spin) density	<50	>2,000		"Most pathology"	Fat, water, acute blood
Fluid-attenuated inversion recovery (FLAIR)	>80	>10,000	Edema, inflammation	Edema, inflammation, gliosis	CSF; otherwise like T2
Diffusion-weighted image (DWI)			Acute infarcts		Blood after several days
Susceptibility sequence			Hemorrhages, calcification		Blood
Short tau inversion recovery (STIR)			Spine and orbit studies (eliminates fat signals)		

Neurovascular Examination and Carotid Artery Bruit

Whereas most cerebral arteries can be evaluated only indirectly, more direct clinical means of physical examination are available for the evaluation of the common and internal carotid arteries in the neck. With severe atherosclerotic stenosis at the level of the carotid sinus auscultation discloses a *bruit*, best heard with the bell of the stethoscope held against the skin just tightly enough to create a seal (excessive pressure creates a diaphragm of the skin and filters the low-pitched frequencies that are typical of the bruit of carotid stenosis). Occasionally, a bruit at the angle of the jaw is caused by stenosis at the origin of the external carotid artery or is a radiated murmur from the aortic valve and can then be misleading. If the bruit is loudest at the angle of the jaw, the stenosis usually lies at the proximal internal carotid; if heard lower in the neck, it is in the common carotid or subclavian artery and may be radiated from the aortic valve. Rarely, stenosis in vertebral arteries or vascular malformations at the base of the brain produce bruits that are heard posteriorly in the neck.

The presence of a bruit in the neck is an indication of cerebrovascular disease but its detection is not highly correlated with the presence of severely stenotic lesions as assessed by ultrasonography or angiography. In the past, the physician was almost completely dependent on the details of the nature of the bruit but these details are now of limited interest. An additional though infrequent sign of carotid occlusion is the presence of a bruit over the opposite carotid artery, heard by placing the bell of the stethoscope over the eyeball (ocular bruit). As pointed out by Pessin and colleagues (1983), this murmur is often caused by augmented circulation through the patent vessel but there have been as many instances in our experience when a bruit over the eye instead reflects a stenosis in the intracranial portion of the carotid artery on that side. These and other tests for assessing carotid flow have been supplanted by ultrasound insonation and imaging of the carotid artery, but retinal examination remains valuable in that it may demonstrate *emboli* within retinal arteries, either shiny white or reddish in appearance; this

is another important sign of carotid disease (crystalline cholesterol, termed Hollenhorst plaque, is sloughed from an atheromatous ulcer).

THE STROKE SYNDROMES

The clinical picture that results from an occlusion of any one artery differs in minor ways from one patient to another, but there is sufficient uniformity to justify the assignment of a typical syndrome to each of the major cerebral arteries and their branches and their identification by careful examination of highly specific neurovascular syndromes is one of the cardinal skills of the clinical neurologist. The following descriptions apply particularly to the clinical effects of ischemia and infarction caused by embolism and thrombosis. The distinction between vascular occlusion from a local atherosclerotic plaque with superimposed thrombosis and an embolic occlusion is made largely on the basis of factors already enumerated: (1) the temporal profile of the stroke syndrome, an immediate stroke favoring embolus, and a slowly evolving or "stuttering" onset or emergence form sleep with a stroke favoring atherosclerosis, and (2) associated medical risk factors such as atrial fibrillation (strongly favoring embolus) or diabetes, hypertension, hyperlipidemia and smoking, together favoring atherosclerosis of the small penetrating, or large trunk vessels. Although hemorrhage within a specific vascular territory may give rise to many of the same effects, the total clinical picture is different because it usually involves regions supplied by more than one artery and, by its deep extension and pressure effects, causes secondary features of headache, vomiting, and hypertension, as well as a series of falsely localizing signs, as described in Chaps. 17 and 31.

Carotid Artery Syndromes

The carotid system consists of three major arteries: the common carotid, internal carotid, and external carotid. As indicated in Fig. 34-1, the right common carotid artery

arises at the level of the sternoclavicular notch from the innominate (brachiocephalic) artery, and the left common carotid comes directly from the aortic arch. The common carotid arteries ascend in the neck to the C4 level, just below the angle of the jaw, where each divides into external and internal branches (sometimes the bifurcation is slightly above or below this point). This part of the extracerebral circulation is essential to an understanding of stroke. The carotid vessels are subject to atherosclerotic narrowing, atherothrombotic occlusion, arterial dissection and rarely, other processes such as various forms of vasculitis.

Occlusion of the common carotid artery accounts for less than 1 percent of cases of carotid artery syndrome, the remainder being because of disease of the internal carotid artery itself. Nevertheless, the common carotid can be occluded by an atheromatous plaque at its origin in the thorax, more often on the left side. Atherosclerotic stenosis or occlusion of the midportion of the common carotid may also occur years after radiation therapy for laryngeal, thyroid, or other head and neck cancer. If the bifurcation is patent, few if any symptoms may result because retrograde flow from the external carotid maintains internal carotid flow and perfusion of the brain.

The remainder of this discussion is concerned with disease of the *internal carotid artery*. The territory supplied by this vessel and its main branches is shown in Figs. 34-1, 34-4 and 34-5.

The territory affected by diminished blood flow in the brain in cases of carotid occlusion is highly dependent on the configuration of the circle of Willis. For example, when the anterior communicating artery is very small, the ipsilateral anterior cerebral territory is affected as well. In extreme instances where the circle of Willis provides no communication to the side of an occluded carotid artery, thus isolating the hemisphere from other blood flow, massive infarction involving the anterior two-thirds or all of the cerebral hemisphere results. If the two anterior cerebral arteries arise from a common stem on one side, infarction may occur in the territories of both vessels. The territory supplied by the posterior cerebral artery will also be included if this vessel is supplied by the internal carotid rather than the basilar artery (a configuration that reflects a residual fetal origin of the posterior cerebral artery). The clinical manifestations of atherosclerotic thrombotic disease of this artery are among the most variable of any cerebrovascular syndrome because the internal carotid is not an end vessel. In most individuals it is in continuity with the vessels of the circle of Willis and those of the orbit, and no part of the brain is completely dependent on it. Therefore occlusion, which occurs most frequently in the first part of the internal carotid artery immediately beyond the carotid bifurcation, may be silent (30 to 40 percent of cases).

If one internal carotid artery had been occluded at an earlier time, occlusion of the other may cause bilateral cerebral infarction. The clinical effects in such cases may

Figure 34-4. Diagram of the left cerebral hemisphere, lateral aspect, showing the courses of the middle cerebral artery and its branches and the principal regions of cerebral localization. Below is a list of the clinical manifestations of infarction in the territory of this artery and the corresponding regions of cerebral damage.

Figure 34-5. Diagram of one cerebral hemisphere, coronal section, showing the regions of blood supply of the major cerebral vessels.

include coma with quadriplegia and continuous horizontal “metronomic” conjugate eye movements.

Occlusion of the distal intracranial portion of the internal carotid artery (the “T”)—for example by an embolus to its distal part—produces a clinical picture like that of middle cerebral artery occlusion: contralateral hemiplegia, hemihypesthesia, and aphasia (with involvement of the dominant hemisphere). When the anterior cerebral territory is included, there are additional clinical features of leg paralysis as described further on. Patients with such large infarctions are usually immediately drowsy or stuporous because of an ill-defined effect on the reticular activating system.

Headache, located as a rule above the eyebrow, on the side of the infarction, may occur with thrombosis or embolism of the carotid artery, but cranial pain is not invariable and is usually mild. The headache associated with occlusion of the middle cerebral artery tends to be more lateral, at the temple; that of posterior cerebral occlusion is located in or behind the eye.

When the circulation of one carotid artery has been incompletely compromised, reducing blood flow in both the middle and anterior cerebral territories on that side, the zone of maximal ischemia lies between the two vascular territories (“cortical watershed”) or, alternatively, in the deep portions of the hemisphere between the territories of the lenticulostriate branches and the penetrating vessels from the convexity (“internal” or “deep

watershed”). The infarction in the first instance occupies a region in the high parietal and frontal cortex and the adjacent subcortical white matter. Its size depends upon the adequacy of collateral vessels. Weakness tends to involve the shoulder and hip more than the hand and face. With long-standing carotid stenosis, the cortical watershed zone shifts downward toward the perisylvian portions of the middle cerebral artery territory, even to the extent that a stroke may weaken facial movement or cause a nonfluent aphasia. With impaired perfusion of the deep watershed, infarctions of varying size are situated in the subfrontal and subparietal portions of the centrum semiovale.

The situation is somewhat different in cases of total circulatory collapse from cardiac arrest, in which perfusion fails not only in the watershed areas between the middle and anterior cerebral arteries but also between the middle and posterior cerebral arteries. Bilateral infarctions are then situated within a zone that extends in a sickle-shaped strip of variable width from the cortical convexity of the frontal lobe through the high parietal lobe, to the occipitoparietal junction. Deeper infarctions also occur, but they more often take the form of contiguous extensions of the just described cortical infarction into the subjacent white matter. There may appear to be several separate infarctions after hypoperfusion states, but these often turn out to be radiographically visible portions of a larger border-zone lesion.

The internal carotid artery also nourishes the optic nerve and retina. For this reason, *transient monocular blindness* occurs prior to the onset of stroke in 10 to 25 percent of cases of symptomatic carotid occlusion. Yet central retinal artery ischemia is a relatively rare manifestation of carotid artery occlusion, presumably because of efficient collateral supply in the globe.

Signs of carotid occlusion include transient monocular blindness or visual loss or dimness of vision with exercise, after exposure to bright light, or on assuming an upright position; retinal atrophy and pigmentation; atrophy of the iris; peripapillary arteriovenous anastomoses in the retinae; and claudication of jaw muscles. However, the cardinal clinical signs of stenoses, ulcerations, and dissections of the internal carotid artery are TIAs. It is a subject of debate whether these are the result of fibrin platelet emboli or a reduction in blood flow. TIAs were discussed earlier, but here it can be stated again that they represent an important risk factor for stroke.

Middle Cerebral Artery Stroke Syndromes

The middle cerebral artery (MCA) has superficial and deep hemispherical branches that together supply the largest portion of the cerebral hemisphere. Through its *cortical branches*, it supplies the lateral (convexity) part of the cerebral hemisphere (see Fig. 34-4) encompassing (1) the cortex and white matter of the lateral and inferior parts of the frontal lobe—including motor areas 4 and 6, contraversive centers for lateral gaze and the motor speech area of Broca (dominant hemisphere); (2) the cortex and white matter of the parietal lobe, including the primary and secondary sensory cortices and the angular and supramarginal gyri; and (3) the superior parts of the temporal lobe and insula, including the receptive language area of Wernicke. The deep *penetrating or lenticulostriate branches* of the MCA supply the putamen, a large part of the head and body of the caudate nucleus (shared with the Heubner artery, see further on), the outer globus pallidus, the posterior limb of the internal capsule, and the corona radiata (see Fig. 34-5).

MCA Stem (M1) Occlusion Syndrome

The MCA may be occluded in its longitudinal portion, or the stem, that is proximal to its bifurcation (the term *M1* is used by radiologists to denote this portion of the vessel). An occlusion at this site blocks the flow in the small deep penetrating vessels as well as in superficial cortical branches. An occlusion at the distal end of the stem blocks only the orifices of the divisions of the artery in the sylvian sulcus but leaves unaffected the deep penetrating vessels. The picture of *total occlusion of the stem* is one of *contralateral hemiplegia (involving the face, arm, and leg as a result of infarction of the posterior limb of the internal capsule), hemianesthesia, and homonymous hemianopia* (because of infarction of the lateral geniculate body), with *deviation of the head and eyes toward the side of the lesion*. In addition, there is a variable but usually *global aphasia with left hemispheric lesions and anosognosia and*

amorphosynthesis with right-sided lesions (see Chap. 22). In the beginning, the patient may be drowsy or stuporous because of an ill-defined effect of widespread paralysis of neurologic function. Once fully established, the motor, sensory, and language deficits remain static or improve little as months and years pass. If the patient is globally aphasic for many months, he seldom ever again communicates effectively (see Chap. 23 for a discussion of the aphasic disorders). If there are adequate collateral vessels over the surface of the hemisphere, only those components of the stroke referable to the deep structures are evident (mainly hemiplegia encompassing the contralateral limbs and face) as discussed below, the cortical elements of aphasia, agnosia, and apraxia then being absent or mild.

Occlusion of the stem of the MCA is usually caused by embolus and less often by a thrombus superimposed on an atherosclerotic plaque. Studies over the years have affirmed that most carotid occlusions are thrombotic, whereas most middle cerebral occlusions are embolic (Fisher, 1975; Caplan, 1989). The emboli may lodge in the stem or, more often, drift into the cortical branches as described below; not more than 1 in 20 will enter deep penetrating branches that originate in the stem. In the less-common circumstance, the MCA may become stenotic from atherosclerosis. The stroke is then the result of occlusion of the vessel by a superimposed thrombus. In several series of such cases, the stroke was preceded by TIAs, producing a picture resembling that of carotid stenosis (see Caplan, 1989). Transient monocular blindness does not occur in this situation because the occlusion is distal to the ophthalmic artery. In epidemiologic studies, certain populations such as Asians are disproportionately affected by this form of intracranial atherosclerosis, as are diabetics.

Striatocapsular Infarction A number of interesting syndromes occur with deep lesions in the territory of the penetrating, lenticulostriate, vessels of the MCA (see Figs. 34-5 and 34-7). Most, as mentioned, are attributable to emboli that lodge in the stem of the main vessel, although imaging studies may show a patent vessel and others are undoubtedly atherothrombotic. There have been few adequate pathologic studies. Although the infarction is centered in the deep white matter, most of the syndromes are fragments of the cortical-subcortical stroke patterns described further on. The most common type in our experience has been a *large striatocapsular infarction*, similar to that described by Weiller and colleagues. All of their patients had a degree of hemiparesis and one-fifth had aphasia or hemineglect. Aphasia, when it occurred, tended to be a limited form of the Broca type and in our experience, has been short-lived. With smaller deep strokes we have most often encountered incomplete motor syndromes affecting only the arm and hand, without language disturbance or neglect; these are difficult to differentiate from small embolic cortical strokes. The lesions in the corona radiata are larger than typical lacunar infarctions (see further on) but probably have a similar pathophysiology.

Homonymous hemianopia may occur with posterior capsular lesions, probably as a result of damage to the

region of the lateral geniculate nucleus, but it is infrequent and must be distinguished from visual hemineglect of contralateral space. Bilateral cerebral infarctions involving mainly the insular–perisylvian (anterior opercular) regions manifest themselves by a diplegia of the face, tongue, and masseters that results in anarthria without aphasia (see Mao et al).

MCA Branch Syndromes

Superior Division An embolus entering the middle cerebral artery most often lodges in one of its two main branches, the superior division (supplying the rolandic and prerolandic areas) or the inferior division (supplying the lateral temporal and inferior parietal lobes). Atherothrombotic occlusion of this vessel is infrequent. Major infarction in the territory of the *superior division* causes a *dense sensorimotor deficit in the contralateral face, arm, but, to a lesser extent the leg, as well as ipsilateral deviation of the head and eyes*; i.e., it differs from the MCA stem occlusion syndrome in that the leg and foot are partly spared and less involved with weakness than the arm and face (“brachiofacial,” or chierobrachial “paralysis”); there is no impairment of alertness. If the occlusion is long-lasting (not merely transient ischemia with disintegration of the embolus) there will be slow improvement; after a few months, the patient is able to walk with a spastic leg, while the motor deficits of the arm and face remain. The sensory deficit may be profound, resembling that of a thalamic infarct (as described in Chaps. 8 and 9) but more often it is less severe than the motor deficit, taking the form of stereoaesthesia, agraphesthesia, impaired position sense, tactile localization, and two-point discrimination, as well as variable changes in touch, pain, and temperature sense (see Chap. 22). With *left-sided lesions there is initially a global aphasia, which changes to a predominantly nonfluent (Broca’s) aphasia*, with the emergence of an effortful, hesitant, grammatically simplified, and dysmelodic speech (see Chap. 23); or quite often there is *Broca’s aphasia from the outset*.

Embolic occlusion limited to one of the *distal branches of the superior division*, perhaps the most common stroke seen in clinical practice, produces a more circumscribed infarct that further fractionates the above-described syndrome. With occlusion of the ascending frontal branch, the motor deficit is limited to the face and arm with little or no weakness of the leg, and the latter, if weakened at all, soon improves; with *left-sided lesions*, there is dysfluent and agrammatic speech and normal comprehension (Broca’s aphasia). Embolic occlusion of the left rolandic branch alone results in sensorimotor paresis with severe dysarthria but little evidence of aphasia. A cortical–subcortical branch occlusion may give rise solely to a brachial monoplegia or hand weakness that simulates a problem in the peripheral nervous system. Embolic occlusion of ascending parietal and other posterior branches of the superior division may cause no sensorimotor deficit but only a conduction aphasia (see Chap. 23) and ideomotor apraxia. There are many other limited stroke syndromes or combinations of the aforementioned deficits relating to small regions of damage in the frontal, parietal, or temporal lobes. Among these

are the Gerstmann syndrome and various forms of agnosia (in some patients, these may be in the territory of the inferior division of the MCA discussed below). Most of these are discussed in Chap. 22, which details the result of lesions in particular parts of the cerebrum. Improvement can be expected within a few weeks to months but some remnant of the original problem usually remains in place. As indicated earlier, the distal territory of the middle cerebral artery may also be rendered ischemic by failure of the systemic circulation, especially if the carotid artery is stenotic; this situation may simulate embolic branch occlusions.

Inferior Division Occlusion of the *inferior division* of the MCA is slightly less frequent than occlusion of the superior one, but again is nearly always the result of embolism. The usual result in left-sided lesions is a *Wernicke’s aphasia*, which generally remains static for days or weeks after which some improvement can be expected. In less-extensive infarcts that are the result of selective distal branch occlusions (superior parietal, angular, or posterior temporal), the deficit in comprehension of spoken and written language may be especially severe. Again, after a few months, the deficits usually improve, often to the point where they are evident only in self-generated efforts to read and copy visually presented words or phrases. With either right- or left-hemispheric lesions, there is usually a *superior quadrantanopia or homonymous hemianopia* and, *with right-sided ones, a left visual neglect* and other signs of amorphosynthesis. Rarely, an agitated confusional state, presumably from nondominant temporal lobe damage, may be a prominent feature of dominant hemispheric lesions and sometimes of non-dominant ones. Some of the syndromes applicable to the angular gyrus and the supramarginal gyrus may occur in strokes within this division, depending on the distributions of the vessels in an individual.

Anterior Cerebral Artery Stroke Syndromes

This artery, through its cortical branches, supplies the anterior three-quarters of the medial surface of the frontal lobe, including its medial-orbital surface, the frontal pole, a strip of the lateral surface of the cerebral hemisphere along its superior border, and the anterior four-fifths of the corpus callosum. Deep branches, arising near the circle of Willis (proximal and distal to the anterior communicating artery) supply the anterior limb of the internal capsule, the inferior part of the head of the caudate nucleus, and the anterior part of the globus pallidus (see Figs. 34-5, 34-6, and 34-7). The largest of these deep branches is the artery of Heubner (“recurrent artery of Heubner”). This artery, which may, in fact, be up to four small vessels, shares its territory of supply with anteriorly placed lenticulostriate arteries that emanate from the middle cerebral artery. Strokes in this territory cause infarction of the head of the caudate. Most strokes are of the embolic variety, far less often atherosclerotic, and occasionally due to other processes such as vasospasm or vasculitis.

The clinical picture of anterior cerebral artery stroke will depend on the location and size of the infarct, which, in turn, relates to the site of the occlusion (proximal or

Figure 34-6. A. Diagram of the right cerebral hemisphere, medial aspect, showing the branches and distribution of the *anterior cerebral artery* and the principal regions of cerebral localization. Below is a list of the clinical manifestations of infarction in the territory of this artery and the corresponding regions of cerebral damage. Also shown is the course of the main branch of the *posterior cerebral artery* on the medial side of the hemisphere. *Note:* Hemianopia does not occur; transcortical aphasia occurs rarely (isolation of the language areas) (see Chap. 23). B. Axial diffusion-weighted MRI showing an acute ischemic infarction in the anterior cerebral artery territory.

distal to the anterior communicating artery), the pattern of the circle of Willis, and the other ischemia-modifying factors mentioned earlier. Well-studied cases of infarction in the territory of the anterior cerebral artery are not numerous; hence the syndromes have not been completely elucidated (see Brust for a review of the literature and a description of developmental abnormalities of the artery).

Occlusion of the stem of the anterior cerebral artery, proximal to its connection with the anterior communicating artery (the A1 segment in neuroradiologic parlance) is usually well tolerated, because adequate collateral flow is provided by the anterior or cerebral artery of the opposite side. Maximal disturbance occurs when both arteries arise from one anterior cerebral stem, in which case there is infarction of the anterior and medial parts of both cerebral hemispheres resulting in paraplegia, incontinence, abulia and nonfluent aphasic symptoms, and frontal lobe personality changes (see Chap. 22). Occlusion of the anterior cerebral arteries is usually embolic, but atherothrombotic lesions are known and instances because of surgical occlusion by an aneurysm clip are well described.

Complete infarction as a result of occlusion of one anterior cerebral artery distal to the anterior communicating artery (A2 segment) results in a sensorimotor deficit of the opposite foot and leg and, to a lesser degree, of the shoulder and arm, with sparing of the hand and face (the distribution of which

is shown in the MRI of Fig. 34-6). This is the complement of the superior division middle cerebral artery pattern. The motor disorder is more pronounced in the foot and leg than in the hip and thigh. Sensory loss, when it occurs, is mainly of the discriminative modalities but it may be mild or absent. The head and eyes may deviate to the side of the lesion. Urinary incontinence, a contralateral grasp reflex, and paratonic rigidity (*gegenhalten*) of the opposite limbs may be evident. With a left-sided occlusion, there may be a “sympathetic apraxia” of the left arm and leg or involuntary misdirected movements of the left arm (alien arm or hand), as described in Chaps. 3 and 22.

Language disturbances, particularly transcortical motor aphasia (see Chap. 23), may occur with anterior cerebral artery territory stroke. Alexander and Schmitt cited cases in which occlusions of the proximal artery (ACA), which included the Heubner artery, resulted in right hemiplegia (predominant in the leg) with grasping and groping responses of the right hand and buccofacial apraxia that were accompanied by a diminution or absence of spontaneous speech, agraphia, and a limited ability to name objects and compose word lists but with a striking preservation of the ability to repeat spoken and written sentences (i.e., transcortical motor aphasia). *Disorders of behavior* that may be overlooked in cases of anterior cerebral artery occlusion; they are abulia, or a slowness and lack of spontaneity in all reactions, muteness or a tendency to speak in whispers, and distractibility. Branch occlusions of the anterior cerebral artery produce only fragments of the total syndrome, usually a spastic weakness or associative sensory loss in the opposite foot and leg.

With occlusion of penetrating branches of the ACA, the anterior limb of the internal capsule and caudate is usually involved. In a series of 18 cases of unilateral caudate region infarcts collected by Caplan and associates, a transient hemiparesis was present in 13. Dysarthria and either abulia or agitation and hyperactivity were also common. Stuttering and language difficulty occurred with two of the left-sided lesions and visuospatial neglect with three of the right-sided ones. To what extent these symptoms were the result of a disturbance of neighboring structures is difficult to determine. With bilateral caudate infarctions, a syndrome of inattentiveness, abulia, forgetfulness, and sometimes agitation and psychosis was observed. Transitory choreoathetosis and other dyskinesias (we have seen two cases of ballismus) have also been attributed to ischemia of the caudate and anterior basal ganglia, occurring sometimes under conditions of prolonged standing and exercise (Caplan and Sergay; Margolin and Marsden).

Anterior Choroidal Artery Stroke Syndrome

This is a long, narrow artery that springs from the internal carotid, just above the origin of the posterior communicating artery. It supplies the internal segment of the globus pallidus and posterior limb of the internal capsule and several contiguous structures including (in most patients) the optic tract (see Fig. 34-5). It then penetrates

the temporal horn of the lateral ventricle, where it supplies the choroid plexus and anastomoses with the posterior choroidal artery. This being a small caliber branch, most strokes in this territory are due to in situ atherosclerosis of the type that occurs in diabetics but occlusion of the orifice of the vessel by an embolus is possible and it is a known complication of clipping of an aneurysm at the upper reaches of the carotid artery.

Only a few complete clinicopathologic studies have been made of the distinctive syndrome caused by occlusion of this artery. It was found by Foix and colleagues to consist of *contralateral hemiplegia*, *hemihypesthesia*, and *homonymous sectorial hemianopia* (not reaching the vertical meridian of the visual fields) as a result of involvement of the posterior limb of the internal capsule and white matter posterolateral to it, through which the geniculocalcarine tract passes, and the lateral geniculate nucleus. This combination of extensive unilateral motor, sensory, and visual impairment in an individual with well-preserved language and cognition distinguishes this stroke syndrome from the more common ones involving the major cerebral arteries. Decroix and colleagues reported 16 cases (identified by CT) in which the lesion appeared to lie in the vascular territory of this artery. In most of their cases, the clinical syndrome fell short of what was expected on anatomic grounds or had additional features.

With right-sided lesions, there may be a left spatial neglect and constructional apraxia; slight disorders of speech and language may accompany left-sided lesions. Hupperts and colleagues have discussed the controversy regarding the effects of occlusion of the artery and in particular the variability of its supply to the posterior paraventricular area of the corona radiata and adjacent regions. They concluded, also from a survey of CT images, that there was no uniform syndrome attributable to occlusion of the vessel and that in most cases its territory of supply was overlapped by small surrounding vessels. It may be remembered that for a time, in order to abolish the tremor and rigidity of unilateral Parkinson disease, the anterior choroidal artery was being surgically ligated without these other effects having been produced.

Posterior Cerebral Artery Stroke Syndromes

In approximately 70 percent of individuals, both posterior cerebral arteries are formed by the bifurcation of the basilar artery and thin posterior communicating arteries join this system to the internal carotid arteries. In 20 to 25 percent, one posterior cerebral artery arises from the basilar in the usual way, but the other arises from the internal carotid, a persistent fetal pattern of circulation; fewer than 5 percent have the unusual configuration in which both arise from the corresponding carotid arteries. Most strokes in this territory are embolic in origin but some individuals are predisposed to atherosclerosis in the proximal posterior cerebral artery. There is also the possibility of ischemia in this territory from occlusion of more proximal vessels, particularly the basilar artery, or infraction in the distal territory of the vessel as a result of global failure of cerebral perfusion, as in severe hypotension.

The configuration and branches of the *proximal segment of the posterior cerebral artery* (P1 segment) are illustrated in Figs. 34-6, 34-8, and 34-9. The *interpeduncular branches*, which arise just above the basilar bifurcation, supply the red nuclei, the substantia nigra bilaterally, medial parts of the cerebral peduncles, oculomotor and trochlear nuclei and nerves, reticular substance of the upper brainstem, decussation of the superior cerebellar peduncles, medial longitudinal fasciculi, and medial lemnisci. The P1 portion of the posterior cerebral artery, giving rise to the interpeduncular branches (that portion between the bifurcation of the basilar artery and the ostium of the posterior communicating artery), is also referred to as the *mesencephalic artery* or the *basilar communicating artery*. As pointed out by Percheron (whose name is often applied to the largest of these vessels), the arterial configuration of the paramedian mesencephalic arteries varies considerably: in some cases, two small vessels arise symmetrically, one from each side; in others, a single artery arises from one posterior cerebral stem (proximal P1), which then bifurcates. In the latter case, one posterior cerebral stem supplies the medial thalamic territories on both sides, and an occlusion of this artery or one common paramedian trunk produces a bilateral butterfly-shaped lesion in the medial parts of the diencephalon. These are elaborated and illustrated by Castaigne et al.

The *thalamoperforate branches* (also called *paramedian thalamic arteries*) arise slightly more distally from the stem, nearer the junction of the posterior cerebral and posterior communicating arteries (P2 segment of the artery) and supply the inferior, medial, and anterior parts of the thalamus. The *thalamogeniculate branches* arise still more distally, opposite the lateral geniculate body, and supply the geniculate body and the central and posterior parts of the thalamus. Medial branches emerging from the posterior cerebral artery as it encircles the midbrain, supply the lateral part of the cerebral peduncle, lateral tegmentum and corpora quadrigemina, and pineal gland. Posterior choroidal branches run to the posterosuperior thalamus, choroid plexus, posterior parts of the hippocampus, and psalterium (decussation of deep white matter fornices).

Most importantly, the terminal or *cortical branches of the posterior cerebral artery* supply the inferomedial part of the temporal lobe and the medial occipital lobe, including the lingula, cuneus, precuneus, and visual Brodmann areas 17, 18, and 19 (see Figs. 34-6, 34-8, and 34-9).

Occlusion of the posterior cerebral artery produces a greater variety of clinical effects than occlusion of any other artery because both the upper brainstem, which is replete with important structures, and the inferomedial parts of the temporal and occipital lobes lie within its supply. The site of the occlusion and the arrangement of the circle of Willis will, in large measure, determine the location and extent of the resulting infarct. For example, occlusion proximal to the posterior communicating artery may be asymptomatic or have only transitory effects if the collateral flow is adequate from the opposite posterior cerebral vessel (see Fig. 34-8; see also Fig. 34-9). Even distal to the posterior communicating artery, an occlusion may cause relatively little damage if the collateral flow

Figure 34-8. A. Inferior aspect of the left hemisphere showing the branches and distribution of the posterior cerebral artery and the principal anatomic structures supplied. The vessel is considered from the perspective of its proximal and distal territories. Listed below are the clinical manifestations produced by infarction in these territories and the corresponding regions of damage. Tremor in repose has been omitted because of the uncertainty of its occurrence in the posterior cerebral artery syndrome. Peduncular hallucinosis may occur in thalamic-subthalamic ischemic lesions, but the exact location of the lesion is unknown. B. Axial diffusion-weighted MRI showing an acute ischemic infarction in the posterior cerebral artery territory.

through border-zone collaterals from anterior and middle cerebral arteries is sufficient.

In the series of posterior cerebral artery strokes studied by Milandre and coworkers, the causes were, in general, similar to those of strokes in other vascular territories except that there was a higher incidence of atherosclerotic occlusion (35 patients) in contrast to cardioembolic types (15 patients). Two of their stroke cases

were attributed to migraine. Our experience has differed in that the proportion of presumed embolic occlusions has been far greater than that of other causes.

For convenience of exposition, it is helpful to divide the posterior cerebral artery syndromes into three groups: (1) proximal (involving interpeduncular, thalamic perforant, and thalamogeniculate branches), (2) cortical (inferior temporal and medial occipital), and (3) bilateral.

Figure 34-10. Diagram of the regions of blood supply of the diencephalon. Proximal Syndromes (See Figs. 34-9 and 34-10)

The *thalamic syndrome of Dejerine and Roussy* (see also Chap. 8) follows infarction of the sensory relay nuclei in the thalamus, the result of occlusion of thalamogeniculate branches. Occlusion of the small vessels supplying these territories from in situ atherothrombosis or embolic occlusion of the posterior cerebral artery is the most common cause. There is both a deep and cutaneous sensory loss, usually severe in degree, of the opposite side of the body, including the trunk and face, sometimes accompanied by a transitory hemiparesis. A homonymous hemianopia may be conjoined. In some instances there is a dissociated sensory loss—pain and thermal sensation being more affected than touch, vibration, and position—or only one part of the body may be anesthetic. The characteristic feature is always sensory loss that includes the entire hemibody up to the midline. After an interval, sensation begins to return, and the patient may develop pain, paresthesia, and hyperpathia in the affected parts. The painful paresthetic syndrome may persist for years. There may also be distortion of taste, athetotic posturing of the hand, and alteration of mood. Mania and depression have occasionally been observed with infarction of the diencephalon and adjacent structures, but the data are usually incomplete.

Central midbrain and subthalamic syndromes are a result of occlusion of the interpeduncular branches of the posterior cerebral artery. The clinical syndromes include palsies of vertical gaze, stupor, or coma. Syndromes of the *paramedian arteries*, including the proximal posterior cerebral artery, have as their main feature a third-nerve palsy combined with contralateral hemiplegia (*Weber syndrome*), contralateral ataxic tremor (*Claude syndrome*), or homolateral ataxia, hemiplegia with contralateral third-nerve palsy (*Benedikt syndrome*), as summarized in Table 34-5.

Anteromedial-inferior thalamic syndromes follow occlusion of the thalamoperforant branches. Here the most common effect is an extrapyramidal movement disorder

(hemiballismus or hemichoreoathetosis or less often, asterixis). Deep sensory loss, hemiataxia, or tremor may be added in various combinations. Hemiballismus is usually a result of occlusion of a small branch to the subthalamic nucleus (of Luys) or its connections with the pallidum. Occlusion of the paramedian thalamic branches to the mediodorsal nucleus is a recognized cause of an amnesic (Korsakoff) syndrome; this simulates but is less common than infarction of the hippocampi from occlusion of the medial temporal branch of the posterior cerebral artery as noted below.

Cortical Syndromes of the Posterior Cerebral Artery

Occlusion of branches to the temporal and occipital lobes gives rise to a homonymous hemianopia as a result of involvement of the primary visual receptive areas (calcarine or striate cortex) or of the converging geniculocalcarine fibers. The hemianopia may be incomplete and involve the upper quadrants of the visual fields more than the lower ones (see Chap. 13). Macular, or central, vision is often spared because of collateral blood supply of the occipital pole from distal branches of the middle (or anterior) cerebral arteries. Other features seen in a few instances are visual hallucinations in the blind parts of the visual fields (Cogan) or metamorphopsia and palinopsia (Brust and Behrens). Occipital infarcts of the dominant hemisphere may cause alexia without agraphia, anomia (amnesic aphasia), a variety of visual agnosias, and rarely some degree of impaired memory. The anomias, when they occur, are most severe for colors, but the naming of other visually presented material such as pictures, mathematical symbols, and manipulable objects may also be impaired. The patient may treat objects as familiar—that is, describe their functions and use them correctly—but be unable to name them. Color anomia (a form of “central achromatopsia”) and amnesic aphasia are more often present in this syndrome than is alexia. The defect in retentive memory is of varying severity and may or may not improve with the passage of time. These syndromes are described in Chaps. 22 and 23.

A complete proximal arterial occlusion leads to a syndrome that combines cortical and anterior-proximal syndromes in part or totally. As mentioned, the vascular lesion may be either an embolus or an atherosclerotic thrombus.

Bilateral Posterior Cerebral Artery Stroke Syndromes

These occur as a result of successive infarctions or from a single embolic or thrombotic occlusion of the upper basilar artery, especially if the posterior communicating arteries are unusually small or absent, or from global failure of circulation.

Bilateral lesions of the occipital lobes, if extensive, cause “cortical blindness” that is essentially bilateral homonymous hemianopia, sometimes accompanied by unformed visual hallucinations. The pupillary reflexes are preserved and the optic discs appear normal. Sometimes the patient is unaware of being blind and denies the problem even when it is pointed out to him (Anton syndrome).

EPONYM ^b	SITE	CRANIAL NERVES INVOLVED	TRACTS INVOLVED	SIGNS	USUAL CAUSE
Weber syndrome	Base of midbrain	III	Corticospinal tract	Oculomotor palsy with crossed hemiplegia	Vascular occlusion, tumor, aneurysm
Claude syndrome	Tegmentum of midbrain	III	Red nucleus, superior cerebellar peduncles after decussation	Oculomotor palsy with contralateral cerebellar ataxia and tremor	Vascular occlusion, tumor, aneurysm
Benedikt syndrome	Tegmentum of midbrain	III	Red nucleus, corticospinal tract, and superior cerebellar peduncles after decussation	Oculomotor palsy with contralateral cerebellar ataxia, tremor, and corticospinal signs, may have choreoathetosis	Infarct, hemorrhage, tuberculoma, tumor
Nothnagel syndrome	Tectum of midbrain	Unilateral or bilateral III	Superior cerebellar peduncles	Ocular palsies (IV), paralysis of gaze, nystagmus, and ataxia	Tumor
Parinaud syndrome	Dorsal midbrain		Supranuclear mechanism for upward gaze and other structures in periaqueductal gray matter	Paralysis of upward gaze and accommodation; fixed pupils	Pinealoma and other lesions of dorsal midbrain, hydrocephalus
Millard-Gubler syndrome and Raymond-Foville syndrome	Base of pons	VII and often VI	Corticospinal tract	Facial and abducens palsy and contralateral hemiplegia; sometimes gaze palsy to side of lesion	Infarct or tumor
Avellis syndrome	Tegmentum of medulla	X	Spinothalamic tract; sometimes descending pupillary fibers, with Bernard-Horner syndrome	Paralysis of soft palate and vocal cord and contralateral hemianesthesia	Infarct or tumor
Jackson syndrome	Tegmentum of medulla	X, XII	Corticospinal tract	Avellis syndrome plus ipsilateral tongue paralysis	Infarct or tumor
Wallenberg syndrome	Lateral tegmentum of medulla	Spinal V, IX, X, XI	Lateral spinothalamic tract Descending pupillodilator fibers Spinocerebellar and olivocerebellar tracts	Ipsilateral V, IX, X, XI palsy, Horner syndrome, and cerebellar ataxia; contralateral loss of pain and temperature sense	Occlusion of vertebral or posterior-inferior cerebellar artery

^aSee also Table 47-1, which lists the brainstem syndromes due to extramedullary lesions.

^bSee Wolf JK: *The Classical Brainstem Syndromes*. Springfield, IL, Charles C Thomas, 1971, for translations of original reports.

More frequently, the lesions are incomplete, and a sector of the vision, usually on one side, remains intact. When the visual remnant is small, vision may seemingly fluctuate from moment to moment as the patient attempts to capture the image in the island of intact vision, in which case hysteria may be incorrectly inferred. In bilateral lesions confined to the occipital poles, there may be a loss of central vision only (homonymous central scotomas). With more anteriorly placed lesions of the occipital pole, there may be homonymous paracentral scotomas, or the occipital poles may be spared, leaving the patient with only central vision. Horizontal or altitudinal field defects are usually a result of similar restricted lesions affecting the upper or lower banks of the calcarine sulci. The Balint syndrome (see Chap. 22) is an effect of bilateral occipitoparietal border-zone lesions.

With bilateral lesions that involve the inferomedial portions of the temporal lobes, including the hippocampi and their associated structures, the impairment of memory may be severe, causing the Korsakoff amnesic state.

In several of our patients, a solely left-sided infarction of the inferomedial temporal lobe impaired retentive memory. Bilateral mesiotemporal-occipital lesions also cause a lack of recognition of faces (prosopagnosia). These and other effects of temporal and occipital lesions are discussed in Chaps. 13 and 22.

Vertebral Artery Stroke Syndromes

The vertebral arteries are the chief arteries of the medulla; each supplies the lower three-fourths of the pyramid, the medial lemniscus, all or nearly all of the retroolivary (lateral medullary) region, the restiform body, and the posteroinferior part of the cerebellar hemisphere through the posterior inferior cerebellar arteries (Fig. 34-11). The relative sizes of the vertebral arteries vary considerably, and in approximately 10 percent of cases, one vessel is so small that the other is essentially the only artery of supply to the brainstem. In the latter cases, if there is no collateral flow from the carotid system via the circle of Willis,

Figure 34-11. Regions supplied by the posterior segment of the circle of Willis, lateral view (A) and basal view (B). A. (1) Posterior cerebral artery; (2) superior cerebellar artery; (3) basilar artery and superior cerebellar artery; (4) posterior inferior cerebellar artery; (5) vertebral artery (posterior inferior cerebellar artery, anterior spinal artery, posterior spinal artery). B. (1) Posterior cerebral artery; (2) superior cerebellar artery; (3) paramedian branches of the basilar artery and spinal artery; (4) posterior inferior cerebellar artery; (5) vertebral artery; (6) anterior inferior cerebellar artery; (7) dorsal spinal artery. occlusion of the one functional vertebral artery is equivalent to occlusion of the basilar artery (see below). The posteroinferior cerebellar artery (PICA) is usually a branch of the vertebral artery but can have a common origin and form a loop with the anteroinferior cerebellar artery (AICA) from the basilar artery. It is necessary to keep these anatomic variations in mind in considering the effects of vertebral artery occlusion.

The vertebral arteries are most often occluded by atherothrombosis in their intracranial portion. Because the

vertebral arteries have a long extracranial course and pass through the transverse processes of C6 to C1 vertebrae before entering the cranial cavity, one might expect them to be subject to trauma, spondylotic compression, and a variety of other vertebral diseases. With the exception of arterial dissection, in our experience the other causes of vascular occlusion happen only infrequently. We rarely see convincing examples of spondylotic occlusion but several such cases have been reported. Extreme extension of the neck, as experienced by women who are having their hair washed in beauty salons, or during yoga positions, may give rise to transient symptoms in the territory of the vertebral artery.

Dissection of the vertebral artery by contrast is well described; it declares itself by cervicooccipital pain and deficits of brainstem function. One's attention is drawn to the diagnosis of vertebral dissection where there have been vigorous and protracted bouts of coughing or trauma to the neck or head. Dissection of the extracranial vessels is discussed in more detail further on. Examples of posterior circulation stroke in children have been reported in association with odontoid hypoplasia and other atlantoaxial dislocations, causing the vertebral arteries to be stretched or kinked in their course through the transverse processes of C1-C2 (Phillips et al).

The results of vertebral artery occlusion are quite variable. If the occlusion of the vertebral artery is so situated as to block the posterior inferior cerebellar artery supplying the lateral medulla and inferior cerebellum (PICA), a characteristic syndrome results with vertigo being a prominent symptom (see "Lateral Medullary Syndrome" described below). If the subclavian artery is blocked proximal to the origin of the left vertebral artery, exercise of the arm on that side may draw blood from the right vertebral and basilar arteries, retrograde down the left vertebral and into the distal left subclavian artery—sometimes resulting in the symptoms of basilar insufficiency. This phenomenon, described in 1961 by Reivich and colleagues, was referred to by Fisher (1961) as the *subclavian steal*. Its most notable features are vertigo and other brainstem signs coupled with transient weakness on exercise of the left arm. There may also be headache and claudication or pain of the arm. In an unusual configuration in which one vertebral artery is occluded just proximal to the origin of its PICA branch, and the opposite vertebral artery is open and sufficient in size, there may be no symptoms because the PICA is still filled by retrograde flow through its vertebral artery.

Less often, occlusion of the vertebral artery or one of its medial branches produces an infarct that involves the medullary pyramid, the medial lemniscus, and the emergent hypoglossal fibers; the resultant syndrome consists of a contralateral paralysis of arm and leg (with sparing of the face), contralateral loss of position and vibration sense, and ipsilateral paralysis and later atrophy of the tongue. This is the *medial medullary syndrome* (Fig. 34-12). A more limited lesion, from occlusion of one spinal artery arising from the vertebral artery, gives rise to a contralateral hemiplegia (rarely a quadriplegia) that spares the face. When the vertebral branch to the anterior spinal artery is blocked, flow from the other (corresponding)

Figure 34-12. Transverse section through the upper medulla, reflecting regions supplied by the vertebral arteries and their branches.

branch is usually sufficient to prevent infarction of the cervical cord, but we and others have described solely pyramidal infarction with hemiplegia or quadriplegia that spares the face (Ropper et al). Occlusion of a vertebral artery low in the neck is usually compensated by anastomotic flow to the upper part of the artery via the thyrocervical, deep cervical, and occipital arteries or by reflux from the circle of Willis.

Lateral Medullary Syndrome

Known also as the *Wallenberg syndrome* (who described a case in 1895), this common stroke is produced by infarction of a wedge of lateral medulla lying posterior to the inferior olivary nucleus (see Fig. 34-12). The complete syndrome, as outlined by Fisher and colleagues (1961), comprises (a) symptoms derived from the vestibular nuclei (vertigo, nystagmus, oscillopsia, vomiting); (b) spinothalamic tract (contralateral or, less often, ipsilateral impairment of pain and thermal sense over half the body); (c) descending sympathetic tract (ipsilateral Horner syndrome—miosis, ptosis, decreased sweating); (d) issuing fibers of the ninth and tenth nerves (hoarseness, dysphagia, hiccough, ipsilateral paralysis of the palate and vocal cord, diminished gag reflex); (e) utricular nucleus (vertical diplopia and illusion of tilting of vision and rotation of the vertical meridian, rarely so severe as to produce upside down vision); (f) olivocerebellar, spinocerebellar fibers, restiform body and inferior cerebellum (*ipsilateral* ataxia of limbs, falling

or toppling to the ipsilateral side, and the sensation of lateropulsion); (g) descending tract and nucleus of the fifth nerve (pain, burning, and impaired sensation over ipsilateral half of the face); (h) nucleus and tractus solitarius (loss of taste); and rarely, (i) cuneate and gracile nuclei (numbness of *ipsilateral* limbs). Fragmentary syndromes are more frequent, especially at the onset of the stroke. These subsyndromes may consist of vertigo and ptosis, toppling and vertical diplopia, hoarseness and disequilibrium, or other combinations short of the entire syndrome. While vertigo is the most frequent feature alone, it is not usually an indication of lateral medullary infarction. The smallest infarction we have studied gave rise only to symptoms of lateropulsion and mild ipsilateral limb ataxia.

The eye signs of lateral medullary infarction are also varied and quite interesting. There is often a fragment of an internuclear ophthalmoplegia or a skew deviation (the globe on the affected side usually being higher). Direction-changing nystagmus (with different head positions) is a useful feature that suggests labyrinthine disease from brainstem forms of nystagmus, but infarction of the vestibular nucleus as part of the lateral medullary syndrome may also produce this sign (see Chap. 15).

The entire lateral medullary syndrome, one of the most striking in neurology, is almost always caused by infarction, with only a small number of cases being the result of hemorrhage, demyelination, or tumor. Although it has traditionally been attributed to occlusion in the course

of the PICA, as mentioned earlier, careful studies have shown that in 8 of 10 cases it is the vertebral artery that is occluded by atherothrombosis; in the remainder, either the posterior inferior cerebellar artery or one of the lateral medullary arteries is occluded. Embolism to the PICA is a less-frequent cause. The inferior cerebellum is usually affected, sometimes in isolation if the embolus travels distal to the origin of PICA, causing a cerebellar infarct with attendant vomiting, vertigo, and ataxia often with occipitotuchal headache.

In recent years, we have had experience with patients who initially have considerable recovery in the first days and weeks, but experience sudden and unexpected death from respiratory or cardiac arrest, even in the absence of cerebellar swelling or basilar artery thrombosis. Cases of this nature have been reviewed by Norrving and Cronqvist. The related and important issue of cerebellar swelling after vertebral artery or PICA occlusion and the need for surgical decompression is discussed later in the chapter.

Basilar Artery Stroke Syndromes

The branches of the basilar artery may be instructively grouped as follows: (1) paramedian, 7 to 10 pairs, supplying a wedge of pons on either side of the midline; (2) short circumferential, 5 to 7 pairs in number, supplying the lateral two-thirds of the pons and the middle and superior cerebellar peduncles; (3) long circumferential, 2 on each side (the superior and anterior inferior cerebellar arteries), which run laterally around the pons to reach the cerebellar hemispheres (see Figs. 34-11 and 34-13

through 15); and (4) several paramedian (interpeduncular) branches at the bifurcation of the basilar artery and origins of the posterior cerebral arteries supplying the high midbrain and medial subthalamic regions. These interpeduncular and other short proximal branches of the posterior cerebral artery were described earlier in the chapter.

Basilar artery occlusion, typically because of local thrombosis that is superimposed on a preexisting atherosclerotic plaque, can arise in several ways: (1) occlusion of the basilar artery itself, usually in the lower or middle third at the site of an atherosclerotic plaque; (2) occlusion of both vertebral arteries, which produces the equivalent of basilar artery occlusion if the circle of Willis is inadequate; and (3) occlusion of a single vertebral artery when it is the only one of adequate size. When there is embolism, the clot usually lodges at the terminal bifurcation of the basilar ("top-of-the-basilar syndrome") or in one of the posterior cerebral arteries, as the clot, if small enough to pass through the vertebral artery, easily traverses the length of the basilar artery, which is of greater diameter than either vertebral artery. Also, thrombosis may involve a branch of the basilar artery rather than the trunk (*basilar branch occlusion*).

The syndrome of *basilar artery occlusion*, as delineated by Kubik and Adams, reflects the involvement of a large number of bilateral structures: corticospinal and corticobulbar tracts; cerebellum, middle and superior cerebellar peduncles; medial and lateral lemnisci; spinothalamic tracts; medial longitudinal fasciculi; pontine nuclei; vestibular and cochlear nuclei; descending hypothalamospinal sympathetic fibers; and the third through eighth

Figure 34-13. Transverse section through the lower pons, reflecting the regions supplied by the lower basilar artery including its anterior inferior cerebellar artery branch.

cranial nerves (the nuclei and their segments within the brainstem). Thus the *complete syndrome* comprises bilateral long tract signs (sensory and motor) with variable cerebellar, cranial nerve, and other segmental abnormalities of the brainstem.

Another important syndrome, the result of occlusion of the distal end of the basilar artery, consists of coma from infarction of the high midbrain reticular activating system. This “top of the basilar” artery occlusion is most often embolic and characterized by transient loss of consciousness, oculomotor disturbances (roving eye movements or eyes looking downward and inward with inability to reflexly elicit upward movements), hemianopia, bilateral ptosis, and pupillary enlargement with preserved reaction to light. Spontaneous recanalization of the vessel is frequent, but occurs in a delayed fashion,

after the infarct has been established. MRI demonstrates a characteristic pattern of central midbrain, bilateral posterior thalamic, and, more variably, uni- or bilateral posterior territory infarction as discussed below.

Yet another configuration, the result of occlusion of the midbasilar artery, gives rise to the locked-in syndrome, in which the patient is mute and quadriplegic but conscious, reflecting interruption of descending motor pathways in the base of the pons but sparing of the reticular activating system (“locked-in” syndrome; see Chap. 17). Horizontal eye movements are obliterated but vertical ones and some ability to elevate the eyelids are spared. The pupils become extremely small but retain some reaction to light. Midbasilar disease may also cause coma if the posterior communicating arteries are inadequate to perfuse the distal basilar artery territory.

In the presence of the full syndrome, it is usually not difficult to make the correct diagnosis. The aim should be, however, to recognize basilar insufficiency long before the stage of total deficit has been reached. The early manifestations (in the form of TIAs) occur in many combinations, described in detail further on.

Basilar Artery Branch Occlusion

Occlusion of branches at the bifurcation (top) of the basilar artery results in a remarkable number of complex syndromes that include, in various combinations, somnolence or coma, memory defects, akinetic mutism, visual hallucinations, ptosis, disorders of ocular movement (convergence spasm, paralysis of vertical gaze, retraction nystagmus, pseudoabducens palsy, retraction of upper eyelids, skew deviation of the eyes), an agitated confusional state, and visual field defects (see Fig. 34-9). These have been summarized by Petit and coworkers and Castaigne and associates and categorized as paramedian thalamic, subthalamic, and midbrain syndromes, and by Caplan as parts of the "top of the basilar" syndrome. Limited, small infarctions on one side of the brainstem are usually due to occlusion of small penetrating vessels that originate in the basilar artery. Emboli coursing through the basilar artery can also occlude the mouths of several small penetrating vessels and cause larger infarctions. A larger infarction in the territory of one circumferential vessel is usually due to an embolus but may also result from an atherosclerotic plaque in the parent basilar artery. The distinction is often made by the rapidity of onset and the presence of risk factors such as atrial fibrillation for embolus or diabetes and hypertension for small vessel occlusion.

The main signs of occlusion of the *superior cerebellar artery*, the most rostral circumferential branch of the basilar, are ipsilateral cerebellar ataxia of the limbs (referable to middle and superior cerebellar peduncles); nausea and vomiting; slurred speech; and loss of pain and thermal sensation over the opposite side of the body (spinothalamic tract). Partial deafness, static tremor of the ipsilateral upper extremity, an ipsilateral Horner syndrome, and palatal myoclonus have also been reported.

With occlusion of the *anterior inferior cerebellar artery* (AICA), the extent of the infarct is extremely variable, as the size of this artery and the territory it supplies vary inversely with the size and territory of supply of the PICA. The principal findings are vertigo, vomiting, nystagmus, tinnitus, and sometimes unilateral deafness; facial weakness; ipsilateral cerebellar ataxia (inferior or middle cerebellar peduncle); an ipsilateral Horner syndrome and paresis of conjugate lateral gaze; and contralateral loss of pain and temperature sense of the arm, trunk, and leg (lateral spinothalamic tract) as shown in Fig. 34-14. The tinnitus, if present at all, may be overwhelming, called "screaming" by some of our patients. If the occlusion is close to the origin of the artery, the corticospinal fibers may also be involved, producing a hemiplegia; if distal, there may be cochlear and labyrinthine infarction. Cerebellar swelling did not occur with AICA territory infarction in the 20 collected by Amarenco and Hauw but it has been a more common occurrence in our material.

The most characteristic manifestation of all these basilar branch strokes is the "crossed" cranial nerve and long tract sensory or motor deficit reflecting a unilateral segmented infarction of the brainstem. These syndromes, which may involve any of cranial nerves III through XII, are listed in Table 34-5. Although the finding of bilateral neurologic signs strongly suggests brainstem involvement, these syndromes make it apparent that in many instances of infarction within the basilar territory, the signs are limited to one side of the body.

In the absence of one of the localizing crossed cranial nerve signs it is often not possible to distinguish a hemiplegia of pontine origin from one of deep cerebral origin on the basis of motor signs alone. In both, the face, arm, hand, leg, and foot are affected because of the compression of the descending motor fibers into a small segmental region. With brainstem lesions as with cerebral ones, a flaccid paralysis gives way to spasticity after a few days or weeks, and there is no satisfactory explanation for the occurrence in some cases of spasticity from the onset of the stroke. There is also often a combined hemiparesis and ataxia of the limbs on the same side. With a hemiplegia of pontine origin, however, the eyes may deviate to the side of the paralysis, i.e., the opposite of what occurs with supratentorial lesions. The pattern of sensory disturbance may also be helpful. A dissociated sensory deficit over the ipsilateral face and contralateral half of the body usually indicates a lesion in the lower brainstem, while a hemisensory loss including the face and involving all modalities indicates a lesion in the upper brainstem, in the thalamus, or deep in the white matter of the parietal lobe. When position sense, two-point discrimination, and tactile localization are affected relatively more than pain or thermal and tactile sense, a cerebral lesion is suggested; the converse indicates a brainstem localization. Bilateral motor and sensory signs are almost certain evidence that the lesion lies in the brainstem. When hemiplegia or hemiparesis and sensory loss are coextensive, the lesion usually lays supratentorially. Additional manifestations that strongly favor a brainstem site are rotational dizziness, diplopia, cerebellar ataxia, a Horner syndrome, and deafness. The numerous brainstem syndromes illustrate the important point that the cerebellar pathways, spinothalamic tract, trigeminal nucleus, and sympathetic fibers can be involved at different rostral-caudal levels so that "neighboring" phenomena are required to identify the exact site of the infarction.

A myriad of proper names have been applied to the brainstem syndromes, as noted in Tables 34-5 and 47-1. Many of them were originally described in relation to tumors, trauma, and other nonvascular diseases. The diagnosis of vascular disorders in this region of the brain is not greatly facilitated by knowledge of these eponymic syndromes; it is much more profitable to be closely familiar with the anatomy of the brainstem. To recapitulate, the principal syndromes to be recognized are the full basilar, vertebral-PICA, posteroinferior cerebellar, anteroinferior cerebellar, superior cerebellar, pontomedullary, and medial medullary. Figures 34-12 through 34-15, supplied by C.M. Fisher and used in all previous editions of this book, present both medial and lateral syndromes at

several levels of the medulla and pons. Other syndromes can usually be identified as fragments or combinations of the major ones.

Lacunar Stroke

As one might surmise, small penetrating branches of the cerebral arteries may become occluded, and the resulting infarcts may be so small or so situated as to cause no symptoms whatsoever. As the softened tissue is removed by macrophages, a small cavity, or lacune, remains. Early in the twentieth century, Pierre Marie referred to the condition as *état lacunaire* (the lesions were first described by Durant-Fardel in 1843). He distinguished these lesions from a fine loosening of tissue around thickened small vessels that enter the anterior and posterior perforated spaces, a change to which he gave the name *état criblé* (cribriform change). Pathologists have not always agreed on these distinctions, but we have adhered to the view of Fisher and Adams that lacunes are usually caused by occlusion of small arteries, 50 to 200 microns in diameter, and the cribriform state, to mere thickening of vessels and fraying of the surrounding tissue—i.e., dilated perivascular spaces (Virchow-Robin spaces) that do not have a corresponding neurologic disease.

In almost all clinical and pathologic material, there has been a strong relationship between the lacunar state and chronic hypertension, but also diabetes and hyperlipidemia. Sacco and colleagues (1991), in a population-based study in Rochester, Minnesota, found that 81 percent of patients with lacunar infarctions were also hypertensive. There appear to be three mechanisms for lacunar infarction but variants of atherothrombosis are foremost. The first, and the one most characteristically tied to lacunes, is a local type of fibrohyalinoid arteriolar sclerosis that involves the orifice or proximal part of a small penetrating blood vessel (lipohyalinosis as described below). The second is atherosclerosis of a large trunk vessel that occludes the origin of these same small vessels. This is prone to involve several adjacent vessels and cause, at times, larger lacunes or the atherosclerosis extends from a trunk vessel into a smaller one. Third is the entry of small embolic material into one of the vessels. The relative frequency of these three pathologies is not known, but the first seems to be most common and occurs without pathologic change in the trunk vessel of the circle of Willis whereas the embolic type is least frequent. When Fisher (1975) examined a series of such lesions in serial sections, from a basal parent artery up to and through the lacune, he was able to confirm a lipohyalin degeneration of the vessel wall and occlusion in the initial course of small vessels in most cases. In some, lipohyalinotic changes had resulted in false aneurysm formation, resembling the Charcot-Bouchard aneurysms, another hypertension-related change that underlies brain hemorrhage (see further on). In a series of 1,042 consecutive adults whose brains were examined postmortem, Fisher (1965b) observed one or more lacunes in 11 percent. He found 4 to 6 and sometimes up to 10 to 15 lacunes in any given brain specimen. In recent years, better treatment of hypertension has greatly reduced this number and the

overall frequency of lacunar infarction, at least as judged by MRI.

Lacunes are situated, in descending order of frequency, in the putamen and caudate nuclei, thalamus, basis pontis, internal capsule, and deep in the central hemispherical white matter. The cavities range from 3 to 15 mm in diameter, and whether they cause symptoms depends entirely on their location.

Lacunar strokes tend to evolve quickly but not typically as suddenly as an embolus, for example. These clinical aspects are discussed extensively in the earlier section “Lacunar TIA.” In broad terms, the essential feature of these deep strokes is the uniform and striking absence of cortical deficits; that is, seizures, aphasia or amnesia (except in limited circumstances of small thalamic infarction), agnosia, apraxia, dysgraphia, alexia, and, a large number of similar cognitive changes that only begin to appear when there are multiple deep strokes and a dementia of the type discussed in Chap. 21. Furthermore, because of the small size of the strokes, certain clinical syndromes that might be expected to result from deep lesions, such as hemianopia, also do not occur. Fisher, in several papers, has delineated the most frequent symptomatic forms of lacunar stroke:

1. Pure motor hemiplegia
2. Pure sensory stroke
3. Clumsy hand–dysarthria
4. Ipsilateral hemiparesis–ataxia

A lacune in the territory of a lenticulostriate artery, i.e., in the internal capsule or adjacent corona radiata, usually causes a highly characteristic syndrome of *pure motor hemiplegia* involving the opposite face, arm, hand, leg, and foot in approximately equal measure. A lacune situated in the ventral pons causes an identical syndrome (Fig. 34-16). In both cases, the lacunar syndrome is identified as much by its signature deficits as by those features that are absent; aphasia, apraxia, agnosia, and visual field defect. Symptoms may be abrupt in onset or evolve over several hours, but in some instances the neurologic deficit evolves stepwise and relatively slowly, over as long a period as 2 to 3 days. Our experience has tended toward the shorter time frame, with most patients reporting that the full deficit is present not instantaneously but within minutes. Recovery, which may begin within hours, days, or weeks, is sometimes nearly complete even in the face of a severe initial stroke. However, many patients are left with some degree of clumsiness or slowness of movement of the affected side.

The motor disorder may take the form of a hemiparesis of the face and arm or arm and leg, or predominantly arm and proximal leg weakness; these fragmented patterns are indicative of a lesion located higher than the internal capsule, in the centrum semiovale. In these cases the stroke simulates an embolic stroke affecting the cortex.

A lacune of the lateral thalamus or (less often of the deep parietal white matter) is the cause of hemisensory defect involving the limbs, face, and trunk extending to the midline with no motor or language difficulty, a *pure sensory stroke*. Partial sensory syndromes involving only parts of the hemibody are less frequent than in motor

lacunar strokes. The incidence, course, and outcome are much the same as in a pure hemiplegia.

As mentioned, in the ventral pons, the lacunar syndrome may be one of pure motor hemiplegia, mimicking that of internal capsular infarction except at times for relative sparing of the face and the presence of an ipsilateral paresis of conjugate gaze in some cases; or there is another highly characteristic lacunar syndrome of a combination of *dysarthria and clumsiness* of one hand. This “clumsy hand–dysarthria” stroke is usually located in the paramedian midpons on the side opposite the clumsy limb but a lacune in the posterior portion of the internal capsule on the side opposite the affected limb. Occasionally a lacunar infarction of the pons, midbrain, internal capsule, or parietal white matter gives rise to a *hemiparesis with ataxia* on the same side as the weakness (Fisher, 1965a; Sage and Lepore). Some of the brainstem syndromes may blend with basilar branch syndromes.

There are many other, less frequent, lacunar configurations but they can be identified by their similarity to one of the archetypal syndromes; they tend to affect one limited system or are fragments of a typical syndrome. Indeed, Fisher (1982) described 20 such variant types and several “miscellaneous” patterns. Some of these are difficult to accept, such as pure motor hemiparesis with confusion and loss of memory, but we have encountered many of the others, admittedly infrequently, including pure dysarthria, hemiballismus, virtual locked-in syndrome from bilateral lacunes in the base of the pons, and pure motor hemiplegia with sixth nerve palsy.

Some strokes that carry the term “lacune” are simply the result of larger deep cerebral infarctions along the lines of the striatocapsular stroke discussed earlier. In order

to retain its clinical utility, the term lacune is probably best applied to small deep lesions that are the result of occlusion of a correspondingly small vessel and not to those strokes that result from occlusion of the orifices of several adjacent small vessels and are typically from larger atheromas in a parent vessel.

Multiple lacunar infarcts involving the corticospinal and corticobulbar tracts are a common cause of pseudobulbar palsy in clinical practice (trailed in frequency by amyotrophic lateral sclerosis and infiltrating tumors). Undoubtedly, an accumulation of lacunes deep in both hemispheres can give rise to gait disorders and also to mental dulling sometimes referred to as multiinfarct dementia (see further on and Chap. 21). The main differential diagnostic considerations are normal-pressure hydrocephalus (see Chap. 31) and the common degenerative brain conditions that affect the frontal lobes and basal ganglia (see Chap. 39).

Finally, it should be emphasized that what appears initially to be a lacunar syndrome may be the initial component or warning sign of a large deep territory infarction in the middle, posterior cerebral, or basilar arteries.

As mentioned earlier, MRI is more reliable than CT in demonstrating the lacunes. Initially, lacunes are seen on the MRI as deep oval or linear areas of T2, fluid-attenuated inversion recovery (FLAIR), and, especially, diffusion-weighted signal abnormality; later they become cavitated. Representative lacunar infarctions are shown in Fig. 34-16. The EEG, while little used for this purpose nowadays, may be helpful in a negative sense; in the case of lacunes in the pons or the internal capsule, there is a notable discrepancy between the unilateral paralysis or sensory loss and the negligible electrical changes over

Figure 34-16. Axial diffusion-weighted MRI of acute lacunar infarctions. A. Left capsular infarction causing a right pure motor hemiplegia. B. Left pontine infarction causing a clumsy hand–dysarthria syndrome.

the affected hemisphere and, even with lacunes of the cerebrum, any EEG changes are disproportionately mild in comparison to the deficit.

TREATMENT OF ISCHEMIC STROKE

The main objective in these forms of ischemic cerebrovascular disease is the amelioration of the existing deficit and the prevention of future stroke. It is now a major goal of general medicine to reduce the incidence of stroke in the general population by the control of modifiable risk factors ("primary prevention"). In addition to reduction of known risk factors such as hypertension, smoking, and glucose control in diabetics, the widespread use of cholesterol-lowering statin medications has been shown in some studies to reduce the primary incidence of and recurrence of stroke. The treatment of stroke may be divided into three parts: management in the acute phase by measures to restore the circulation and arrest the pathologic process, physical therapy and rehabilitation, and measures to prevent further strokes and progression of vascular disease.

Management in the Acute Phase

The relative advantages of placing the seriously ill acute stroke patient in a special "stroke" unit have been the subject of much study. The outcome in these patients in terms of morbidity and mortality is improved, although the differences have been small and difficult to document. However, this organizational plan has not been widely implemented and instead protocols for rapid evaluation of stroke and the emergence of a specialty of stroke neurology have proliferated instead. If nothing else, this is the result of a general recognition that stroke, like myocardial infarction, requires special expertise and focus. Protocols to prevent excessive hypertension after thrombolytic treatment are best instituted in units that have staffing patterns that create familiarity with these and other protocols. As already emphasized, the prevention of aspiration and pneumonia is paramount by identifying those patients at risk. The patients at risk also benefit from systematic application of protocols. Also deserving attention is the prevention of venous thrombosis in the legs, pulmonary embolism, and coronary syndromes. Some units find it advisable to keep patients supine for the first hours or day after an ischemic stroke, mainly to prevent hypotension and cerebral hypoperfusion; this approach has not been studied systematically. When sitting and walking begin, special attention should be given to the maintenance of normal blood pressure.

Several studies have confirmed the high prevalence of new or enhanced levels of hypertension immediately following an ischemic stroke and its tendency to decline over subsequent days even without medications. The treatment of previously unappreciated hypertension is preferably deferred until the neurologic deficit has stabilized. As suggested by Britton and colleagues, it is prudent to avoid antihypertensive drugs in the first few days unless there is active myocardial ischemia or

the blood pressure is high enough to pose a risk to other organs, particularly the kidneys, or there is a special risk of cerebral hemorrhage as a result of the use of thrombolytic drugs.

Measures to Restore the Circulation and Arrest the Pathologic Process

Efforts are directed at establishing a diagnosis of thrombotic stroke at the earliest possible stage and circumventing the full deficit by all means available without risking the safety of the patient. Even when the symptoms and signs have become static, some of the affected tissue may not be irreversibly damaged and will survive if perfusion can be reestablished (the penumbra). If the patient is under care within 4.5 h of onset of the first symptom and this time can be established with confidence, thrombolytic therapy with tissue plasminogen activator (tPA) is usually indicated. The contraindications and implementation of thrombolytic therapy is given in detail in the next section.

Intravenous Thrombolytic Agents

Tissue plasminogen activators (recombinant tPA) convert plasminogen to plasmin. These drugs are effective in the treatment of coronary artery occlusion (but are associated with a 1 percent risk of cerebral hemorrhage) and have a reasonably clear role in the treatment of acute ischemic stroke. As an alternative to the usual form of tPA, alteplase and tenecteplase are genetically engineered mutant form of plasminogen activators. In the following discussion, we use "tPA" to represent all of the tissue plasminogen activators.

The benchmark study organized by the National Institute of Neurological and Communicative Disorders and Stroke (see the NINCDS and Stroke rtPA Stroke Study Group in the references) has provided evidence of benefit later from *intravenous tPA* when patients were examined months later. Treatment within 3 h of the onset of symptoms led to a 30 percent increase in the number of patients who remained with little or no neurologic deficit when reexamined 3 months after the stroke; this benefit persisted when assessed 1 year later in the study by Kwiatkowski and associates. It is not easy to comprehend why the benefits extended to all types of ischemic strokes, including those caused by occlusion of small vessels (lacunes) and why improvement was not apparent in the days immediately following treatment, only at later times.

The tPA in the NIH study was administered in a dose of 0.9 mg/kg, 10 percent of which was given as an initial bolus, followed by an infusion of the remainder over 1 h. This has been adopted as a conventional approach in practice. A dose of 90 mg was not exceeded, this being lower than the dose used for myocardial infarction. The relative improvement in neurologic state came at the expense of a 6 percent risk of symptomatic cerebral hemorrhage, i.e., a far lower rate than in most previous studies but twice the expected rate without thrombolysis (some of the hemorrhages were into the area of infarction and did not cause symptomatic worsening). Patients were excluded from the study if they had massive infarctions

(encompassing more than two-thirds of the territory of the middle cerebral artery), had high scores on a clinical stroke scale that was devised for the National Institutes of Health (NIH) study (available at: http://www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pdf and from other sources) had uncontrolled hypertension, were more than 80 years of age, or had recently received anticoagulants (except aspirin). Further analysis of the NINCDS trial revealed that patients who were treated earliest within the 3-h time frame had more benefit than those treated later; indeed, the administration of tPA in the time period between 2.5 and 3 h after the stroke was of less value.

Attempts to establish that patients with a longer duration of ischemic symptoms benefit from tPA have varied in success but have favored an effect up to 4.5 h as noted below. In particular, a subgroup of patients with carotid–middle cerebral artery strokes of moderate severity did appear to benefit. In some patients with basilar artery occlusion and coma of brief duration and those without extensive thrombosis, prompt tPA treatment also resulted in an overall improvement in neurologic function, but there were numerous exceptions. Following from these findings, a randomized trial of over 800 patients receiving tPA between 3 and 4.5 h after the onset of symptoms demonstrated that 10 percent more achieved a good outcome if given the drug than placebo and, although more had cerebral hemorrhages, the overall mortality was the same in the treated and untreated groups (Hacke et al, 2008). This study has altered practice to extend the acceptable interval for drug administration to 4.5 h if proper care is taken to select low-risk patients and prevent excessive blood pressure after tPA is given. A summary of the sequence of clinical trials that have led to the current recommendations for the use of tPA in acute stroke has been reviewed by Wechsler. Taken from a summary by the American Heart Association are the generally agreed upon inclusion and exclusion criteria for the use of intravenous tPA in Table 34-6. Intracranial and systemic bleeding is, of course, the great concern but a minor but interesting point is that some patients, who had been receiving angiotensin-converting enzyme inhibitors for the treatment of hypertension, seem to display angioneurotic edema as a side effect of tPA.

Generally excluded are those in whom the deficit is either very small (e.g., hand affected only, dysarthria alone, minor aphasia) or, more importantly, is so large as to implicate almost the entire territory of the middle cerebral artery. Many centers have expanded their practices beyond the confines of the NIH study, treating patients older than age 80 years and some with large strokes. Attempts are currently being made to identify patients in whom there is a mismatch between regional cerebral perfusion and preservation of brain tissue (typically shown by the absence of restricted water diffusion on MRI), but several studies so far have failed to demonstrate that selection of patients on this basis improves clinical outcome. Also ambiguous is the treatment of patients with acute stroke in whom the referable cerebral vessels are entirely patent.

An apparently effective ancillary technique has been to supplement intravenously administered tPA with 2 h

Table 34-6

CRITERIA FOR THE USE OF INTRAVENOUS TPA IN ACUTE ISCHEMIC STROKE^a**Inclusion criteria**

- Acute ischemic stroke with measurable neurologic deficit
- Onset of symptoms less than 3 h before institution of treatment (all preliminary diagnostic tests must be completed)
- Onset of symptoms between 3 and 4.5 h and patient younger than 80 years, and with NIH stroke score below 25, nondiabetic, and having received no recent anticoagulant medication, regardless of INR^b
- Age over 18 years

Exclusion criteria

- Cerebral imaging showing intracerebral hemorrhage
- Cerebral imaging demonstrating large infarction, >1/3 territory of a cerebral hemisphere (CT hypodensity or diffusion restriction on MRI)
- Head trauma within 3 months prior to stroke
- History of intracranial hemorrhage
- Elevated blood pressure; systolic >185 mm Hg or diastolic >110 mm Hg that has not responded to medications
- Active bleeding or arterial puncture at noncompressible site
- Hematologic alternations including
 - Platelet count <100,000/mm³
 - Heparin administered within 48 h resulting in a PTT above normal range
 - Current use of anticoagulation with INR >1.7 or prothrombin time >15 s
- Blood glucose <50 mg/dL (2.7 mmol/L)

Relative contraindications

- Minor or resolving stroke
- Seizure at onset
- Major surgery or trauma within 14 days
- Gastrointestinal or urinary bleeding within 21 days
- Myocardial infarction within 3 months

^aAdapted from 2010 American Heart Association Guidelines.

^bAdditional restrictions for the time period 3 to 4.5 h are taken from the European Cooperative Acute Stroke Study III (ECASS III); see Hacke, 2008.

of continuously applied transcranial ultrasound aimed at the occluded vessel. According to Alexandrov and colleagues, complete recanalization of the middle cerebral artery or clinical recovery occurred within 2 h but the outcome at 3 months did not differ from those who did not receive ultrasound in part because other similar trials were terminated prematurely as a result of high rates of cerebral hemorrhage. The technique has not been adopted into general clinical work. At least one small trial has shown alteplase to be slightly superior to tPA in restoring vascular patency if certain technical features of maintained cerebral perfusion were used to select patients (see Parsons and coworkers).

Although a valid approach to acute stroke, the use of acute thrombolytic therapy depends on the early identification of an as yet limited group of patients who arrive under care well before the 4.5 h from the onset; therefore this therapy is applicable to only a proportion of patients who present to the emergency department soon after the first symptoms (approximately 10 percent in most surveys) or those who have strokes while under observation in the hospital. It is noteworthy that attempts to

reproduce the beneficial effects of tPA in a community setting have demonstrated deviations from treatment guidelines and an excess number of hemorrhages (Katzan et al). Nonetheless, acute intravenous thrombolysis that is managed by experienced individuals using validated protocols is an appropriate treatment for acute ischemic stroke. Public health education should increase the numbers of stroke patients who seek early attention and thus raise the proportion who are eligible for tPA treatment.

Intraarterial Thrombolysis

Thrombolytic substances injected intraarterially, or mechanical lysis for disruption or removal of an intravascular clot, can in some instances restore blood flow of the middle cerebral and basilar arteries. There is a high incidence of reocclusion of the treated vessel unless anticoagulants and stenting are also used. The most recent approaches involve one of a number of devices that retrieve clots from the intravascular lumen. Although early studies suggested that the results of intravascular clot lysis or removal were somewhat better than for intravenous or intraarterial thrombolysis, when more rigid criteria and trial design were applied, no such benefit has been shown.

In particular, three studies with different approaches to comparing these methods showed no clinical benefit for intraarterial means of restoring vascular patency in comparison to intravenous tPA (Broderick et al, and also Ciccone et al); and interventional methods were not superior when patients were selected on the basis of imaging patterns that demonstrated an area of ischemic tissue that was not yet infarcted (Kidwell and coworkers). Arguments notwithstanding that better mechanical devices will lead to improved outcomes, the results of systematic studies so far make it difficult to endorse intraarterial methods to revascularize cerebral vessels after acute stroke outside the confines of a clinical trial. The question of reversing the neurologic deficit from basilar artery thrombosis without cerebellar infarctions is nonetheless being studied.

Acute Surgical Revascularization

This refers to the opening of the carotid artery or an area of intracranial atherosclerosis immediately after a stroke with the intention of improving the clinical outcome; the issue of endarterectomy for the prevention of future strokes is another matter and is taken up in a later section. In past decades, there had been limited experience with immediate surgical removal of a clot from the carotid artery or the performance of a bypass to restore function. Ojemann and colleagues (1995) operated on 55 such patients as an emergency procedure; 26 of these had stenotic vessels and 29 acutely thrombosed vessels. Of the latter, circulation was restored in 21, with an excellent or good clinical result in 16. In 26 patients with stenotic carotid arteries, an excellent or good result was obtained in 19. Usually several hours will have elapsed before the diagnosis is established. If the interval is longer than 12 h, opening the occluded vessel is usually of little value and may present additional dangers. In any case, this approach has been largely supplanted by the

above-described endovascular techniques. Reoperation because the vessel has closed or caused an embolus immediately after carotid endarterectomy is a special circumstance in which rapid removal of a clot or repair of an intimal tear is performed more or less routinely and is also mentioned in a later section. This subject is reviewed again further on.

The separate issue of the endovascular treatment of intracranial atherosclerosis is considered here for convenience. The risks of manipulating intracranial vessels are obvious, particularly those of the circle of Willis with no surrounding tissue because they are located within the subarachnoid space. In an attempt to determine if a stent and angioplasty would improve outcome in patients who had TIAs or minor strokes as a result of an intracranial stenosis, Chimowitz and colleagues (2011) reported that their trial was stopped early because of poor outcomes of the group who were treated by stent in comparison to medical management. The treatment of symptomatic intracranial atherosclerosis therefore remains problematic and is delegated to the antiplatelet drugs and lipid-lowering agents discussed further on.

Anticoagulation

Several considerations weigh in any discussion of the institution and choice of antiplatelet or anticoagulant treatment (meant here to denote the agents that alter the clotting cascade) for stroke. First is the distinction between anticoagulation to prevent the progression of an acute stroke and the prophylactic use of anticoagulation for the prevention of future strokes. The pivotal issue in prevention of further strokes is whether the stroke or TIA is atherothrombotic or cardioembolic. As discussed further on, several studies point conclusively to a role for anticoagulation in stroke due to certain cardioembolic sources, particularly atrial fibrillation, while the indications in atherothrombotic disease are less certain.

Heparin Treatment during an Acute Evolving Stroke

Although not intuitive, if one holds the concept that a thrombus must form on an atherosclerotic plaque in order to cause stroke, it is apparent that anticoagulants have little effect at preventing the recurrence or progression of a thrombotic stroke and are certainly no more effective than agents that interfere with platelet aggregation. The two situations in which the immediate administration of heparin or an equivalent agent such as enoxaparin have drawn the most support from clinical practice are in basilar artery thrombosis with fluctuating deficits and in impending carotid artery occlusion from thrombosis or dissection. In these situations, the administration of heparin may be initiated while the nature of the illness is being clarified; the drug is then discontinued if contraindicated by new findings. Satisfactory clinical studies in support of this approach of acute anticoagulation have not been carried out and most authoritative writers find no evidence for the use of heparin in these situations (see, for example, Report of the Joint Stroke Guideline Development Committee authored by Coull et al). One fact seems fairly clear—that the administration of anticoagulants is not of great value once the stroke is fully developed.

Swanson has reviewed several trials evaluating heparin (including the International Stroke Trial and the TOAST study) and suggested that there was no net benefit from heparin in acute stroke because of an excess of cerebral hemorrhages. However, in these series there was a low incidence, estimated as 2 percent, of recurrent stroke in the first weeks after a cerebral infarction in the untreated groups. An early recurrent stroke rate this low almost precludes demonstrating a benefit from the use of heparin or heparinoid drugs. The issue of administering heparin in cases of recent cardioembolic cerebral infarction, particularly as a “bridge,” while waiting for the effects of warfarin to be established is addressed further on.

In the event heparin is used, and assuming tPA has not been used in the preceding 24 h, heparin may be given intravenously, beginning with a bolus of 100 U/kg followed by a continuous drip (1,000 U/h) and adjusted according to the partial thromboplastin time (PTT). Bleeding into any organ may occur when the PTT is greater than 3 times the pretreatment level. When the PTT exceeds 100 s, it is preferable to discontinue the infusion, check the blood clotting values, and then reinstitute the infusion at a lower rate based on the test results (rather than simply lower the infusion rate). In circumstances of fluctuating basilar artery ischemia, it is our practice to permit higher values of PTT.

The use of low-molecular-weight heparin (enoxaparin or nadroparin) given subcutaneously within the first 48 h of the onset of symptoms have uncertain benefit. In a limited trial, there was no increase in the frequency of hemorrhagic transformation of the ischemic region when compared to placebo treatment (Kay et al). Because the outcome measures in this study were coarse (death or dependence 6 months after stroke), further investigations of this approach need to be carried out. We can only infer that the use of low-molecular-weight heparin (approximately 4,000 U subcutaneously, tid) appears to be safe but there is no compelling evidence supporting their use in acute ischemic stroke.

Warfarin for the Prevention of Recurrent Strokes from Atrial Fibrillation (see Table 34-3) The most convincing evidence favoring the efficacy of anticoagulants in the prevention of embolism comes from the Boston Area Anticoagulant Trial for Atrial Fibrillation. A group of patients at risk for stroke from chronic atrial fibrillation was randomized to be maintained for 2 years on warfarin (INR of 1.5 to 2) or no anticoagulation; there were 212 anticoagulated patients and 208 controls. Recurrent strokes were reduced by 86 percent in the warfarin group and the death rate was lower. One fatal hemorrhage occurred in each group; minor hemorrhages occurred in 38 of the warfarin-treated group and in 21 of the control group. In a similar study from Copenhagen, the incidence of stroke in a group receiving warfarin was calculated to be 2 percent per year in comparison to 5.5 percent per year in an untreated group. Several subsequent trials have attested to the efficacy of warfarin in the prevention of stroke in patients with nonrheumatic atrial fibrillation (see Singer). Subsequent studies suggest that an INR between 2 and 3 confers better protection than levels below 2. It should be pointed out, however, that patients younger than

65 years of age in these trials did not clearly benefit from long-term prophylactic anticoagulation unless there were additional cerebrovascular risk factors such as diabetes, hypertension, congestive heart failure, or cardiac valvular disease. Those younger than 65 years old and without such additional features (*lone fibrillators*), constituting about one-third of adults with atrial fibrillation, have a low risk of stroke. These observations are incorporated into the CHADS scores summarized in Table 34-3. Aspirin does not appear to afford the same degree of protective benefit as does anticoagulation, but some studies suggest a slightly better outcome than with no treatment; it has been used in the younger group of patients and in those unable to take warfarin.

Intracranial hemorrhage must be excluded by CT or MRI. A determination of prothrombin and partial thromboplastin activity is needed before therapy is started, but if this is not feasible, the initial doses of anticoagulant drugs can usually be given safely if there is no clinical evidence of bleeding anywhere in the body and there has been no recent surgery. Warfarin therapy, beginning with a dose of 5 to 10 mg daily, is relatively safe provided that the international normalized ratio (INR) is brought to 2 to 3 (formerly measured as a prothrombin time between 16 and 19 s) and the level is determined regularly (an approximate plan is once a day for the first 5 days, then 2 or 3 times a week for 1 to 2 weeks, and finally once every several weeks). Because there is no reliable evidence that complications are more frequent in the presence of mild to moderate hypertension if the INR is not allowed to exceed 2 to 3 times normal, we have not withheld anticoagulant therapy in these patients. However, when the blood pressure is greater than 220/120 mm Hg, an attempt is made to lower it gradually at the same time. Numerous drugs may alter the anticoagulant effects of the coumarins or add to the risk of bleeding—aspirin, cholestyramine, alcohol, carbamazepine, cephalosporin and quinolone antibiotics, sulfa drugs, and high-dosage penicillin being the most important ones. Hemorrhagic skin necrosis is a rare but dangerous complication. It is the result of a paradoxical microthrombosis of skin vessels and is liable to occur in patients with unsuspected deficiencies of endogenous clotting proteins (S and C). Although the disseminated form of skin necrosis occurs within days of initiating warfarin therapy, we have seen one patient with a form of this lesion following local skin injury after months on treatment.

For patients with atrial fibrillation of recent onset, an attempt should be made to restore normal sinus rhythm by the use of electrical cardioversion or a trial of antiarrhythmic drugs. If these fail, prophylactic anticoagulant therapy is recommended. Before attempting cardioversion of more long-standing atrial fibrillation anticoagulation for several days or longer is advisable to reduce emboli.

As noted below, opinions vary about the use and precise timing of instituting anticoagulation with warfarin after an embolic stroke, in part because the risk of recurrent stroke in the first days and weeks is low. In the past, there had been a theoretical risk of transient hypercoagulability when starting warfarin (on the basis of upregulation of protein S); this, and a desire to institute

anticoagulation rapidly, led to a strategy of “bridging” with heparin or a low-molecular-weight heparin while awaiting the effects of warfarin to be evident. This risk has seemingly not had clinical significance. Therefore, on the basis of the aforementioned trials of acute anticoagulation that showed only a 1 to 2 percent frequency of early recurrent stroke, most clinicians have eschewed the “bridging” approach. The view that opposes heparin or a similar anticoagulant is based also on a retrospective study by Hallevi and colleagues, supported by a meta-analysis reported by Whiteley and coworkers, that found higher rates of symptomatic and serious bleeding in the brain or systemically with the bridging strategy.

In patients with very large cerebral infarcts that have a component of deep (basal ganglionic) tissue damage, especially in those patients who are also hypertensive, there may be a risk of anticoagulant-related hemorrhage into the acute infarct—“hemorrhagic conversion” (Shields et al). With the exception of urgent circumstances such as a mechanical heart valve that requires continuous anticoagulation, current practice has been to delay instituting warfarin when the stroke is large, a definition that is admittedly difficult to quantify—perhaps greater than half or a third of the territory of the middle cerebral artery supply. In these patients, anticoagulation therapy perhaps should be delayed for several weeks but even this is uncertain.

A frequent clinical problem arises in an elderly patient with atrial fibrillation who is at risk of falling from any of a number of causes including the stroke itself. In a review of selected administrative database records, Gage and colleagues concluded that the overall risk of inducing cerebral hemorrhage in older patients with atrial fibrillation treated with warfarin was lower than the risk of recurrent stroke. In those patients who had hemorrhages while receiving warfarin, they were, however, more likely to be fatal. Of course, decisions about anticoagulation must be tailored to the conditions of the individual patient. Alternatives to warfarin in patients with atrial fibrillation have been explored, such as the thrombin inhibitor ximelagatran, which has the advantage of not requiring monitoring by blood tests (see the Stroke Prevention Using an Oral Thrombin Inhibitor in Atrial Fibrillation [SPORTIF] trial).

Anticoagulant therapy may also be desirable for at least several weeks in patients with acute myocardial infarction, especially if the left side of the heart is involved. No guidelines have been established in these circumstances; the new common use of one or more platelet aggregation inhibitor drugs after myocardial infarction may preclude the concurrent use of warfarin. In cerebral embolism associated with bacterial endocarditis, anticoagulant therapy should be used cautiously because of the danger of intracranial bleeding, and one proceeds instead with antibiotics. Generally, we have not anticoagulated these patients.

Warfarin for the Prevention of Further Strokes in the Weeks and Months after a First Stroke Not due to Atrial Fibrillation Despite its established benefit in preventing embolic strokes from atrial fibrillation, whether warfarin is effective in preventing strokes in patients with TIAs or recent stroke that are not due to atrial fibrillation is

a question that has never been answered satisfactorily. Decisions regarding this matter depend not only on the putative ability of warfarin to prevent stroke but on an assessment of the relative risk of causing cerebral or systemic hemorrhage. The problem that continues to plague all attempts to use long-term anticoagulants, as already noted in the discussion regarding heparin in the acute situation, is the risk of hemorrhage estimated by Whisnant and colleagues to be 5 percent overall and considerably higher in elderly patients who have been treated for more than 1 year.

There had been a notion that warfarin is of some value in the first 2 to 4 months following the onset of an ischemic stroke due to *atherosclerotic* disease. However, the results of controlled studies have indicated that there is no reason to favor warfarin in comparison to aspirin in cases of atherothrombotic stroke. This was amply shown in the Warfarin-Aspirin Recurrent Stroke Study (WARSS; not including cardioembolic stroke) reported by Mohr and colleagues (2001); over 2 years the recurrent stroke rate was about 16 percent in both groups, and, surprisingly, the rate of cerebral hemorrhage was similar (near 2 percent). Similarly, for the special case of TIA or stroke that is shown to be because of intracranial atherosclerosis, Chimowitz and colleagues in the Warfarin-Aspirin Symptomatic Intracranial Disease (WASID) trial have suggested that warfarin provided no benefit over aspirin in preventing subsequent cerebrovascular events but warfarin had more risk as commented below. The WASID trial exposed not so much the deficiency of warfarin in prevention of stroke as much as the difficulties in its use, as pointed out by Koroshetz.

In contrast to the situation with atherothrombotic disease, warfarin is still used by some clinicians for prevention of a second stroke in *cardioembolic* disease. This applies more specifically to instances of a demonstrated source for the embolus in the cardiac chambers, valves, or through a patent foramen ovale as well as atrial fibrillation discussed earlier. The larger number of “*cryptogenic strokes*,” many of which may nevertheless be cardioembolic, cannot be confidently treated with warfarin. Of course, the extent of the evaluation to establish that an embolic stroke may have its origin in the heart, determines the likelihood of delineating a stroke as cryptogenic. In particular, several studies have shown that prolonged heart rhythm monitoring (event monitors) for up to 30 days moderately increases the rate of detection of atrial fibrillation. This creates a conundrum for the clinician confronted with a patient with an otherwise unexplained embolic stroke. There is therefore some latitude in deciding on treatment to prevent stroke in the subsequent months: none, aspirin (see below), or warfarin, as older studies had suggested. The issue of delaying anticoagulation after a large ischemic stroke was discussed in the preceding section.

The justification for, and excess risk of hemorrhage, when combining an antiplatelet agent with warfarin, has not been quantified. There seems to be relatively small risk if low-dose (81 mg) aspirin is included in a regimen of warfarin for atrial fibrillation. Beyond this statement, little can be said with authority but our personal experience, certainly tainted by the weaknesses engendered

by the availability heuristic, is that subdural hematomas abound in elderly patients, with or without falls, who are on one or more agents. Even the relatively rapid reversal of anticoagulation with vitamin K and one of the clotting factor preparations or fresh plasma do little more than allow for safer surgery to remove intracerebral clots. Certain conditions such as chronic renal failure may confer a greater risk of cerebral hemorrhage with either drug, but the stroke risk from atrial fibrillation is also increased in comparison to patients with normal renal function as described in the epidemiologic study by Olesen and colleagues.

The introduction of factor Xa inhibitors has offered an alternative to the vitamin K antagonist, warfarin, for reducing strokes in patients with atrial fibrillation. In one study by Granger and coworkers that introduced apixaban for this purpose, there were slightly fewer strokes and fewer cerebral hemorrhages than with warfarin when the intended goal with warfarin was to keep the INR between 2 and 3. Dabigatran and rivaroxaban confer similar reductions in stroke to apixaban and warfarin (c.f., Patel et al). These drugs have the advantage over warfarin of not requiring regular blood tests for the measurement of the INR and of having fewer drug interactions. However, although they have short half-lives compared to warfarin, they are still present for many hours after discontinuation and anticoagulation is not easily reversible should there be systemic or cerebral bleeding.

Any type of serious bleeding with warfarin, even if not a result of overdosage, justifies immediate administration of fresh-frozen plasma and large doses of vitamin K. An INR above 5 in a patient who must remain anticoagulated—for example, one with a prosthetic heart valve—may be corrected with small doses of vitamin K (0.5 to 2 mg), preferably given intravenously.

Thus, it would appear that with long-term administration of warfarin, except in certain circumstances—such as a severely stenotic cerebral vessel, atrial fibrillation, prosthetic heart valve, and certain blood disorders—the risk of hemorrhage outweighs the benefit from prevention of stroke.

Antiplatelet Drugs

Aspirin has proved to be the most consistently useful drug in the prevention of thrombotic and possibly, embolic strokes. One currently favored approach, based in part on the above-mentioned WARSS trial, is to simply administer aspirin in all cases of acute stroke (except perhaps if tPA has been used). This approach is further endorsed by the WASID trial comparing aspirin (1,300 mg/d) to warfarin for treatment of intracranial arterial stenosis on the basis that warfarin was no better at preventing strokes while aspirin was associated with fewer gastrointestinal hemorrhages and a lower overall death rate. Confirmation of this approach was given by the IST and CAST trials that established a modest reduction in mortality and stroke recurrence if aspirin was given within 48 h of stroke.

The acetyl moiety of aspirin combines with the platelet membrane and inhibits platelet cyclooxygenase, thus preventing the production of thromboxane A₂, a vasoconstricting prostaglandin, and also prostacyclin,

a vasodilating prostaglandin. In patients who cannot tolerate aspirin, the platelet aggregate inhibitor clopidogrel or a similar drug (such as *ticlopidine* or *dipyridamole*) can be substituted (see below).

A number of controlled studies have attested to the therapeutic value of aspirin and ticlopidine, clopidogrel, or dipyridamole in stroke prevention (not acute treatment as discussed above), but it is important not to exaggerate the magnitude of their effects. With few exceptions, it can be concluded that aspirin is beneficial in preventing stroke; whether low doses (50 to 100 mg) and high doses (1,000 to 1,500 mg) provide equivalent protection is still uncertain.

From a review of several studies, it appears that both dosages are effective and that the addition of dipyridamole further reduces the risk of stroke by a small amount. Ticlopidine and clopidogrel are considered, on the basis of clinical trials, to be equivalent to or marginally more effective than aspirin for the prevention of stroke but they are more expensive. Furthermore, both drugs are potentially toxic; ticlopidine may produce neutropenia and clopidogrel may cause thrombotic thrombocytopenic purpura. Dipyridamole in high doses has not been as well tolerated by many of our patients because of dizziness induced by peripheral vasodilatation.

The combined use of these antiplatelet drugs with aspirin has generally been slightly superior to aspirin alone in secondary stroke prevention, but with an increased risk of cerebral hemorrhage in some studies. In most large trials, the incremental benefits of adding one of these drugs to aspirin has been of the order of 1 to 3 percent (see the ESPRIT study and Bhatt et al and Sacco et al, a trial that failed to show benefit for the addition of extended release of dipyridamole to aspirin). A recent study with over 5,000 patients from China, the CHANCE trial reported by Wang and coworkers, did demonstrate a reduction in stroke recurrence during the first 90 days after the first minor stroke or TIA by adding clopidogrel to aspirin, either 75 mg or 300 mg, and no increase in cerebral hemorrhages. All that can be said at the moment is that the use of dual antiplatelet function agents may confer slight benefit over aspirin alone after a stroke but we remain wary of the potential risks.

In trials comparing aspirin to anticoagulation for stroke prevention in atrial fibrillation, anticoagulation has still been superior (see ACTIVE Writing Group). These studies notwithstanding, the therapeutic effectiveness of aspirin is still rather slight and the addition of clopidogrel to aspirin in patients who were not deemed suitable for warfarin reduces strokes over several years of observation but increases the risk of major bleeding so that the combination cannot be endorsed (ACTIVE Investigators). Moreover, in each of the trials, a significant number of subsequent ischemic strokes occurred in patients while they were receiving aspirin.

The best course of treatment for patients who have lacunar or atherothrombotic strokes while already receiving antiplatelet medications is not clear. Switching to warfarin from antiplatelet agents is sensible in some circumstances but should be done with caution. Control of blood pressure and the administration of a lipid-lowering

drug are advisable, even if lipid levels are normal. In the most comprehensive study of statins to date, the institution of high doses of drug reduced the incidence of subsequent stroke after a TIA or first stroke by 2 percent over 5 years (see Stroke Prevention by Aggressive Reduction in Cholesterol Investigators [SPARCL trial]). This was at the expense of a slight increase in the other large studies that have not shown this effect with lower doses of statin drugs. Whether this is adequate to adapt into routine practice is unclear to us.

Other Forms of Medical Treatment

In the past, treatment by hemodilution was popularized by the studies of Wood and Fleischer, who showed a high incidence of short-term improvement when the hematocrit was reduced to approximately 33 percent. That lowering blood viscosity improves regional blood flow in the heart had been known for some time, and a similar effect on the brain has been demonstrated by CBF studies. Earlier observations had shown a reduction in the overall neurologic deficit, but almost all larger randomized trials—which included patients in many settings who were treated at various times up to 48 h after stroke—failed to confirm any such benefit, and the use of this treatment has been virtually abandoned. While this treatment cannot be recommended as a routine approach, it may have some merit in selected situations, such as fluctuating stroke. Therapies aimed at improving blood flow by enhancing cardiac output (aminophylline, pressor agents), by improving the microcirculation (mannitol, glycerol, dextran), or by use of a large number of vasodilating drugs (see below) have failed to show consistent benefits, but several are still under study. Normobaric and hyperbaric oxygen may reduce ischemic deficits temporarily but have no sustained effect. Induced hypothermia limits the size of ischemic stroke, but it is technically difficult to administer and often has serious side effects.

Calcium channel blockers of the types administered for cardiac disease have also been found to increase CBF and to reduce lactic acidosis in stroke patients. However, several multicenter clinical trials that compared calcium channel blockers with placebo did not establish a difference in outcome in the two groups. There has also been interest, as noted earlier in this chapter, in drugs that inhibit excitatory amino acid transmitters and free-radical scavengers such as dimethyl sulfoxide (DMSO) and growth factors, but so far none of these has been successfully applied to humans.

Despite some experimental evidence that certain vasodilators, such as CO₂ and papaverine, increase CBF, none has proved beneficial in carefully studied human stroke cases at the stage of TIAs, thrombosis in evolution, or established stroke. Vasodilators may actually be harmful, at least on theoretical grounds, because by lowering the systemic blood pressure or dilating vessels in normal brain tissue (the autoregulatory mechanisms are lost in vessels within the infarct); they may reduce the intracranial anastomotic flow. Moreover, the vessels in the margin of the infarct (border zone) are already maximally dilated. New discoveries regarding the role of nitric oxide in vascular control will probably give rise to

new pharmacologic agents that will require evaluation. The metabolic stresses of ischemia and the production of destructive oxygen-free radicals were referred to earlier. Among the numerous “brain-sparing” agents that have been tried in an attempt to reduce the size of infarction, certain ones have had erratic results in large randomized trials. Two recent trials, for example, gave initially promising results and later proved ineffective (Shuaib et al). These agents were of interest because they can be administered up to several hours after the stroke (continuing for 72 h). So far, the results of neuroprotective agents in stroke have been discouraging.

Closure of Patent Foramen Ovale (PFO)

The role of the patent foramen ovale as a cause of stroke that is otherwise cryptogenic, has been a matter of contention for three decades. Certainly in some instances, such as a young individual who has demonstrable clots in the venous system of the legs or pelvis or who has had a recent pulmonary embolism, this mechanism becomes an appealing explanation. As mentioned earlier in the chapter, several epidemiologic and other studies have demonstrated a statistical association between strokes in the presence of a PFO. In other studies of older patients, however, the presence of a patent foramen did not increase the risk of stroke or TIA. It has also been a matter of some contention whether the size of the cardiac defect or the presence of an associated atrial septal aneurysm raise the risk of stroke. Even in younger patients, simply the discovery of a PFO with the use of echocardiography and injection of agitated saline or similar method that highlights the potential for movement of material from the right into the left atrium is not nearly proof of a causative mechanism. Our practice has been to perform noninvasive studies in younger patients with a PFO in order to determine if there are clots present, and in younger women, to consider imaging procedures of the pelvic veins.

Even if a putative relationship between cryptogenic stroke and PFO were established, it has been difficult to demonstrate that closing the defect provides protection against further strokes. Moreover, the value of anticoagulation, either alone or in comparison to closure of the PFO, has been uncertain. Two studies, one by Furlan and associates and the other by Meier and coworkers, have shown that closure of a PFO in a patient had a stroke, does not provide benefit, at least for 2 to 4 years after the procedure. It is instructive from both of these studies that the rate of recurrent stroke was close to 1 to 2 percent per year in both the groups who had a procedure to close the defect and those who were treated with either warfarin or aspirin. Although neither trial was designed to settle the question of which form of medical treatment was superior, at least over the short duration of these studies, the results were similar. At this time, closure of the PFO is recommended only as a component of a clinical trial and the clinician is left with limited direction regarding the need for, and type of, anticoagulation. There may be instances in which repeated strokes, coupled with known thrombi in lower extremity or pelvic veins, coupled with a sizable PFO might justify the procedure.

Treatment of Infarctive Brain Swelling and Raised Intracranial Pressure (See also Chap. 35)

In the first few days following massive cerebral infarction, brain edema of the necrotic tissue may threaten life. Most often this occurs with a complete infarction in the territory of the middle cerebral artery, i.e., encompassing the deep and distal vascular territory. Some degree of mass effect may be evident on a CT in the first 24 h. Additional infarction in the territory of the anterior cerebral artery (total carotid occlusion) worsens the situation. Clinical deterioration occurs usually on the third to fifth days, sometimes later, but may rarely evolve as quickly as several hours after the onset (Fig. 34-17). The clinical indicators of worsening—drowsiness, a fixed (but not necessarily enlarged) pupil, a Babinski sign on the side of the infarction (on the preserved side of the body), and changes in breathing pattern, as well as characteristic imaging signs—are all a result of secondary tissue shifts, as described in Chaps. 17 and 30 and are detailed in the studies of Hacke and colleagues (1996), and Ropper and Shafran. Frank has shown that clinical deterioration is not always associated with an initial elevation of intracranial pressure (ICP). It is not clear if it is advisable, in selected cases, to measure the ICP directly before embarking on an aggressive medical regimen to lower the pressure.

Intravenous mannitol in doses of 1 g/kg, then 50 g every 2 or 3 h, may forestall further deterioration, but most of these patients, once comatose, are likely to die unless drastic measures are taken. In such instances, controlled hyperventilation may be useful as a temporizing maneuver. Corticosteroids are probably of little value; several trials have failed to demonstrate their efficacy.

In the past several years there has been interest in *hemicraniectomy* as a means of reducing the mass effect

and intracranial pressure in these extreme circumstances. One favored approach has been to perform hemicraniectomy fairly early in the course of brain swelling, in the first 2 or 3 days, when the patient is drowsy but before coma supervenes. A pooled analysis of three randomized trials based on this premise has been given by Vahedi and colleagues. Excluding patients older than age 60 years, a total of 93 patients who were not fully alert could be analyzed. A large advantage in survival was found favoring the group operated within 48 h. There has been controversy regarding the functional status of survivors and this involves the matter of the desirability of patients remaining with modified Rankin scale scores of 4, meaning they are dependent on others for their personal care. A more carefully controlled trial conducted in patients over age 60 has confirmed a beneficial effect of hemicraniectomy in preventing death from brain swelling after stroke. However, not surprisingly, the proportion of survivors with good functional outcomes in this older group was not as high as for younger patients.

Our recent practice has been to wait for signs of deterioration, generally leading to operation on fewer than half of patients with large MCA territory strokes and, generally having operations from the third through fifth days. The family must understand the risks involved and the likelihood that the stroke deficits will persist so that approximately a third of surviving patients will be dependent for care. Hemicraniectomy combined with an overlying duraplasty is then undertaken if the patient is progressing from a stuporous state to coma and imaging studies show increasing mass effect. Whether anterior temporal lobectomy is of added benefit is not known, but it is now infrequently included. The value of surgical decompression has not been limited to patients with right-hemispheric strokes; those with initially limited

Figure 34-17. Large ischemic infarction of the left cerebral hemisphere mainly in the distribution of the superior division of the middle cerebral artery. CT at 24 h (*left*) and 72 h (*right*) following the onset of stroke symptoms. The second scan (*right*) demonstrates marked swelling of the infarcted tissue and rightward displacement of central structures.

degrees of aphasia may also be appropriate candidates. After a protracted period of coma with bilaterally enlarged pupils or with evidence that the midbrain has been irrevocably damaged, the procedure may be futile.

In the special case of large *cerebellar infarctions*, usually from occlusion of a vertebral artery, swelling may compress the lower brainstem within hours or days. This complication carries the risk of sudden respiratory arrest. Cerebellar swelling may occur with or without an associated lateral medullary stroke and the situation is comparable to medullary compression caused by cerebellar hemorrhage. Hydrocephalus usually develops as a prelude to deterioration and is manifest as drowsiness and stupor, increased tone in the legs, and Babinski signs; other sentinel signs of compression of the brainstem are gaze paresis, sixth nerve palsy, or hemiparesis ipsilateral to the ataxia (Kanis and Ropper). It is at times difficult to differentiate the effects of increasing hydrocephalus from those of brainstem infarction from thrombus propagation in the basilar artery (Lehrich et al). Surgical decompression of the infarcted and swollen tissue should be undertaken almost as soon as cerebellar edema becomes clinically apparent by the emergence of hydrocephalus or brainstem signs, as further swelling can be anticipated. A brief period of observation before committing to surgery is not unreasonable if the fourth ventricle and peribrainstem cisterns are open and the patient is awake. Mannitol may be used to prepare the patient for surgery or if a period of observation is anticipated but its value is not clear. As in the case of cerebellar hemorrhage, ventricular drainage alone is usually inadequate and, in any case, is unnecessary if the pressure is relieved by hemicraniectomy and resection of infarcted tissue.

Carotid Artery Stenosis

Comments have already been made concerning the opening of an occluded carotid artery soon after a stroke. Here we discuss the patient who has had TIAs or who has passed the acute period of stroke, when surgery is considered to be safer. The region that most often lends itself to such therapy is the carotid sinus (the bulbous expansion of the internal carotid artery just above its origin from the common carotid). Other sites suitable for surgical management include the common carotid, innominate, and subclavian arteries. Operation on the vertebral artery at its origin has proved successful only in exceptional circumstances. In recent years, balloon angioplasty and stenting of the carotid artery have become increasingly popular as an alternative to surgery (see below).

Surgery and angioplasty, in our opinion, are as yet applicable mainly to the group of patients with *symptomatic* carotid artery stenosis (the asymptomatic ones are discussed below) who have substantial extracranial stenosis but not complete occlusion, and, in special instances, in those with nonstenotic ulcerated plaques. Those with stenosis constitute less than 20 percent of all patients with TIAs (Marshall); but from the perspective of surgical therapy, the term *symptomatic* encompasses both TIAs and large or small strokes ipsilateral to the stenosis, some of which may be evident only with cerebral imaging. There is

evidence that well-executed surgery in appropriately chosen cases arrests the TIAs and diminishes the risk of future strokes. These views received strong affirmation from two often-cited randomized studies—the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST). The conclusion reached in each of these studies was that carotid endarterectomy for symptomatic lesions causing degrees of stenosis greater than 70 to 80 percent in diameter reduces the incidence of ipsilateral hemispherical strokes and shows greater benefit with increasing degrees of stenosis. These two trials differed in the method of estimating the degree of stenosis, but when adjustments are made, the results are comparable (Donnan et al, 1998). Further analysis of the North American trial by Gasecki and colleagues indicated that the risk of cerebral infarction on the side of the symptomatic stenosis is increased if there is a contralateral carotid stenosis but that operated patients (on the side of symptomatic stenosis) still had fewer strokes than those treated with medication alone. In those with bilateral carotid disease, the risk of stroke after 2 years was 69 percent, and if operated, 22 percent.

As to the timing of endarterectomy, opinions have diverged but a metaanalysis reported by Rothwell and colleagues (2004) has suggested that the maximum benefit is accrued if surgery is performed within 2 weeks of a TIA or minor stroke.

In the final analysis, the relative benefits of surgery or medical treatment (anticoagulation or aspirin) depend mainly on the actual surgical risk—i.e., on the record of an individual surgeon. If there is an established operative complication rate of less than 3 percent, then surgery can be recommended in symptomatic patients with carotid stenosis greater than 70 percent. This benefit extends to elderly patients and, indeed, it has been shown on a statistical basis to be most evident in patients older than age 75 (see the post hoc analysis of NASCET data by Alamowitch et al).

Before operation or angioplasty, the existence of the carotid lesion and its extent must be determined. Conventional arteriography, the procedure that yields the best images and most accurate measurements of the residual lumen, carries a small risk of worsening the stroke or producing new focal signs though this notion has never been documented systematically. CTA and MRA have emerged as a surrogate that well demonstrates the carotid bulb and carries only the risk of renal damage from dye infusion (Fig. 34-18). Severe stenosis is also indirectly reflected in angiography by the filling of the distal branches of the external carotid artery before the branches of the middle cerebral artery are opacified—a reversal of the usual filling pattern. Increasingly, the diagnosis of carotid stenosis is being initially made by less invasive methods, but with ultrasonography and magnetic resonance arteriography there is some difficulty in quantifying severe stenosis and in separating it from complete carotid artery occlusion. If the patient is in good medical condition, has normal vessels on the contralateral side, and has normal cardiac function (no heart failure, uncontrolled angina, or recent infarction), symptomatic lesions with greater than 70 percent stenosis, roughly corresponding to a residual luminal diameter

Figure 34-18. A. Axial diffusion-weighted MRI showing multifocal acute infarctions in the left ACA-MCA arterial border zone. B. Magnetic resonance angiography displays severe stenosis of the left internal carotid artery (*arrow*), just above the common carotid artery bifurcation.

of less than 2 mm, can usually be dealt with safely by endarterectomy.

Carotid angioplasty and stenting were mentioned earlier. The role of this approach in clinical practice in comparison to endarterectomy has been recently clarified. Stenting offers an alternative for the patient who is too ill to undergo surgery. Direct comparisons have been made in several organized studies. In one early trial reported by the CAVATAS investigators (Carotid and Vertebral Artery Transluminal Angioplasty Study), the incidence of minor (nonstroke) complications was lower in patients who had angioplasty and stenting. Also, a higher proportion of patients undergoing angioplasty had restenosis. Otherwise, the recurrent stroke rates were similar, 10 percent for both groups. A useful comparison between angioplasty and surgical endarterectomy has been made in the trial reported by Mas and associates (2006) and in the “SPACE” trial. While the first of these favored a surgical approach for severe symptomatic stenosis, the second gave equivalent results of approximately 6 percent combined stroke and death rates with either procedure.

Endarterectomy, in a small number of cases may be followed by a *new hemiplegia or aphasia that becomes evident in the hours after the procedure*, usually by the time the patient arrives in the recovery room. In these cases, surgeons prefer to return the patient to the operating room and open the artery, as discussed earlier on. An intimal

flap at the distal end of the endarterectomy and varying amounts of fresh clot proximal to it are usually encountered; but after removal and repair of the vessel, the effects of the stroke, if one has occurred, are not usually improved. The postoperative care of carotid endarterectomy focuses on reversing reflex hypotension that is induced by exposing the carotid wall to high perfusion pressure. This phenomenon can be reduced by infiltrating the carotid sinus with anesthetic prior to the operation. An uncommon but rather striking *hyperperfusion syndrome* develops several days to a week after carotid endarterectomy. The features are headache, focal deficits, seizures, brain edema, or cerebral hemorrhage. These are thought to reflect autoregulatory failure of the cerebral vasculature in the face of abrupt restoration of normal blood pressure and perfusion. After a long period of autoregulatory compensation for a stenotic carotid artery, then a normal cerebral perfusion pressure may result in endothelial incompetence with leakage of water across the blood-brain barrier. Unilateral severe headache is the most common symptom and may be the only manifestation. On occasion, cerebral edema is so massive as to lead to death (Breen et al). Treatment is by control of hypertension; it is unclear whether antiepileptic medications are required if there has been a seizure as a component of the syndrome. We mention here that an identical syndrome of focal cerebral deficits and brain edema, perhaps with the exception

of seizures, has been seen, rarely and with no explanation, in migraineurs, including two patients under our care.

For intracranial internal carotid occlusion that extends into the siphon and distally, a transcranial (superficial temporal–middle cerebral) anastomosis had been employed in the past. Although this operation is technically feasible, its therapeutic value has been questioned by the multicenter study of Barnett and collaborators (1985), who found that it did not produce a reduction in TIAs, strokes, or deaths. That study was criticized for having a skewed patient selection and several smaller and uncontrolled trials have suggested that the procedure may benefit some patients. There may be particular circumstances that justify its use; for example, when there are ongoing TIAs in relation to upright posture or with episodes of mild hypotension. Bypass procedures and their derivatives such as temporal-pial synangiosis may be useful in reestablishing flow to a hemisphere when there has been progressive intracranial carotid stenosis. Testament to the success of the bypass procedure is the regression of symptoms and of the network of collateral vessels in moyamoya disease (see further on).

Asymptomatic Carotid Stenosis

Finally, there is the problem of the asymptomatic bruit over a carotid artery or incidentally discovered carotid artery stenosis. A bruit generally corresponds to the reduction in luminal diameter of the artery to 2 mm or less and, while found in a large proportion of patients with severe stenosis, it is not specific and is heard in up to 10 percent of older patients who have little or no stenosis. The population studies by Heyman and associates over 30 years ago shed some light on this. They found, not surprisingly, that cervical bruits in men constituted a risk for death from ischemic heart disease, and that the presence of asymptomatic bruits in men (but not in women) carried a slightly increased risk of stroke. Notably, the subsequent stroke often did not usually coincide in its angioanatomic locus and laterality with the cervical bruit so that asymptomatic stenosis is in the short term a general marker for atherosclerosis more so than for a proximate stroke. Other investigators have reported similar findings. On the other hand, Wiebers and colleagues (1990) found that patients with asymptomatic carotid bruits who were followed for 5 years were approximately three times more likely to have ischemic strokes than an age- and sex-matched population sample without carotid bruits.

The appropriate step when a carotid bruit is found during a routine examination is probably to obtain ultrasonography in order to quantify the presence of and degree of stenosis and to make subsequent decisions cautiously based on the studies discussed below. We usually also obtain imaging of the brain to determine if there has been a stroke on the side of the carotid disease—this aids in decisions regarding therapy. A note is made here regarding the *self-audible bruit*, which occasionally indicates carotid stenosis, dissection, or fibromuscular dysplasia, but is usually of less consequence and in some instances is associated with an enlarged and superiorly located jugular bulb—a benign anatomic variant that can be discerned on CT (Adler and Ropper).

Many attempts have been made to clarify the role of surgically correcting asymptomatic carotid stenosis by means of endarterectomy. The Asymptomatic Carotid Atherosclerotic Study (ACAS), as reported by its Executive Committee, found that the frequency of strokes could be reduced from 11 percent to 5 percent over 5 years by removing the plaque if there was a stenosis greater than 60 percent (in diameter). These conclusions have been tempered by a reanalysis of the ACAS data, in which almost half of the strokes were of lacunar or cardioembolic (Inzitari et al). Data from a European trial, encompassing 3,120 patients (MRC Asymptomatic Carotid Surgery Trial [ACST] Collaborative Group), have indicated that asymptomatic carotid stenosis of more than 70 percent carries a 2 percent annual risk of stroke over a 5-year period and that the risk is reduced to 1 percent with endarterectomy. It was concluded that endarterectomy may be justified for asymptomatic carotid stenosis of this degree in men (not so in women) but that an audited surgical risk below 3 percent was required to obtain favorable results (just as for symptomatic carotid stenosis). However, all of these trials were conducted before the ubiquitous use of statin drugs, which seemingly stabilize carotid plaques. Several trials comparing endarterectomy to stenting, some of which were commented on earlier, included asymptomatic patients but there were too few on which to base conclusions.

From these and other trials it can be inferred that endarterectomy does not reduce the incidence of strokes in patients who have asymptomatic carotid stenosis with luminal narrowing that is less than 60 to 70 percent of normal diameter. For those with greater degrees of stenosis, the benefits are slight and apply predominantly to men. It is not clear if the presence of an ulcerated plaque or heavy calcification alters this view but it probably does not. These comments also apply to patients with asymptomatic carotid stenosis who are about to undergo major surgery such as cardiac bypass grafting, but adequate studies in this circumstance have not been performed. As already noted, any advice should be tempered by the surgical risk in a particular institution. Our usual practice with asymptomatic cases has been to reevaluate the lumen of the internal carotid artery (using ultrasonography) at 6- to 12-month intervals. If the stenosis is advancing and becomes narrowed to about 2 mm or less, or if there is an event that could be construed as a TIA referable to the stenotic side, then surgery is considered. In the case of an asymptomatic but progressive stenosis, statin agents, accompanied by smoking cessation, aspirin therapy, and glucose control where applicable, are a reasonable alternative approach.

These comments reflect the guidelines for carotid endarterectomy set forth by the American Heart Association as reported by Moore and colleagues (1995) but there must be a careful evaluation of the circumstances in each patient and a recognition that residual lumen diameters and percent stenoses are measured in different ways by varying techniques, both in the above-described studies and in clinical practice.

Course and Prognosis of Ischemic Stroke

It is a fair statement that no rules have yet been formulated that allow prediction of the early or late course

of stroke. A mild paralysis may become a disastrous hemiplegia or the patient's condition may worsen only temporarily. In cases of basilar artery occlusion, dizziness and dysphagia may progress in a few days to total paralysis and deep coma. Or, in both cases, the deficit may completely resolve. Anticoagulation and thrombolytic therapy may alter the course as discussed further on, but cerebral thrombosis is so often progressive that a cautious attitude on the part of the physician in what first appears to be a mild stroke is usually justified, at least for the first day.

During the period 1970–1974 in Rochester, Minnesota, 94 percent of patients with ischemic strokes survived for 5 days and 84 percent for 1 month (Garraway et al, 1983a and b). The *survival rate* was 54 percent at 3 years and 40 percent at 7 years. These were significantly greater than had been the case during the period 1965–1969. These figures, which were gathered retrospectively, are comparable to more recent ones reported by Bamford and colleagues from patients who had strokes in the 1980s. The mortality rate following cerebral infarcts (no separation being made between thrombotic and embolic types) at the end of 1 month was 19 percent and at the end of 1 year, 23 percent. Of the survivors, 65 percent were capable of an independent existence. In every series, among long-term survivors, heart disease is a more frequent cause of death than additional strokes. It has been repeatedly pointed out that pneumonia as a result of faulty swallowing is a major determinant of survival; further discussion regarding aspiration problems following stroke are found in later sections of the chapter.

Several other circumstances influence the *early prognosis* in cerebral infarction. In the case of very large infarcts in the middle cerebral artery territory, swelling of the infarcted tissue may occur, followed by displacement of central structures, transtentorial herniation, and death of the patient after several days. This can at times be anticipated by the sheer volume of the infarct and is usually evident on the CT or MRI scan within a day of the stroke. Smaller infarcts of the inferior surface of the cerebellum may also cause a fatal herniation into the foramen magnum. Milder degrees of swelling and increased intracranial pressure in both of the above-cited cases may progress slightly for 2 to 3 days but do not prove fatal. (See earlier under "Treatment of Infractive Brain Swelling and Raised Intracranial Pressure.")

In extensive brainstem infarction associated with deep coma caused by basilar artery occlusion, the early mortality rate approaches 40 percent. In any type of stroke, if coma or stupor is present from the beginning, survival is largely determined by success in keeping the airway clear, controlling brain swelling, preventing aspiration pneumonia, and maintaining fluid and electrolyte balance, as described further on. With smaller thrombotic infarcts, the mortality is 3 to 6 percent, much of it from myocardial infarction and aspiration pneumonia.

As for the *eventual prognosis* of the neurologic deficits, some improvement is the rule if the patient survives. The patient with a lacunar infarct usually fares well but may take months to improve to the maximum extent. With other small infarcts, recovery may start within a day

or two, and restoration may be complete or nearly complete within a week. In cases of severe deficit, there may be little significant recovery; after months of assiduous efforts at rehabilitation, the patient may remain bereft of speech and understanding, with the upper extremity still useless and the lower extremity serving only as an uncertain prop during attempts to walk. Between these two extremes there is every gradation of recovery. Measurement of central motor conduction by magnetic stimulation has been predictive of recovery but is not widely used for clinical work. If clinical recovery does not begin in 1 or 2 weeks, the outlook is poor for both motor and language functions. Constructional apraxia, uninhibited anger (with left and rarely with right temporal lesions), nonsensical logorrhea and placidity, unawareness of the paralysis and neglect (with nondominant parietal lesions), and confusion and delirium (with nondominant temporal lesions) all tend to diminish and may disappear within a few weeks. A hemianopia that has not cleared in a few weeks will usually be permanent, although reading and color discrimination may continue to improve. In lateral medullary infarction, difficulty in swallowing may be protracted, lasting 4 to 8 weeks or longer, yet relatively normal function is finally restored in nearly every instance. Aphasia, dysarthria, cerebellar ataxia, and walking may improve for a year or longer, but for all practical purposes it may be said that whatever motor and language deficits remain after 5 to 6 months will be permanent.

Characteristically, the paralyzed muscles are flaccid in the first days or weeks following a stroke; the tendon reflexes are usually unchanged but may be slightly increased or decreased. Gradually spasticity develops, and the tendon reflexes become brisker. The arm tends to assume a flexed adducted posture and the leg an extended one. Function is rarely if ever restored after the slow evolution of spasticity; however, the use of botulinum toxin may help considerably in relieving the spasticity. Conversely, the early development of spasticity in the arm or the early appearance of a grasp reflex may presage a favorable outcome. In some patients with extensive temporoparietal lesions, the hemiplegia remains flaccid; the arm dangles and the slack leg must be braced to stand. The physiologic explanation of this remains obscure. If the internal capsule is not interrupted completely in a stroke that involves the lenticular nucleus or thalamus, the paralysis may give way to hemichorea, hemitremor, or hemiataxia, depending on the particular anatomy of the lesion. Bowel and bladder control usually returns; sphincteric disorders persist in only a few cases. Physical therapy should be initiated early in order to prevent pseudocontracture of muscles and capsulitis at the shoulder, elbow, wrist, knuckles, knee, and ankle. These are frequent complications and often a source of pain and added disability, particularly of the shoulder. Occasionally, atrophy of bone and pain in the hand may accompany the shoulder pain (shoulder-hand syndrome). An annoying dizziness and unsteadiness often persists after damage to the vestibular system in brainstem infarcts.

Seizures are a relatively uncommon sequel of thrombotic strokes in comparison to embolic cortical infarcts,

which are followed by seizures in up to 10 percent of patients. Most often in our experience, the EEG in these cases had never normalized and showed sharp activity over the region of the infarct even many months after the stroke (see further on for advice on the treatment of seizures after stroke).

Many patients complain of fatigability and are depressed, possibly more so after strokes that involve the left frontal lobe (Starkstein et al); other studies implicate an infarct on either side of the brain. The explanation of these symptoms is uncertain; some are certainly expressions of a reactive depression. Several small series have suggested that prophylactic treatment with antidepressants reduce the incidence of depression as described in the review by Chen and colleagues, but the routine administration of these medications has not found its way into general practice. Only a few patients develop serious behavior problems or are psychotic after a stroke, but paranoid trends, confusion, stubbornness, and peevishness may appear, or an apathetic state ensues. Large lesions affect concentration as well as synthetic and executive mental functions in rough proportion to their size; these mental changes are independent of any disturbances in language function.

When multiple infarcts occur over a period of months or years, special types of dementia and gait failure may develop. In some, the major lesions involve the white matter and spare, relatively, the cortex and basal ganglia; the lesions may be lacunar or larger infarctions. This disorder, referred to as arteriosclerosis dementia and *Binswanger subcortical leukoencephalopathy*, probably represents the accumulation of multiple white matter infarcts and lacunes (see further on and the papers by Mohr and Mast and by Babikian and Ropper). The white matter that is destroyed tends to lie in the border zones between the penetrating cortical and basal ganglionic arteries. Large patches of subcortical myelin loss and gliosis, in combination with small cortical and subcortical infarcts, are evident with brain imaging. This process and the histologically similar but biologically unique inherited condition of white matter termed *CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarct and leukoencephalopathy)* are discussed further on.

Physical Therapy and Rehabilitation

In all but the most seriously ill patients, beginning within a few days of the stroke the paralyzed limbs ideally should be carried through a full range of passive movement several times a day. The purpose is to avoid contracture (and capsulitis), especially at the shoulder, elbow, hip, and ankle. Soreness and aching in the paralyzed limbs should not be allowed to interfere with exercises to the extent possible. Patients should be moved from bed to chair as soon as the stroke is completed and blood pressure is stable. Prophylaxis for deep venous thrombosis with compression boots or anticoagulation is appropriate if the patient cannot be mobilized. An assessment for swallowing difficulty should be made early during recovery and dietary adjustments on the insertion of a nasogastric tube made if there is a risk of aspiration. Nearly all hemiplegic patients regain the ability to walk to some

extent, usually within a 3- to 6-month period, and this should be a primary aim in rehabilitation. The presence of deep sensory loss or anosognosia in addition to hemiplegia, are the main limiting factors. A short or long leg brace is often required. By teaching patients with cerebellar ataxia new strategies, balance and gait disorders can be made less disabling. As motor function improves and if mentality is preserved, instruction in the activities of daily living and the use of various special devices can help the patient become at least partly independent at home. Whatever little research is available on the effectiveness of stroke rehabilitation suggests that a greater intensity of physical therapy does indeed achieve better scores on some measures of walking ability and dexterity. In a randomized trial, Kwakkel and colleagues achieved these results by applying an additional 30 min per day beyond conventional physical therapy of focused treatments to the leg or arm, 5 days per week, for 20 weeks. Other studies have demonstrated clearly the undesirable effects of immobilizing a limb in a splint after a stroke.

Experimental work in monkeys and limited data from patients suggest that improvement can be obtained by restraining the normal limb and forcing use of the sound limb. In a randomized trial, Wolf and colleagues (2006) were able to demonstrate a benefit from this form of “*constraint therapy*” by forcing the patient to wear a mitt on the good hand while engaging in persistent exercises with the hemiplegic limb for more than 90 percent of their waking time through 2 weeks. This may reflect functional expansion of the cortical motor representation into adjacent undamaged cortical areas, indicating the potential for some degree of reorganization that corresponds to clinical recovery. A related approach, “*mirror therapy*” confronts the patient with a mirror that creates an illusion of moving the paretic side when the good side is activated. The Cochrane metaanalysis of 14 such studies indicates a modest benefit in motor recovery and a more prominent benefit for relief of pain and quality of life improvement (Thieme and colleagues).

The neural substrates of improvement after stroke are just beginning to be studied. Considerable clinical experience and physiologic data such as those reported by Luft and colleagues have demonstrated that the injured brain has some degree of plasticity; remodeling of brain tissue and reorganization of neural function may occur with training even months after large strokes.

Speech and language therapy is particularly valuable in identifying the risk of aspiration as noted above. Specific therapy should be given in appropriate cases and certainly improves the morale of the patient and family. Further comments on the value of such treatments can be found in Chap. 23.

Secondary Preventive Measures

Because the primary objective in the treatment of atherothrombotic disease is prevention, efforts to control the risk factors must continue after stroke. The carotid vessels, being readily accessible, may be examined for the presence of a bruit; the latter often indicates a stenosis, although not all stenoses cause a bruit and many bruits heard are transmitted sounds from a stenotic aortic valve.

Ultrasonography, CT, or MRA examination of the cervical and intracranial vessels is justified in almost all patients with TIAs and ischemic stroke. The management of patients with asymptomatic carotid bruits has been considered above.

For patients who have had a stroke from atherothrombotic disease, preventive measures include the following: (1) aspirin, which reduces the risk of second stroke slightly, but its effect, as already noted, is modest (see earlier under “Antiplatelet Drugs”); (2) administration of any required antihypertensive agents but with caution in the first days after ischemic stroke; (3) administration of cholesterol-lowering drugs as commented below; (4) smoking cessation; and (5) during future general surgical procedures, maintenance of systemic blood pressure and oxygenation, especially in elderly patients. Regarding the appropriate dose of aspirin, a consensus has been that 50 to 100 mg is adequate as a preventative measure (typically 81 mg in the United States) and that higher doses do not offer additional benefit. Many patients are taking the higher dose levels for peripheral or coronary artery disease.

The issue of “aspirin resistance” has not been resolved but it can be stated that no laboratory test has been devised to accurately predict the clinical effects of aspirin dose. “Aspirin failure” on the other hand, refers to continued TIAs or strokes while on low doses of the medication. It has not been established that changing to a higher dose level is the correct course of action; many clinicians do so and others instead add a second antiplatelet agent or switch to another drug.

There may be additional but modest value in administering high doses of statin drugs even in patients with normal cholesterol levels who have had an atherothrombotic stroke. A large study mentioned earlier, the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial, has shown that secondary stroke prevention is possible in patients with TIA or stroke in the prior 6 months with the use of high-dose atorvastatin (80 mg) but the magnitude of benefit was small (approximately 3 percent). The trial included mainly patients whose LDL cholesterol levels were modestly elevated. The clinician should be mindful of the risk of a statin-induced myopathy, and it is not known if lower doses of medication have the same preventative effect. Consistent with some other trials using statins, there was a slight increase in the number of hemorrhages in the treated group compared to the placebo group. The higher rate of cerebral hemorrhage in this study, however, contrast with at least one other large secondary prevention trial (the Heart Protection Collaborative Study) that used simvastatin at lower doses.

GENERALIZED BRAIN ISCHEMIA AND HYPOXIA (See also Chap. 40)

This constitutes a special type of infarction that follows cardiac arrest and other forms of prolonged hypotension or hypoxia. The most typical configuration, seen with imaging, is of widespread cortical infarction affecting also

the deep nuclei, i.e., the most metabolically active regions of the cerebral hemispheres. In the case of reduced blood flow to the cerebral hemispheres, there is a tendency for regional infarctions to occur in the areas of lowest blood flow that lie between the major surface arteries, referred to metaphorically as a watershed infarction. An important distinction is drawn between the concept of end-arterial distribution, the site of distal embolization, and the area of lowest flow between two or more end territories, which is compromised in any form of globally returned blood flow. In extreme cases of hypotension, there is global infarction of the brain accompanied by the clinical syndrome of brain death.

Pure hypoxia-anoxia without hypotension produces another type of damage in areas susceptible to reduced oxygen delivery, mainly affecting the hippocampus; a Korsakoff syndrome results. Most often, ischemic and hypoxic states coexist and produce complex patterns of cerebral damage. This topic is discussed fully in Chap. 40. The special problem of cerebral ischemia during cardiac surgery with the use of a bypass pump is discussed further on in the section “Stroke With Cardiac Surgery.”

LESS-COMMON CAUSES OF ISCHEMIC CEREBROVASCULAR DISEASE

Fibromuscular Dysplasia

This is a segmental, nonatheromatous, noninflammatory arterial disease of unknown etiology, almost exclusively in women. It is uncommon (0.5 percent of 61,000 arteriograms in the series of So et al) but is being reported with increasing frequency because of improved arteriographic techniques. In our experience, it has often been an incidental finding in asymptomatic individuals undergoing vascular imaging for other reasons. Approximately 10 percent of cases have been reported to be familial.

First described in the renal artery by Leadbetter and Burkland in 1938, fibromuscular dysplasia is now known to affect other vessels including cervicocerebral ones. The internal carotid artery is involved most frequently, followed by the vertebral and cerebral arteries. The radiologic picture is of a series of transverse constrictions, giving the appearance of an irregular string of beads or a tubular narrowing; it is observed bilaterally in 75 percent of cases. Usually only the extracranial part of the artery is involved. A single transverse web that occupies a portion of the carotid lumen is probably a variant of the fibromuscular condition or could conceivably represent an entirely different static congenital process. In the series of Houser and colleagues, 42 of 44 patients were women and 75 percent were older than 50 years of age. All of the patients reported by So and coworkers were women, ranging in age from 41 to 70 years. Cerebral ischemia may be associated with the process but the rate of this complication has not been established; our impression is that it is low. In the study by Corrin and colleagues, among 79 untreated asymptomatic patients followed for an average of 5 years, 3 had a cerebral infarct 4 to 18 years after the initial diagnosis. Also, between 7 and 20 percent

of affected individuals are found to have intracranial saccular aneurysms (rarely a giant aneurysm), which may be sources of subarachnoid hemorrhage, and up to 12 percent develop arterial dissections, as described below.

The narrowed arterial segments show degeneration of elastic tissue and irregular arrays of fibrous and smooth muscle tissue in a mucous ground substance. Interspersed dilatations are a result of atrophy of the coat of the vessel wall. There is atherosclerosis in some and small degrees of arterial dissection in others. Usually vascular occlusion is not present, though there may be marked stenosis. Schievink and colleagues have summarized the pathology of this disease. In some instances the mechanism of the cerebral ischemic lesion is unexplained, but is presumed to be from thrombi in the pouches or in relation to intraluminal septa.

The disease is not amenable to endarterectomy. So and colleagues have recommended excision of the affected segments of the carotid artery if ischemic neurologic symptoms are related to them, and conservative therapy if the fibromuscular dysplasia is an incidental and asymptomatic arteriographic finding. It is now possible to dilate the affected vessel by means of endovascular techniques and several case reports have suggested that benefit is achieved at lower risk than with surgical excision. Intracranial saccular aneurysms, which may accompany this disease as noted above, should be sought by arteriography, CT, or MRA and obliterated if their size warrants. It is not known if anticoagulation or antiplatelet therapy confers protection from stroke.

Dissection of the Cervical and Intracranial Arteries

Internal Carotid Artery Dissection

It has long been appreciated that the process formerly known as Erdheim's medionecrosis aortica cystica, the main cause of aortic dissection, may independently involve or extend into the common carotid arteries, occluding them and causing massive infarction of the cerebral hemispheres. Examples of such occurrences were cited by Weisman and Adams in 1944 in their study of the neurology of dissecting aneurysms of the aorta, and Chase and colleagues gave the clinicopathologic details of 16 cases they studied. The principal neurologic features in both series were syncope, hemiparesis, or coma. The frequency of cerebral stroke with aortic dissection has varied from 10 to 50 percent and that of spinal stroke has been approximately 10 percent (see Chap. 44).

In more recent years, attention has been drawn to the occurrence of both spontaneous and traumatic dissection of the internal carotid artery, not necessarily associated intrinsic disease of the vessel walls, as an important cause of nonatherosclerotic stroke in young adults. Many large series of such cases have been reported in separate studies by Ojemann and colleagues (1972) and by Mokri and coworkers (1986). Although the disease is overrepresented in women, it occurs frequently in men, typically in their late thirties or early forties for either sex. It is

a spontaneous event or arises in relation to a whiplash injury, bouts of violent coughing, or direct trauma to the head or neck, which need not be severe—e.g., being struck in the neck by a golf or tennis ball. We have encountered cases that occurred during pregnancy and immediately after delivery. Indeed, it is questionable if most cervical arterial dissections are truly “spontaneous,” as many can be connected to some strenuous event but a relation to trauma is often only presumed. Three of our patients over the years had a carotid dissection that was manifest as a hemiplegia days after blunt head injury.

A small number of patients have fibromuscular disease as discussed above. The Ehlers-Danlos and Marfan syndromes, osteogenesis imperfecta, Loeys-Dietz syndrome (transforming growth factor [TGF]- β receptor mutation), and α_1 -antitrypsin deficiency are also associated with an increased risk of vascular dissection. One of these conditions should be suspected if multiple extracranial vessels are involved in spontaneous dissections or if there is joint and skin laxity or widespread vascular tortuosity (neck and thoracic trauma or aortic arch dissection are more common causes of multiple extracranial dissections).

A few patients with carotid dissection have had preceding unilateral cranial or facial pain lasting days, followed by stroke in the territory of the internal carotid artery. The pain is aching, may fluctuate in severity, and is centered most often in and around the eye; less often, it is in the frontal or temporal regions, angle of the mandible, or high anterior neck over the carotid artery. Rapid and marked relief of the pain after the administration of corticosteroids in a young person may be a helpful diagnostic feature (see below). Neck pain over a site of dissection is usually present as well; however, it may be absent, particularly if the dissection originates near the base of the skull.

The ischemic manifestations consist of transient attacks in the territory of the internal carotid, followed frequently by the signs of hemispherical stroke, which may be abrupt or evolve smoothly over a period of minutes to hours or over several days in a fluctuating or stepwise fashion. A unilateral Horner syndrome is often present. A cervical bruit, sometimes audible to the patient, amaurosis fugax, faintness and syncope, and facial numbness are less common symptoms. Most of the patients described by Mokri and colleagues (1986) had one of two distinct syndromes: (1) unilateral headache associated with an ipsilateral Horner syndrome, essentially the Raeder syndrome, or (2) unilateral headache and delayed focal cerebral ischemic symptoms. One lesson is that a *painful Horner syndrome* is usually due to an underlying structural lesion. Some patients have evidence of involvement of one or more of the vagi, spinal accessory, or hypoglossal nerve on the side of a carotid dissection; these nerves lie in close proximity to the carotid artery and are nourished by small branches from it.

In most cases, dissection of the internal carotid artery can be detected by ultrasonography and confirmed by MRI and CTA, which show a double lumen (Fig. 34-19) within the vessel on axial MRI sections. Arteriography by any of these methods, including by conventional

Figure 34-19. Cervical artery dissections. T1 MRI with fat saturation (*left*) and magnetic resonance angiography (*right*). The upper images show bilateral internal carotid artery dissections (*arrows*). The lower images show a left vertebral artery dissection (*arrows*). The T1 hyperintensity that is shown in the left upper and lower images is due to thrombus within the false lumen of the vessel.

angiography usually reveals an elongated, but variable length, irregular narrow column of dye, usually beginning 1.5 to 3 cm above the carotid bifurcation and extending to the base of the skull, a picture that Fisher has called the *string sign*. There may be a characteristic tapered occlusion or an outpouching at the upper end of the string. It is the site and the shape of the occlusion that are helpful in identifying dissection. Less often the dissection is confined to the midcervical region, and occasionally it extends into the middle cerebral artery or involves the opposite carotid artery or the vertebral and basilar arteries.

The pathogenesis of spontaneous carotid dissection is at present uncertain. In most reported cases, cystic medial necrosis has not been found on microscopic examination of the involved artery. In some, there has been disorganization of the media and internal elastic lamina, but the specificity of these changes is in doubt, as Ojemann and colleagues (1972) noted similar changes in some of their control cases. In a small proportion of cases there are the changes of fibromuscular dysplasia, as noted earlier. Several groups have found structural collagen abnormalities in the skin biopsies of patients with dissection. A more thorough study of these vessels is needed.

Vertebral Artery Dissection

Dissection of these arteries may originate in the neck and extend into the intracranial portion of the vessel or remain isolated to either of these segments as noted below. In both instances there is a tendency to form pseudoaneurysms, mostly with the intracranial type, and in the latter there is a risk of rupture through the adventitia leading to a subarachnoid hemorrhage. Rapid and extreme rotational movement of the neck is the most common identifiable cause of vertebral artery dissection, as in turning the head to back up a car or with chiropractic manipulation. Extending the neck to have one's hair washed, swinging a golf club, and direct neck trauma have also been precipitants. Forceful coughing may also cause dissection, as it may in the carotid vessels. There is no clear female predominance (as there may be in carotid dissection) but the previously cited intrinsic weaknesses of the vascular wall from Ehlers-Danlos disease and fibromuscular dysplasia are risk factors.

The dissection most commonly originates in the C1-C2 segment of the vessel, where it is mobile but tethered as it leaves the transverse foramen of the axis and turns sharply to enter the cranium. The symptoms, mainly vertigo, are fragments of the lateral medullary syndrome, often with additional features referable to the pons or midbrain, particularly diplopia and dysarthria. The clinical manifestations in our experience have fluctuated over minutes and hours, quite unlike the usual vertebrobasilar TIA.

Less-common strokes include artery-to-artery embolism to the posterior cerebral territory or, a syndrome that has come to our attention several times in the past few years, a centrally placed infarction of the cervical spinal cord with brachial weakness, presumably from occlusion of the anterior spinal arteries. Another interesting but rare association with dissection has been the reversible cerebral vasoconstriction syndrome. Mawet and colleagues reported on 20 cases they extracted from their experience but could not determine which process occurred first and could only speculate as to the relationship. Dissection of the vertebral artery was a more common association with "RCVS" than was carotid artery dissection.

The diagnosis of vertebral dissection should be suspected if persistent occipitonal pain and vertigo or related medullary symptoms arise following one of the known precipitants—such as chiropractic manipulation of the neck, head trauma, or Valsalva straining or coughing activities—but it may otherwise escape detection until the full-blown medullary or cerebellar stroke is established. The stroke may follow the inciting event by several days or weeks or even longer, obscuring the relationship. Axial MRI images, particularly the T1-weighted sequences, show a double lumen in the dissected vessel, as described for carotid artery dissection earlier, and skillful ultrasound investigation documents the same. Some patients will be found to have evidence of spontaneous or traumatic dissection of multiple extracranial vessels; this also occurs as a consequence of dissection of the aortic arch from chest trauma.

No generally agreed upon method has been devised to detect the infrequent instance of subarachnoid

hemorrhage from dissection. Lumbar puncture is not routinely performed. CT is probably adequate for this purpose but it must be acknowledged that it, too, is not often obtained, except in cases of strong suspicion that the dissection has extended into the subarachnoid space, as evidenced by lower cranial-nerve palsies.

Once a stroke has occurred, even though embolic in most cases, prompt reopening of the artery can at times prove beneficial; this is currently performed by endovascular techniques. Most neurologists take the approach that warfarin, if used, may be discontinued after several months or a year, when angiography or MRA shows the lumen of the carotid artery to be patent, or at least reduced to no more than 50 percent of the normal diameter, and smooth walled. Despite numerous publications demonstrating the ability of skilled operators to reopen a dissection by endovascular methods, acute intervention has not been studied in a way that allows a judgment regarding its value. Of both therapeutic and diagnostic value is the relief of pain afforded by corticosteroids in cervical and intracranial dissections, as mentioned earlier. Pseudoaneurysms in the cervical portions of the vessels generally do not require specific treatment; the series of 38 cases collected by Benninger and colleagues is instructive in that none of the aneurysms ruptured during several years of followup and one had a delayed ischemic stroke.

The study by Mokri and colleagues (1988) reported a complete or excellent recovery in 85 percent of patients with the angiographic signs of cervical artery dissection; mainly, these were patients who had fluctuating ischemic symptoms but without stroke. The outcome in cases complicated by stroke is far less benign. Approximately 25 percent of such patients succumb and most others remain seriously impaired. If early recanalization of the occluded artery is observed (as determined by ultrasonography), there may also be good functional recovery. Local pseudoaneurysms form in a small proportion of patients and generally do not require surgical repair; they also do not preclude cautious anticoagulation. Subarachnoid hemorrhage from transmural rupture is mostly a complication of vertebral artery dissection discussed below.

Intracranial Arterial Dissection

Dissections of intracranial arteries are less common than extracranial ones and they present in several unusual ways. A number of times we have misinterpreted the arteriographic appearance of a short segment of narrowing of the basilar or proximal middle cerebral arteries, assuming these changes to represent embolism or arteritis when in fact they proved to be dissections of the vessel wall. In the case of purely intracranial dissection of the middle cerebral or basilar arteries, there is usually no preceding trauma, but a few patients have had minor head injuries, extreme coughing, or other recently Valsalva-producing events (e.g., after childbirth)—or they had used cocaine. The typical picture is of fluctuating symptoms referable to the affected circulation and severe cranial pain on the side of the occlusion—retroorbital

in the case of middle cerebral dissection, occipital in the case of basilar dissection, occipital combined with supraorbital in the case of vertebral dissection (see above). A few patients have had sudden strokes that suggested embolic infarction, and a small number present with subarachnoid hemorrhage.

Treatment of Cervical Artery Dissection

As an overall comment pertaining to dissection, treatment is primarily with anticoagulation for several weeks or months and followed up with some form of arteriography. The choice between aspirin and warfarin has not been clarified as the rate of stroke is low, in the range of 5 percent or less, and remains so with either agent (Georgiadis and colleagues); however, there have not been adequately controlled trials to determine if this is true for large groups of patients. If the dissection has produced complete occlusion of the vessel, the role of anticoagulation is less clear. Endovascular revascularization has been attempted with mixed results, the main problem being catastrophic and sometimes fatal vessel rupture during angioplasty. An issue pertaining to treatment is in establishing the presence of dissection into the subarachnoid space of the intracranial compartment. For carotid dissection, such extensions would seem to present a risk of subarachnoid hemorrhage if the lesion reaches

beyond the cavernous sinus. Within the sinus, any bleeding would create a cavernous-carotid fistula, which is not usually fatal. In vertebral dissection, this question arises when the false lumen extends into the foramen magnum, beyond the dural entry of the vessel.

Although there are no data to determine the proper approach to anticoagulation in these circumstances that entail a risk of a subarachnoid hemorrhage, in general we do use heparin and warfarin for a brief period because of the greater concern for embolus, unless there is existing subarachnoid blood on a CT scan or if there is a pseudoaneurysm within the intracranial portion of the dissection (see Metso et al). Some stroke specialists have suggested that a lumbar puncture be performed before initiating anticoagulation but this has not been our practice.

Moyamoya Disease

Moyamoya is a Japanese word for a “haze,” “puff of smoke”; it has been used to refer to an *extensive basal cerebral rete mirabile*—a network of small anastomotic vessels at the base of the brain around and distal to the circle of Willis, seen in carotid arteriograms, associated with segmental stenosis or occlusion of the terminal intracranial parts of both internal carotid arteries (Fig. 34-20). This form of cerebrovascular disease is predominant in,

Figure 34-20. Moyamoya disease. Digital subtraction angiography in the coronal plane of the left common carotid artery. On the left image, there is occlusion of the left internal carotid artery near its terminus, and evidence of abnormal vascular proliferation involving the lenticulostriate vessels (*arrow*). The external carotid artery branches fill normally. The right image shows the same contrast injection during the early capillary phase; the characteristic “puff of smoke” is encircled.

but not limited to the Japanese. The authors have periodically observed such patients, as have others, in the United States, Western Europe, and Australia. Certain hemoglobinopathies, particularly sickle cell anemia, may cause a vasoocclusive condition equivalent to moyamoya disease, possibly because of sickling of red blood cells in the vasa vasorum of the supraclinoid carotid artery. An association between moyamoya, Down syndrome, and certain human leukocyte antigen (HLA) types favors a hereditary basis (Kitahara et al). A familial component has long been suspected but can be established in only 10 percent of cases, possibly in an autosomal dominant pattern with incomplete penetrance due to a site on chromosome 17q that has been implicated as one possible locus. Also, a rare condition in either Asians or Europeans of atherosclerotic occlusion of the distal intracranial carotid arteries can cause deep collateral vessels to enlarge and simulate moyamoya. In this way, moyamoya can be considered either a radiologic pattern or a disease process.

Nishimoto and Takeuchi reported on 111 cases that were selected on the basis of the two main radiologic criteria. The condition was observed mainly in infants, children, and adolescents (more than half the patients were younger than 10 years of age, and only 4 were older than age 40 years). All of their patients were Japanese, in whom the disease seems disproportionately prevalent; both males and females were affected, and 8 were siblings. The symptom that led to medical examination was usually a sudden weakness of an arm, leg, or both on one side. The symptoms tended to clear rapidly but recurred in some instances. Headache, convulsions, impaired mental clarity, visual disturbance, and nystagmus were less frequent. In older patients, subarachnoid hemorrhage was the most common initial manifestation. Other symptoms and signs were speech disturbance, sensory impairment, involuntary movements, and unsteady gait. Characteristics noted in other series have included prolonged TIAs (this accords with our experience), characteristically induced by hyperventilation or hyperthermia, parenchymal rather than subarachnoid hemorrhages (most situated in the basal ganglia or thalamus), and an unusual "rebuildup" EEG phenomenon in which high-voltage slow waves reappear 5 min after the end of hyperventilation.

Postmortem examinations of cases of moyamoya have yielded a reasonably clear picture of the intracranial distal carotid lesion. The adventitia, media, and internal elastic laminae of the stenotic or occluded arteries were normal, but the intima was greatly thickened by fibrous tissue. No inflammatory cells or atheromata were seen. In a few cases, hypoplasia of the vessel with absent muscularis has been described. The profuse rete mirabile consists of a fine network of vessels over the basal surface of the brain (in the pia-arachnoid), which, according to Yamashita and coworkers, reveals microaneurysm formation because of weakness of the internal elastic lamina and thinness of the vessel wall. The latter lesion is the source of subarachnoid hemorrhage. Thus one part of the symptomatology is traced to the distal carotid stenosis and another to the rupture of the vascular network. Opinion is divided as to whether the basal rete mirabile

represents a congenital vascular malformation (i.e., a persistence of the embryonal network) or a rich collateral vascularization secondary to a congenital hypoplasia, acquired stenosis, or occlusion of the internal carotid arteries early in life.

Treatment The treatment of moyamoya is far from satisfactory. Certain surgical measures have been employed, including transplantation of a vascular muscle flap, omentum, or pedicle containing the superficial temporal artery to the pial surface of the frontal lobe temporal pial synangiosis with the idea of creating neovascularization of the cortical convexity. These measures have reportedly reduced the number of ischemic attacks, but whether they alter the natural history of the illness cannot be stated. Anticoagulation is considered risky in view of the possibility of cerebral hemorrhage, but there have not been systematic studies. The reader is referred to a contemporary review of the clinical features and surgical treatments by Scott and Smith.

Binswanger Disease

This entity was mentioned briefly in the discussion of the course and prognosis of atherothrombotic infarction and as a cause of dementia in Chaps. 21 and 39. The term has come to denote a widespread degeneration of cerebral white matter having a vascular causation and observed in the context of hypertension, atherosclerosis of the small blood vessels, and multiple strokes. Hemiparesis, dysarthria, TIAs, and typical lacunar or cortical strokes are admixed in many cases. The process has been associated with a particular radiologic appearance that reflects confluent areas of white matter signal change. The term *leukoaraiosis* describes the imaging appearance of hypointense periventricular tissues, presumably damaged by chronic ischemia. It is likely that leukoaraiosis exist in a continuum with Binswanger disease and many elderly individuals who have these changes show cognitive impairment as discussed below. Whether multiple discrete lacunes in the deep white matter constitute Binswanger disease may be a semantic issue, but we adhere to the notion that the former is characterized by a more widespread ischemic and gliotic change in the deep white matter.

Dementia, a pseudobulbar state, and a gait disorder, alone or in combination, are the main features of Binswanger cases. They have been attributed to the cumulative effects of the ischemic changes producing a white matter degeneration. It is likely that the pathologic basis of such a clinical entity is arteriolar sclerosis but surprisingly, as pointed out in Fisher's review, the lumens are open. Yet another problem is to distinguish such a state from deficits produced by the cumulative effect of numerous larger lacunes, which have for a century been known to cause the aforementioned syndromes of dementia, gait disturbance, and a pseudobulbar syndrome. From time to time, imaging studies of the brain disclose large regions of white matter change or the occurrence of multiple infarctions in the absence of hypertension, and it is not clear how such cases should be classified. Some prove to be areas of demyelination or metabolic dysmyelination;

others are mitochondrial disorders, and perhaps some are related to the familial CADASIL syndrome or Susac syndrome discussed below. Fabry disease also enters into the differential diagnosis of multiple small infarctions in the cerebrum that may coalesce into areas of white matter damage. Readers may consult the reviews on the subject by Babikian and Ropper, by Caplan (1995), and the mentioned review by CM Fisher.

Familial Subcortical Infarction (CADASIL and CARASIL)

A process with an imaging appearance of large confluent cerebral white matter changes, somewhat similar to Binswanger leukoencephalopathy, has been identified as an autosomal dominant familial trait linked in several families to a missense mutation on chromosome 19. In the past, it had been described under a number of names, including *hereditary multiinfarct dementia*. The acronym CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is now applied. In these patients recurrent small strokes beginning in early adulthood culminate in a subcortical dementia (see Chap. 21). Migraine headaches, often with neurologic accompaniments, may precede the strokes by several years, as may numerous and varied TIAs that are attributed, probably incorrectly, to the migraine. On the other hand, some individuals display few clinical changes while yet others are demented or have strokes that simulate lacunes. We are unable to comment on the encephalopathy and coma accompanied by fever

described by Schon and colleagues that has been attributed to this condition.

The familial nature of the process may not be appreciated because genetic penetrance is not complete until after 60 years of age. On MRI, clinically unaffected family members may show substantial changes in the white matter well before strokes or dementia arises (Fig. 34-21). A syndrome of early alopecia and lumbar spondylosis with the white matter changes typical of CADASIL has been identified as a recessively inherited disease (cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy [CARASIL]) and is discussed separately below.

The MRI and CT appearance is of multiple confluent white matter lesions of various sizes, many quite small and concentrated around the basal ganglia and periventricular areas. Lesions anterior to the temporal horns of the lateral ventricles are particularly characteristic of the entity. When the affected regions are asymmetrical and periventricular, they are difficult to distinguish from the lesions of multiple sclerosis. In the autopsy cases studied by Jung and colleagues, numerous partially cavitated infarctions were found in the white matter and basal ganglia. Small vessels in the regions of these infarctions, 100- to 200- μ m diameters, contained basophilic granular deposits in the media with degeneration of smooth muscle fibers. Attribution of the white matter lesions to these vascular changes presents the same problems as in Binswanger disease, particularly in view of patency of most of the many small vessels in the examined material. Nevertheless, CADASIL is probably the main cause of sporadic instances of what otherwise

Figure 34-21. Axial T2-FLAIR MRI of cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). There is confluent symmetric abnormal hyperintensity within the periventricular white matter and internal and external capsules (*left*) and characteristically, also in the anterior temporal lobes (*right*).

passes for Binswanger disease; the anterior temporal changes, however, are typical of the former. Also, migraine headaches are not a component of Binswanger disease.

The responsible mutation is a missense change on chromosome 19 of the *NOTCH 3* gene, in the same locus as the gene for familial hemiplegic migraine, and has been characterized by Joutel and colleagues; this provides a diagnostic test that can be performed on the blood or skin. The gene may now be sequenced in commercial laboratories. The diagnosis can also be confirmed by finding eosinophilic inclusions in the arterioles of a skin biopsy (osmophilic with electron microscopy).

An entirely different vasculopathy with widespread white matter signal change has been reported in Japan. Migraine is not a component of the syndrome, and the *NOTCH* gene, implicated in CADASIL, is normal. Inheritance is as a recessive trait (hence, CARASIL) from a mutation in the *HTAR1* gene (see Hara et al). The result is fragmentation and duplication of the internal elastic lamina of cerebral vessels with narrowing of their lumens. As intriguing from this mutation is an associated osteoid growth that causes severe lumbar stenosis and alopecia.

An interesting mutation of the *COL4A1* gene for type 4 collagen leads to familial small vessel disease and intracerebral hemorrhage in mice and humans (Gould et al). More often, as in the cases described by Verreault and colleagues, there are numerous white matter infarctions that are not explained by hypertension and similar lesions may be found in family members by MRI.

Under the terms HERNS (hereditary endotheliopathy, retinopathy, nephropathy, and strokes) and CRV (cerebroretinal vasculopathy), rare dominantly inherited conditions have been described that cause subcortical white matter degeneration, presumably on a microvascular occlusive basis. Ocular symptoms and retinopathy are the main features and the neurologic aspects. Awareness of these vascular forms of white matter degenerations adds to the list of inherited leukoencephalopathies discussed in Chap. 38 and the action of the implicated genes reveals novel mechanisms of damage to small cerebral vessels.

Strokes in Children and Young Adults

As indicated in Table 34-2 in an earlier section, ischemic necrosis of cerebral tissue can occur in utero. The resulting stroke is usually referred to as *congenital hemiplegia* but there are heterogeneous causes and in most instances, the underlying vascular disease cannot be discerned. The adjacent ventricular region tends to expand into the stroke cavity and may cause a porencephalic cyst.

Acute hemiplegia in infants and children is a rare but well-recognized phenomenon. In a series of 555 consecutive postmortem examinations at the Children's Medical Center in Boston (now Boston Children's Hospital), there were 48 cases (8.7 percent) of occlusive vascular disease of the brain (Banker). The occlusions, studied neuropathologically, were both embolic (mainly associated with congenital heart disease) and thrombotic, and the latter were actually more common in veins than in arteries.

Similarly, stroke is not an uncommon event in young adults (ages 15 to 45 years), accounting for an estimated

3 percent of cerebral infarctions in typical series. In terms of causation, this group is also remarkably heterogeneous. Among 144 such patients, more than 40 possible etiologies were identified by H.P. Adams and colleagues. Nevertheless, most of the strokes could be accounted for by three categories, more or less equal in size: (1) atherosclerotic thrombotic infarction (usually with a recognized risk factor); (2) cardiogenic embolism (particularly in the past association with rheumatic heart disease, infective and non-infective endocarditis, paradoxical embolism through patent foramen ovale and other cardiac defects, and prosthetic heart valves); and (3) one of several nonatherosclerotic vasculopathies (arterial trauma, dissection of the carotid artery, moyamoya, lupus erythematosus, drug-induced vasculitis). Hematologically related disorders—use of oral contraceptives (discussed further on), the postpartum state, and other hypercoagulable states—were the probable causes in 15 percent patients. The presence of antiphospholipid or anticardiolipin antibodies (lupus anticoagulant) explains some of these cases and is discussed further in the section on “Stroke as a Complication of Hematologic Disease”; the majority of these patients are women in their thirties without manifest systemic lupus erythematosus.

Despite the attention they have received recently as a cause of strokes in the juvenile and young adult period, the frequency of inherited deficiencies of naturally occurring anticoagulant factors as a cause of stroke is low. Table 34-7 summarizes the main inherited prothrombotic clotting defects. They predispose primarily to cerebral venous thrombosis. Most arise from partial protein deficiencies as a result of heterozygous mutations in the genes encoding proteins in the clotting cascade (antithrombin III, proteins S and C) and from those that disturb clotting balance (resistance to activated protein C, or factor V Leiden mutation, and prothrombin mutations as well as excess factor VIII) (see discussion by Brown and Bevan). When homozygous, these mutations may be associated with devastating neonatal hemorrhagic conditions. In some series that report cases of strokes in youth, such as the one reported by Becker and colleagues, up to half of stroke cases had one of these disorders, the most common being the factor V Leiden mutation, but others have found this mutation to be much less frequent, which is more consonant with our experience. Nevertheless, in children with unexplained stroke, particularly venous ones or if there is a family history of stroke in early life, and especially if there has been a previous thrombosis or if the strokes are recurrent, it is advisable to carry out an extensive hematologic investigation, including testing for antiphospholipid antibody (an acquired defect), as described in the later section on “Antiphospholipid Antibody (Hughes) Syndrome.” Establishing a diagnosis of a prothrombotic clotting gene variant has further significance because strokes are prone to occur in the setting of additional risks, such as the use of oral contraceptives and smoking. In adults, the evaluation for inherited clotting defects is less fruitful. Furthermore, it should be kept in mind that the levels of proteins C and S and of antithrombin are temporarily depressed after stroke, so that any detected abnormalities must be confirmed months later and in the absence of anticoagulation.

Table 34-7

STROKE ASSOCIATED WITH GENETIC DISORDERS

	GENE	INHERITANCE	STRUCTURES AFFECTED	GENERAL POPULATION (%)	WITH CEREBRAL THROMBOSIS (%)
Causes of arterial or venous infarction					
Activated protein C resistance	Leiden factor V mutation	AR	v	2–15	5–20
Prothrombin 20210	Prothrombin	AR	v	0.1	1–5
Protein C deficiency	Protein C gene	AR	v	0.2–0.4	3–6
Protein S deficiency	Protein S gene	AR	v	0.03–0.13	1–5
Increased factor VIII	von Willebrand factor deficiency	AR	v	10	25
Antithrombin III deficiency	Antithrombin III	AR	v	Rare	3–8
Plasminogen deficiency	Plasminogen activator-1	AR	v		
Lipoprotein (a)	Apolipoprotein (a)	AR	v		
Marfan syndrome	Fibrillin 1		v, h, ao	0.03	
Fabry disease	Alpha-galactosidase	AR	v		
Sickle cell syndrome	Globin genes		v, a		
Heparin cofactor II	Heparin cofactor II	AR	v	Rare	? 5
Platelet collagen receptor	Platelet collagen receptor	AR	v		
Factor XII	Factor XII	AR	v		
Phosphodiesterase 4D	Phosphodiesterase 4D	Complex	a		
CADASIL	Notch 3	AD	a		
CARASIL	HTAR1	AR	a		
Hyperhomocysteinemia	Methylene tetrahydrofolate reductase	AR	a	Rare	20 in young
Homocysteinemia	Cystathionine beta-synthase	AR	a		
Homocysteinemia	Homocysteine methyl transferase	AR	a		
Ehlers Danlos disease	Collagen type III, numerous mutations	Mainly AD	a		
MELAS (mitochondrial)	mtDNA	Maternal			
Causes of cerebral hemorrhage associated with congenital diseases					
von Hippel-Lindau (see Chap. 31)	pVHL	AD	hemorrhage		
Cavernous malformations	Cerebral cavernous malformations (CCM1)	AD	"		
Cerebral amyloidosis	Apolipoprotein E ₄	Complex	"		
Cerebral hemorrhage with amyloidosis			"		
Dutch type	Amyloid precursor protein	AD	"		
Icelandic type	Cystatin C	AD	"		
Hereditary hemorrhagic telangiectasia	Endoglin	AD	"		
Hereditary hemorrhagic telangiectasia	Activin receptor-like kinase (ALK-1)	AD	"		
Polycystic kidney disease	Polycystin 1, 2	AD	"		

a, arterial; AD, autosomal dominant; ao, aorta; AR, autosomal recessive; h, heart; v, venous.

Persistent cerebral ischemia and infarction may occasionally complicate migraine in young persons as discussed in Chap. 10. Wolf and colleagues identified a prolonged aura in young women with an established history of migraine as a risk for strokes, most of which occurred in the posterior circulation. The combination of migraine and oral contraception is particularly hazardous, as detailed below. Despite the common occurrence of mitral valve prolapse in young adults, it is probably only rarely a cause of stroke (see previous comments). Stroke because of either arterial or venous occlusion occurs occasionally in association with inflammatory bowel disease in young persons. Evidence points to a hypercoagulable state during exacerbations of the enteritis but a precise defect in coagulation

has not been identified. Meningovascular syphilis and fungal and tuberculous meningitis and other forms of chronic basal meningitis are also considerations in this age group; the strokes are usually of the lacunar type, resulting from inflammatory occlusion of small basal vessels.

Sickle cell anemia is a rare but important cause of stroke in children of African ancestry; acute hemiplegia is the most common manifestation but all types of focal cerebral disorders have been observed. The pathologic findings are those of infarction, large and small; their basis is assumed to be vascular obstruction associated with the sickling process. The association of sickle cell anemia with the moyamoya syndrome was mentioned earlier and surveillance for the development of supraclinoid stenosis

may be undertaken by transcranial Doppler. Exchange transfusions have prevented or retarded the formation of moyamoya and the report by RJ Adams and colleagues indicates that the procedure may reduce the risk of stroke if the arteriopathy is detected. Intracranial bleeding (subdural, subarachnoid, and intracerebral) and cerebral venous thrombosis may also complicate sickle cell anemia, and—probably because of autosplenectomy—there is an increased incidence of pneumococcal meningitis. Treatment of the cerebral circulatory disorder, based presumably on sludging of red blood cells, is with intravenous hydration and transfusion. Cerebral venous sinus thrombosis in young children and neonates from various causes represents a special problem, difficult to diagnose, and with a poor prognosis (see deVeber et al).

Certain hereditary metabolic diseases (*homocystinuria* and *Fabry angiokeratosis*) and the mitochondrial disorder MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) may give rise to strokes in children or young adults; investigation of these causes is undertaken if the aforementioned clotting disorders have been excluded or if there is a family history. Figure 34-22 demonstrates an example of stroke related to MELAS.

Overall, in children and young adults with ischemic stroke, the main diagnoses to be considered are carotid and vertebral dissection, drug abuse (mainly cocaine), thrombosis induced by contraceptive estrogens (see below), antiphospholipid antibody syndrome, and cardiac disease including patent foramen ovale (PFO). Migraine might be added to this list, but it is a diagnosis by exclusion in these circumstances and CADASIL, albeit rare, should also be considered if migraine headaches and TIAs precede a stroke. Inherited prothrombotic

states—such as those caused by the various clotting factor deficiencies discussed above, Fabry disease, moyamoya, and Takayasu arteritis—arise in the younger age group and require exploration if clinical circumstances suggest one of these processes on the basis of unusual TIAs (orthostatic, hyperventilation, or fever induced), Down syndrome, or strong family history of strokes in youth.

Oral Contraceptives, Estrogen, and Cerebral Infarction

The early studies of Longstreth and Swanson and of Vessey and associates indicated that women who take oral contraceptives in the childbearing years—particularly if they are older than 35 years of age and also smoke, are hypertensive, or have migraine—are at increased risk of cerebral infarction. Stroke in these cases is usually a result of arterial occlusion, occurring in both the carotid–middle cerebral and vertebrobasilar territories and sometimes to occlusion of cerebral veins. In most of the reported fatal cases, the thrombosed vessel has been free of atheroma or other disease. The vascular lesion underlying cerebral thrombosis in women taking oral contraceptives was studied by Irey and colleagues. It consists of nodular intimal hyperplasia of eccentric distribution with increased acid mucopolysaccharides and replication of the internal elastic lamina. Similar changes have been found in pregnancy and in humans and animals receiving exogenous steroids, including estrogens. These observations, coupled with evidence that estrogen alters the coagulability of the blood, suggest that a state of hypercoagulability is the important factor in the genesis of contraceptive-associated infarction.

Figure 34-22. Two axial T2-FLAIR images of mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS). Multifocal asymmetric areas of cortical and subcortical T2 hyperintensity are seen.

Mainly at increased risk of stroke are women taking high-dose (0.50-mg) estrogen pills; in recent years, lowering the estrogen content has substantially reduced, but not eliminated, this risk. The use of progestin-only pills or of subcutaneously implanted capsules of progestin has not been associated with stroke as far as can be currently determined (Petitti et al). The epidemiologic study reported by Lidegaard and colleagues puts the risk of hormonal contraception in perspective; in a large cohort of Danes, the risks of thrombotic strokes and myocardial infarction over 15 years was very low with estradiol-containing compounds but it increased with age and with the dose of estradiol. It has also become apparent that mutations of the prothrombin gene are more frequent in patients who have cerebral venous thrombosis while on oral contraceptive pills than they are in the general population. Martinelli and associates propose that these genetic abnormalities account for 35 percent of idiopathic cases of cerebral vein thrombosis; and they have contended that contraceptives increase this risk 20-fold.

Stroke in Pregnancy and the Postpartum Period

In addition to the eclamptic-hypertensive state, there is an increased incidence of cerebrovascular events during pregnancy and the postpartum period. The risk of both cerebral infarction and intracerebral hemorrhage appears to be mainly in the 6-week period after delivery rather than during the pregnancy itself (Kittner et al). Fisher (1971) reviewed the literature and analyzed 12 postpartum, 9 puerperal, and 14 contraceptive cases, as well as 9 patients receiving estrogen therapy; arterial thrombosis was demonstrated in half of these cases. Most of the focal vascular lesions during pregnancy were a result of arterial occlusion in the second and third trimesters and in the first week after delivery. Venous occlusion tended to occur 1 to 4 weeks postpartum. In Rochester, New York, the incidence rate of stroke during pregnancy was 6.2 per 100,000, but it doubled with each advance in age from 25 to 29, 30 to 39, and 40 to 49 years. Included in most past series are cases with cardiac disease, particularly valve-related embolism. It is perhaps surprising that subarachnoid hemorrhage is not more frequent during the Valsalva activity of childbirth. Carotid artery dissection may also be encountered late in pregnancy or soon after delivery.

The occurrence of paradoxical embolus is always a consideration in pregnancy because of a tendency to form clots in the pelvic and leg veins, coupled with increased right heart pressures. Amniotic fluid embolus may rarely cause stroke in this manner and should be suspected in multiparous women who have had uterine tears; there are almost invariably signs of acute pulmonary disease from simultaneous occlusion of lung vessels. A rare peripartum cardiomyopathy is yet another source of embolic stroke.

Stroke With Cardiac Surgery

Incident to cardiac arrest and bypass surgery, there is risk of both generalized and focal ischemia of the brain. Improved operative techniques have lessened the frequency

of these complications but they are still distressingly frequent. Fortunately, most are transient. Atherosclerotic plaques may be dislodged during cross-clamping of the proximal aorta and are an important source of cerebral emboli. In the last decade, the incidence of stroke related to cardiac surgery has dropped to between 2 and 3 percent in large series numbering thousands of patients (Libman et al; Ahlgren and Arén). Advanced age, congestive heart failure, and more complex surgeries have been listed as risk factors for stroke from various reports.

Representative is a retrospective study by Dashe and colleagues, in which 2 percent had strokes; most minor, but the risk was greatly increased on the side of a carotid stenosis. Curiously, almost one-fifth of postoperative strokes in some series have been of lacunar type. In one prospective study of 2,108 patients who underwent coronary operations in several institutions, 3 percent had strokes or TIAs; the adverse effects mostly occurred in older patients and were transient (Roach et al). Mohr and coworkers (1978) examined 100 consecutive cases pre- and postoperatively and observed two types of stroke-like complications—one occurring immediately after the operation and the other after an interval of days or weeks. The immediate neurologic disorder consisted of a delay in awakening from the anesthesia; subsequently there was slowness in thinking, disorientation, agitation, combativeness, visual hallucinations, and poor registration and recall of what was happening. These symptoms, in the form of a confusional state sometimes verging on delirium or acute psychosis, usually cleared within 5 to 7 days, although some patients were not entirely normal mentally some weeks later. As the confusion cleared, about half of the patients were found to have small visual field defects, dyscalculia, Balint syndrome (see Chap. 22), alexia, or defects of perception suggestive of lesions in the parietooccipital regions. The immediate effects were attributed to hypotension and various types of embolisms (atherosclerotic, air, silicon, fat, platelets). The delayed effects were more clearly embolic and were especially frequent in patients having prosthetic valve replacements or other valve repairs.

In addition to overt and covert strokes detected only by imaging, a degree of cognitive decline and depression is to be expected in a proportion of patients undergoing coronary artery bypass grafting. The frequency of these changes is reported to be between 40 and 70 percent (see Chap. 20). It is our impression that many of these neurologic complications, both small strokes and cognitive abnormalities, pass unnoticed in many cardiac surgical units. This was emphasized in the study by McKhann and colleagues, who tested several neuropsychologic functions and found that only 12 percent of patients escaped some type of early cognitive problem. However, his group and others, for example, Mülges and colleagues, have shown that only a small proportion (13 percent in the latter series) retained permanent effects 5 years after operation. Others have reported higher rates, but it is clear that the cognitive problems improve over time in the majority of patients.

The use of Doppler insonation of the middle cerebral arteries is being studied to detect transient signals called

HITs (high-intensity transients) as a manifestation of small emboli during surgery but, as for the transients frequently noted during cerebral arteriography, the clinical importance of these emboli is not known. In an attempt to avoid neurologic complication related to extracorporeal circulation, off-pump coronary artery bypass has been popularized in many centers. Unfortunately, most studies have found no fewer cognitive complications as compared to conventional coronary artery bypass surgery (e.g., see Shroyer et al). This is contrary to the notion that the extracorporeal apparatus is the cause of the problem. The issue of the neurologic complications of cardiac surgery may be summarized by noting that strokes originating from the aorta are the main cause of cognitive failure. The clinical syndromes seem to fall on a continuum; a few strokes (less than 3 percent) are recognizable as obvious deficits (e.g., hemiplegia), instead, many have multiple small emboli that are evident with imaging and these are manifest as an acute encephalopathy. When the burden of emboli is lower, no deficit is recognized in the acute period. It is likely that in patients with premorbid presymptomatic Alzheimer disease, confusion and dementia are made manifest by the stress of cardiac surgery and the surgery is then blamed for the emergence of an ostensibly new problem (see Samuels).

The other special stroke problems relating to prosthetic heart valves—mainly infective endocarditis causing embolic strokes and anticoagulant-related cerebral hemorrhage—are described in later sections of this chapter.

INTRACEREBRAL HEMORRHAGE

This is the third most frequent cause of stroke, following cerebral embolism and thrombotic disease. Although more than a dozen causes of nontraumatic intracranial hemorrhage are listed in Table 34-8, hypertensive primary (“spontaneous”) intracerebral hemorrhage, ruptured saccular aneurysm and vascular malformation, and hemorrhage associated with the use of anticoagulants or thrombolytic agents account for the majority. Cerebrovascular amyloidosis and acquired or congenital bleeding disorders account for a smaller number. The small brainstem hemorrhages secondary to temporal lobe herniation and brainstem compression (Duret hemorrhages), hypertensive encephalopathy, and brain purpura might be included in this group, but they do not simulate a stroke.

Primary Intracerebral Hemorrhage

This is the often devastating “spontaneous” brain hemorrhage. It is predominantly a result of chronic hypertension and degenerative changes in cerebral arteries. In recent decades, with increased awareness of the need to control blood pressure, the proportion of hemorrhages attributable to causes other than hypertension, mainly anticoagulation, has greatly increased so that more than half such hemorrhages on our services now occur in normotensive individuals, and the hemorrhages more often arise in locations that are not typical for hypertension.

Table 34-8

CAUSES OF CEREBRAL HEMORRHAGE (INCLUDING INTRACEREBRAL, SUBARACHNOID, AND VENTRICULAR)

1. Primary (hypertensive) intracerebral hemorrhage
2. Ruptured saccular aneurysm
3. Ruptured arteriovenous malformation; less often, venous and dural vascular malformations
4. Cavernous angioma
5. Trauma including posttraumatic delayed apoplexy
6. Hemorrhagic disorders: leukemia, aplastic anemia, thrombocytopenic purpura, liver disease, complication of anticoagulant or thrombolytic therapy, hypofibrinogenemia, hemophilia, etc.
7. Hemorrhage into primary and secondary brain tumors
8. Septic embolism, mycotic aneurysm
9. With hemorrhagic infarction, arterial or venous
10. With inflammatory and infectious disease of the arteries and veins
11. With cerebrovascular amyloidosis
12. Pituitary apoplexy
13. Postcraniotomy or brain biopsy
14. Primary intraventricular hemorrhage
15. Miscellaneous rare types: vasopressor drugs, cocaine, moyamoya, herpes simplex encephalitis, meningeal melanomatosis, acute necrotizing hemorrhagic encephalitis (Hurst disease), tularemia, anthrax, etc.

Nevertheless, the hypertensive cerebral hemorrhage serves as a model for understanding and managing other cerebral hemorrhages.

In approximate order of frequency, the most common sites of a cerebral hemorrhage are (1) the putamen and adjacent internal capsule (50 percent); (2) the central white matter of the temporal, parietal, or frontal lobes (lobar hemorrhages, not strictly associated with hypertension); (3) the thalamus; (4) one or the other cerebellar hemisphere; and (5) the pons. The vessel that ruptures, giving rise to the hemorrhage, is usually a small penetrating artery that originates from a larger trunk. Approximately 2 percent of primary hemorrhages are multiple. Multiple, nearly simultaneous intracerebral hemorrhages raise the possibility of amyloid angiopathy or a bleeding diathesis (see further on) but may occur when one conventional hypertensive intracerebral hemorrhage causes hypertension, which in turn leads to one or more additional hemorrhages.

The extravasation of blood into the substance of the brain forms a roughly circular or oval mass that disrupts the tissue and can grow in volume if the bleeding continues. Adjacent brain tissue is distorted and compressed. If the hemorrhage is large, midline structures are displaced to the opposite side of the cranium and the reticular activating and respiratory centers are compromised, leading to coma and death in the manner described in Chap. 17. It has been long known that both the size and the location of the clot determine the degree of secondary brainstem compression and this was confirmed by Andrew and associates. Rupture or seepage of blood into the ventricular system or rarely to the surface subarachnoid space may occur, and the CSF becomes bloody in these cases.

In the first hours and days following the hemorrhage, varying degrees of edema evolve around the clot and add to the mass effect. Hydrocephalus may occur as a result of bleeding into the ventricular system or from compression of the third ventricle.

The extravasated blood undergoes a predictable series of changes. At first fluid, the collection becomes a clot within hours. Before the clot forms, red cells settle in the dependent part of the hematoma and form a meniscus with the plasma above; this is particularly prone to occur in cases of anticoagulant-induced hemorrhage. The resultant fluid–fluid level can be observed on CT and MRI (“hematocrit effect”). Hematomas, when examined in autopsy material, contain only masses of red blood cells and proteins; rarely one sees a few remnants of destroyed brain tissue. The hematoma is often surrounded by petechial hemorrhages from torn arterioles and venules. Within a few days, hemoglobin products, mainly hemosiderin and hematin, begin to appear. The hemosiderin forms within histiocytes that have phagocytized red blood cells (RBCs) and takes the form of ferritin granules that stain positively for iron. As oxyhemoglobin is liberated from the RBCs and becomes deoxygenated, methemoglobin appears. This begins within a few days and imparts a brownish hue to the periphery of the clot. Phagocytosis of red cells begins within 24 h, and hemosiderin is first observed around the margins of the clot in 5 to 6 days. The clot changes color gradually over a few weeks from dark red to pale red, and the border of golden-brown hemosiderin widens. The edema disappears over many days or weeks. In 2 to 3 months, larger clots are filled with a chrome-colored thick fluid, which is slowly absorbed, leaving a smooth-walled cavity or a yellow-brown scar. The iron pigment (hematin) becomes dispersed and studs adjacent astrocytes and neurons and may persist well beyond the border of the hemorrhage for years.

Imaging techniques demonstrate a predictable sequence of changes as shown in Fig. 34-23. On CT, fresh blood is visualized as a white mass as soon as it is shed. The “spot sign,” the appearance of contrast within the hemorrhage during CT angiography, is associated with a high rate of hematoma expansion. The mass effect and the surrounding extruded serum and edema are hypodense on CT. After 2 to 3 weeks, the surrounding edema begins to recede and the density of the hematoma decreases, first at the periphery. Gradually the clot becomes isodense with brain. There may be a ring of enhancement from the hemosiderin-filled macrophages and the reacting cells that form a capsule for the hemorrhage. At one point several weeks after the bleed, the appearance may transiently simulate a tumor or abscess. By MRI, either in conventional T1- or T2-weighted images, the hemorrhage is not easily visible in the 2 or 3 days after bleeding, as oxyhemoglobin is diamagnetic or, at most, is slightly hypointense, so that only the mass effect is evident. MR gradient echo or equivalent sequences that display areas of magnetic susceptibility show hemorrhages earlier and detect remnants of deposited hemosiderin even years afterward.

After several days the surrounding edema is hyperintense in T2-weighted images. As deoxyhemoglobin and methemoglobin form, the hematoma signal becomes bright

on T1-weighted images and dark on T2. The hematoma is then subacute and the dark signal gradually brightens. When methemoglobin disappears and only hemosiderin remains, the entire remaining mass is hypodense on T2-weighted images, as are the surrounding deposits of iron. The sizes of cerebral hemorrhages vary widely. *Massive* refers to hemorrhages several centimeters in diameter, usually larger than 50 mL; *small* applies to those 1 to 2 cm in diameter and less than 20 mL in volume. The volume and location relate to outcome and the nature of the initial neurologic deficit.

Pathogenesis

The hypertensive vascular lesion that leads to arteriolar rupture in most cases appears to arise from an arterial wall altered by the effects of hypertension, i.e., the change referred to in a preceding section as segmental lipohyalinosis and the false aneurysm (microaneurysm) named for Charcot and Bouchard. Ross Russell’s work affirmed the relationship of these microaneurysms to hypertension and hypertensive hemorrhage and their frequent localization on penetrating small arteries and arterioles of the basal ganglia, thalamus, pons, and subcortical white matter. However, in the few hemorrhages examined in serial sections by our colleague C.M. Fisher, the bleeding could not be traced to Charcot-Bouchard aneurysms. Takebayashi and coworkers, in an electron microscopic study, found breaks in the elastic lamina at multiple sites, almost always at bifurcations of the small vessels. Possibly these represented points of secondary rupture from tearing of small vessels by the expanding hematoma. Amyloid impregnation of vessel walls represents a different mechanism for vessel rupture, as discussed further on.

Clinical Syndrome

Of all the cerebrovascular diseases, brain hemorrhage is the most dramatic and from ancient times has been given its own name, “apoplexy.” The prototype was an obese, plethoric, hypertensive male who falls senseless to the ground—impervious to shouts, shaking, and pinching—breathes stertorously, and dies in a few hours. A massive blood clot escapes from the brain as it is removed postmortem. With smaller hemorrhages, the clinical picture conforms more closely to the usual temporal profile of a stroke, i.e., an abrupt onset of symptoms that evolve gradually and steadily over minutes or hours, depending on the speed and expansion of bleeding.

Several general features of intracerebral hemorrhage should be emphasized. *Acute reactive hypertension*, far exceeding the patient’s chronic hypertensive level, is a feature that, in the context of a stroke, suggests hemorrhage; it is seen particularly with moderate and large clots situated in deep regions. *Vomiting* at the onset of intracerebral hemorrhage occurs much more frequently than with infarction and likewise suggests bleeding as the cause of an acute hemiparesis. Severe headache is generally considered to be an accompaniment of intracerebral hemorrhage and in many cases it is, but in almost half of cases it has been absent or mild. *Nuchal rigidity* is infrequent. If there is stiffness of the neck, it characteristically

Figure 34-23. Unenhanced CT showing hypertensive hemorrhages in the putamen (A), thalamus (B), pons (C), and cerebellum (D). The thalamic hemorrhage (B) has extended into the posterior horn of the right lateral ventricle and the cerebellar hemorrhage (D) has extended into the fourth ventricle.

disappears as coma deepens. Or, the patient may be alert and responding accurately when first seen. Only if bleeding into the ventricles is massive or there is substantial distortion of the midbrain, does coma result.

Seizures, usually focal, occur in the first few days in only 10 percent of cases of supratentorial hemorrhage, rarely at the time of the ictus and more commonly as a delayed event, months or years after the hemorrhage.

In the selected population of patients with cerebral hemorrhage who are continuously monitored by EEG in an intensive care unit, the frequency may be higher, up to one-third of which half are purely electrographic, according to Claassen and associates. This finding is interesting but does not seem to justify routine EEG monitoring.

The fundi often show hypertensive changes in the arterioles. Infrequently, fresh preretinal (subhyaloid)

hemorrhages occur; the latter are much more common with ruptured aneurysm, arteriovenous malformation, or severe cranial trauma. Therefore, *headache, acute hypertension, and vomiting* with hemiplegia in the case of bleeding into the cerebral hemisphere are the cardinal features and serve most dependably to distinguish hemorrhage from ischemic stroke. In the localization of an intracerebral hemorrhage, ocular signs may be particularly useful. In putaminal hemorrhage, the eyes are deviated to the side opposite the paralysis; in thalamic hemorrhage, the most common ocular abnormality is downward deviation of the eyes and the pupils may be unreactive; in pontine hemorrhage, the eyeballs are fixed and the pupils are tiny but reactive; and in large cerebellar hemorrhage, the eyes may be deviated laterally to the side opposite the lesion and ocular bobbing may occur (as often in cerebellar hemorrhage in awake patients there are no eye signs).

Small hemorrhages in some regions of the brain may escape clinical detection. Usually there are no warnings or prodromal symptoms; headache, dizziness, epistaxis, or other symptoms do not occur with any consistency. In the majority of cases, the hemorrhage has its onset while the patient is up and active; onset during sleep is not common. There is no age predilection among adults except that the average age of occurrence is lower than in thrombotic infarction and neither sex is more disposed. The incidence of hypertensive cerebral hemorrhage is higher in African Americans than in whites and it occurs with higher frequency in people of Japanese descent.

There has long been a notion that acute hypertension can precipitate the hemorrhage. This is based on the known occurrence of cerebral hemorrhage at moments of extreme fright or anger or intense excitement, presumably as the blood pressure rises abruptly beyond its chronically elevated level. Similarly, hemorrhages have been described in relation to taking sympathomimetic medications such as phenylpropanolamine (Kernan et al), ephedra, or cocaine, and to numerous other hypertensive circumstances. However, in fully 90 percent of instances, the hemorrhage occurs when the patient is calm and unstressed, according to Caplan (1993). The level of blood pressure rises early in the course of the hemorrhage but the preceding chronic hypertension is usually of the "essential" type. Nonetheless, causes of hypertension must always be considered—renal disease, renal artery stenosis, eclampsia, pheochromocytoma, hyperaldosteronism, adrenocorticotrophic hormone or corticosteroid excess and, of course, sympathetically active drugs as mentioned.

It has been recognized by serial CT that in many instances, there is enlargement of the hematoma. In the series reported by Brott and colleagues, 25 percent were found to have enlarged in the first hour and another 12 percent in the first day. Contrast extravasation into the adjacent brain after CTA was associated in a retrospective study with expansion of a hematoma, the aforementioned "spot sign" (Goldstein et al), but there are no other clear predictive factors of expansion of the clot. Blood in cerebral tissue is absorbed slowly over months during which time symptoms and signs recede. Hence the neurologic deficit is never transitory in intracerebral hemorrhage, as it so often is in TIA or embolism.

The main types and locations of cerebral hemorrhage are described below and shown in Fig. 34-23. Chronic hypertension is associated with bleeding into the putamen, thalamus, pons, and cerebellum. Intracerebral bleeding at other sites, "lobar hemorrhages," has numerous causes.

Putaminal Hemorrhage

The most common syndrome is the one caused by *putaminal hemorrhage* with extension to the adjacent internal capsule (see Fig. 34-23A). Neurologic symptoms and signs vary slightly with the precise site and size of the extravasation, but hemiplegia from interruption of the capsule is a consistent feature of medium-sized and large clots. Vomiting occurs in about half the patients. Headache is frequent but not invariable. With large hemorrhages, patients lapse almost immediately into a stupor with hemiplegia and their condition visibly deteriorates as the hours pass. As often, there is headache or some other abnormal cephalic sensation. Within a few minutes or less the face sags on one side, speech becomes slurred or aphasic, the arm and leg weaken and are flaccid, and the eyes tend to deviate away from the side of the paretic limbs. These events, occurring gradually over a period of several minutes or more, are strongly suggestive of intracerebral bleeding. More advanced stages are characterized by signs of upper brainstem compression (coma); bilateral Babinski signs; irregular or intermittent respiration; dilated, fixed pupils, first on the side of the clot; and decerebrate rigidity.

Neuroimaging has disclosed the frequent occurrence of many smaller putaminal hemorrhages, which in former years would have been misdiagnosed as embolic or thrombotic strokes. With hemorrhages confined to the anterior segment of the putamen, the hemiplegia and hyperreflexia tend to be less severe and to clear more rapidly according to Caplan (1993). There is also prominent abulia, motor imperistence, temporary unilateral neglect, and with left-sided lesions, nonfluent aphasia, and dysgraphia. With small posterior lesions, weakness is also mild and is attended by sensory loss, hemianopia, impaired visual pursuit to the opposite side, Wernicke-type aphasia (left-sided lesions), and anosognosia (right-sided).

The effects of relatively pure *caudate hematoma* have been difficult to define. Those extending laterally and posteriorly into the internal capsule behave much like large putaminal hemorrhages. Those extending medially into the lateral ventricle give rise to drowsiness, stupor, and either confusion and underactivity or restlessness and agitation.

Thalamic Hemorrhage

The central feature here is severe sensory loss on the entire contralateral body. If large or moderate in size, thalamic hemorrhage also produces a hemiplegia or hemiparesis by compression or destruction of the adjacent internal capsule (see Fig. 34-23B). The sensory deficit involves all of the opposite side including the trunk and may exceed the motor weakness. A fluent aphasia or

anemia may be present with lesions of the dominant side and contralateral neglect, with lesions of the nondominant side. A homonymous field defect, if present, usually clears in a few days.

Thalamic hemorrhage, by virtue of its extension into the subthalamus and high midbrain, may also cause a series of ocular disturbances—pseudobabbling palsies with one or both eyes turned asymmetrically inward and slightly downward, palsies of vertical and lateral gaze, forced deviation of the eyes downward, inequality of pupils with absence of light reaction, skew deviation with the eye ipsilateral to the hemorrhage assuming a higher position than the contralateral eye, ipsilateral ptosis and miosis (Horner syndrome), absence of convergence, retraction nystagmus, and tucking in (retraction) of the upper eyelids. Extension of the neck may be observed. Compression of the adjacent third ventricle leads to enlargement of the lateral ventricles that may require temporary drainage. Small and moderate-sized hemorrhages that rupture into the third ventricle have been associated with fewer neurologic deficits and better outcomes, but early hydrocephalus is common.

Pontine Hemorrhage

Hemorrhage into the pons is almost invariably associated with deep coma within a few minutes; the remainder of the clinical picture is dominated by total paralysis with bilateral Babinski signs, decerebrate rigidity, and small (1-mm) pupils that react to light. Lateral eye movements, evoked by head turning or caloric testing, are impaired or absent. Death usually occurs within a few hours, but there are exceptions in which consciousness is retained and the clinical manifestations indicate a smaller lesion in the tegmentum of the pons (disturbances of lateral ocular movements, crossed sensory or motor disturbances, small pupils, and cranial-nerve palsies) in addition to signs of bilateral corticospinal tract involvement. A number of our patients with limited tegmental hemorrhages and blood in the CSF have survived with good functional recovery. In a series of 60 patients with pontine hemorrhage reviewed by Nakajima, 19 survived (8 of whom had remained alert). Similarly, Wijdicks and St. Louis reported that 21 percent made a good recovery—mostly those who were awake on admission. Figure 34-23C depicts a typical pontine hemorrhage.

Cerebellar Hemorrhage

This usually develops over a period of 1 or more hours, and loss of consciousness at the onset is unusual. Repeated vomiting is a prominent feature, with occipital headache, vertigo, and inability to sit, stand, or walk. Often these are the only abnormalities, making it imperative to have the patient attempt to ambulate; otherwise the examination may erroneously seem to be normal. In the early phase of the illness other clinical signs of cerebellar disease are usually minimal or lacking; only a minority of cases show nystagmus or cerebellar ataxia of the limbs, although these signs must always be sought. A mild ipsilateral facial weakness, diminished corneal reflex, paresis of conjugate lateral gaze to the side of the hemorrhage, or an ipsilateral sixth-nerve weakness occur with larger hemorrhages that

compress the pons or extend into the cerebellar peduncle. Dysarthria and dysphagia may be prominent in some cases but usually are absent. Other infrequent ocular signs include blepharospasm, involuntary closure of one eye, skew deviation, “ocular bobbing,” and small, often unequal pupils that continue to react until very late in the illness. Contralateral hemiplegia and ipsilateral facial weakness occur if there is marked displacement and compression of the medulla against the clivus.

Occasionally at the onset there is a spastic paraparesis or a quadriplegia with preservation of consciousness. The plantar reflexes are flexor in the early stages but extensor later. When these signs occur, hydrocephalus is usually found and may require drainage. In the series collected by St. Louis and colleagues, patients with vermian clots and hydrocephalus were at the highest risk for rapid deterioration. As the hours pass, and occasionally with unanticipated suddenness, the patient becomes stuporous and then comatose or suddenly apneic as a result of brainstem compression, at which point reversal of the syndrome, even by surgical therapy, is seldom successful. As discussed further on, cerebellar hemorrhage is the most amenable to surgical evacuation with good results. A typical case is shown with imaging in Fig. 34-23D.

Lobar Hemorrhage

Bleeding in areas other than those listed above, specifically in the subcortical white matter of one of the lobes of the cerebral hemisphere, is not associated strictly with hypertension. Any number of other causes are usually responsible, the main ones being anticoagulation or thrombolytic therapy, acquired coagulopathies, cranial trauma, arteriovenous malformation (discussed further on), trauma, and, in the elderly, amyloidosis of the cerebral vessels. The role of antiplatelet agents in precipitating intracerebral hemorrhage has been a matter of contention with numerous surveys and studies giving divergent results regarding larger, expanding or more clinically destructive hematomas.

Most lobar hemorrhages are spherical or ovoid, but a few follow the contour of the subcortical white matter tracts and take the form of a slit (subcortical slit hemorrhage). It is our impression that many of these are the result of a bleeding diathesis, such as thrombocytopenia.

In a consecutive series of 26 cases of lobar hemorrhage, we found 11 to lie within the occipital lobe, causing pain around the ipsilateral eye and a dense homonymous hemianopia; 7 in the temporal lobe that produced pain in or anterior to the ear, partial hemianopia, and fluent aphasia; 4 in the frontal lobe, with frontal headache and contralateral hemiplegia, mainly of the arm; and 3 in the parietal lobe that presented with anterior temporal headache and hemisensory deficit contralaterally (Ropper and Davis). The smaller hematomas simulate an embolic stroke in the same territory. The occurrence of a progressively worsening headache, vomiting, or drowsiness in conjunction with any one of these syndromes is virtually diagnostic, and, of course, the presence of a lobar hemorrhage is readily corroborated by an unenhanced CT. Of our 26 patients, 14 had normal blood pressure, and in several of the fatal cases there was amyloidosis of the affected vessels; 2 patients were receiving anticoagulants,

2 had an arteriovenous malformation, and 1 had a metastatic tumor. Similarly, in the series of 22 patients with lobar clots reported by Kase and colleagues, 55 percent were normotensive; metastatic tumors, arteriovenous malformations, and blood dyscrasias were found in 14, 9, and 5 percent of the patients, respectively. The role of amyloid angiopathy in lobar hemorrhage in the elderly patient is discussed further on.

Laboratory Findings

For the rapid diagnosis of intracerebral hemorrhage, the CT occupies the foremost position (see Fig. 34-23). It is reliable in the detection of hemorrhages that are less than 1.0 cm in diameter. Very small pontine hemorrhages may be overlooked because of the artifact produced by adjacent bone. The spot sign on CT angiography has been mentioned above in relation to hematoma expansion. At the same time, coexisting hydrocephalus, tumor, cerebral swelling, and displacement of the intracranial contents are readily appreciated. MRI is particularly useful for demonstrating brainstem hemorrhages and residual hemorrhages, which remain visible long after they are no longer detectable on the CT (after 4 to 5 weeks). Hemosiderin and iron pigment have characteristic appearances, as described earlier and in Chap. 2.

In general, lumbar puncture is ill advised, for it may precipitate or aggravate an impending shift of central structures and herniation. The white cell count in the peripheral blood may rise transiently to 15,000/mm³, a higher figure than in thrombosis, but it is most often normal. The sedimentation rate may be mildly elevated in some patients. Determination of the INR, partial thromboplastin time, and platelet count is advisable.

Course and Prognosis

The immediate prognosis for large and medium-sized cerebral clots is grave; some 30 to 35 percent of patients die in 1 to 30 days. In these cases, either the hemorrhage has extended into the ventricular system or intracranial pressure becomes elevated to levels that preclude normal perfusion of the brain. Or the hemorrhage seeps into vital centers such as the hypothalamus or midbrain. A formula that predicts outcome of hemorrhage based on clot size was devised by Broderick and coworkers (1993); it is mainly applicable to putaminal and thalamic clots. A volume of 30 mL or less, calculated by various methods from the CT predicted a generally favorable outcome; only 1 of their 71 patients with clots larger than 30 mL had regained independent function by 1 month. By contrast, in patients with clots of 60 mL or larger and an initial Glasgow Coma Scale score of 8 or less, the mortality was 90 percent (this scale is detailed in Table 35-1). As remarked earlier, it is the location of the hematoma, not simply its size that determines the clinical effects. A clot 60 mL in volume is almost uniformly fatal if situated in the basal ganglia but may allow reasonably good outcome if located in the frontal or occipital lobe. From the studies of Diringer and colleagues (1998), hydrocephalus is also an important predictor of poor outcome, and this accords with our experience. Prompt drainage of the ventricles can markedly improve the clinical state.

Several other scoring systems that predict prognosis fairly well have been devised and validated as predictive of outcome. The two in main use, shown in Table 34-9, are "FUNC" produced by Rost and coworkers, which incorporates the patient's age, size and location of hematoma, the presence of preexisting cognitive impairment, and Glasgow Coma score (see Chap. 17); and the "ICH score" devised by Hemphill and colleagues that uses GCS, volume, presence of intraventricular hemorrhage, the location—supra- or infratentorial, and age above or below 80 years. The value of these scores may be in advising families regarding the appropriate intensity of medical care but it must be realized that these point estimates of outcomes based on numerical scores have wide confidence intervals. Indeed, of all the cerebrovascular diseases, cerebral hemorrhage may give the most discouraging clinical

Table 34-9

picture initially and yet have a reasonable clinical outcome and such scores must be tempered by clinical experience.

In patients who survive, there can be a surprising degree of restoration of function, because, in contrast to infarction, the hemorrhage has to some extent pushed brain tissue aside rather than destroyed it. Function returns very slowly, however, because extravasated blood takes time to be removed from the tissues. Healed scars impinging on the cortex are liable to be epileptogenic; the frequency of seizures after each type of hemorrhage has not been established, but it is lower than for ischemic strokes. There is no need to administer anticonvulsive medication unless a seizure has occurred.

The poor prognosis of all but the smallest pontine hemorrhages has already been mentioned. Cerebellar hemorrhages present special problems that are discussed below.

Treatment

The management of patients with large intracerebral hemorrhages and coma includes the maintenance of adequate ventilation, selective acute use of controlled hyperventilation to a P_{CO_2} of 25 to 30 mm Hg, monitoring of intracranial pressure in some cases and its control by the use of tissue-dehydrating agents such as mannitol (osmolality kept at 295 to 305 mOsm/L and Na at 145 to 150 mEq), and limiting intravenous infusions to normal saline. Qureshi's group offered data suggesting that aggressive measures to reduce intracranial pressure may be lifesaving and result in good outcome even in patients who have signs of transtentorial herniation. In our experience, this type of recovery is exceptional, but medical treatment of raised intracranial pressure may be justified in patients whose medical condition allows it.

As mentioned, virtually all patients with intracerebral hemorrhage are hypertensive immediately after the stroke because of a generalized sympathoadrenal response. The natural trend is for the blood pressure to diminish over several days; therefore active treatment in the acute stages has been a matter of controversy. Rapid reduction of moderately elevated blood pressure (between 140 and 160 mm Hg systolic), in the hope of reducing further bleeding, is not recommended, because it risks compromising cerebral perfusion in cases of raised intracranial pressure. On the other hand, sustained mean blood pressures of greater than 110 mm Hg (generally above 160 mm Hg systolic) may exaggerate cerebral edema and perhaps enhance the risk extension of the clot. It is at approximately this level of acute hypertension that the use of beta-blocking drugs (esmolol, labetalol) or angiotensin-converting enzyme (ACE) inhibitors is recommended. The major calcium channel-blocking drugs are used less often for this purpose because of reports of adverse effects on intracranial pressure, although this information derives mainly from patients with brain tumors. Hayashi and associates have shown that although blood pressure is lowered with nifedipine after cerebral hemorrhage, intracranial pressure is raised, resulting in an unfavorable net reduction in cerebral perfusion pressure. Nevertheless, we have used all classes of medication in patients with small- and medium-sized clots without adverse effects. Diuretics are helpful in

combination with any of the antihypertensive medications. More rapidly acting and titratable agents such as nitroprusside may be used in extreme situations, recognizing that they may further raise intracranial pressure.

Although it would appear intuitively that *evacuation of a hematoma might be beneficial*, surgical results have not been superior to those with medical measures alone (Waga and Yamamoto; Batjer et al; Juvela et al; Rabinstein et al). A large, multicenter, randomized study involving 1,033 patients with supratentorial hemorrhage, under the auspices of the Surgical Trial in Intracerebral Haemorrhage (STICH) study reported by Mendelow and colleagues, has failed to show a benefit from early surgery on survival or neurologic functioning at 6 months. This negative result extended to almost all levels of neurologic deficit and all age groups. In a post hoc analysis, clots that were small and close to the surface of the brain may have benefited from evacuation. As a result, a direct surgical approach has been used less frequently than in the past, but we acknowledge that in a few instances with ongoing deterioration in young patients with hematomas that were easily accessible from the cortical surface, we have asked our neurosurgical colleagues to undertake evacuation of the clot.

Mayer and coworkers studied the promising approach of administering clotting factor VII within 4 h of hemorrhage. In a preliminary study, survival was improved and there was a reduction in enlargement of the hematoma, but their subsequent series has failed to confirm the benefit on survival so that infusion of factor VII is not currently part of routine practice.

If acute hydrocephalus has resulted from a centrally placed hemorrhage or rupture into the ventricular system, a drain is needed. It has been appreciated for some time that intraventricular extension of cerebral hemorrhage generally denotes a poor outcome. An exception may be small thalamic hemorrhages. There was an ongoing study of the reduction of intraventricular hemorrhage size by the use of infused tissue plasminogen activator through a ventricular catheter. Preliminary results suggest that this approach may reduce mortality, and similar practices have been adopted for some time on many neurosurgical services.

Once the patient with a supratentorial hemorrhage becomes deeply comatose with dilated fixed pupils, the chance of recovery is negligible. Even in retrospective studies in which clinical worsening was the reason for surgery, such as the one by Rabinstein and colleagues, only 25 percent of patients attained a state of functional independence and all of their patients who lost their brainstem reflexes and had extensor posturing died despite surgery; there have been a few exceptions to this observation.

In comatose patients with large hemorrhages, the placement of a device for monitoring of intracranial pressure enables the clinician to use medical measures with greater precision, as outlined in Chap. 17, but there is no evidence that outcome is significantly improved (Ropper and King). Whether hemispherectomy is of value, as it is with large hemispherical strokes, is not known but it seems unlikely.

The issue often arises of the appropriate timing of restarting anticoagulation in patients whose hemorrhage occurred on warfarin. In some instances, such as a prosthetic heart valve requires warfarin, medication

is often reintroduced after a week or two. However, for the more common indication of this drug, namely atrial fibrillation, there have been diverging suggestions from different surveys. In an often-cited study by Majeed and colleagues, a retrospective review of almost 3,000 patients over 6 years suggested that the risk of creating another hemorrhage by restarting warfarin earlier than 10 to 30 weeks after the initial stroke was quite high.

Surgical Evacuation of Cerebellar Hematoma In contrast, the surgical evacuation of cerebellar hematomas is a generally accepted treatment and is a more urgent matter because of the proximity of the mass to the brainstem and the risk of abrupt progression to coma and respiratory failure. Also, hydrocephalus from compression of the fourth ventricle more often complicates the clinical picture and further raises intracranial pressure (St. Louis et al). As a rule, a cerebellar hematoma less than 2 cm in diameter leaves most patients awake and infrequently leads to deterioration, therefore generally not requiring surgery. Hematomas that are 4 cm or more in largest diameter, especially if located in the vermis, pose the greatest risk, and some surgeons have recommended evacuation of lesions of this size no matter what the clinical status of the patient. In determining the need for surgical evacuation, we have been guided by the patient's state of consciousness, the mass effect caused by the clot as visualized on CT (particularly the degree of compression of the quadrigeminal cistern, as pointed out by Taneda and colleagues), and the presence or absence of hydrocephalus. Assessment may require daily or even more frequent CT. The patient who is stuporous or displays arrhythmic breathing is best intubated and brought to the operating room within hours or sooner. Once coma and pupillary changes supervene, few patients survive, even with surgery; however, rapid

medical intervention with mannitol and hyperventilation, followed by surgical evacuation of the clot and drainage of the ventricles within hours of the onset of coma has been successful in a few cases. Patients who are drowsy and those with hematomas of 2 to 4 cm in diameter in the cerebellar hemisphere pose the greatest difficulty in determining if, and when, surgery is advisable. If the level of consciousness is fluctuating or if there is obliteration of the perimesencephalic cisterns, particularly if coupled with hydrocephalus, we believe that the risk of surgery is less than that of a sudden deterioration. In only a very limited number of patients have we found it practical to perform only drainage of the enlarged ventricles, although some groups still favor this procedure and eschew a posterior fossa operation. Evacuation of the clot in our experience has been more important than reduction of the hydrocephalus.

SPONTANEOUS SUBARACHNOID HEMORRHAGE AND RUPTURED SACULAR ANEURYSM

This is the fourth most frequent cerebrovascular disorder—following atherothrombosis, embolism, and primary intracerebral hemorrhage, but one that is often disastrous. Saccular aneurysms also have been called “berry” aneurysms. They take the form of small, thin-walled blisters protruding from arteries of the circle of Willis or its major branches. Their rupture causes a flooding of the subarachnoid space with blood under high pressure. As a rule, the aneurysms are located at vessel bifurcations and branchings (Fig. 34-24) and are generally presumed

Figure 34-24. Diagram of the circle of Willis showing the principal sites of intracranial aneurysms. Approximately 90 percent of aneurysms arise from branches of the anterior half of the circle. The sizes of the aneurysms depicted correspond roughly to the frequency of occurrence at those sites.

to result from developmental defects in the media and elastica of the arteries. An alternate theory holds that the aneurysmal process is initiated by focal destruction of the internal elastic membrane, which is produced by hemodynamic forces at the apices of bifurcations (Ferguson). As a result of the local weakness in the vessel wall, the intima bulges outward, covered only by adventitia; the sac then gradually enlarges and may finally rupture. Cerebral aneurysms vary in size from 2 mm to 2 or 3 cm in diameter, averaging 7.5 mm (Wiebers et al, 1981 and 1987). Those that rupture usually have a diameter of 10 mm or more, but rupture also occurs, albeit less often, in those of smaller size. Aneurysms vary greatly in form. Some are round and connected to the parent artery by a narrow stalk; others are broad-based without a stalk; and still others take the form of narrow cylinders. The site of rupture is usually at the dome of the aneurysm, which may have one or more secondary sacculations. A review of the subject by Schievink gives further details of this extensively studied subject.

The incidence of unruptured aneurysms in routine autopsies is almost 2 percent—excluding minor vessel outpouchings of 3 mm or less. Moreover, aneurysms are multiple in 20 percent of patients. In the past, it was estimated that 400,000 Americans harbored unruptured aneurysms and that there were 26,000 aneurysmal subarachnoid hemorrhages per year (Sahs et al, 1981 and 1984). Rupture of saccular aneurysms in childhood is rare, and they are seldom found at routine postmortem examination in this age group; beyond childhood, they gradually increase in frequency to reach their peak incidence between ages 35 and 65 years. Therefore aneurysms cannot be regarded as fully formed congenital anomalies; rather, they appear to develop over the years on the basis of either a developmental or acquired arterial defect. There is an increased incidence of congenital polycystic kidneys, fibromuscular dysplasia of the extracranial arteries, moyamoya, arteriovenous malformations of the brain, and coarctation of the aorta among persons with saccular aneurysms and vice versa. An accompanying saccular aneurysm occurs in approximately 5 percent of cases of cerebral arteriovenous malformation, usually on the main feeding artery of the malformation.

Numerous reports have documented a familial occurrence of saccular aneurysms, lending support to the idea that genetic factors play a role in their development. The number of first-degree relatives found to harbor an unsuspected aneurysm has been approximately 4 percent in most series. This low rate, the finding that half of the discovered aneurysms are small, and the complications of surgery make routine screening of siblings, children, and parents of patients with ruptured aneurysms impractical, according to the Magnetic Resonance Angiography in Relatives of Patients with Subarachnoid Hemorrhage Study Group. However, because aneurysms of the familial variety tend to be larger at the time of rupture and more numerous than in patients who have sporadic ones, there are exceptions to this statement (Ruigrok et al), and there is little question that, in practice, the close relatives of patients with ruptured aneurysms ask for, and are accommodated, screening for aneurysms. From a survey

in Scotland, the lifetime risk of hemorrhage was only 4.7 percent for a first-degree relative and 1.9 percent for a second-degree relative (Teasdale et al). From several series, it is apparent that the risk is highest for individuals with two or more first-degree relatives and negligible for one second-degree relative.

Although hypertension is more frequently present than in the general population, aneurysms most often occur in persons with normal blood pressure. Pregnancy does not appear to be associated with an increased incidence of aneurysmal rupture, although there is always concern about the possibility of inducing bleeding during the straining of natural delivery. Atherosclerosis, although present in the walls of some saccular aneurysms, probably plays no part in their formation or enlargement.

Approximately 90 to 95 percent of saccular aneurysms lie on the anterior part of the circle of Willis (see Fig. 34-24). The four most common sites are (1) the proximal portions of the anterior communicating artery, (2) at the origin of the posterior communicating artery from the stem of the internal carotid, (3) at the first major bifurcation of the middle cerebral artery, and (4) at the bifurcation of the internal carotid into middle and anterior cerebral arteries. Other sites include the internal carotid artery in the cavernous sinus, at the origin of the ophthalmic artery, the junction of the posterior communicating and posterior cerebral arteries, the bifurcation of the basilar artery, and the origins of the cerebellar arteries. Aneurysms of the carotid artery that rupture in the cavernous sinus give rise to an arteriovenous fistula (see further on).

There are several types of aneurysms other than saccular, e.g., mycotic, fusiform, diffuse, and globular. The mycotic aneurysm is caused by a septic embolus that weakens the wall of the vessel in which it lodges, almost always at a site in a distal cerebral vessel, well beyond the circle of Willis. These lesions are discussed separately in a later section of this chapter. The others are named for their predominant morphologic characteristics and consist of enlargement or dilatation of the entire circumference of the involved vessels, usually the internal carotid, vertebral, or basilar arteries. Fusiform deformities are also referred to as arteriosclerotic aneurysms, as they frequently show atheromatous deposition in their walls, but it is likely that they are at least partly developmental in nature. Some are very large (so-called giant aneurysms) and press on neighboring structures or become occluded by thrombus, but they rupture only infrequently (as discussed further on).

Clinical Syndrome

With rupture of the aneurysm, blood under high pressure is forced into the subarachnoid space and the resulting clinical events assume one of three patterns: (1) the patient is stricken with an excruciating generalized headache and vomiting and falls unconscious almost immediately; (2) severe generalized headache develops in the same instantaneous manner but the patient remains relatively lucid with varying degrees of stiff neck—the most common syndrome; (3) rarely, consciousness is lost so quickly that there is no preceding complaint. If the hemorrhage

is massive, death may ensue in a matter of minutes or hours, so that ruptured aneurysm must be considered in the differential diagnosis of sudden death. A considerable proportion of such patients probably never reach a hospital. Decerebrate rigidity and brief clonic jerking of the limbs may occur at the onset of the hemorrhage, always in association with unconsciousness. Persistent deep coma is accompanied by irregular respirations, attacks of extensor rigidity, and finally respiratory arrest and circulatory collapse. In these rapidly evolving cases, the subarachnoid blood has greatly increased the intracranial pressure to a level that approaches arterial pressure and caused a marked reduction in cerebral perfusion. In some instances, the hemorrhage has dissected intracerebrally and entered the brain or ventricular system.

Rupture of the aneurysm usually occurs while the patient is active rather than during sleep, and in a few instances during sexual intercourse, straining at stool, lifting heavy objects, or other sustained exertion (see "Headaches Related to Sexual Activity" in Chap. 10). A momentary Valsalva maneuver, as in coughing or sneezing, has generally not caused aneurysmal rupture (it may cause arterial dissection). In patients who survive the initial rupture, the most feared complication is rerupture, an event that may occur at any time from minutes up to 2 or 3 weeks.

In less-severe cases, consciousness, if lost, may be regained within minutes or hours, but a residuum of drowsiness, confusion, and amnesia accompanied by severe headache and stiff neck persists for at least several days. Because the hemorrhage in most cases is confined to the subarachnoid space, there are few if any focal neurologic signs. That is to say, hemiparesis, hemianopia, and aphasia are absent. On occasion, a jet of blood emanating from an aneurysm ruptures into the adjacent brain or insular cistern and produces a hemiparesis or other focal syndrome. This may be more common when the aneurysm has bled in the past, after which it adheres to the brain, thus predisposing to intracerebral hemorrhage at the time of subsequent rupture. There is, however, a transient focal acute syndrome that occasionally occurs in the territory of the aneurysm-bearing artery. The pathogenesis of such manifestations is not fully understood, but a transitory fall in pressure in the circulation distal to the aneurysm or some form of acute transient vasospasm has been postulated. An entirely separate problem of delayed vasospasm is responsible for focal signs that emerge after several days as discussed below. Transient deficits when they do occur constitute reliable indicators of the site of the ruptured aneurysm (see below).

Convulsive seizures, usually brief and generalized, occur in 10 to 25 percent of cases according to Hart and associates (but far less often in our experience) in relation to acute bleeding or rebleeding. These early seizures do not correlate with the location of the aneurysm and do not appear to alter the prognosis.

After rupture, saccular aneurysms are usually asymptomatic. Exceptionally, if large enough to compress pain-sensitive structures, they may cause localized cranial pain. With a cavernous or anterolaterally situated aneurysm

on the first part of the middle cerebral artery, the pain may be projected to the orbit. An aneurysm on the posteroinferior or anteroinferior cerebellar artery may cause unilateral occipital or cervical pain. The presence of a partial oculomotor palsy with dilated pupil may be indicative of an aneurysm of the posterior communicating–internal carotid junction or at the posterior communicating–posterior cerebral junction. Occasionally, large aneurysms just anterior to the cavernous sinus compress the optic nerves or chiasm, third nerve, hypothalamus, or pituitary gland. A monocular visual field defect may also develop with a supraclinoid aneurysm near the anterior and middle cerebral bifurcation or the ophthalmic–carotid bifurcation. In the cavernous sinus, they may compress the third, fourth, or sixth nerve, or the ophthalmic division of the fifth nerve.

Whether a small leak of blood from an aneurysm may serve as a warning sign of a subsequent more catastrophic rupture ("warning leak") has been disputed. An entity known as "sentinel headache" has been used in an imprecise way to refer to both a headache that precedes subarachnoid hemorrhage and to a small leakage prior to a major rupture. The former in our view has little validity, as headaches are so ubiquitous that many, even severe ones, are coincidental in relation to subarachnoid hemorrhage. The frequency of true warning leaks is unknown but is not likely to be high. We have seen several cases where an acute and severe exertional or spontaneous headache was found to be associated with a small subarachnoid hemorrhage that was discovered by lumbar puncture; more often the headache is unrelated to hemorrhage and is attributable to migraine. This type of "thunderclap headache," may be a variant of migraine, or less often, cerebral venous thrombosis, diffuse vasospasm (the Call-Fleming syndrome), or even less often, pituitary apoplexy, hypertensive encephalopathy, intracranial hypotension, and intracranial or extracranial arterial dissection. The details of the CSF examination assume great importance in the diagnosis of subarachnoid hemorrhage and the exclusion of the disorders mentioned above.

Laboratory Findings

A CT will detect blood locally or diffusely in the subarachnoid spaces or within the brain or ventricular system in more than 90 percent of cases and in practically all cases in which the hemorrhage has been severe enough to cause momentary or persistent loss of consciousness (Fig. 34-25). Therefore, this should be the initial investigative procedure. Because the blood may appear as a subtle shadow along the tentorium or in the sylvian or adjacent fissures, it is more easily appreciated in the noncontrast study. A large localized collection of subarachnoid blood or a hematoma in brain tissue or within the sylvian fissure indicates the adjacent location of the aneurysm and the likely region of subsequent vasospasm, as already noted. When two or more aneurysms are visualized, the CT can identify the one that had ruptured by the clot that surrounds it. Also, coexistent hydrocephalus will be demonstrable. If the CT documents subarachnoid blood with certainty, a spinal tap is not necessary. MRI can

Figure 34-25. Subarachnoid hemorrhage as a result of rupture of a basilar artery aneurysm. *Left:* Axial CT at the level of the lateral ventricles showing widespread hyperdense blood in the subarachnoid spaces and layering within the ventricles with resultant hydrocephalus. There is a blood–CSF level in the posterior horns of the lateral ventricles, typical of recent bleeding. *Right:* At the level of the basal cisterns, blood can be seen surrounding the brainstem, in the anterior sylvian fissures, and the anterior interhemispheric fissure. The temporal horns of the lateral ventricles are enlarged, reflecting acute hydrocephalus.

also detect blood in the proton-density sequence; after a day has passed, this is also appreciated with the FLAIR technique.

In all other cases where subarachnoid hemorrhage is suspected but not apparent on imaging studies, a lumbar puncture should be undertaken. Usually the CSF becomes grossly bloody within 30 min or sooner of the hemorrhage, with RBC counts up to 1 million/mm³ or even higher. Blood may not be easily apparent in a lumbar puncture minutes after the hemorrhage. With a relatively mild hemorrhage, there may be only a few thousand cells, a severe headache syndrome from subarachnoid hemorrhage is associated with at least several hundred cells. It is also probably not possible for an aneurysm to rupture entirely into brain tissue without some leakage of blood into the subarachnoid fluid. In other words, the diagnosis of ruptured saccular aneurysm is essentially excluded if blood is not present in the CSF, provided the spinal fluid is examined more than 30 min after the event. Xanthochromia is found after centrifugation if several hours or more have elapsed from the moment of the ictus. In a patient who reports a headache that was consistent with subarachnoid hemorrhage but that had occurred several days earlier, the CT may be normal and xanthochromia is the only diagnostic finding. To determine whether xanthochromia is present, fresh CSF must be centrifuged in a tube with a conical bottom and the supernatant compared to clear water in good light or examined by spectrophotometric techniques. It has been our experience that most hospital

laboratories cannot be depended on to give accurate results for this test. Also helpful after several days is the MRI taken with the FLAIR sequence as mentioned, which will demonstrate blood (the proton-density sequence is more sensitive to blood in the first day).

The problem of a “traumatic tap” often clouds the early diagnosis, and several aids to detecting this misleading laboratory result are discussed in Chap. 2. Here it is reiterated that in addition to the absence of xanthochromia, the most important features indicating that blood has been spuriously introduced by entering small veins in the epidural space with the lumbar puncture needle are the clearing of blood as one continues to collect fluid and a marked reduction in the number of RBCs in serial tubes of spinal fluid. A normal opening pressure also suggests puncture of a local vessel rather than a ruptured aneurysm. The combination of subarachnoid hemorrhage and a traumatic tap generally requires that vascular imaging procedures be performed to resolve the issue. The CSF in the first days is under increased pressure, as high as 500 mm H₂O—but usually closer to 250 mm H₂O—an important finding in differentiating spontaneous subarachnoid hemorrhage from a traumatic tap. In both a traumatic puncture and early in subarachnoid hemorrhage, the proportion of WBCs to RBCs in the CSF is usually the same as in the circulating blood (approximately 1:700), but in some patients with genuine hemorrhage a brisk CSF leukocytosis appears within 48 h, sometimes reaching more than 1,000 cells/mm³.

The protein is slightly or moderately elevated and in some instances glucose is reduced sometimes dramatically so.

Bilateral carotid and vertebral ("four-vessel") angiography is the most dependable means of demonstrating an aneurysm and does so in essentially all patients who harbor an aneurysm, but in addition to other causes of subarachnoid hemorrhage, approximately 5 to 10 percent of patients with aneurysmal rupture will not have an aneurysm evident. Some of these instances are a result of the obliteration of the lesion in the process of rupture. Others are because of somewhat more benign lesions. Patients with the typical clinical picture of spontaneous subarachnoid hemorrhage in whom an aneurysm or arteriovenous malformation cannot be demonstrated angiographically have a distinctly better prognosis than those in whom the lesion is visualized (Nishioka et al). For example, in a series of 323 angiographically negative cases followed for an average of 10 years, there was rebleeding in only 12 (Hawkins et al). After 22 years, 69 percent of these patients had survived. If the first study does not reveal an aneurysm, it is customary in most centers to repeat an arteriogram in several weeks because it has been observed that vascular spasm may have earlier obscured the aneurysm. Even when there is no vasospasm visualized, it is sometimes the case that a second study shows the lesion. It is advantageous to obtain images from several different angles in order to expose those views that may be obscured by adjacent overlying vessels. If the first study involves all cerebral vessels and uses several views of the basal circulation, it has been our experience that the second arteriogram is infrequently revealing, but we follow general practice and repeat it nonetheless.

Another clinical circumstance with a favorable outcome is a limited *perimesencephalic hemorrhage* as described by van Gijn and colleagues. The cisterns surrounding the midbrain and upper pons are symmetrically filled with

blood, the headache is mild, and signs of vasospasm do not develop. No aneurysm is found at the expected site for blood in this region, i.e., at the top of the basilar artery. The patient usually does well and a second arteriogram is probably not required. It has been speculated that the bleeding has a venous rather than an aneurysmal source.

MRI detects most aneurysms of the basal vessels and of their first branches but may not yet be of sufficient sensitivity to replace CT or conventional angiography in cases where an aneurysm is strongly suspected but too small to be detected by MRA. Even when MRA demonstrates the aneurysm, the surgeon usually requires the kind of anatomic definition that can be obtained only by conventional angiography. CT technology scanning with contrast infusion has certainly begun to equal the detail provided by conventional angiography and has additional advantages of showing the lesion in relation to the adjacent brain and skull in multiple views (Fig. 34-26).

Vasospasm Delayed hemiplegia and other deficits because of focal vasospasm usually appear 3 to 10 days after rupture and rarely before or after this period. Fisher and coworkers (1980) have shown that the most severe vasospasm occurs in arteries that are surrounded by collections of clotted subarachnoid blood after 24 h. These same authors devised a widely used scale that rates the extent and location of remaining clot. The reduction in the caliber of blood vessels (vasospasm) appears to be a direct effect of some blood product on the adventitia of the adjacent artery. Areas of ischemic infarction in the territory of the vessel bearing the aneurysm, without thrombosis or other intraluminal changes in the vessel, is the usual finding in such cases. The mechanism is presumed to be purely a reduction in blood flow distal to the area of vasospasm but therefore influenced by systemic blood pressure and by collateral circulation in the cortex. The ischemic lesions are often multiple and had in the past occurred with great frequency, according to Hijdra and associates.

Figure 34-26. Berry aneurysm of the anterior communicating artery. *Left:* CT angiogram showing the aneurysm (arrow) arising from the branch point of the anterior communicating artery and the A1 segment; *Right:* Reconstructed image from CT angiogram data showing the aneurysm (arrow) in relation to the adjacent bony and vascular structures.

After a few days, arteries in chronic spasm undergo a series of morphologic changes. The smooth muscle cells of the media become necrotic, and the adventitia is infiltrated with neutrophilic leukocytes, mast cells, and red blood corpuscles, some of which have migrated to a subendothelial position. The current notion is that these changes are caused by products of hemolyzed blood seeping inward from the pia-arachnoid into the muscularis of the artery.

The clinical features of delayed cerebral vasospasm depend on the affected blood vessel but typically include a fluctuating hemiparesis or aphasia and increasing confusion that must be distinguished from the effects of hydrocephalus (see below). In the past, an arteriogram was required to verify the diagnosis, although it is not often performed now because of the slight associated risk of worsening vascular spasm and the ease with which the condition can be recognized by its clinical presentation. Severe vasospasm is also visualized with MRA and CT techniques (Fig. 34-27). Transcranial Doppler ultrasonography measurements provide an indirect way of following, by observations of blood flow velocity, the caliber of the main vessels at the base of the brain but they are somewhat imprecise for this purpose. Almost all patients have a greatly increased velocity of blood flow in the affected vessel that can be detected by ultrasound in the days after hemorrhage. However, progressive elevation of flow velocity in any one vessel (especially if over 175 cm/s) suggests that focal vasospasm is occurring. There is a reasonable correlation between these findings and the radiographic appearance of vasospasm, but the clinical manifestations of ischemia depend on additional factors such as collateral blood supply and the cerebral perfusion pressure.

Hydrocephalus If a large amount of blood ruptures into the ventricular system or floods the basal subarachnoid space, it may find its way into the ventricles through

Figure 34-27. Vasospasm following subarachnoid hemorrhage due to rupture of an anterior communicating artery aneurysm. Sagittal CT angiography reveals multifocal narrowing of segments of the anterior cerebral artery (arrows).

the foramina of Luschka and Magendie. The patient then becomes confused or unconscious as a result of *acute hydrocephalus*. The clinical signs are reversed by draining the ventricles, either by external ventriculostomy or, in selected cases, by lumbar puncture, but the routine use of ventricular drainage after subarachnoid hemorrhage is not uniformly agreed upon.

Delayed and *subacute hydrocephalus* as a result of blockage of the CSF pathways by blood may appear after 2 to 4 weeks and is managed similarly. Many of these latter cases improve. There are further instances of long-delayed hydrocephalus that present as normal-pressure hydrocephalus (NPH) months or years after subarachnoid hemorrhage, as described in Chap. 30.

Anatomic–Clinical Correlations of Aneurysms

In most patients, the neurologic manifestations do not point to the exact site of the aneurysm, but it can often be inferred from the location of the main clot on CT. A collection of blood in the anterior interhemispheric fissure indicates rupture of an anterior communicating artery aneurysm; in the sylvian fissure, a middle cerebral artery aneurysm; in the anterior perimesencephalic cistern, a posterior communicating or distal basilar artery aneurysm. In other instances clinical signs provide clues to its localization, as follows: (1) third-nerve palsy (ptosis, diplopia, dilatation of pupil, and divergent strabismus), indicates an aneurysm at the junction of the posterior communicating artery and the internal carotid artery—the third nerve passes immediately lateral to this point or at the posterior cerebral-posterior communicating artery junction; (2) transient paresis of one or both of the lower limbs at the onset of the hemorrhage suggests an anterior communicating aneurysm that has interfered with the circulation in the anterior cerebral arteries; (3) hemiparesis or aphasia points to an aneurysm at the first major bifurcation of the middle cerebral artery; (4) unilateral blindness indicates an aneurysm lying anteromedially in the circle of Willis (usually at the origin of the ophthalmic artery or at the bifurcation of the internal carotid artery); (5) a state of retained consciousness with akinetic mutism or abulia favors a location on the anterior communicating artery; (6) the side on which the aneurysm lies may be indicated by a unilateral preponderance of headache or by unilateral preretinal (subhyaloid) hemorrhage (Terson syndrome), the occurrence of monocular pain, or, rarely, lateralization of an intracranial sound heard at the time of rupture of the aneurysm. Sixth-nerve palsy, unilateral or bilateral, is usually attributable to raised intracranial pressure and is less often of localizing value.

In summary, the clinical sequence of sudden severe headache, vomiting, collapse, relative preservation of consciousness with few or no lateralizing signs, and neck stiffness is diagnostic of subarachnoid hemorrhage caused by a ruptured saccular aneurysm.

Other clinical data may be of assistance in reaching a correct diagnosis. Levels of blood pressure of 200 mm Hg systolic are seen occasionally just after rupture, but usually the pressure is elevated only moderately and fluctuates with the degree of head pain. Nuchal rigidity is usually present but occasionally absent, and the main

complaint of pain may be referable to the interscapular region or even the low back rather than to the head. Examination of the fundi frequently reveals smooth-surfaced, sharply outlined collections of blood that cover the retinal vessels—preretinal or subhyaloid hemorrhages (Terson syndrome); Roth spots are seen occasionally. Bilateral Babinski signs are found in the first few days following rupture if there is hydrocephalus. Fever up to 39°C (102.2°F) may be seen in the first week, but most patients are afebrile. Rarely, escaping blood enters the subdural space and produces a hematoma, evacuation of which may be lifesaving.

Systemic Changes Associated With Subarachnoid Hemorrhage

Acute subarachnoid hemorrhage is associated with several characteristic responses in the systemic circulation, water balance, and cardiac function. The ECG changes include symmetrically large peaked T waves (“cerebral T waves”) and other alterations, suggesting subendocardial or myocardial ischemia. There may be a minor elevation of troponin and the myocardial band (MB) of creatine phosphokinase (CPK). In some patients, the cardiac dysfunction is severe enough to seriously reduce the ejection fraction and cause heart failure. There is a tendency to develop hyponatremia; this abnormality and its relationship to intravascular volume depletion play a key role in treatment, as discussed further on. Albuminuria and glycosuria may be present for a few days. Rarely, diabetes insipidus occurs in the acute stages, but water retention or a natriuresis is more frequent. There may be a leukocytosis of 15,000 to 18,000 cells/mm³, but the sedimentation rate and C-reactive protein are usually normal, or any elevation is attributable to another cause.

Rebleeding and Prognosis

The outstanding characteristic of this condition, mentioned earlier, is the tendency for the hemorrhage to recur from the same site in more than one-third of patients, often catastrophically. This threat colors all prognostications and dominates modern treatment strategies. There does not appear to be a way of determining reliably which patients will bleed again. The cause of recurrent bleeding is not understood but is related to naturally occurring mechanisms of clot lysis at the site of initial rupture, usually at the dome of the aneurysm.

As regards prognosis of aneurysmal hemorrhage, McKissock and colleagues decades ago found that the patient’s state of consciousness at the time of arteriography was the single best index of outcome, and this remains largely true today. Their data, representative of the status of aneurysm management in the 1950s and consonant with the natural history before the advent of modern surgical and intensive care techniques, indicated that of every 100 patients reaching a hospital and coming to arteriography, 17 were stuporous or comatose and 83 appeared to be recovering from the ictus. At the end of 6 months, 8 of every 100 patients had died of the original hemorrhage and 59 had a recurrence (with 40 deaths), making a total of 48 deaths and 52 survivors. In regard to recurrence of bleeding, it was found that of 50 patients seen on the

first day of the illness, 5 rebled in the first week (all fatal), 8 in the second week (5 fatal), 6 in the third and fourth weeks (4 fatal), and 2 in the next 4 weeks (2 fatal), making a total of 21 recurrences (16 fatal) in 8 weeks.

The most comprehensive long-term analysis of the natural history of the disease, outdated but still instructive, is contained in the report of the Cooperative Study of Intracranial Aneurysms and Subarachnoid Hemorrhage (Sahs et al, 1984). The study was based on long-term observations of 568 patients who sustained an aneurysmal bleed between 1958 and 1965 and were managed only by a conservative medical program. A followup search in 1981 and 1982 disclosed that 378, or two-thirds of the patients, had died; 40 percent of the deaths had occurred within 6 months of the original hemorrhage. For the patients who survived the original hemorrhage for 6 months, the chances of survival during the next two decades were significantly worse than those of a matched normal population. Rebleeding occurred at a rate of 2.2 percent per year during the first decade and 0.86 percent per year during the second, and these were fatal in 78 percent of cases. Although these statistics reflect the outcome prior to the modern era of microsurgery and neurologic intensive care management, current figures are only modestly better. In a prospective clinical trial conducted by the International Cooperative Study in 1990 and based on observations of 3,521 patients (surgery performed in 83 percent), it was found that the 6-month evaluation that 26 percent had died and 58 percent had made a good recovery (Kassell et al). Vasospasm and rebleeding were the leading causes of morbidity and mortality in those who survived the initial hemorrhage.

In respect to rebleeding, all series indicate that the risk is greatest in the first day but extends for weeks. The observations of Aoyagi and Hayakawa are representative of other series; they found that rebleeding occurred within 2 weeks in 20 percent of patients, with a peak incidence in the 24 h after the initial episode. Surgical treatment is largely oriented toward reducing this complication.

Treatment

This is influenced by the neurologic and general medical state of the patient as well as by the location and morphology of the aneurysm. Ideally, all patients should have the aneurysmal sac obliterated, but the mortality is high if the patient is stuporous or comatose. Before deciding on a course of action, it has been useful to assess the patient with reference to the widely employed scale introduced by Botterell and refined by Hunt and Hess, as follows:

Grade I. Asymptomatic or with slight headache and stiff neck

Grade II. Moderate to severe headache and nuchal rigidity but no focal or lateralizing neurologic signs

Grade III. Drowsiness, confusion, and mild focal deficit

Grade IV. Persistent stupor or semicomatose, early decerebrate rigidity and vegetative disturbances

Grade V. Deep coma and decerebrate rigidity

The general medical management in the acute stage includes the following, all or in part: bed rest, fluid administration to maintain above-normal circulating blood volume and central venous pressure; use of elastic

stockings and stool softeners; administration of calcium channel blockers to reduce infarction from vasospasm (see below); additional beta-adrenergic blockers, intravenous nitroprusside, or other medication to reduce greatly elevated blood pressure and then maintain systolic blood pressure at 150 mm Hg or less; and pain-relieving medication for headache (this alone will often reduce the hypertension). The prevention of systemic venous thrombosis is critical; it usually is accomplished by the use of cyclically inflated whole-leg compression boots. The use of antiepileptic drugs is controversial; many neurosurgeons administer them early, with a view of preventing a seizure-induced risk of rebleeding. Several small studies suggest they may be detrimental and we have generally avoided them unless a seizure has occurred.

Calcium channel blockers are used to reduce the incidence of stroke from vasospasm. Nimodipine 60 mg administered orally every 4 h is currently favored. Although calcium channel blockers do not alter the incidence of angiographically demonstrated vasospasm, they have reduced the number of strokes in each of five randomized studies, beginning with the one conducted by Allen and colleagues. Several groups use angioplasty techniques to dilate vasospastic vessels and report symptomatic improvement, but there are as yet insufficient controlled data to judge the merits and safety of this procedure.

The most notable advances in this disease have been in the techniques for the early obliteration of aneurysms, particularly the operating microscope and endovascular approaches, and in the management of circulatory volume. In the majority of patients, intravascular volume is depleted in the days after subarachnoid hemorrhage. This, in turn, greatly increases the chances of ischemic infarction from vasospasm. In part, this volume contraction can be attributed to bed rest, but sodium loss, probably resulting from the release of atrial natriuretic factor (ANF), a potent oligopeptide stimulator of sodium loss in renal tubules, may also be a factor. Hyponatremia develops in the first week after hemorrhage, but it is unclear whether this also results from the natriuretic effects of ANF or is an effect of antidiuretic hormone, causing water retention. The work of Diring and coworkers (1988) suggests that both mechanisms are operative but it is the volume depletion, not hyponatremia per se, that is of the greatest clinical consequence.

Both the risk of rerupture of the aneurysm and some of the secondary problems that arise because of blood in the subarachnoid space can be obviated by early obliteration of the aneurysm. Because of the changes in water balance and the risk of delayed stroke from vasospasm, there has been an emphasis on early volume expansion and sodium repletion by the intravenous infusion of crystalloids. As Solomon and Fink point out, this can be accomplished without fear of aneurysmal rupture if blood pressure is allowed to rise only minimally. Of course, fluid replacement and a modest elevation of blood pressure become completely safe if the aneurysm has been surgically occluded. Thus the current approach is to operate or eliminate the aneurysm by endovascular means early, within 24 h if possible, for patients in

grades I and II, and then to increase intravascular volume and maintain normal or above-normal blood pressures. This precludes rebleeding, with its high mortality, and ameliorates the second cause of morbidity, stroke from vasospasm. The timing of surgery or endovascular treatment for grade III patients is still controversial but if their medical condition allows, they, too, probably benefit from the same early and aggressive approach. In grade IV patients, the outcome is generally dismal, no matter what course is taken, but we have usually counseled against early operation; some neurosurgeons disagree. The insertion of ventricular drains into both frontal horns has occasionally raised a patient with severe hydrocephalus to a better grade and facilitated early operation. In the hands of experienced anesthesiologists and cerebrovascular surgeons, the operative mortality, even in grades III and IV patients, has now been reduced to 2 to 3 percent. For a detailed account of the operative approach to each of the major classes of saccular aneurysm, the reader is referred to the monograph by Ojemann and colleagues (1995).

Several alternative therapeutic measures are in common use but are still being studied. Among these, endovascular obliteration of the lumen of the aneurysm holds the most promise. This has become the preferred approach for aneurysms that are surgically inaccessible—for example, those in the cavernous sinus—and for patients whose medical state precludes an operation. Among several trials that have compared surgery with endovascular placement of coils in the aneurysm, most have shown equivalence or a slight superiority of the latter. For example, the International Subarachnoid Aneurysm Trial Group randomly assigned more than 2,000 patients to surgery or coil deployment; the overall rate of death or dependence at 1 year was 24 percent in the endovascular group and 31 percent in the operated group, a difference that was sustained at 2 years of followup (Molyneux et al). Doubtless, further studies will continue to clarify the relative benefits of the treatment. It is self-evident that the skill of the surgeon and the quality of postoperative care are major determinants of outcome; perhaps the simplicity of endovascular treatment and the improvements in the training of interventional specialists will prove its advantage over time.

Because of the current approach of ablating the aneurysm early, the previously popular use of antifibrinolytic agents as a means of impeding lysis of the clot at the site of aneurysmal rupture has been generally abandoned. Repeated drainage of the CSF by lumbar puncture is also no longer practiced as a routine. One lumbar puncture is generally carried out for diagnostic purposes if the CT is inconclusive; thereafter, spinal fluid drainage is performed only for the relief of intractable headache or to detect recurrence of bleeding. As mentioned earlier, patients with stupor or coma who have massive hydrocephalus often benefit from decompression of the ventricular system. This is accomplished initially by external drainage and may require permanent shunting if the hydrocephalus returns. The common practice of draining milder degrees of hydrocephalus has not been proven to be helpful. Some risk may attend rapid removal of CSF by this method or lumbar puncture. The risk of infection

of the external shunt tubing is high if it is left in place for much more than 3 days. Replacement with a new drainage tube, preferably at another site, reduces this risk.

Unruptured Intracranial Aneurysms

Quite often in clinical practice, cerebral angiography, MRI, MRA, or CT performed for an unrelated reason discloses the presence of an unruptured saccular aneurysm. Or, a second or third aneurysm is found during the angiogram to assess a ruptured one. There is now a reasonably sound body of information about the natural history of these lesions. Wiebers and colleagues (1987) observed 65 patients with one or more unruptured aneurysms for 5 years or longer after their detection. The only feature of significance relative to rupture was aneurysmal size. Of the 44 aneurysms smaller than 10 mm in diameter, none had ruptured, whereas 8 of 29 aneurysms 1 cm or larger eventually did so, with a fatal outcome in 7 cases. Two large studies have attempted to refine these statistical data. In the older Cooperative Study of Intracranial Aneurysms, none of the aneurysms less than 7-mm diameter "had further trouble." A more recent and sizable cooperative study that included 4,060 patients and gathered data prospectively for 5 years, conducted by the International Study of Unruptured Intracranial Aneurysms Investigators, found an extremely low rate of rupture, approximately 0.1 percent yearly, for aneurysms smaller than 7 mm in diameter, an annual risk of 0.5 percent for aneurysms between 7 and 10 mm, and a risk ranging from 0.6 to 3.5 percent for lesions between 13 and 24 mm (depending on location). The risk ranged up to 10 percent for aneurysms greater than 25-mm diameter. The yearly rates for rupture were higher in all categories if there had been prior bleeding from another site. The location of the lesion also had great bearing on the risk of rupture, as did increasing age; notably, vertebrobasilar and posterior cerebral aneurysms bled at a rate many

times higher than the others. Such data aids in comparing the risk of surgery and endovascular treatment, which, for example, exceed the risk of bleeding within 5 years for small aneurysms located in the carotid circulation. In almost all other circumstances, there is overall benefit to obliterating the unruptured aneurysm.

A special problem pertains to clots within an aneurysm that cause transient ischemic attacks or small strokes in the vascular territory distal to the site. The frequency of this complication is not clear and it occurs at times without evident intraluminal clot on an angiogram.

Giant Cerebral Aneurysms

These are believed to be congenital anomalies even when there is considerable atherosclerosis in their walls. They may become enormous in size, by definition greater than 2.5 cm in diameter, but sometimes twice or more as large. Most are located on a carotid, basilar, anterior, or middle cerebral artery, but also are found on the vertebral artery (Fig. 34-28). They grow slowly by accretion of blood clot within their lumens or by the organization of surface blood clots from small leaks. At a certain point they may compress adjacent structures, e.g., those in the cavernous sinus, optic nerve, or lower cranial nerves. The giant fusiform aneurysm of the midbasilar artery, with signs of brainstem ischemia and lower cranial-nerve palsies, is a relatively common form. Clotting within the aneurysm may cause ischemic infarction in its territory of supply, as mentioned in the case of berry aneurysms. Giant aneurysms may also rupture and cause subarachnoid hemorrhage, but not nearly as often as saccular aneurysms. These clinical observations were confirmed by the International Study, referred to above.

Treatment of saccular aneurysms is surgical if the lesion is symptomatic and it is accessible; endovascular techniques have been employed if the lesion is in the vertebral or midbasilar artery. Obliteration of the lumen,

Figure 34-28. Giant aneurysm of the anterior cerebral artery. *Left:* T1-weighted MRI without gadolinium infusion. The white signal is thrombus within the anterior aspect of the aneurysm; there is some blood flow within the lesion evidenced by the darker signal. *Right:* Cerebral angiogram, left common carotid injection, lateral view, showing the residual flow in the posterior aspect of the aneurysm.

coupled with vascular bypass procedures, has been successful in the hands of cerebrovascular neurosurgeons, but the morbidity is high. Some giant aneurysms can be ligated at their necks, others by trapping or by the use of an intravascular detachable balloon. Drake summarized his surgical experience in the treatment of 174 such cases. Some fusiform aneurysms have been wrapped in muslin or similar material with mixed results. We have followed one such patient who had been operated on by T. Sundt more than 35 years ago. Recent attempts at stabilizing the expansion of the aneurysm by deploying an intravascular stent are under study.

Mycotic Aneurysm

The term *mycotic aneurysm* designates an aneurysm caused by a localized bacterial or fungal inflammation of an artery. (Osler introduced the misnomer *mycotic* aneurysm to describe an infectious process in the wall of a vessel.) With the introduction of antibiotics, mycotic aneurysms have become less frequent, but they are still being seen in patients with bacterial endocarditis and in intravenous drug abusers. Peripheral arteries are involved more often than intracranial ones; about two-thirds of the latter are associated with bacterial endocarditis caused by streptococcal infections. In recent years, the number of mycotic aneurysms caused by staphylococcal infections and acute endocarditis has increased. The usual pathogenic sequence is an embolic occlusion of a small artery, which may announce itself clinically by an ischemic stroke with white blood cells in the CSF. Later, or sometimes as the first manifestation, the weakened vessel wall ruptures and causes a subarachnoid or brain hemorrhage. An important point is that the aneurysm may appear within days of seeding of the vessel and rupture at any time, although the rates of rupture with subarachnoid hemorrhage are low.

The mycotic aneurysm may appear on only one artery or several arteries, and the hemorrhage, if it has happened, may recur. A consensus regarding the treatment of mycotic aneurysm has not been reached. The underlying endocarditis or bacteremia mandates appropriate antibiotic therapy and, in at least 30 percent of cases, healing of the aneurysm can be observed in successive arteriograms with this approach alone. Antibiotic or antifungal treatment is usually continued for at least 6 weeks. Some neurosurgeons favor excising an accessible aneurysm if it is solitary and the systemic infection is under control. Many mycotic aneurysms do not bleed, and in our view medical therapy takes precedence over surgical therapy.

Convexity Subarachnoid Hemorrhage

The finding of blood over a convexity of the cerebral hemisphere, usually discovered because of an evaluation for sudden headache, has become a common occurrence. The causes for this bleeding are numerous, the most obvious being cranial trauma but a diversity of processes may be responsible including cerebral amyloid angiopathy, reversible cerebral vasoconstriction syndrome, cortical vein thrombosis, the use of cocaine, cavernous angioma,

dural arteriovenous fistula, and posterior reversible leukoencephalopathy. It is interesting to note that this list largely overlaps with the causes of “thunderclap headache,” discussed earlier and in Chap. 10. Of course, in the appropriate clinical circumstances, ruptured aneurysm and mycotic aneurysm are still concerns. In a survey conducted by Kumar and associates, it was suggested that younger patients present with abrupt headache and older ones, with TIA-like symptoms and imaging findings that were consistent with cerebral amyloid angiopathy. Further notable is the later occurrence of meningeal hemosiderosis as a result of these lesions, particularly with amyloid angiopathy (see Linn and colleagues).

ARTERIOVENOUS MALFORMATIONS OF THE BRAIN

An arteriovenous malformation (AVM) consists of a tangle of dilated vessels that form an abnormal communication between the arterial and venous systems. These developmental abnormalities represent persistence of an embryonic pattern of blood vessels and not a neoplasm, but the constituent vessels may proliferate and enlarge with the passage of time. Venous malformations, consisting purely of distended veins deep in the white matter, are a separate entity; they may be the cause of seizures and headaches but seldom of hemorrhage. When a small hemorrhage occurs, it is usually the result of an associated malformation of the so-called cavernous type; these are small hamartomatous lesions of multiple juxtaposed endothelium-lined cavities without interposed neural tissue. These are discussed further on.

True vascular malformations vary in size from a small blemish a few millimeters in diameter lying in the cortex or white matter to a huge mass of tortuous channels constituting an atrioventricular (AV) shunt of sufficient magnitude to raise cardiac output. Hypertrophic dilated arterial feeders can be seen approaching the main lesion and to break up into a network of thin-walled blood vessels that connect directly with draining veins. The latter often form greatly dilated, pulsating channels, carrying away arterial blood. The tangled blood vessels interposed between arteries and veins are abnormally thin and do not have the structure of normal arteries or veins. AVMs occur in all parts of the cerebrum, brainstem, and cerebellum (and spinal cord), but the larger ones are more frequently found in the central part of a cerebral hemisphere, commonly forming a wedge-shaped lesion extending from the cortex to the ventricle. Some lie on the dural surface of the brain or spinal cord, but these more often turn out to be direct arteriovenous fistulas, as discussed further on.

When hemorrhage occurs from an AVM, blood may enter the subarachnoid space, producing a picture almost identical to that of a ruptured saccular aneurysm, but generally less severe. Because most AVMs lie within cerebral tissue, bleeding is more than likely to be intracerebral as well, or to be solely intracerebral, causing a hemiparesis, hemiplegia, and so forth, or even death.

AVMs are about one-tenth as common as saccular aneurysms and about equally frequent in males and females. The two lesions—AVM and saccular aneurysm (on the main feeding artery of the AVM)—are associated in approximately 5 percent of cases; the conjunction increases with the size of the AVM and the age of the patient (Miyasaka et al). AVMs rarely occur in more than one member of a family in the same generation or successive ones.

For a review of the embryologic theories of formation of AVMs, the reader is directed to the article by Fleetwood and Steinberg.

Clinical Features

Bleeding or seizures are the main modes of presentation. Most AVMs are clinically silent for a long time. Although the lesion is present from birth, onset of symptoms is most common between 10 and 30 years of age; occasionally it is delayed to age 50 or even beyond. In almost half of patients, the first clinical manifestation is a cerebral subarachnoid hemorrhage; in 30 percent, a seizure is the first and only manifestation; and in 20 percent, the only symptom is headache. Progressive hemiparesis or other focal neurologic deficit is present in approximately 10 percent of patients. The first hemorrhage may be fatal, but in more than 90 percent of cases the bleeding stops and the patient survives. Most often there are no symptoms before rupture. Chronic, recurrent headache may be a complaint; usually it is of a nondescript type but a classic migraine with or without neurologic accompaniment occurs in approximately 10 percent of patients—probably with greater frequency than it does in the general population. Most of the malformations associated with migraine-like headaches lie in the parietooccipital region of one cerebral hemisphere, and about two-thirds of such patients have a family history of migraine.

Huge AVMs may produce a slowly progressive neurologic deficit because of compression of neighboring structures by the enlarging mass of vessels and by shunting of blood through greatly dilated vascular channels. It has also been proposed that an “intracerebral steal” can result in hypoperfusion of the surrounding brain (Homan et al). When the vein of Galen is enlarged as a result of drainage from an adjacent AVM, hydrocephalus may result, particularly in children. With moderate size and large lesions, one or both carotid arteries frequently pulsate unusually forcefully in the neck. A systolic bruit heard over the carotid in the neck or over the mastoid process or the eyeballs in a young adult is suggestive of an AVM. However, such bruits have been heard in fewer than 25 percent of our patients. Exercise such as repeated squatting that increases the pulse pressure may bring out a bruit if none is present at rest. There is no relation of the existence of an AVM, or its rupture, to chronic hypertension (the same pertains to cerebral aneurysms).

Inspection of the eye grounds will rarely disclose a retinal vascular malformation that is coextensive with a similar lesion of the optic nerve and basal portions of the brain. Cutaneous, orbital, and nasopharyngeal AVMs may occasionally be found in relation to a cerebral lesion. Skull films rarely show crescentic linear calcifications in the larger malformations.

To summarize the size, location, and venous drainage characteristics of a cerebral AVM for surgical planning, Spetzler and Martin devised a widely used grading scale. The summed score gives guidance as to the difficulty in surgical removal and has a less certain relationship to the clinical behavior of the lesion. Lesions 1 to 3 mm are considered small, and give 1 point; 3 to 6 mm are medium sized and 2 points; over 6 mm are large and assigned 3 points; location in an eloquent site gives 1 point and venous drainage to the deep veins gives another point (the summed score is between 1 and 5). The use of this scale to plan treatment is discussed in the next section.

Features that have been related to risk of bleeding in some series have been a deep location of the AVM or deep venous drainage channels, and mostly, a previous hemorrhage summarized by Stapf and colleagues. The natural history of AVMs has been studied by Ondra and colleagues, who have presented data on a large and comprehensive series of untreated malformations in Finland over a 30-year period, and another similar series has been reported by Crawford and coworkers in Great Britain. The rate of rebleeding in most series has been 2 to 4 percent per year over decades but may be as high as 6 to 9 percent in the year after a first hemorrhage. In the latter study, comprising 343 patients, 217 were managed without surgery and observed for many years (mean: 10.4 years). Hemorrhage occurred in 42 percent and seizures in 18 percent. By 20 years after diagnosis, 29 percent had died and 27 percent of the survivors had a neurologic handicap. In a series of 1,000 patients referred mainly for proton-beam radiation of an AVM and studied by our colleague R.D. Adams, 464 had a hemorrhage as the first manifestation and 218 had a seizure (mainly with frontal and frontoparietal lesions). In those few AVMs that came to attention as a result of a progressive neurologic deficit, most were situated in the posterior fossa or axially in the cerebrum. The combination of a prolonged history of headaches, seizures, and a progressive deficit in Adams' series almost always indicated a large malformation. The matter of an increased risk of AVM rupture during pregnancy has been disputed. The weight of evidence suggests that the risk is not raised by pregnancy alone.

Fully 90 percent of AVMs are disclosed by CT if performed with contrast infusion, and an even larger number by MRI (Fig. 34-29). Magnetic-susceptibility MRI shows small areas of previous bleeding around AVMs. Arteriography is usually necessary to establish the diagnosis with certainty and will demonstrate AVMs larger than 5 mm in diameter; MRI may fail to reveal smaller lesions. Another value of arteriography, particularly if performed with rapid sequential and delayed images is to define all of the feeding arteries, the presence of an associated aneurysm and the channels of venous drainage, all of which inform the expectations of future bleeding and the most advisable methods of obliterating the lesion. The decision to obtain imaging to detect an AVM in cases of typical cerebral hemorrhage of the type discussed in earlier sections is based on factors such as young age (childhood and adolescence onset is particularly suggestive), a history of an unusual unilateral headache syndrome, a focal seizure disorder, the absence

Figure 34-29. Left parietal arteriovenous malformation. *Upper left:* T2-weighted MRI shows a tangle of vessels interspersed throughout the parietal lobe. The largest of these vessels are dilated draining veins. *Upper right:* CT angiography demonstrates enhancement of the abnormal vessels throughout the left hemisphere. The AVM is fed primarily via branches of the left MCA. Cerebral angiography. Contrast injected into the left internal carotid artery reveals the feeding arteries (*lower left*) and abnormal early filling of dilated draining veins (*lower right*) due to blood bypassing the capillary bed.

of other apparent cause (e.g., coagulopathy, chronic hypertension, metastatic tumor), but most of all, recurrent bleeding in one location of the brain.

Treatment

The preferred approach in most centers is surgical excision. The Spetzler-Martin Scale gives guidance as to the

surgical difficulty and risk. Grades IV and V are generally not resected; grade III lesions may be approached surgically but often with preceding interventional embolization of parts of the lesion. Some 20 to 40 percent of AVMs are amenable to block dissection, with an operative mortality rate of 2 to 5 percent and a morbidity of 5 to 10 percent (see Fleetwood and Steinberg for a summary

of reported surgical results up to 2002). For inaccessible lesions, attempts have been made to obliterate the malformed vessels by ligation of feeding arteries or by the use of endovascular embolization with liquid adhesives or particulate material that is injected via a balloon catheter that has been navigated into a feeding vessel. Complete obliteration of large AVMs is usually not possible by these methods but they are highly effective in reducing the size of the AVM prior to surgery.

Several modes of radiosurgery are used to decrease the size of the lesion, albeit with a substantial delay. This approach is utilized most often with AVMs of 3 cm or smaller located in an area of the brain in which resection would be likely to produce a serious neurologic disability. Kjellberg and Chapman pioneered the treatment of AVMs using a single dose of subnecrotizing stereotactically directed proton radiation. The technique of radiosurgery has been adopted by others using photon radiation sources, such as a linear accelerator, gamma Knife, and other modes of focused x-ray radiation as accepted alternatives to operative treatment of lesions situated in deep regions, including the brainstem, the thalamus, or in "eloquent" areas of the cortex. Generally, malformations smaller than 3 cm diameter are treatable in this way. The main drawback to "radiosurgery" is that obliteration of AVMs occurs in a delayed manner, usually with a latency of at least 18 to 24 months after treatment, during which the patient is unprotected from rebleeding. The likelihood of successful radiotherapy treatment and the nature of the risks depend on the location and size of the AVM and the radiation dose delivered. After 2 years, 75 to 80 percent of AVMs smaller than 2.5 cm in diameter have been obliterated. Even for those AVMs that have not been totally eliminated, the radiation effect appears to confer some long-term protection from bleeding. Of the larger ones, a majority shrink or appear less dense. The rest show no change at this low-dose level, but even in this group, the morbidity and mortality are lower than in the untreated group. A proportion of larger AVMs that are initially obliterated will later recanalize, and many of these will subsequently bleed. Among more than 250 patients whose AVMs disappeared following proton-beam therapy, there has been no recurrence of hemorrhage for up to 10 years. The results of treatment with focused radiation have been about the same. In one study, the risk of hemorrhage was reduced by 54 percent between the time of radiation and obliteration of the malformation and by 88 percent thereafter (Maruyama et al).

Two types of complications of radiation occur at a combined rate of approximately 2 to 4 percent. The first is delayed radiation necrosis, which is predictable based on the radiation dose, and the second is venous congestion that occurs several weeks or months after treatment. The latter is indicative of the desired effect of thrombosis of the malformation. Both may cause local symptoms for weeks or months. Radiation necrosis may be reduced by the administration of corticosteroids but the vascular problem generally is not helped.

The treatment of AVMs by endovascular techniques is increasingly being used but is only recently being fully evaluated. Nearly every AVM has several feeding arteries, some not reachable by a catheter, and some part of

the AVM may remain after treatment. In most series, 25 percent or more of AVMs, mostly of small and medium size, have been completely obliterated, with a mortality rate below 3 percent and morbidity of 5 to 7 percent, both of which compare favorably with surgical outcomes. These techniques are also particularly suited to lesions of a combined AVM and an aneurysm on the feeding vessel.

In the past several years, combined therapy that begins with endovascular reduction of the lesion and is followed by either surgery or radiation has been viewed favorably. Using this approach, more than 90 percent of lesions can be obliterated with a very low rebleeding rate over several years. It is clear that the plan for each patient must be individualized based on the size, location, nature of feeding vessels, the presence of other vascular lesions (aneurysm or additional AVM), and the age of the patient. Another strategy for otherwise untreatable grade IV and V lesions has been to stage radiosurgery in order to reduce parts of the lesions sequentially as described by Sirin and colleagues. Even then, there will be differences of opinion based on local resources and experience.

Finally, if the primary problem is recurrent seizure, eliminating the malformation achieves reduction or cessation of seizures in a very high proportion of cases. In the interval, antiepileptic drugs are required and may be needed for a period of years after obliteration. A recent summary has been provided by Friedlander.

Dural Arteriovenous Fistula

These curious vascular abnormalities, occurring in both the cranial and spinal dura, have different presentations at each site. The spinal form, more common in general experience, is discussed with other diseases of the spinal cord in Chap. 44. The cranial type is being detected with increasing frequency as refinements continue to be made in imaging of the cerebral vessels, but its incidence and pathogenesis are not fully known. The defining features are radiologic—a nidus of abnormal arteries and veins with arteriovenous shunting contained entirely within the leaflets of the dura. The lesion is usually fed by dural arterial vessels derived from the internal cranial circulation and often, more prolifically, from the external cranial circulation (external carotid artery and muscular branches of the vertebral artery). Venous drainage of these lesions is often complex and is largely directed to the dural venous sinuses (Fig. 34-30). The rapid transit of injected angiographic dye through dural fistulas accounts for the early opacification of the draining venous structures. In the case of high-flow connections, this may not be seen unless images are taken almost immediately after the injection. A number of potential feeding vessels must be individually opacified to demonstrate all the conduits into the lesion. On CT and MRI, the fistula is sometimes detected as a thickening or enhancement of a region of dura, generally close to a large dural venous sinus. In other cases, the dilated draining vessels may be seen only with the injection of dye or gadolinium. Probably, many are not detected by either of these techniques.

Several classification systems (Borden; Cognard) have been developed that are based on the nature and

Figure 34-30. Cerebral angiogram of a cerebral dural arteriovenous malformation. The nidus is located at the cerebral convexity (arrow). There is rapid filling of the cerebral venous system after injection of contrast into one internal carotid artery.

direction of the drainage of the lesion. There are some associations between the nature of these drainage patterns, as summarized by the classification systems, and clinical presentation.

The origin of these vascular lesions has not been settled—several mechanisms may be involved. Most evidence suggests that at least some of them, unlike conventional cerebral AVMs and aneurysms, are not developmental in origin. The best-defined examples of acquired fistulas are those that arise adjacent to a venous sinus thrombosis or in association with a vascular atresia, most often of the transverse sigmoid sinus or adjacent to the cavernous sinus. However, it is not always clear whether the abnormality of the venous sinus is the cause or the result of the dural fistula. In a number of cases, a dural fistula has appeared after a forceful head injury, often in a region remote from the site of impact. Another small group that is clearly developmental is associated with the Klippel-Trenaunay or Osler-Weber-Rendu syndromes, diseases in which a conjunction with AVMs is well known. (In the first of these, they may also be an associated enlargement of the affected limb.) Usually, these causes can be excluded by physical examination and an absence of family history and the largest group remains idiopathic.

A major obstacle to understanding of dural fistula is the varied ways in which this lesion presents itself clinically. Subdural hemorrhage is an infrequent but dramatic mode of presentation, sometimes creating a large and fatal clot; another syndrome is a cerebral-subarachnoid hemorrhage, although this occurs with not nearly the same frequency or severity as bleeding from brain AVMs. Indeed, the risk of bleeding from dural fistulas and the evolution of these lesions is far less precise than it is for cerebral AVMs. It appears that the dural lesions most at risk of bleeding are those located in the anterior

cranial fossa and those at the tentorial incisura. Seizures are distinctly uncommon. Yet another special syndrome linked to dural AVMs, although it may occur also with high-flow cerebral malformations, is of headache, vomiting, and papilledema—namely, *pseudotumor cerebri* (see Chap. 30). Whether the increased intracranial pressure is the cause or the result of the fistula is unsettled, but relief of venous insufficiency may result in regression of fistulae. A cranial bruit, audible to either the examiner or patient, is infrequent with fistula but may be sought. In small children, the high-flow lesions may shunt so much blood as to cause congestive heart failure, similar to arteriovenous malformations of the vein of Galen.

Treatment is by surgical extirpation or endovascular embolization, at times a painstaking procedure because of the multitude of potential feeding vessels. Surgery seems preferable for the smaller lesions and embolization for larger and inaccessible ones. Slowed flow in a venous sinus that is draining a malformation risks venous thrombosis but the issue of anticoagulation in this circumstance remains uncertain.

Cavernous Malformations (Cavernoma)

Vascular malformations composed mainly of clusters of thin-walled veins without important arterial feeders and with little or no intervening nervous tissue make up a significant group, some 7 to 8 percent of AVMs. Conventional subdivisions of this group into cavernous, venous, and telangiectatic types have not proven useful. Most clinicians roughly designated them all as *cavernous*. Several attributes set them apart from other vascular malformations. Their tendency to bleed is probably no less than that of the more common AVMs, and far more often, the hemorrhages are small and clinically silent. The incidence of bleeding is uncertain but is estimated to be less than 1 percent per year per lesion but quite often they are multiple lesions so that the cumulative risk in any one patient is higher. Flemming and colleagues, in a survey of 292 patients followed for an average of almost 10 years, gave the rate as 0.3 percent annually for asymptomatic lesions and found that individuals who had a previous episode of bleeding or had more than one lesion were 2.5 times more likely to have another hemorrhage.

As mentioned, approximately 10 percent of these lesions are multiple and 5 percent are familial. In one family we followed, there were 29 affected members in three generations; the inheritance followed an autosomal dominant pattern. At the present, several genes have been identified as possibly causative in certain families. One interesting characteristic of this group, as pointed out by Labauge and colleagues, is the appearance over time of new lesions in one-third of patients. The followup of some of our patients has affirmed this.

The diagnosis is based on clinical manifestations and MRI, which discloses a cluster of vessels surrounded by a zone of hypodense ferritin in the T1-weighted images (Fig. 34-31), the product of previous small episodes of bleeding. An uncertain number is associated with adjacent deep venous anomaly visualized by imaging studies and these are discussed in a separate section below.

Figure 34-31. Cavernous malformation in the right parietal lobe. Axial T2 MRI (*left*) shows a round lesion which is heterogeneously hyperintense and hypointense. This appearance is due to vascular channels which are immediately adjacent to each other without interspersed normal brain tissue, containing blood products in different stages of degradation. An axial gradient echo MRI (*right*) shows that the lesion is hypointense, again due to blood products.

About one-half of all cavernous angiomas lie in the brainstem, and in the past (before the availability of MRI), many of them were misdiagnosed as multiple sclerosis because of the stepwise accumulation of neurologic deficits with each hemorrhage. A large series of cavernous malformations of the brainstem, most in the pons, has been described by Porter and colleagues. They describe a higher rate of bleeding than had been reported for similar malformations in the cerebral hemispheres, frequent adjacent venous anomalies, and good results from surgical ablation. They estimated the rate of bleeding to be 5 percent per year and the rate of rebleeding close to 30 percent per year.

Treatment Cavernous angiomas on the surface of the brain, within reach of the neurosurgeon, even those in the brainstem, can be plucked out like blackberries, with low morbidity and mortality. Kjellberg and colleagues treated 89 deeply situated cavernous angiomas with low-dose proton radiation, but our impression is that these vascular malformations, like hemangioblastomas, respond poorly to radiation and are not amenable to treatment by endovascular techniques.

Lesions that cause recurrent bleeding and are surgically accessible with little risk are often removed but incidentally discovered angiomas, even if they have caused a small hemorrhage, and those that are inaccessible may be left alone. Although this conservative approach is usually taken, there are not adequate data on the rate and risk of bleeding to determine the proper course of action.

Deep (Developmental) Venous Anomaly

This is perhaps the most common cerebral vascular malformation, estimated to occur in almost 3 percent of large

autopsy series (attributed to Swar and McCormick). As with cavernous angiomas, these lesions are frequently detected as asymptomatic problems in brain imaging. The defining characteristics are of a caput medusae draining into a small collecting vein. The draining vein itself is often visualized most easily and fills with contrast concurrently with normal cerebral (Fig. 34-32). As mentioned

Figure 34-32. A developmental venous anomaly (DVA) and its collecting vein in the left cerebellum on a T1-weighted MRI with contrast.

above, perhaps up to 40 percent of cavernous malformations (probably fewer) have an associated deep venous anomaly. Although the risks of stroke in relation to one of these anomalies is low, certainly less than 1 percent per year, small hemorrhage or infarction surrounding a deep venous anomaly may result from acute thrombosis in a collecting vein. An extensive summary of the clinical and imaging features of venous anomalies is given by Ruiz and colleagues. They reviewed the interesting cases reported in the literature in which the anomaly has thrombosed, and discuss the possible pathophysiologic relationship between the vein and the development of a cavernous malformation.

The management of developmental venous anomalies has not been clarified although numerous forms of surgery, embolization, or focused radiation, have been used depending on the nature of an associated lesion such as cavernous malformation, and the occurrence of repeated bleeding. In general, incidentally discovered lesions are simply followed with imaging at reasonable intervals.

Other Causes of Intracranial Bleeding and Multiple Cerebral Hemorrhages

Next in frequency to hypertension, *anticoagulant therapy* is currently the most common cause of cerebral hemorrhage. The hemorrhages that develop, although sometimes situated in the sites of predilection of hypertensive hemorrhage, are more likely to occur elsewhere, mainly in the lobes of the brain. When the bleeding is precipitated by warfarin therapy, treatment with fresh-frozen plasma and vitamin K, sometimes prothrombin complex concentrate (PCC) and similar products, which contains clotting factors, is recommended. The use of *thrombolytic drugs* in the treatment of stroke or myocardial infarction is complicated by intracranial hemorrhage in 6 to 20 percent of cases, depending on the dose and timing of drug administration in relation to the onset of symptoms, as discussed in the section earlier on "Thrombolytic Agents." The newer antifactor X and direct thrombin-inhibiting anticoagulants are not as easily subject to reversal. When bleeding is associated with aspirin therapy or other agents that affect platelet function, fresh platelet infusion, often in massive amounts, may be used to control the hemorrhage, however, their effectiveness in management of cerebral hemorrhage has been questioned.

In the elderly, *amyloid angiopathy* appears to be a major cause of lobar bleeding, especially if hemorrhages appear in succession or are multiple. Several of our patients who later proved to have amyloid angiopathy had minor head injuries in the weeks before hemorrhage. In our own material, only severe impregnation of vessels with amyloid and fibrinoid change in the vessel wall were associated with hemorrhage (Vonsattel et al). Greenberg and colleagues found that apolipoprotein E4, the same marker that is overrepresented in Alzheimer disease, is associated with severe amyloid angiopathy and a risk of intracerebral hemorrhage, but others have found an association with the E2 allele. Contrary to previous pronouncements, there is probably no greater risk in evacuating these clots surgically than in the case

of other cerebral hemorrhages, but most of them are of a size that allows conservative management and evidence is lacking that surgery improves outcome as discussed earlier.

Several *primary hematologic disorders* are also complicated by hemorrhage into the brain. The most frequent of these are leukemia, aplastic anemia, and thrombocytopenia of various causes. Often they give rise to multiple intracranial hemorrhages, some in the subdural and subarachnoid spaces. As a rule, this complication signals a fatal outcome. Other, less-common causes of intracerebral bleeding are advanced *liver disease*, uremia that is being treated with dialysis, and lymphoma. Usually several factors are operative in these hematologic cases: reduction in prothrombin or other clotting elements (fibrinogen, factor V), bone marrow suppression by antineoplastic drugs, and disseminated intravascular coagulation. Any part of the brain may be involved, and the hemorrhagic lesions are usually multiple. Frequently there is also evidence of abnormal bleeding elsewhere (skin, mucous membranes, kidney) by the time cerebral hemorrhage occurs. Plasma exchange, used in the treatment of myasthenia gravis and Guillain-Barré disease, lowers the serum fibrinogen to a marked degree, but we have not observed a single instance of intracerebral hemorrhage in more than 500 patients treated in this way.

Occasionally the origin of intracranial hemorrhage cannot be determined clinically or pathologically. In some postmortem cases, a careful microscopic search discloses a small arteriovenous malformation; this is the basis for suspecting that an overlooked lesion of this type may be the cause of cerebral hemorrhage in other cases. *Primary intraventricular hemorrhage*, a rare event in adults, can sometimes be traced to a vascular malformation or neoplasm of the choroid plexus or one of the choroidal arteries; more often, such a hemorrhage is the result of periventricular bleeding often from a medial thalamic hemorrhage, in which blood enters the ventricle without producing a large parenchymal clot.

Hemorrhage into primary and secondary brain tumors is not rare. When this is the first clinical manifestation of the neoplasm, diagnosis may be difficult. Choriocarcinoma, melanoma, renal cell and bronchogenic carcinoma, pituitary adenoma, thyroid cancer, glioblastoma multiforme, intravascular lymphoma, carcinoid, and medulloblastoma may present in this way, but bleeding is most characteristic of the first three types. Careful inquiry will usually disclose that neurologic symptoms compatible with intracranial tumor growth had preceded the onset of hemorrhage or the primary neoplasm had been revealed previously. Needless to say, a thorough search should be made in these circumstances for evidence of intracranial tumor or of secondary tumor deposits in other organs, particularly the lungs.

A number of disparate diseases may result in a multitude of simultaneous or at least temporally clustered cerebral hemorrhages. Among the most common causes are cerebrovascular amyloidosis (amyloid angiopathy) as mentioned earlier, those related to hematologic and clotting disease, particularly ones that progress rapidly, such as leukemia, but almost any coagulopathy, including those

brought on by the administration of medications. The most overwhelming examples in our experience have occurred in the hours after injecting tPA for acute stroke. Serious cranial injury itself may produce a passel of scattered contusions, some of which have the appearance of ball hemorrhages, but most are recognized to be along force lines (see Chap. 35). Occlusion of cerebral veins, particularly of the superior sagittal sinus, causes several biparietal hemorrhages.

Multiple small hemorrhages, brain “microbleeds,” are most commonly considered to be the result of vascular amyloid as discussed in the next section, but may also be associated with chronic hypertension according to Cordonnier and colleagues, but we have been unable to confirm this latter view from our own material. Often, these dozens of small areas of residual blood products or acute hemorrhages do not cause symptoms and are revealed on MRI that is performed for other reasons with gradient-echo and other susceptibility sequences (Fig. 34-33). Certainly, other forms of cerebrovascular disease are found disproportionately in these patients and several series suggest that they represent a risk for future bleeding or ischemic stroke, including lacunes. Multiple cavernous angiomas, the earlier-described amyloid angiopathy, CADASIL, bacterial endocarditis, moyamoya, and mutations that affect blood vessel integrity may also be implicated but the cause in any individual case often remains uncertain.

The pathologic entity called *brain purpura* (pericapillary encephalorrhagia), incorrectly referred to as “hemorrhagic encephalitis,” consists of multiple petechial hemorrhages scattered throughout the white matter of

the brain. The clinical picture is that of a diffuse encephalopathy, but diagnosis is essentially a pathologic one. Blood does not appear in the CSF, and the condition should not be confused with a stroke. The pathologic appearance is highly characteristic. The lesions in brain purpura are small, 0.1 to 2.0 mm in diameter, and are confined to the white matter, particularly the corpus callosum, centrum ovale, and middle cerebellar peduncles. Each lesion is situated around a small blood vessel, usually a capillary. In this para-adventitial area, both the myelin and axis cylinders are destroyed, and the lesion is usually though not always hemorrhagic. Fibrin exudation, perivascular and meningeal infiltrates of inflammatory cells, and widespread necrosis of tissue are not observed. In these respects, brain purpura differs fundamentally from acute necrotizing hemorrhagic leukoencephalitis. Usually the patient becomes stuporous and comatose without focal neurologic signs.

The etiology of brain purpura is quite obscure and there may be several causes. It may complicate viral pneumonia, uremia, promyelocytic leukemia, arsenical intoxication, and, rarely, metabolic encephalopathy and sepsis, or there may be no associated disease. Amyloid angiopathy and an uncharacterized cerebral small vessel disease also have caused this picture of a multiplicity of small hemorrhages. Primary or secondary thrombotic thrombocytopenic purpura (TTP) may be the final common pattern for this entity.

A degree of brain hemorrhage is to be expected in acute hemorrhagic leukoencephalitis (Hurst type), which represents an extreme form of acute disseminated encephalomyelitis (see Chap. 36), and in herpes encephalitis (see Chap. 33). The other rare types of hemorrhages, listed in Table 34-8, are self-explanatory.

Hemorrhages of *intraspinal* origin, all of them rare, may be the result of trauma, AVM (the usual cause of nontraumatic hematomyelia), dural AV fistula, anterior spinal artery aneurysms, or bleeding into tumors such as hemangioblastoma. Spinal subarachnoid hemorrhage from an AVM may simulate an intracranial subarachnoid hemorrhage, causing a stiff neck, headache, and even subhyaloid hemorrhages. Subarachnoid hemorrhage in which interscapular or neck pain predominates should raise the suspicion of an aneurysm of the anterior spinal artery or of a spinal AVM or cavernous angioma. Angiographic study of the radicular spinal vessels and the origins of the anterior spinal arteries from the vertebral arteries may disclose the source of bleeding. Extradural and subdural spinal extravasations may be *spontaneous* (sometimes in relation to rheumatoid arthritis) but are far more often a result of trauma, anticoagulants, or both. Extradural spinal hemorrhage causes the rapid evolution of paraplegia or quadriplegia; diagnosis must be prompt if function is to be salvaged by surgical drainage of the hematoma. These entities are discussed further in Chap. 44.

Cerebral Amyloid Angiopathy

This angiopathy consists of the deposition of amyloid in the media and adventitia of small vessels, predominantly in the meninges, cortex, and cortical penetrating vessels. The incidence at autopsy of vascular amyloid deposition in the brain is related to the age of the population

Figure 34-33. Axial gradient echo MRI showing innumerable lobar and juxtacortical hypointense microhemorrhages in a patient with cerebral amyloid angiopathy.

studied; rates of 12 percent are cited in patients older than 85 years of age (the same changes are present in more than 25 percent of individuals with Alzheimer disease, but the nature of the amyloid [$A\beta_{40}$ in the pure cerebrovascular form] is different in the two conditions). The result of this deposition is several large or numerous small hemorrhages at various ages, mainly deposited in the cerebral hemispheres. There is a propensity for hemorrhages in the posterior parts of the brain. A strong association has been found with the homozygous APOE $\epsilon 4/\epsilon 4$ genotype. As alluded to several times in earlier sections on cerebral hemorrhage, this is the main cause of otherwise unexplained single or multiple cerebral hemorrhage in older people. Telltale signs of multiple small and larger hemorrhages are often present in these cases; they are seen to advantage with gradient-echo sequences on the MRI. The location of these hemorrhages, subcortical, frequently posteriorly in the brain, and sometimes subpial, imparts a distinctive pattern that is characteristic of this disease. The biology of cerebrovascular amyloid is summarized by Viswanathan and Greenberg.

Some reports have emphasized multiple TIA-like syndromes, some with migrainous features such as spreading sensory symptoms; these are not consistently ischemic and may be associated with microhemorrhages, or white matter changes of uncertain nature. In some cases, there is a fairly rapid progression to dementia but that is more characteristic of the inflammatory type of cerebrovascular amyloid discussed just below.

Over the last few years, our colleague S.M. Greenberg has emphasized certain clinical features associated with a rare inflammatory type of cerebrovascular amyloidosis (see Kinnecom et al). The MRI appearance is of large subcortical patches of T2 signal change suggestive of cerebral edema. Included in the clinical picture are encephalopathy, seizures, and focal cerebral symptoms such as aphasia. The frequency of this interesting condition in the elderly is unclear. It is treated with a short course of high-dose corticosteroids.

There is a separate familial amyloidotic condition of diffuse white matter degeneration with dementia, associated in some families with calcification in the occipital lobes, and the aforementioned mutations in the *COL4A* gene cause a disruption of the small vessel wall that can cause small cerebral hemorrhages that are similar to those of cerebrovascular amyloid.

HYPERTENSIVE ENCEPHALOPATHY (POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME [PRES], REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY [RPLE])

Clinical Features

Hypertensive encephalopathy is the term applied to a relatively rapidly evolving syndrome of severe hypertension in association with headache, nausea and vomiting, visual disturbances, confusion, and—in advanced cases—stupor and coma. Multiple seizures may occur and may be more

marked on one side of the body. In special circumstances, the absolute level of blood pressure seems less pertinent than is a rapid rise in pressure as occurs in eclampsia and with exposure to certain drugs. The neurologic syndrome is usually dominated by symptoms referable to the occipital and adjacent parietal region. There may be field deficits, hallucinations, Balint syndrome, and cortical blindness. An indistinguishable syndrome with similar imaging characteristics also occurs with the use of a variety of mainly cancer chemotherapeutic agents as discussed in Chap. 43 and Table 43-1.

Diffuse cerebral disturbance may be accompanied by focal or lateralizing neurologic signs, either transitory or lasting, which may suggest cerebral hemorrhage or infarction, i.e., the more common cerebrovascular complications of severe chronic hypertension. A clustering of multiple microinfarcts and petechial hemorrhages (the basic neuropathologic changes in hypertensive encephalopathy) in one region may occasionally result in a mild hemiparesis, aphasic disorder, or rapid failure of the above-noted distortion of vision. The last of these, as mentioned, is particularly characteristic of accelerated hypertension and has special features of signal changes in the occipital white matter; for which reason the terms reversible posterior leukoencephalopathy (RPLE) and posterior or reversible leukoencephalopathy syndrome (PRES) have been applied to this condition, as noted below and shown in Fig. 34-34.

In instances of typical accelerated hypertension, by the time the neurologic manifestations appear, the hypertension has usually reached the malignant stage, with diastolic pressures above 125 mm Hg, retinal hemorrhages, exudates, papilledema, and evidence of renal and cardiac disease. However, instances of encephalopathy at lower pressures are common, especially if the rise in pressure has been abrupt (see below). If the rate of elevation is high enough, the syndrome may be seen with blood pressure considered to be close to the normal range. Presumably, these circumstances have to do with a change in the permeability of cerebral vessels that is part of the process in special cases such as eclampsia and the hemolysis, elevated liver enzymes, low platelet count (HELLP) syndrome that are mentioned further on. The term *hypertensive encephalopathy* should probably be reserved for the above syndrome and should not be used to refer to chronic recurrent headaches, dizziness, epileptic seizures, TIAs, or strokes, which may occur in association with elevated blood pressure.

Encephalopathy may complicate extreme hypertension from any cause (chronic renal disease, renal artery stenosis, acute glomerulonephritis, acute toxemia, pheochromocytoma, Cushing syndrome), cocaine, or administration of drugs such as aminophylline or phenylephrine, but it occurs most often in patients with rapidly worsening “essential” hypertension.

In *eclampsia*, which from a neurologic perspective may be considered a special form of hypertensive encephalopathy, and in *acute renal disease*, particularly in children, encephalopathic symptoms may develop at blood pressure levels considerably lower than those of hypertensive encephalopathy of “essential” type. Eclamptic retinal and cerebral lesions are the same as those that complicate

Figure 34-34. Hypertensive encephalopathy. Axial T2-FLAIR images showing fairly symmetric abnormal hyperintensity predominately in the parietooccipital lobes. The lesion affects the cortex and subcortical white matter and there is little mass effect. In severe cases, there may be hemorrhage and heterogeneous infarction in the cerebral cortex. The same imaging findings may occur in eclampsia (see also Chap. 43).

malignant nephrosclerosis; in both there is also failure of autoregulation of the cerebral arterioles. A discussion of eclamptic seizures can be found in the section on that subject in Chap. 16.

Imaging Features

Hypertensive encephalopathy is marked by changes already alluded to on CT and MRI. The findings are of large areas of white matter signal change of edema, but their tendency to normalize over several weeks is remarkable. As summarized by Hauser and coworkers, the main feature is a bilateral increase in T2 signal intensity in the white matter on MRI and a corresponding reduced density on CT, usually concentrated in the posterior part of the hemispheres (see Fig. 34-34). Thus the condition is one of the causes of reversible posterior leukoencephalopathy. These imaging characteristics are a result of an accumulation of fluid, but—unlike the edema in trauma, neoplasm, or stroke—there is little or no mass effect and the water does not tend to course along white matter tracts such as the corpus callosum. In addition, scattered cortical lesions may occur in a watershed vascular distribution and probably correspond to small infarctions. These same findings in the white matter and cortex occur in eclampsia and have been seen in cases of diffuse vasospasm caused by sympathomimetic and serotonergic drugs, discussed further on.

Hypertensive encephalopathy and eclampsia may cause subarachnoid hemorrhage. Most such cases are not caused by the rupture of an intracranial aneurysm

and are not as overwhelming as in aneurysmal hemorrhage; indeed, the headache associated with PRES tends to be milder than with aneurysmal rupture and it may be absent. The bleeding, if it occurs, is mainly a feature that is appreciated on MRI examination, as described by Shah. The mechanism is obscure.

In many, but not all, cases, the CSF pressure and protein values are elevated; the latter to more than 100 mg/dL, but there is no cellular reaction.

Pathophysiology

Neuropathologic examination reveals a rather normal-looking brain, but in some cases cerebral swelling, hemorrhages of various sizes, or both will be found. In extreme instances, a cerebellar pressure cone reflects an increased volume of tissue and increased pressure in the posterior fossa; lumbar puncture appears to have only rarely precipitated fatalities. Microscopically there are widespread minute infarcts in the brain, the result of fibrinoid necrosis of the walls of arterioles and capillaries and occlusion of their lumens by fibrin thrombi (Chester et al). This is often associated with zones of cerebral edema. Similar vascular changes are found in other organs, particularly in the retinae and kidneys.

Volhard originally attributed the symptoms of hypertensive encephalopathy to vasospasm. This notion was reinforced by Byrom, who demonstrated, in rats, a segmental constriction and dilatation of cerebral and retinal arterioles in response to severe hypertension. However, the

observations of Byrom and of others indicate that overdilation of the arterioles (which have lost their adaptive capacity), rather than excessive constriction, may be responsible for the necrosis of the vessel wall (see reviews of Auer and of Chester et al). The brain edema is the result of active exocytosis of water rather than simply a passive leak from vessels subjected to high pressures. In toxemia or eclampsia, rising levels of the antiangiogenic proteins endoglin, vascular endothelial growth factor, and placental growth factor had been postulated to play a role (Levine et al, 2006) but this has not been fully corroborated. The net result is of various forms of endothelial dysfunction, including presumably, in the brain. We have been impressed that the distribution of lesions on the MRI differs between eclamptic and older hypertensive patients, suggesting some difference in pathophysiology, or perhaps simply that chronic hypertension in the latter group predisposes to the occipital lesions. The forms of PRES that are induced by chemotherapeutic and other agents are more complex and are discussed in Chap. 43. A few eclamptic women will develop hemolysis, hepatic failure, and thrombocytopenia—HELLP syndrome—an illness that has similarities to TTP and the hemolytic uremic syndrome (HUS). The interplay between eclampsia and HELLP syndrome in relation to cerebral lesions is complex and not fully understood.

Treatment

In the past, when effective treatment was not available, the outcome was often fatal. Lowering of the blood pressure with antihypertensive drugs may reverse the picture in a day or two. The same can be accomplished by administering magnesium sulfate in the eclamptic woman. However, antihypertensive drugs must be used cautiously; a safe target is a pressure of 150/100 mm Hg or a 20 percent reduction in mean pressure. One may use intravenous sodium nitroprusside, 0.5 to 0.8 mg/kg/min; a calcium channel blocker such as nifedipine, 10 to 20 mg sublingually; or intravenous beta-adrenergic blockers (labetalol, 20 to 40 mg intravenously followed by an infusion at 2 mg/min, or esmolol are favored). Longer-acting antihypertensive agents, such as ACE inhibitors and calcium channel blockers, must follow these. If there is already evidence of brain edema and increased intracranial pressure, dexamethasone, 4 to 6 mg every 6 h, is sometimes added, but its effect, and the use of hyperosmolar therapy, have not been studied systematically; our clinical impression is that they have little effect.

DIFFUSE CEREBRAL VASOSPASM (REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME [RCVS], CALL-FLEMING SYNDROME)

A widespread multifocal or diffuse reduction in the caliber of the cerebral vessels and their branches constitutes a special syndrome of several causes. Vasospasm is, of course, a well-known complication of subarachnoid hemorrhage

Table 34-10

CONDITIONS THAT HAVE BEEN ASSOCIATED WITH DIFFUSE OR WIDESPREAD CEREBRAL VASOSPASM

Idiopathic
Postpartum state
Eclampsia
Hypertensive encephalopathy
Massive subarachnoid hemorrhage
Ergot, sympathomimetic, and serotonergic drugs including
"triptans" and cocaine
"Thunderclap headache" (see Chap. 10)
Head trauma
Cervical arterial dissection, mainly vertebral
Acute porphyria
Hypercalcemia
Migraine?

as described earlier. But the process under discussion has different characteristics. Some degree of attenuation of large cerebral vessels is observed in hypertensive encephalopathy and eclampsia, but a more diffuse and sustained reduction in vascular caliber can result from various causes summarized in Table 34-10.

This type of vasculopathy is produced by sympathomimetic drugs alone, such as ephedra in health food supplements, phenylpropanolamine, pseudoephedrine, methamphetamine, and cocaine, but there are few well-studied cases, as also discussed just below. In all cases, including those noted above, the treatment is cessation of the offending drugs; calcium channel blockers, corticosteroids, nitroglycerin, nitroprusside, and beta-adrenergic or papaverine infusions have been tried with uncertain effect. We have generally prescribed calcium channel-blocking drugs orally. Singhal and colleagues and others have brought to attention that serotonergic drugs may produce reversible multifocal vasospasm, severe headache, and stroke. One of their patients was using the antimigraine medicine sumatriptan; others were using serotonin reuptake inhibitor antidepressants and, in addition, had taken over-the-counter cold remedies that included pseudoephedrine and dextromethorphan; we are aware of other similar cases. These authors proposed that in these cases a "serotonin syndrome" had occurred, similar to what has been seen with overdoses of this class of antidepressants.

In addition, there is a less well-defined syndrome that is apparent on vascular imaging and affects few or many vessels distal to the circle of Willis (Fig. 34-35). Call and colleagues have described a striking idiopathic widespread segmental vasospasm of cerebral vessels that is characterized clinically by severe headache (often of the "thunderclap" variety, as described in Chap. 10) and fluctuating TIA-like episodes (termed Call-Fleming syndrome). The middle cerebral artery and its branches are mainly affected; the angiographic appearance may be mistaken for arteritis. The patients we have seen with this process, after several days or weeks of dramatically fluctuating focal neurologic symptoms and disabling headache, have recovered completely or nearly so, but several

Figure 34-35. Reversible cerebral vasoconstriction syndrome. Axial (*left*) and sagittal (*right*) CT angiogram showing segmental narrowing of the middle and anterior cerebral artery branches (*arrows*).

have had small strokes. There may be an associated posterior leukoencephalopathy that is similar to the imaging appearance in hypertensive encephalopathy. Sometimes the headache is minimal and the attenuation of vessels is found in imaging performed for other reasons. The spinal fluid, except perhaps for elevated pressure, is normal.

The nature of this condition when there is no hyperadrenergic precipitant, trauma, or arterial dissection, is unknown. A relationship to hypertensive encephalopathy or to delayed postpartum eclampsia has been suggested because of the aforementioned white matter changes and the observation of widespread vasospasm in eclamptic women. Two of our patients have been in the postpartum period and other such patients with Call-Fleming have been described in the first 3 weeks after delivery. It is clear that, in addition to the idiopathic variety, several disorders cause this type of vasculopathy (see Table 34-10).

CEREBRAL VASCULITIS

Infectious Vasculitis

Inflammatory diseases of the blood vessels that are of infectious origin and their effects upon the nervous system are considered in detail in Chap. 32. There it was pointed out that meningovascular syphilis, tuberculous meningitis, fungal meningitis, and the subacute (untreated or partially treated) forms of bacterial meningitis may be accompanied by inflammatory changes in the walls of vessels that pass

through the subarachnoid space and result in occlusion of the arteries or veins. For example, a small deep stroke is the first clinical sign of chronic basilar meningitis, but more often it develops well after the meningeal symptoms are established. The nature of the cerebral vasculitis that may rarely accompany AIDS is unclear. Independent of this possible mechanism, an increasing incidence of stroke in patients with AIDS has drawn considerable attention, for example, the epidemiologic survey by Ovbiagele and Nath has indicated a 60 percent increase in hospitalizations for stroke in HIV patients over a recent decade. However, the autopsy study carried out by Connor and coworkers emphasized that the causes of stroke were of the mundane types seen in others, and, while some non-descript vasculopathy was seen in small vessels, this was not related to vasculitis.

Typhus, schistosomiasis, mucormycosis, aspergillosis, malaria, and trichinosis are infrequent causes of inflammatory arterial disease, which, unlike the above-mentioned infections, are not secondary to meningeal infections. In *typhus and other rickettsial diseases*, capillary and arteriolar changes and perivascular inflammatory cells are found in the brain; presumably they are responsible for the seizures, acute psychoses, cerebellar syndromes, and coma characterizing the neurologic disorder in these diseases. The internal carotid artery may be secondarily occluded in diabetic patients as part of the orbital and cavernous sinus infections with *mucormycosis*. In *trichinosis*, the cause of the cerebral symptoms has not been clearly established. Parasites have been found in the brain; in one of our patients the cerebral lesions were produced

by bland emboli arising in the heart and related to a severe myocarditis. In *cerebral malaria*, convulsions, coma, and, sometimes, focal symptoms appear to be due to the blockage of capillaries and precapillaries by masses of parasitized red blood corpuscles. Schistosomiasis may invade cerebral or spinal arteries. These diseases are discussed further in Chap. 32.

Noninfectious Inflammatory Diseases of Cranial Arteries

Included under this heading is a diverse group of arteritides that have little in common except their tendency to involve the cerebral vasculature. One group involves the larger caliber vessels and includes the *giant cell arteritides*—extracranial (temporal) arteritis; granulomatous arteritis of the brain; and aortic branch arteritis, one form of which is known as Takayasu disease.

A second group that affects the medium- and smaller-sized vessels includes polyarteritis nodosa, the Churg-Strauss type of arteritis, Wegener granulomatosis, systemic lupus erythematosus, Behçet disease, hypersensitivity angiitis, Kohlmeier-Degos disease, and the small vessel disorder of Susac syndrome. Immunologic studies show that in most of these processes there is an abnormal deposit of complement-fixing immune complex on the endothelium, leading to inflammation, vascular occlusion, or rupture with small hemorrhage. The initial inflammatory event is thought in some cases to be evoked by a virus, bacterium, or drug, but these are rarely proven in any one case. It is postulated by some immunologists that in the *granulomatous arteritides*, a different mechanism is operative—that an exogenous antigen induces antibodies that attach to the primary target (the vessel wall) as immune complexes, damage it, and attract lymphocytes and mononuclear cells. The giant cells form around remnants of the vessel wall. Wegener granulomatosis may fit this model. An acute necrotizing cerebral angiitis sometimes complicates ulcerative colitis and responds to treatment with prednisone and cyclophosphamide; it may also belong in this category. Mixed essential cryoglobulinemia, a vasculitic disorder that more often affects the peripheral than the central nervous system, may nonetheless produce an encephalopathy.

Temporal Arteritis (Giant Cell Arteritis, Cranial Arteritis) (See also Chap. 10)

In this disease, which is common among older persons, arteries of the external carotid system, particularly the temporal branches, are the sites of a subacute granulomatous inflammatory exudate consisting of lymphocytes and other mononuclear cells, neutrophilic leukocytes, and giant cells. The most severely affected parts of the artery usually become thrombosed. The sedimentation rate is characteristically elevated above 80 mm/h and sometimes exceeds 120 mm/h, but a small number of cases occur with values below 50 mm/h. The disease is included in this chapter because it uncommonly affects the extracranial internal and vertebral arteries and may result in stroke on the basis of ischemic occlusion or secondary embolus. However, significant inflammatory involvement

of *intracranial arteries* from temporal arteritis is uncommon, perhaps because of a relative lack of elastic tissue.

Regional or bilateral headache or head pain is the chief complaint, and there may be severe pain, aching, and stiffness in the proximal muscles of the limbs associated with the markedly elevated sedimentation rate. Thus the clinical picture overlaps that of *polymyalgia rheumatica* as discussed in Chap. 10. Occlusion of branches of the ophthalmic artery (mainly those to the posterior ciliary artery and the choroidal circulation that supply the anterior optic nerve) results in blindness in one or both eyes, is the most feared complication, often unpredictably. This is one of the main forms of anterior ischemic optic neuropathy discussed in Chap. 13. In a few cases, blindness is preceded by transient visual loss, thereby simulating a TIA (transient monocular blindness). Other symptoms include jaw claudication due to ischemia of the masseter muscles. Occasionally the arteries of the oculomotor nerves are also involved, causing various ophthalmoplegias.

The administration of prednisone, 50 to 75 mg/d, provides striking relief of the headache and polymyalgic symptoms within days and sometimes within hours, and also prevents blindness. The medication must be given in very gradually diminishing doses for at least several months or longer, guided by the symptoms and the sedimentation rate. The latter begins to drop within days but seldom falls below 25 mm/h. These issues are discussed in greater detail in Chap. 10.

Intracranial Granulomatous Arteritis

Scattered examples of small- and medium-sized vessel giant cell arteritis of undetermined etiology in which only brain vessels are affected have come to medical attention over the years. The clinical aspects have taken diverse forms, sometimes presenting as low-grade, nonfebrile meningitis with sterile CSF followed by infarction of one or several parts of the cerebrum or cerebellum. In other cases it has evolved over a period of weeks, with strokes or an unusual dementia. Headaches (variable in our experience but sometimes severe), focal cerebral or cerebellar signs of gradual (occasionally stroke-like) evolution, confusion with memory loss, pleocytosis and elevated CSF protein, and papilledema as a result of increased intracranial pressure (in about half of reported cases but far fewer in our experience) constitute the most frequently encountered syndromes. The symptoms usually persist for several months. In contrast to temporal arteritis, the sedimentation rate is generally normal or only slightly elevated. An extensive early report given by Kolodny and colleagues still serves as a useful reference.

In about half the patients the diagnosis can be made by angiography, which demonstrates an irregular narrowing and in some cases blunt ending of several medium-sized cerebral arteries (Fig. 34-36). CT and MRI show multiple irregular white matter and cortical changes and small cortical lesions; sometimes these cannot be differentiated from a tumor or demyelinating or infectious process. If the white matter abnormalities become confluent, the radiologic appearance simulates Binswanger disease. The diagnosis is made most often by a brain biopsy, which includes a sample of the meninges with vessels, but even

Figure 34-36. Granulomatous angiitis of the brain. Cerebral arteriogram from a common carotid artery injection, lateral projection, demonstrating numerous areas of irregular narrowing (arrows) and, in some areas, contiguous slight dilatation (“beading”), particularly in the anterior cerebral artery.

with tissue sampling, about half of suspected cases show the typical histopathologic changes. It is not unusual, however, for patients with normal angiograms to have the typical arteritic findings on biopsy. Tissue excised during an operation (or brain biopsy) for a suspected brain tumor, lymphoma, or white matter disease has revealed the characteristic vasculitis in some of our patients; in others, the diagnosis has been made only at autopsy, the findings coming as a distinct surprise.

The affected vessels are mainly in the 100- to 500- μ m diameter arteries and arterioles and are surrounded and infiltrated by lymphocytes, plasma cells, and other mononuclear cells; giant cells are distributed in small numbers in the media, adventitia, or perivascular connective tissue. Infarction of brain tissue can be traced to widespread thrombosis in these vessels. The meninges are variably infiltrated with inflammatory cells. Sometimes only a part of the brain has been clinically affected—in one of our cases the cerebellum, in another, one frontal lobe and the opposite parietal lobe.

Among the most important considerations in this disease is the cerebral arteritis caused by varicella zoster virus of the ophthalmic division of the trigeminal nerve; it simulates in radiographic appearance granulomatous arteritis and giant cell arteritis. On occasion, intravascular lymphoma may present a similar picture and sympathomimetic agents, as mentioned earlier, cause a vasculopathy with segmental narrowing of cerebral vessels that has many similarities. The clinical and radiologic appearance of brain arteritis also raises the question of sarcoidosis, which is sometimes limited to the nervous system, of CADASIL,

Antiphospholipid Antibody syndrome, or of the polyarteritis (allergic granulomatous angiitis) described by Churg and Strauss. Unlike some of these diseases, however, the lungs and other organs are spared; there is no systemic eosinophilia, increase in sedimentation rate or antineutrophil cytoplasmic antibodies (ANCA), or anemia.

Some patients with isolated angiitis of nervous system presenting as an aseptic meningitis and multiple cerebral infarcts have responded to corticosteroid and cyclophosphamide therapy (Moore, 1994), and we have used this combined approach from the time the diagnosis is established. The severity and configurations of the process are so variable that judging the effects of treatment is difficult, but our untreated patients have uniformly deteriorated or died without treatment.

Takayasu Disease (“Pulseless Disease”)

This is a nonspecific chronic arteritis involving mainly the aorta and the large arteries arising from its arch. It is similar in some ways to giant cell arteritis except for its propensity to involve the proximal rather than the distal branches of the aorta. Most of the patients have been young Asian women, but there are now numerous reports of similar cases from the United States, Latin America, and Europe. The etiology has never been ascertained but an autoimmune mechanism is suspected.

Constitutional symptoms such as malaise, fever, anorexia, weight loss, and night sweats usually introduce the illness. The erythrocyte sedimentation rate is elevated in the early and active stages. Later there is evidence of occlusion of the brachiocephalic, subclavian, carotid, vertebral, and other arteries that may be asymptomatic or cause neurologic ischemic symptoms. The affected arteries no longer pulsate, hence the descriptive term *pulseless disease*. When renal arteries are involved, hypertension results, and there may be coronary occlusion, which may be fatal. Involvement of the pulmonary artery may lead to pulmonary hypertension. Coolness of the hands and weak radial pulses are common indicators of the disease and headaches are frequent. Blurring of vision, especially upon physical activity or fever, dizziness, and hemiparetic and hemisensory syndromes are the usual neurologic manifestations (Lupi-Herrera et al). The frequency of posturally induced neurologic symptoms has been emphasized, as well as the relative infrequency of major strokes despite multiple TIA-like spells. The inflamed vessels in the thorax are revealed by radionuclide scans using gallium. Pathologic studies disclose a periarteritis of the large vessels, often with giant cells and reparative fibrosis.

Many of the patients die in 3 to 5 years. According to Ishikawa and colleagues, the administration of corticosteroids in the acute inflammatory stage of the disease improves the prognosis. Reconstructive vascular surgery has helped some of the patients in the later stages of the disease.

Polyarteritis Nodosa and Churg-Strauss Angiitis of Cerebral Vessels

The inflammatory necrosis of arteries and arterioles throughout the body in this disease rarely affects the

central (in contrast to frequent involvement of the peripheral) nervous system. The lungs are usually spared, which is the basis of distinguishing polyarteritis vasculitis from the Churg-Strauss granulomatous angiitis. It has been estimated that the brain is involved in fewer than 5 percent of cases of either of these processes and takes the form of one or more microinfarcts; macroscopic infarction is a rarity. The clinical manifestations vary and have included headache, confusion and fluctuating cognitive disorders, convulsions, hemiplegia, and brainstem signs. We have also observed one instance of acute spinal cord lesions. Brain hemorrhage is rare and usually occurs in a setting of extreme renal hypertension. Both of these diseases assume greater importance in the field of vasculitic neuropathy as discussed in Chap. 46.

Wegener Granulomatosis

This is a rare disease of unknown cause, affecting adults as a rule and favoring males slightly. A subacutely evolving vasculitis with necrotizing granulomas of the upper and lower respiratory tracts followed by necrotizing glomerulonephritis are its main features. Neurologic complications come later in one-third to one-half of cases and take two forms: (1) a peripheral neuropathy either in a pattern of polyneuropathy or, far more frequently, in a pattern of mononeuropathy multiplex (see discussion in Chap. 46), and (2) multiple cranial neuropathies as a result of direct extension of the nasal and sinus granulomas into adjacent upper cranial nerves and from adjacent to pharyngeal lesions to the lower cranial nerves (see Chap. 47). We have seen this disease produce the syndrome of episodic hemicrania, with periorbital ecchymosis. The basilar parts of the skull may be eroded, with spread of granuloma to the cranial cavity and more remote parts. A description is included here because cerebrovascular events, seizures, and cerebritis are less common but well-described neurologic complications. Spastic paraparesis, temporal arteritis, Horner syndrome, and papilledema have been observed but are rare (see Nishino et al). The orbits are involved in 20 percent of patients and lesions here simulate the clinical and radiologic appearance of orbital pseudotumor, cellulitis, or lymphoma. Pulmonary granulomas, usually asymptomatic but evident on a chest CT, are also common.

The vasculitis implicates both small arteries and veins. There is a fibrinoid necrosis of their walls and an infiltration by neutrophils and histiocytes. The sedimentation rate is elevated, as are the rheumatoid and antiglobulin factors. The presence in the blood of cytoplasmic antineutrophil cytoplasmic antibodies (cANCA) has been found to be relatively specific and sensitive for Wegener disease but it may also be present in intravascular lymphoma.

A degree of therapeutic success in this formerly fatal disease has been achieved by the use of cyclophosphamide, chlorambucil, rituximab, or azathioprine. Cyclophosphamide in oral doses of 1 to 2 mg/kg per day has ameliorated 90 to 95 percent of the cases. In acute cases, rapidly acting steroids—prednisone, 50 to 75 mg/d—is usually given in conjunction with the immunosuppressant drug(s).

Systemic Lupus Erythematosus

Involvement of the nervous system is an important aspect of this disease. In the pathologic and clinical series reported by Johnson and Richardson, the central nervous system (CNS) was affected in 75 percent of cases, but our recent experience has suggested a lower frequency of clinical manifestations, especially if minor neurologic aspects such as headache are excluded. Disturbances of mental function—including alteration of consciousness, seizures, and signs referable to cranial nerves—are the usual neurologic manifestations; most often they develop in the late stages of the disease, but they may occur early and may be mild and transient. Hemiparesis, paraparesis, aphasia, homonymous hemianopia, movement disorders (chorea), and derangements of hypothalamic function occur but have been infrequent in our experience. Larger infarcts are usually traceable to emboli from Libman-Sacks (a form of nonbacterial thrombotic) endocarditis.

In some instances the CNS manifestations resemble multiple sclerosis, especially when there is an optic neuritis or myelopathy. Two manifestations that should be noted are of “longitudinally extensive myelopathy” that simulates Devic disease, and of white matter changes in the cerebral hemispheres with varied clinical manifestations, (“Sjogren sclerosis,” or “lupus sclerosis”). These are discussed in Chap. 36 with multiple sclerosis and diseases that simulate it. The presence of serum antinuclear antibodies is of help in the differentiation of lupus erythematosus but in itself does not establish the diagnosis. Antibodies to double-stranded DNA (anti-dsDNA) are a sensitive indicator of the disease. The CSF is normal or shows only a mild lymphocytic pleocytosis and slight increase in protein content, although in some patients—primarily those with peripheral neuropathy and myelopathy—the protein content may be greatly increased.

Some of the neurologic manifestations can be accounted for by widespread microinfarcts in the cerebral cortex and brainstem; these, in turn, are related to destructive and proliferative changes in arterioles and capillaries. The acute lesion is subtle; it is not a typical fibrinoid necrosis of the vessel wall, like that in hypertensive encephalopathy, and there is no cellular infiltration. Attachment of immune complexes to the endothelium is the postulated mechanism of vascular injury. Thus, the changes do not represent a vasculitis in the strict sense of the word. However, there is also an immune component to some of the white matter and cord lesions that do not require implicating a vasculopathy (see Chap. 36).

Other neurologic manifestations are related to hypertension, which frequently accompanies the disease and may precipitate cerebral hemorrhage; to endocarditis, which may give rise to cerebral embolism; to thrombotic thrombocytopenic purpura, which commonly complicates the terminal phase of the disease (Devinsky et al); and to treatment with corticosteroids, which may precipitate or accentuate muscle weakness, seizures, and psychosis. In other cases, steroids appear to improve these neurologic manifestations. A similar set of neurologic problems arises in relation to the antiphospholipid antibody syndrome,

which may be a feature of lupus or arise independently (see “Antiphospholipid Antibody (Hughes Syndrome”). It is not entirely clear to us what proportion of the cerebrovascular features of lupus might be explained on the basis of the coagulation disorder or Libman-Sacks endocarditis.

Arteritis Symptomatic of Underlying Systemic Disease and Sympathomimetic Drug Ingestion

Drug-induced vasculitis, typical of the ingestion of sympathomimetic compounds, is difficult to distinguish from a more common state of focal vasospasm that may also be induced by these same agents, as discussed earlier under “Diffuse and Focal Cerebral Vasospasm, Call-Fleming Syndrome, Postpartum Cerebral Vasculopathy.” A true cerebral or spinal cord vasculitis can occur in association with systemic lymphoma, particularly with Hodgkin disease. The nature of this process is indeterminate but may be related to the deposition of circulating immune complexes in the walls of cerebral vessels.

The cerebrovascular problems resulting from cocaine use are quite varied. Seizures and death may occur as a result of a syndrome of delirium and extreme hyperthermia. More pertinent to this chapter are the strokes that arise during and just after cocaine use. Here, as emphasized by Levine and colleagues (1991), a clear distinction should be made between the complications of cocaine hydrochloride (the usual form of ingestible cocaine) and the alkaloid form, or “crack cocaine.” The former, when injected intravenously more so than when used intranasally, is prone to cause cerebral hemorrhage as a result of acute hypertension, similar to the bleeding that may be precipitated by other sympathomimetic drugs such as amphetamine and phenylpropanolamine. Both subarachnoid and intracerebral hemorrhage may result. Or, the features of hypertensive encephalopathy are precipitated, including changes in the posterior white matter of the cerebral hemispheres that are so striking on imaging studies (PRES, as discussed earlier). The strokes with crack cocaine, however, are more often ischemic, typically involving the territory of a large vessel. Some ambiguity attends the vasculopathy induced by crack cocaine, cocaine hydrochloride, and the amphetamines, particularly the first of these. There are undoubted instances of a true cerebral inflammatory vasculitis, perhaps of a hypersensitivity type such as those reported with biopsy verification by Krendel and colleagues, by Merkel and associates, and by others. What is confusing about these cases is the normal angiographic appearance in many instances and large vessel occlusions in others, in contrast to the pathologic changes, which are concentrated in small cortical vessels. Many cases seem to be of an entirely different type, displaying long segments of vascular attenuation in the angiogram and no evidence of an inflammatory process in biopsy or autopsy material. The correct treatment, aside from lowering the blood pressure, is uncertain. A similar apparently vasospastic disorder is emerging from the use of *high-potency cannabinoids* (e.g., K-2, “spice”), including strokes.

Whether there is an increased incidence of arteriovenous malformation and cerebral aneurysm in patients who have cerebral hemorrhages after ingestion of cocaine,

as suggested in several articles, is uncertain but this, in any case, suggests that sympathomimetic drugs can precipitate hemorrhage from an underlying developmental vascular lesion (Fessler et al).

Crack cocaine may also cause a choreiform disorder (“crack dancing”), not unlike that associated with antiphospholipid antibody but generalized rather than focal (see further on); usually there are small infarctions in the basal ganglia, but an immune mechanism has also been suggested.

Another entirely different type of small vessel arteritis occurs as a hypersensitivity phenomenon. Often it is associated with an allergic skin lesion (Stevens-Johnson vasculopathy or a leukocytoclastic vasculitis). The clinical picture does not resemble that of polyarteritis nodosa, but the central or peripheral nervous system is affected in rare instances. The response to corticosteroids is excellent.

The special case of intravascular lymphoma, which closely simulates a cerebral vasculitis, is discussed in Chap. 31.

Susac Syndrome

This is yet another poorly understood form of vasculitis, consisting of a microangiopathy affecting mainly the brain and retina. Psychiatric symptoms, headache, dementia, sensorineural deafness, vertigo, and impairments of vision are the clinical manifestations. Funduscopy (multiple retinal artery branch occlusions) and retinal angiography manifest evidence of the vasculopathy (Susac and colleagues, 1979). The MRI may show characteristic white matter lesions, particularly in the corpus callosum (see Susac and colleagues, 2003). Antibodies to endothelial cells have been identified by Magro and colleagues in many of the cases. The patients seem to respond to steroid therapy. Only biopsy material has been examined.

Behçet Disease

This disorder is suitably considered here because it is a chronic, recurrent vasculitis, involving small vessels, with prominent neurologic manifestations. It is most common in Turkey, where it was first described, in other Mediterranean countries, and in Japan, but it occurs throughout Europe and North America, affecting men more often than women. The disease was originally distinguished by the triad of relapsing iridocyclitis and recurrent oral and genital ulcers, but it is now recognized to be a systemic disease with a much wider range of symptoms, including erythema nodosum, thrombophlebitis, polyarthritis, ulcerative colitis, and a number of neurologic manifestations, some of them encephalitic or meningitic in nature. The most reliable diagnostic criteria, according to the International Study Group that assembled data on 914 cases from 12 medical centers in 7 countries, were recurrent aphthous or herpetiform oral ulceration, recurrent genital ulceration, anterior or posterior uveitis, cells in the vitreous or retinal vasculitis, and erythema nodosum or papulopustular lesions.

The nervous system is affected in approximately 30 percent of patients with Behçet disease (Chajek and Fainaru); the manifestations are recurrent meningoencephalitis, cranial nerve (particularly abducens) palsies, cerebellar ataxia, corticospinal tract signs, and venous

occlusion disease. There may be episodes of diencephalic and brainstem dysfunction resembling minor strokes. A few postmortem examinations have related these small foci of necrosis to a vasculitis, including perivascular and meningeal infiltration of lymphocytes. There may also be cerebral venous thrombosis. The neurologic symptoms usually have an abrupt onset and are accompanied by a brisk spinal fluid pleocytosis (lymphocytes or neutrophils may predominate), along with elevated protein but normal glucose values (in one of our patients, 3,000 neutrophils per cubic millimeter were found at the onset of an acute meningitis). As a rule, neurologic symptoms clear completely in several weeks, but they have a tendency to recur, and some patients are left with persistent neurologic deficits. Rarely, the clinical picture is that of a progressive confusional state or dementia (see the reviews of Alema and of Lehner and Barnes for detailed accounts).

The cause of Behçet disease is unknown. A pathergy skin test—the formation of a sterile pustule at the site of a needle prick—is listed as an important diagnostic test by the International Study Group, but on the basis of admittedly limited U.S. experience, we and our colleagues have found it to be of questionable value. Administration of corticosteroids has been the usual treatment, on the assumption of an autoimmune etiology. Because the episodes of disease naturally subside and recur, evaluation of treatment is difficult.

THROMBOSIS OF CEREBRAL VEINS AND VENOUS SINUSES

Thrombosis of the cerebral venous sinuses, particularly of the superior sagittal or lateral sinus and the tributary cortical and deep veins, gives rise to a number of important neurologic syndromes. Cerebral vein thrombosis may develop in relation to infections of the adjacent ear and paranasal sinuses or to bacterial meningitis, as described in Chap. 32. More common is noninfectious venous occlusion resulting from one of the many hypercoagulable states discussed below.

Occlusion of cortical veins that are the tributaries of the dural sinuses takes the form of a venous infarctive stroke. It may be difficult to determine if the thrombus originated in the dural sinuses and propagates to the tributary cortical veins, or the reverse. The diagnosis is difficult except in certain clinical settings known to favor the occurrence of venous thrombosis, such as the taking of birth control pills or postpartum and postoperative states, which are often characterized by thrombocytosis and hyperfibrinogenemia. Hypercoagulable conditions also occur in cancer (particularly of the pancreas and colon and other adenocarcinomas), cyanotic congenital heart disease; cachexia in infants; sickle cell disease; antiphospholipid antibody syndrome, the aforementioned Behçet disease, factor V Leiden mutation, protein S or C deficiency, antithrombin III deficiency, resistance to activated protein C; primary or secondary polycythemia and thrombocythemia; and prooxysmal nocturnal hemoglobinuria.

The administration of drugs such as tamoxifen, bevacizumab, and erythropoietin, and even the hypercoagulable reaction to heparin that is associated with thrombocytopenia have all been cited as risks for cerebral venous thrombosis.

The study by Martinelli and colleagues, mentioned earlier in the chapter, attributed 35 percent of cases of cerebral vein thrombosis in the context of oral contraceptive use to a mutation in the factor V or in the prothrombin gene. Averback, who reported seven cases of venous thrombosis in young adults, has emphasized the diversity of the clinical causes. Two of his patients had carcinoma of the breast and one had ulcerative colitis. A few cases will follow head injury or remain unexplained.

A stroke in a patient suffering from any one of these systemic conditions should suggest venous thrombosis, although in some instances—e.g., postpartum strokes—arteries are occluded as often as veins. A slower evolution of the clinical stroke syndrome, the presence of multiple cerebral lesions not in arterial territories, and a convulsive and hemorrhagic character favor venous over arterial thrombosis.

The reasons for these clinical features and their variability as well as the differences from ischemic brain damage caused by arterial occlusion become apparent in the discussions below. Stam has undertaken a review of this subject.

Cortical Vein Thrombosis (Superficial Thrombosis of Cortical Veins)

Certain syndromes occur with sufficient regularity that they suggest thrombosis of a particular vein or sinus. The signature features of isolated *thrombosis of superficial cortical veins* are the presence of large superficial (cortex and subjacent white matter) hemorrhagic infarctions and a marked tendency to focal seizures. Hemiparesis, incomplete hemianopia, and aphasia, any of which may fluctuate over days, are also characteristic according to Jacobs and colleagues. These variable syndromes reflect the inconstant location of the main surface veins. Thrombosis of the vein of Labbé causes infarction of the underlying superior temporal lobe, and occlusion of the vein of Trolard implicates the parietal cortex. A concern is the propagation of the clot into the larger draining veins or dural sinuses.

Quite often, in our experience, the focal deficit worsens immediately after a focal seizure. The intracranial pressure is not elevated, as it is when the dural venous sinuses are occluded. The diagnosis is made by careful examination of the MRV or by the venous phase of the conventional angiogram. Cortical vein thrombosis should be suspected in the situation of multiple hemorrhagic infarctions in one hemisphere without a source of embolism or atherothrombosis.

Dural Sinus Thrombosis

Sagittal and Transverse (Lateral) Sinus Thrombosis

In the case of *sagittal sinus thrombosis*, intracranial hypertension with headache, vomiting, and papilledema may constitute the entire syndrome; this is the main consideration in the differential diagnosis of pseudotumor cerebri

(see Chaps. 13 and 30) or it may be conjoined with hemorrhagic infarction. Paraparesis, hemiparesis, fluctuating unilateral or bilateral sensory symptoms, or aphasia result only if the thrombosis propagates to surface veins. Focal or odd sensory or motor seizures occur on the same basis but are not as common as with cortical vein thrombosis.

The transverse sinuses are usually asymmetrical; slightly more than half of individuals have a dominant right vein and approximately a quarter are symmetrical. (The larger sinus corresponds to a smaller occipital lobe on that side—a *petalia*). Unilateral occlusion of the nondominant transverse sinus may not be symptomatic, whereas thrombosis of the dominant side generally gives the equivalent syndrome to blockage of the sagittal sinus. Increased intracranial pressure without ventricular dilatation occurs with thrombosis of the superior sagittal sinus, the main jugular vein, and the transverse sinus or the confluence of the sinuses.

The common imaging feature that results from occlusion of the superior sagittal sinus is of bilateral superficial paramedian parietal or frontal hemorrhagic infarctions or edematous venous congestion. In the case of CT with contrast infusion in axial images, a lack of dye opacification in the posterior sagittal sinus can be observed with careful adjustment of the viewing window ("empty delta sign"). The spinal fluid pressure is increased, and the fluid may be slightly sanguinous. Transverse sinus thrombosis causes hemorrhagic infarction of the temporal lobe convexity, usually with considerable vasogenic edema. The enhanced CT, arteriography (venous phase), and MRV (Fig. 34-37) facilitate diagnosis by directly visualizing the venous occlusion by showing an absence of opacification of a sinus or, at times, a clot within a vein. Once a venous thrombosis becomes established for several days or longer, the tributary surface veins take on a "corkscrew" appearance that is appreciated on the venous phase of an angiogram.

Cavernous Sinus Thrombosis As pointed out in Chaps. 13 and 14, in cases of *cavernous sinus thrombosis* there may be marked chemosis and proptosis, corresponding to

a clot in the anterior portion of the sinus and there may be disordered function of cranial nerves III, IV, VI, and the ophthalmic division of V when the posterior portion is affected. If there is spread of the clot to the inferior petrosal sinus, palsies of cranial nerves VI, IX, X, and XI may result. Also involvement of the *superior petrosal sinus* may be accompanied by a fifth nerve palsy.

Thrombosis of the venous sinuses in neonates presents special problems in diagnosis. In the series reported by deVeber and colleagues, various perinatal complications, including systemic illness such as severe dehydration or infection were common precedents; the outcome was poor. In young children the risk factors differed, in that connective tissue and prothrombotic disorders and head and neck infections were more common.

Deep Cerebral Vein Thrombosis

Occlusion of the vein of Galen and of the internal cerebral veins is the least common and clinically most obscure of the venous syndromes.

From the few cases that have been studied, a picture of bithalamic infarction emerges, sometimes reversible, and consisting mainly of inattention, spatial neglect, and amnesia in the case reported by Benabdeljili and colleagues, and of akinetic mutism and apathy in the case of Gladstone and associates. The case series of van den Bergh and colleagues emphasizes the difficulty in diagnosis of partial syndromes of this nature. In most reports of this condition, it is the neuropsychologic aspects that are emphasized. Other cases have manifested coma and pupillary changes referable to the ischemic diencephalon and rostral midbrain. Perhaps most striking is the MRI, with a large bilobular region of signal change that encompasses the thalami. Much of the signal change probably represents reversible edema and venous congestion, because substantial clinical improvement may occur. Angiography is needed to confirm the diagnosis, most often a magnetic resonance venogram.

Figure 34-37. Venous sinus thrombosis. Coronal (left) and sagittal (center) magnetic resonance venogram demonstrating absence of flow in the superior sagittal and left transverse sinuses (arrows). Note that the straight sinus and right transverse sinuses remain patent. Axial T2-FLAIR MRI shows left otomastoiditis, which was the cause of the extensive thrombosis.

Treatment of Cerebral Venous Thrombosis

Anticoagulant therapy beginning with heparin or an equivalent for several days, followed by warfarin, and combined with antibiotics if the venous occlusion is infectious (it rarely is in recent times) has been lifesaving in some cases. Nonetheless, the overall mortality rate remains high, with large hemorrhagic venous infarctions found in 10 to 20 percent of cases. The clinical trial conducted by Einhaupl and colleagues generally settled the question of therapy in favor of aggressive anticoagulation, but this could not be confirmed by de Bruijn and coworkers, who found a minimal difference between patients who were treated with low-molecular-weight heparin followed by oral anticoagulation. Most treated patients do well, but it may take weeks for the headaches to remit. Coma and multiple cerebral hemorrhages, on the other hand, are usually fatal.

The local infusion of tPA has been used, but not subjected to the same randomized testing. Thrombolytic therapy by local venous or systemic infusion has been successful in small series of cases, such as the 5 patients treated with urokinase and heparin by DiRocco and colleagues. We have reserved thrombolysis for extreme cases of dural sinus thrombosis with stupor or coma and greatly raised CSF pressure.

STROKE DUE TO HYPERCOAGULABLE STATES

Nonbacterial Thrombotic (Marantic) Endocarditis

Sterile vegetations, referred to also as *nonbacterial thrombotic endocarditis*, consist of fibrin and platelets and are loosely attached to the mitral and aortic valves and contiguous endocardium. They are a common source of cerebral embolism (almost 10 percent of all instances of cerebral embolism according to Barron et al, but lower in the experience of other series). In past series, almost half the patients had vegetations associated with a malignant neoplasm; the remainder occurs in patients debilitated by other diseases (Biller et al). Recent experience suggests that the majority is related to systemic cancer.

The setting in which embolism from nonbacterial endocarditis occurs is distinctive. There may also be prototypic clinical features that permit differentiation from other forms of cerebral embolism. In particular, the strokes may be multiple, sequential over days or weeks, and generally small, imparting a picture of incomplete stroke syndromes with a superimposed encephalopathy. The sudden nature of the embolic deficits helps to distinguish this process from the usual forms of cerebral metastases.

The disease is essentially a manifestation of chronic disseminated intravascular coagulation (DIC) discussed below and therefore it is not surprising that similar laboratory changes are found, including an elevation in circulating fibrin split products, specifically D-dimer and indications of microangiopathic hemolysis in the blood smear. There

is typically moderate thrombocytopenia. The echocardiogram is often obtained but it is insensitive.

The hazards of using anticoagulants in gravely ill patients with widespread malignant disease may outweigh the benefits from this treatment, but drugs that prevent platelet aggregation, while possibly helpful, have not been studied systematically for this condition. Quite often the embolic strokes continue despite treatment.

Stroke as a Complication of Hematologic Disease

The brain is involved in the course of many hematologic disorders, some of which have already been mentioned. A number of the better-characterized ones are discussed here.

Disseminated Intravascular Coagulation

This is perhaps the most common and most serious disorder of coagulation affecting the nervous system. The basic process depends on the release of thromboplastic substances from damaged tissue, resulting in the activation of the coagulation process and the formation of fibrin, in the course of which clotting factors and platelets are consumed. Virtually any mechanism that produces tissue damage can result in the release of tissue thromboplastins into the circulation. Thus, disseminated intravascular coagulation (DIC) complicates a wide variety of clinical conditions—overwhelming sepsis, massive trauma, cardiothoracic surgery, heat stroke, burns, incompatible blood transfusions and other immune complex disorders, diabetic ketoacidosis, leukemia, obstetric complications, cyanotic congenital heart disease, and shock from many causes.

The essential pathologic change in DIC is the occurrence of widespread fibrin thrombi in small vessels, resulting in numerous small infarctions of many organs, including the brain. Sometimes DIC is manifest by a hemorrhagic diathesis in which petechial hemorrhages are situated around small penetrating vessels. In some cases, cerebral hemorrhage is quite extensive, similar to a primary hypertensive hemorrhage. The main reason for the hemorrhage is the consumption of platelets and various clotting factors that occurs during fibrin formation; in addition, fibrin degradation products have anticoagulant properties of their own.

The diffuse nature of the neurologic damage may suggest a metabolic rather than a vascular disorder of the brain. In the absence of a clear metabolic, infective, or neoplastic cause of an encephalopathy, the onset of acute and fluctuating focal neurologic abnormalities or a generalized and sometimes terminal neurologic deterioration during the course of a severe illness should arouse suspicion of DIC, and coagulation factors and fibrin split products should be measured. Platelet counts are invariably depressed and there is evidence of consumption of fibrinogen and other clotting factors, indicated by prolonged prothrombin and partial thromboplastin times.

In the related illness abbreviated as HELLP mentioned earlier in the sections on hypertensive and eclamptic encephalopathy, women with eclampsia develop liver failure and thrombocytopenia; the contribution of this limited form of DIC to the eclamptic

effects on the nervous system have not been established (see earlier discussion of eclampsia).

Antiphospholipid Antibody (Hughes) Syndrome

This condition, in which TIAs, or stroke, migraine, and thrombocytopenia in various combinations, occur in young adults, has already been discussed under "Strokes in Children and Young Adults." Phospholipids are a family of lipoproteins that influence clotting. Some of the phospholipids with which the antibodies react are shared with clotting factors, particularly prothrombin. Autoantibodies directed at the binding protein of phospholipids thereby induce blood clotting. The first of the antibodies to be described were *lupus anticoagulant* and *anticardiolipin*. Most classifications of the antiphospholipid syndrome also include antibodies to β_2 -glycoprotein 1, a protein that may be necessary for the binding and procoagulant effect of anticardiolipin antibody. The formal criteria for the diagnosis of the syndrome require that an ischemic event be accompanied by the detection of autoantibodies on two occasions at least 6 weeks apart.

Testing for this disease consists of detection of IgM, IgG, and mixed antibodies to each of these three main phospholipids; there is a partial overlap in many patients, in which more than one antibody subclass is present against more than one lipoprotein—80 percent of patients with lupus anticoagulant have anticardiolipin antibody but fewer than 50 percent of those with anticardiolipin antibody have lupus anticoagulant. Antibodies to β_2 -glycoprotein 1 are most specific for the disease. Nonetheless, the main laboratory feature of the illness is a prolonged partial thromboplastin time. The titer of anticardiolipin broadly correlates with the risk of thrombosis and the specificity for the syndrome is higher for IgG than for IgM autoantibodies. An increased incidence of migraine has long been discussed and also disputed. A review has been given by Levine.

These comments pertain mainly to a "primary" idiopathic autoimmune form of the disease but many cases occur secondarily to lupus erythematosus, Sjögren disease, neuroleptic drugs such as the phenothiazines, butyrophenones and others drugs, and to certain infections.

The most frequent neurologic abnormality is a TIA, often taking the form of amaurosis fugax (transient monocular blindness), with or without retinal arteriolar or venous occlusion (Digre et al). Stroke-like phenomena are more frequent in patients who also have migraine, hyperlipidemia, or antinuclear antibodies, and in those who smoke or take birth control pills. Almost one-third of the 48 patients reported by Levine and associates (1990) had thrombocytopenia and 23 percent had a false-positive Venereal Disease Research Laboratory (VDRL) test. The vascular lesions are mainly in the cerebral white matter and are infarcts, seen well with MRI. Angiography reveals occlusions of arteries at unusual sites (Brey et al). The mechanism of stroke is not entirely clear and may derive from emboli originating on mitral valve leaflets similar to nonbacterial thrombotic endocarditis; alternatively, and more likely in our view, there is a noninflammatory *in situ* thrombosis of medium-sized cerebral vessels, as suggested by the limited pathologic material studied by Briley and colleagues.

These circulating antibodies may also cause a syndrome of transient bilateral chorea or hemichorea; some patients have an additional slight hemiparesis or other subtle focal signs. Almost all of the affected patients we have seen have been women with thrombocytopenia, some of whom probably had systemic lupus, at least on the grounds of laboratory studies. A direct connection of the choreic syndrome to the antibodies comparable to what is proposed in Sydenham chorea may be valid, but at the moment is unproven. Some cases display microinfarctions in the basal ganglia, perhaps on the basis of valvular vegetations. The choreic syndrome may be precipitated in these patients by the introduction of estrogen-containing birth control pills and is improved, usually promptly, by corticosteroids or antiplatelet agents.

The *Sneddon syndrome* is an arteriopathy producing deep blue-red skin lesions of livedo reticularis and livedo racemosa in association with multiple ischemic strokes. Many, but not all, patients have high titers of antiphospholipid antibodies. Although the skin lesions show a noninflammatory vasculopathy with intimal thickening, the pathology of the occlusive disease has not been adequately studied. In a report of 17 such patients by Stockhammer and coworkers, 8 had strokes and MRI showed lesions in 16 patients. The age of patients with strokes was 30 to 35 years; hence this condition is considered in young adults with cerebrovascular disease. Many of the lesions on MRI were small, deep, and multiple. Although there is a tendency for strokes to recur, many of the patients have remained well for years after a single stroke. Skin biopsy aids in diagnosis.

There are instances in which the radiologic changes caused by recurrent small infarctions of antiphospholipid syndrome are difficult to distinguish from multiple sclerosis, as discussed in several parts of Chap. 36, on demyelinating diseases. Associations of the antiphospholipid syndrome with transverse myelitis (see Chap. 44), hearing loss, and a number of other processes have been suspected but not proven.

Treatment During the period in which the diagnosis is being established by repeating the antibody tests, or after just a single arterial ischemic stroke, consensus groups have stated that it is reasonable to treat these patients with antiplatelet or anticoagulant agents (see Lim and colleagues). Warfarin, the definitive therapy, alters the testing for antibodies and several guidelines recommend confirming the presence of antibodies after an interval of two weeks before starting treatment. However, warfarin has been used with greatest benefit and we have sometimes started this medication on suspicion of the syndrome. Khamashta and colleagues have found that the INR must be maintained close to 3 for effective prevention of stroke. According to the study conducted by Crowther and colleagues, an INR of 2 to 3 conferred the same degree of protection from thrombosis as did higher levels, but the number of thrombotic events was low in both groups and there was only 1 stroke in 114 patients over a period of about 3 years. Patients with severe thrombocytopenia and with other intrinsic coagulopathies should be treated with warfarin very cautiously. Although the INR is used as a gauge of

the level of anticoagulation, it is also altered by the antibodies; no ideal method for monitoring the treatment has been devised. Aspirin, on uncertain grounds, is thought not to confer protection for stroke, but in only a few small series has its effect been analyzed. In "catastrophic" cases with repetitive strokes, intravenous immunoglobulin and plasma exchange have been used with some effect.

It is important to eliminate smoking and estrogen-containing compounds, as these greatly raise the risk of stroke in this syndrome. Aspirin and heparin are favored in women with recurrent fetal loss related to antiphospholipid antibody (Lockshin and Sammaritano).

Thrombotic Thrombocytopenic Purpura (TTP, Moschowitz Syndrome) and Hemolytic Uremic Syndrome

These are serious diseases of the small blood vessels combined with microangiopathic hemolytic anemia characterized by widespread occlusions of arterioles and capillaries involving practically all organs of the body, including the brain. It was described by Adams and colleagues (1948) and named thrombotic thrombocytopenic purpura. Fibrin components have been identified by immunofluorescent techniques; some investigators have demonstrated disseminated intravascular platelet aggregation rather than fibrin thrombi. Sporadic TTP is caused by an acquired circulating IgG inhibitor of the von Willebrand factor-cleaving protease (termed "a disintegrin and metalloproteinase with thrombospondin type 1 motif, member 13 [ADAMTS13]"). A rarer familial form (The Upshaw-Shulman syndrome) is caused by an inherited deficiency of ADAMTS13.

Clinically, the main features of this disease are fever, anemia, symptoms of renal and hepatic disease, and thrombocytopenia—the latter giving rise to the common hemorrhagic manifestations (petechiae and ecchymoses of the skin, retinal hemorrhages, hematuria, gastrointestinal bleeding, etc.). Neurologic symptoms are practically always present and are the initial manifestation of the disease in about half the cases. Confusion, delirium, seizures, and hemiparesis—sometimes remittent or fluctuating in nature—are the usual manifestations of the nervous system disorder and are readily explained by the widespread microscopic ischemic lesions in the brain. Garrett and colleagues have emphasized the presentation of nonconvulsive status epilepticus in TTP, and we have encountered two such cases. Gross infarction was not observed. In most patients who survive, recovery of the focal neurologic deficits can be expected unless there is an identifiable infarction on CT or MRI. The CSF is normal except for elevated protein in some cases. To our knowledge, a mononeuritis multiplex does not occur.

The diagnosis is made by finding a microangiopathic hemolytic anemia in the context of the characteristic clinical picture. An assay for ADAMTS13 activity is available using an enzyme-linked immunosorbent assay but the initiation of treatment usually cannot await confirmation of the diagnosis. There is an important overlap among TTP, HUS, toxemia of pregnancy, the hemolytic anemia with elevated liver function tests and platelet count (HELLP syndrome), hypertensive encephalopathy, and

other causes of the posterior reversible leukoencephalopathy syndrome (PRES, see earlier discussion). In all of them, the central nervous system problem is mediated by endothelial dysfunction with breakdown of the blood-brain barrier. The recommended treatment for TTP is plasma exchange or plasma infusion. Further details can be found in *Harrison's Principles of Internal Medicine*.

Polycythemia Vera, Thrombocytosis, and Thrombocythemia

Polycythemia vera is a myeloproliferative disorder of unknown cause, characterized by a marked increase in RBC mass and in blood volume and often by an increase in WBCs and platelets. The condition must be distinguished from the many secondary or symptomatic forms of polycythemia (erythrocytosis), in which the platelets and white cells remain normal. The slightly increased incidence of thrombosis in primary polycythemia is attributed to the high blood viscosity, engorgement of vessels, and reduced rate of blood flow. The majority of patients with cerebrovascular manifestations have TIAs and small strokes, but we have seen one case of sagittal sinus thrombosis. With very high hematocrit, sludging of red cells may be seen in the retinal vessels. The cause of cerebral hemorrhage in this disease is less clear, although a number of abnormalities of platelet function and of coagulation have been described (see Davies-Jones et al).

Instances of platelet counts above 800,000/mm³ are considered to be a form of myeloproliferative disease allied with polycythemia vera. In some patients there is an enlarged spleen, polycythemia, chronic myelogenous leukemia, or myelosclerosis. In several of our patients, no explanation of the thrombocytosis was found. They presented with recurrent cerebral and systemic thrombotic episodes, often of minor degree and transient. Cytapheresis, to reduce the platelets, and antiplatelet drugs (hydroxyurea anagrelide) to suppress megakaryocyte formation, are helpful in ameliorating the neurologic symptoms. In one of the cases we followed, several small lesions, presumably infarctions, were situated in the white matter and simulated multiple sclerosis. Another patient with essential thrombocytosis developed dramatic new migraine with aura when her platelet counts exceeded 1,000,000/mm³.

A wide variety of bleeding disorders—such as leukemia, aplastic anemia, thrombocytopenic purpura, and hemophilia—may also give rise to cerebral hemorrhage. Many rare forms of bleeding disease may be complicated by hemorrhagic manifestations; these are reviewed by Davies-Jones and colleagues.

Sickle Cell Disease

This inherited disease is related to the presence of the abnormal hemoglobin S in the red corpuscles. Clinical abnormalities occur mainly in patients with sickle cell disease—i.e., with the homozygous state, and not in those with the sickle cell trait, which represents the heterozygous state. We have seen neurologic symptoms in patients with a heterozygous mixed hemoglobinopathy, such as sickle-thalassemia, sickle-S, and sickle-D, but all are less severe and less frequent than in sickle

cell anemia. The disease, which is practically limited to persons of central African and certain Mediterranean origins, begins early in life and is characterized by “crises” of infection (particularly pneumococcal meningitis), pain in the limbs and abdomen, chronic leg ulcers, and infarctions of bones and visceral organs. Ischemic lesions of the brain, both large and small, are the most common neurologic complications, but cerebral, subarachnoid, and subdural hemorrhage may also occur, and the vascular occlusions may be either arterial or venous. Patients with sickle cell anemia may develop progressive stenosis of the supraclinoid intracranial carotid artery with consequent collateral formation, producing a syndrome akin to moyamoya disease described earlier in the chapter. These fragile collateral vessels may rupture causing intracranial hemorrhage.

Lee and colleagues demonstrated that exchange transfusions with monitoring of the velocities of flow in the middle cerebral artery by transcranial Doppler examination reduces the risk of this important neurologic complication. In the stroke prevention trial of sickle cell anemia, the risk of first stroke was reduced by 90 percent in 63 children who received periodic transfusions as compared to 67 children who received only supportive care.

SPECIAL CLINICAL PROBLEMS IN CEREBROVASCULAR DISEASE

Inevitably, most patients are seen first by clinicians who may not be expert in all the fine points of cerebrovascular disease. Situations arise in which critical decisions must be made regarding anticoagulation, further laboratory investigation, and the advice and prognosis to be given to the family. The following are some of the situations encountered by the authors that may be of value to students and residents and to nonspecialists in the field.

The Patient With a History of an Ischemic Attack or Small Stroke in the Past

The patient may be functioning normally when examined, but it has been ascertained by the history or radiologic procedures that a stroke or TIA occurred in the past. The problem is what measures should be taken to reduce the risk of further strokes. This is particularly problematic if a surgical procedure is planned. A brief focal TIA, several minutes or less in duration, or many stereotyped spells usually represent severe stenosis of the internal carotid artery on the side of the affected cerebral hemisphere. If the symptoms have occurred recently, these may be forerunners of complete occlusion. If the TIA was far in the past—more than several weeks previously—the immediate risks of occlusion are reduced. The initial approach is to establish the patency of the carotid arteries by ultrasonography or MRA. If there is a reduction in diameter of greater than 70 percent when compared with an adjacent normal segment of vessel, and probably if

there is a severely ulcerated but not critically stenotic plaque, carotid surgery (or angioplasty with stenting) is advisable. If a single TIA lasted more than an hour or the neurologic examination discloses minor signs referable to the region of the hemisphere affected by the TIA, a search for a source of embolus is indicated. Appropriate diagnostic studies include ECG, a transesophageal echocardiogram, monitoring for cardiac arrhythmia, ultrasonography of the carotid arteries, and a CT or MRI if it has not already been performed. Control of elevated blood pressure and addressing high cholesterol levels are ancillary steps. The mistake is to ignore the potential significance of a prior small stroke or TIA.

The Patient With a Recent Stroke That May Not Be Complete

If hours have passed since the first symptoms of stroke but the syndrome is fluctuating or advancing, the basic problem is whether a thrombotic infarction (venous or arterial) will spread and involve more brain tissue; or if embolic, whether the ischemic tissue will become hemorrhagic or another embolus will occur; or if there is an arterial dissection, whether it will give rise to emboli. Therapies are controversial in most of these circumstances. In some centers, it is the practice to try to prevent propagation of a thrombus by administering heparin (or low-molecular-weight heparin) followed by warfarin, as discussed earlier. Some stroke deficits fluctuate with blood pressure, suggesting occlusion of the carotid or of another large vessel. Attention to adequate cerebral perfusion by omitting the patient's usual blood pressure medications, assuring adequate hydration and avoiding hemoconcentration, and potentially utilizing a head-down position may all assist in stabilizing the situation.

The Inevitable or Misconstrued Syndromes of Cerebrovascular Disease

Although hemiplegia is the typical manifestation of stroke, cerebrovascular disease may manifest itself by signs that spare the motor pathways but have the same serious diagnostic and therapeutic implications. The following stroke syndromes tend to be overlooked.

Sometimes disregarded is a leaking aneurysm presenting as a sudden and intense generalized headache lasting hours or days and unlike any headache in the past. Examination may disclose no abnormality except for a slightly stiff neck and raised blood pressure. Failure to investigate such a case by imaging procedures and examination of the CSF may permit the occurrence of a later massive subarachnoid hemorrhage. Small cerebral hemorrhages, subdural hematomas, and brain tumors figure into the differential diagnosis, which is usually settled by a CT or MRI.

A second nonobvious stroke is one caused by occlusion of the posterior cerebral artery, usually embolic. This may not be recognized unless the visual fields are carefully tested at the bedside. The patient himself may not be aware of the difficulty or will complain

only of blurring of vision or the need for new glasses. Accompanying deficits are inability to name colors or recognize manipulable objects or faces, difficulty in reading, etc. MRI or CT usually corroborates the clinical diagnosis, and therapy is directed against further emboli or extension of the thrombosis.

An inapparent stroke that may be mistaken for psychiatric disease is an attack of paraphasic speech from embolic occlusion of a branch of the left middle cerebral artery. The patient talks in nonsensical phrases, appears confused, and does not fully comprehend what is said to him. He may perform satisfactorily at a superficial level and offer socially appropriate greetings and gestures. Only scrutiny of language function and behavior will lead to the correct diagnosis. Infarction of the dominant or nondominant temporal lobe and rarely of the caudate may produce an agitated delirium with few focal findings. This may be mistaken for a toxic or withdrawal state.

Parietal infarctions on either side (usually nondominant hemisphere) are often missed because the patient is entirely unaware of the problem or the symptoms create only a subtle confusional state, drowsiness, or only subtle problems with calculation, dialing a phone, reaching accurately for objects, or loss of ability to write. Extinction of bilaterally presented visual or tactile stimuli gives a clue; marked asymmetry of the optokinetic nystagmus response is sometimes the only definite sign.

A cerebellar hemorrhage may at first be difficult to recognize as a stroke. An occipital headache and complaint of dizziness with vomiting may be interpreted as a labyrinthine disorder, gastroenteritis, or myocardial infarction. A slight ataxia of the limbs, inability to sit or stand, and mild gaze paresis may not have been properly tested or have been overlooked. The entire syndrome may be missed if the patient is not asked to get off the gurney and walk. Early intervention by surgery may be lifesaving; but once the syndrome has progressed to the point of coma with pupillary abnormalities with bilateral Babinski signs, surgery is usually less likely to result in a good outcome. Similarly, a lateral medullary infarction causing incessant vomiting and dizziness may be mistaken for gastroenteritis unless nystagmus and gait ataxia are appreciated.

The Comatose Stroke Patient

The most common causes of vascular coma are intracranial hemorrhage—usually deep in the hemisphere, less often in the cerebellum or brainstem, extensive subarachnoid hemorrhage, and basilar artery occlusion. After several days, brain edema surrounding a large infarction in the territory of the middle cerebral artery or adjacent to a hemorrhage may compress the midbrain and produce the same effect. Certain remedial surgical measures are still available in these circumstances: drainage of blood from the ventricles, shunting of the ventricles in cases of secondary hydrocephalus due to obstruction of the third ventricle or aqueduct, evacuation of a cerebral hemorrhage in cases of recent decline into stupor and coma, and hemicraniectomy in the case of massive stroke edema.

Also, thrombolytic therapy and anticoagulants are sometimes successful in reversing the progression of basilar artery thrombosis that has caused coma by ischemia or infarction of the upper brainstem.

Seizures Following Stroke

With the exception of infarction caused by cerebral venous occlusion, convulsive seizures following stroke are not a great problem. As mentioned earlier and in other chapters of the book, seizures are quite infrequent as the initial manifestation of an ischemic stroke, and when they do occur in this fashion, an embolus is usually the causative mechanism. More often, they are delayed by months or years after the infarction or hemorrhage. In the data presented by Lamy and colleagues (who were studying stroke in young patients with patent foramen ovale), when seizures occurred not at the outset but within the first week after stroke, as they did in 2 to 4 percent of their cases, about half had another seizure, usually single, during the next several years. However, the same was true for those with a first seizure after 1 week. Perhaps not surprisingly, the rate of seizures is higher after hemorrhagic than ischemic strokes and for the latter category, larger cortical strokes were more likely to result in a seizure disorder. An overview of the low rate of seizures that occurred soon after a stroke can be appreciated from the report by Beghi and colleagues, about 6 percent.

No satisfactory study has been conducted to determine if these patients benefit from antiepileptic therapy to prevent the second or subsequent seizures. Following the practice of most other neurologists, we prescribe one of the main epilepsy medications only if there has been a seizure, and continue it for about 12 months. If the EEG shows focal sharp waves or other epileptic activity at that time, we continue the drug; if not, we may discontinue the medication. It is also clear that prophylactic anticonvulsant treatment of all stroke patients is not necessary.

Dementia With Cerebrovascular Disease

Dementia of the Alzheimer type is often ascribed, on insufficient and conceptually incorrect grounds, to the occurrence of multiple small strokes. If vascular lesions are responsible, evidence of an acute stroke episode or episodes and of focal neurologic deficits to account for at least part of the syndrome are evident. However, there is a process in which diffuse white matter changes on the basis of vascular disease lead to a less saltatory decline in cognitive function—vascular dementia. Complicating the understanding of this syndrome is the frequent coexistence, and possibly interdependence, of the lesions of both vascular and Alzheimer disease. There may be difficulty in determining to what extent each of them is responsible for the neurologic deficits. Several studies have shown an increased incidence or an acceleration of Alzheimer dementia if there are concurrent vascular lesions.

Craniocerebral Trauma

Among the vast array of neurologic diseases, cerebral trauma ranks high in order of frequency and gravity. In the United States, trauma is the leading cause of death in persons younger than 45 years of age and more than half of these deaths are a result of head injuries. According to the American Trauma Society, an estimated 500,000 Americans are admitted to hospitals yearly following cerebral trauma; of these, 75,000 to 90,000 die and even larger numbers, most of them young and otherwise healthy, are left permanently disabled.

The basic problem in craniocerebral trauma is at once both simple and complex: simple because there is usually no difficulty in determining causation, namely, a blow to the head, and complex because of a number of delayed effects that complicate the injury. As for the trauma itself, little can be done, for it is finished before the physician or others arrive on the scene. At most there can be an assessment of the full extent of the immediate cerebral injury, an evaluation of factors conducive to complications and further lesions, and the institution of measures to avoid such additional problems. Specifically, the neck can be stabilized and adequate perfusion and oxygenation can be secured. But of the disastrous intracranial phenomena that can be initiated by head injury, few offer possibilities of treatment. New techniques of cellular biology are exposing phenomena that are set in motion by traumatic injury of nerve cells and glia. Some of these changes may be reversible, but at the moment, such knowledge is limited.

It is a common misconception that craniocerebral injuries are matters that concern only the neurosurgeon and not the general physician or neurologist. Actually, 80 percent of head injuries are first seen by a physician in an emergency department, and fewer than 20 percent ever require neurosurgical intervention of any kind, and even this number is decreasing. The neurologist must be familiar with the clinical manifestations and the natural course of primary brain injury and its complications and have a sound grasp of the underlying physiologic mechanisms. Such knowledge must also relate to the interpretation of CT and MRI, both of which have greatly enhanced our ability to deal with traumatic brain injury. The present chapter reviews the salient facts concerning craniocerebral injuries and outlines a clinical approach that the authors have found useful over the years. Matters

pertaining to spinal injuries, often coexistent with head trauma, are considered in Chap. 44.

DEFINITIONS AND MECHANISMS

The very language that one uses to discuss certain types of head injuries divulges a number of misconceptions inherited from previous generations of physicians. Certain terms have crept into the medical vocabulary and have been retained long after the ideas for which they stood have been refuted, attesting to the disadvantage of premature adoption of explanatory terms rather than descriptive ones. The word *concussion*, for example, implies a violent shaking or jarring of the brain and a resulting transient functional impairment. Yet despite numerous postulates of physical changes within nerve cells, axons, or myelin sheaths (vibration effects, formation of intracellular vacuoles) that putatively occurred with concussion, confirmation of their existence has proved difficult in humans and experimental animals.

In all attempts to analyze the mechanisms of *closed*, or *blunt* (*nonpenetrating*), head injury, one fact is preeminent: there must be the sudden application of a physical force of considerable magnitude to the head. Unless the head is struck, the brain suffers no injury except in the rare instances of violent flexion–extension (whiplash) of the neck and possibly in explosion–blast injury with a sudden extreme increase of atmospheric pressure. In military medical practice, blast injuries assume great importance and in theory, challenge many concepts of loss of consciousness in closed head injury; i.e., there is no contact with, or sudden acceleration or deceleration of the cranium. The mechanical factors of importance in brain injury are the differential mobility of the head on the neck, and of the brain within the cranium, the tethering of the upper brainstem that allows movement of the cerebral hemispheres around that vertex, and the striking of parts of the brain on dural septa and bony prominences. As to concussive injuries, it is useful to point out that concussions usually involve a physical force that imparts motion to the stationary head or more commonly, a hard surface that arrests the motion of a moving head, i.e., concussion does not occur if the head remains stationary.

This sudden deceleration or acceleration of the cranium is the mechanism of most civilian head injuries, and they are notable in two respects: they often induce at least a temporary loss of consciousness, and the brain may suffer gross damage even though the skull is not penetrated, i.e., contusion, laceration, hemorrhage, and swelling. A theory that brings coherence to all of these physical and gross neuropathologic changes and their relation to transient loss of consciousness (concussion) and prolonged coma has only been tentatively formulated.

In contrast to closed head injury, high-velocity missiles penetrate the skull and cranial cavity, or rarely, the skull may be compressed between two converging forces that crush the brain without causing significant displacement of the head or the brain. In these circumstances, the patient may suffer severe and even fatal injury without preceding loss of consciousness. Hemorrhage, destruction of brain tissue, and, if the patient survives for a time, meningitis or abscess are the principal pathologic changes created by injuries of these types. They offer little difficulty to our understanding. Figure 35-1 illustrates these various types of head injuries.

The relation of *skull fracture* to brain injury has been viewed in changing perspective throughout the history of this subject. In the first half of the last century, fractures dominated the thinking of the medical profession, and

cerebral lesions were regarded as secondary. Later, it became clear that the skull, although rigid, is still flexible enough to yield to a blow that injures the brain without causing fracture. Therefore the presence of a fracture, although a rough measure of the force to which the brain has been exposed, is not an infallible index of the presence of cerebral injury (see further on in discussion of predictive features for imaging abnormalities with concussion). Even in immediately fatal head injuries, autopsy reveals an intact skull in 20 to 30 percent of cases. Of course, many patients suffer skull fractures without serious or prolonged disorder of cerebral function, partly because the energy of a blow is dissipated in the fracture. Indeed, this diffusion of the impact might be expected to reduce underlying brain damage.

Nevertheless, fractures cannot be dismissed without further comment for several reasons. Overall, brain injury is estimated to be 5 to 10 times more frequent with skull fractures than without them and perhaps 20 times more frequent with severe and multiple fractures. Fractures assume further importance in providing an explanation for cranial-nerve palsies, and in creating potential pathways for the ingress of bacteria and air or the egress of cerebrospinal fluid (CSF leak). In these respects, fractures through the base of the skull are of special significance, and are considered below.

Figure 35-1. Mechanisms of craniocerebral injury. A. Cranium distorted by forceps (birth injury). B. Gunshot wound of the brain. C. Falls (also traffic accidents). D. Blows on the chin ("punch-drunk"). E. Injury to skull and brain by falling objects. (From Courville.)

Basal Skull Fractures and Cranial Nerve Injuries

Figure 35-2 illustrates the major sites and directions of basilar skull fractures. One can readily perceive the possibilities of injury to cranial nerves. Fractures of the base are difficult to detect in plain skull films and may be missed by other imaging techniques, but their presence should be suspected in the presence of any one of a number of characteristic clinical signs. Fracture of the petrous pyramid often deforms the external auditory canal or tears the tympanic membrane, with resultant leakage of CSF (otorrhea); or, blood may collect behind an intact tympanic membrane and discolor it. If the fracture extends more posteriorly, damaging the sigmoid sinus, the tissue behind the ear and over the mastoid process becomes boggy and discolored (Battle sign). Basal fracture of the anterior skull may also cause blood to leak into the periorbital tissues, imparting a characteristic “raccoon” or “panda bear” appearance. The presence of

Figure 35-2. The course of fracture lines through the base of the skull. Arrows indicate point of application and direction of force. (From Courville.)

any of these signs calls for CT scanning of the skull base using bone window settings to detect a fracture.

The existence of a basal fracture is also indicated by signs of cranial nerve damage. The olfactory, facial, and auditory nerves are the ones most liable to injury, but any one, including the twelfth, may be damaged. *Anosmia* and *an apparent loss of taste* (actually a loss of perception of aromatic flavors as the elementary modalities of taste are unimpaired) are frequent sequelae of head injury, especially with falls on the back of the head. In the majority of cases the anosmia is permanent. If unilateral, it will not be noticed by the patient. However, mechanism of these disturbances is thought to be a displacement of the brain and tearing of the olfactory nerve filaments in or near the cribriform plate, through which they course, rather than being attributable to a fracture. A fracture in or near the sella may tear the stalk of the pituitary gland with resulting *diabetes insipidus*. Rarely, such a fracture may cause bleeding from a preexisting pituitary adenoma and produce the syndrome of pituitary apoplexy (see Chap. 31). A fracture of the sphenoid bone may lacerate the optic nerve, with blindness from the beginning. The pupil is unreactive to a direct light stimulus but still reacts to a light stimulus to the opposite eye (consensual reflex). The optic disc becomes pale, i.e., atrophic, after an interval of several weeks. Partial injuries of the optic nerve result in scotomas and a troublesome blurring of vision.

Complete *oculomotor nerve injury* is characterized by ptosis and diplopia, a divergence of the globes with the affected eye resting in an abducted and slightly depressed position, loss of medial and most of the vertical movements of the eye, and a fixed, dilated pupil, as described in Chap. 13. The most common symptom is diplopia that is worse on looking down and compensatory tilting of the head indicating a *trochlear nerve injury*. In a series of 60 patients with head injury, Lepore confirmed that fourth-nerve palsy was the most common cause of diplopia, occurring unilaterally twice as often as bilaterally, followed in frequency by damage to one or both third nerves, then, least often, a unilateral or bilateral sixth-nerve palsy. Five of his patients had palsies that reflected damage to more than one nerve and seven had supranuclear disorders of convergence. The long, circumferential subarachnoid course of the fourth nerve is usually given as the explanation for its frequent injury, but this mechanism has never been validated. These optic and ocular motor nerve disorders must be distinguished from those caused by displacement of the globe or entrapment of an extraocular muscle as a result of direct injury to the orbit.

Injury to the *ophthalmic and maxillary divisions of the trigeminal nerve* may be the result of either a basal fracture across the middle cranial fossa or a direct extracranial injury to the branches of the nerves. Numbness and paresthesia of the skin supplied by the nerve branch or chronic neuralgia can be troublesome sequelae of these injuries.

The *facial nerve* may be involved in one of two ways. In the first type of injury, associated with transverse fractures through the petrous bone, there is an immediate facial palsy, probably caused by contusion or transection

of the nerve. Surgical anastomosis has sometimes been successful in restoring function in this circumstance. The second, more common type, is associated with longitudinal fractures of the petrous bone, the facial palsy then often being delayed for several days, a sequence that may be misinterpreted as progression of the intracranial traumatic lesion. This latter type is usually transitory, and its mechanism is not known.

Injury to the *eighth cranial nerve* because of petrous fractures results in a loss of hearing or in postural vertigo and nystagmus coming on immediately after the trauma. Deafness as a result of nerve injury must be distinguished from the high-tone hearing loss due to *cochlear* injury and from deafness caused by bleeding into the middle ear and disruption of the ossicular chain (conduction deafness). Also, vertigo must be distinguished from the very common symptom of posttraumatic dizziness discussed in a later section. The rare condition of fracture through the hypoglossal canal causes weakness of one side of the tongue. It should be kept in mind that blows to the upper neck may also cause lower cranial-nerve palsies, either by direct injury to their peripheral extensions or as a result of *carotid artery dissection* in the cervical segment of the artery.

Carotid–Cavernous Fistula

A basal fracture through the sphenoid bone may lacerate the internal carotid artery or one of its intracavernous branches where it lies in the cavernous sinus. Within hours or a day or two, a disfiguring pulsating exophthalmos develops as arterial blood enters the sinus and distends the superior and inferior ophthalmic veins that empty into the sinus. The orbit feels tight and painful, and the eye may become partially or completely immobile because of pressure on the ocular nerves traversing the sinus (see Fig. 14-5). The sixth nerve is affected most often, and the third and fourth nerves less often. Also, there may be a loss of vision as a result of ischemia of the optic nerve and retina, although the mechanism has not been entirely clear; congestion of the retinal veins and glaucoma are potential factors in the visual failure. Some 5 to 10 percent of fistulas resolve spontaneously, but the remainder must be obliterated by interventional radiologic means (by a detachable balloon inserted into the carotid artery via a transfemoral catheter) or by a direct surgical repair of the fistula (see Stern).

Not all carotid–cavernous fistulas are traumatic. They may occasionally occur with rupture of an intracavernous saccular aneurysm or in Ehlers-Danlos disease, where the connective tissue is defective; or the cause may be unexplained. Occasionally, a dural-based arteriovenous fistula opens in the region of the cavernous sinus after an injury; most such cases are spontaneous and they cause less in the way of orbital swelling and congestion.

Pneumocephalus, Aerocele, and Rhinorrhea (Cerebrospinal Fluid Leak)

If the skin over a skull fracture is lacerated and the underlying meninges are torn, or if the fracture passes through

the inner wall of a paranasal sinus, bacteria may enter the cranial cavity, with resulting meningitis or abscess formation. CSF that leaks into the sinus presents as a watery discharge from the nose (*CSF rhinorrhea*). The nasal discharge can be identified as CSF by testing it for glucose with diabetic test tape (mucus has no glucose) or by the presence of fluorescein or radionuclide-labeled dye that is injected into the lumbar subarachnoid space and then absorbed by pledgets placed in the nasal cavity. Mucus, when absorbed onto a handkerchief and allowed to dry, will leave the material stiff, whereas CSF, will not. A more elaborate test is to detect tau protein in the discharge; it is present only in CSF and not in mucus or blood. Most cases of acute CSF rhinorrhea heal by themselves. An indwelling lumbar drain for a few days may aid the process. If the condition is persistent or is complicated by an episode of meningitis, repair of the torn dura is indicated. The prophylactic use of antibiotics to prevent meningitis in cases of nasal CSF leak is controversial, but many neurosurgeons continue this practice, particularly in children.

A collection of air in the cranial cavity (aerocele) is a common occurrence following skull fracture or any extended neurosurgical procedure. The pocket of air is apparent by CT scan in the epidural or subdural space over the cerebral convexities or between the hemispheres, and serves only to warn of a potential route for the entry of bacteria into the cranium. Small collections of air are usually absorbed without incident, but a large volume may act as a mass and cause clinical deterioration after injury (tension pneumocranium; Fig. 35-3). Inhalation of 100 percent oxygen has a slight salutary effect, but aspiration of the air is required if the collection is causing clinical signs.

Figure 35-3. CT of postoperative tension pneumocranium (aerocele) that caused progressive drowsiness and required removal by aspiration. The air is apparent as a very-low-density collection that compresses the right frontal lobe.

Depressed skull fractures are of significance only if the underlying dura is lacerated or the brain is compressed by indentation of bone. They then are surgically elevated, preferably within the first 24 to 48 h.

Concussion

Much has been written about the mechanisms of concussion in closed head injury and its definition has undergone serial revision. In the past, a transient loss of consciousness and amnesia after a blow to the head had been considered necessary to qualify as concussion but lesser degrees of mild confusion, incoordination, or even symptoms such as headache and fatigue that follow mild head injury are now encompassed under the term. Whether all these problems derive from the same mechanism cannot be stated with confidence.

History of Concepts of Concussion The mechanism of concussive "cerebral paralysis" has been interpreted in various ways throughout medical history in light of the state of knowledge at a particular period of time. The favored hypotheses for the better part of a century were "vasoparalysis" (suggested by Fischer in 1870) or an arrest of circulation by an instantaneous rise in intracranial pressure (ICP) (proposed by Strohmeyer in 1864 and popularized by Trotter in 1932). Jefferson, in his essay on the nature of concussion (1944), convincingly refuted these vascular hypotheses. Later, Shatsky and coworkers, by the use of high-speed cineangiography, showed displacement of vessels but no arrest of circulation immediately after impact.

Beginning with the work of Denny-Brown and Russell in 1941, the physical factors involved in head and brain injuries were subjected to careful analysis. These investigators demonstrated that in monkey and cat the concussion resulted when the freely moving head was struck by a heavy mass. If the head was prevented from moving at the moment of impact, the same degree of force invariably failed to produce concussion. The importance of head motion was verified by Gennarelli and colleagues, who were able to induce concussion in primates by rapid acceleration of the freely moving head without impact, a condition that rarely occurs in humans.

Holbourn, a Cambridge physicist, from a study of gelatin models under conditions simulating head trauma, deduced that when the head is struck, movement of the partly tethered but suspended brain always lags (because of inertia), but inevitably the brain moves also, and when it does it must rotate in an arc because of attachment to the neck. Ommaya and Gennarelli (1974) proved the correctness of this assumption by photographing the brain through a transparent calvarium at the moment of impact. The brain was thus subjected to stresses set up by rotational forces mainly in the sagittal plane, centered at its point of tethering in the high midbrain. The torque at the level of the upper reticular formation would explain the immediate loss of consciousness, as described later. An extensive and scholarly review of the pathophysiology of concussion was done by Shaw (although we are uncertain of the validity of his view of a seizure-concussive mechanism).

Mechanism of Concussion The core features of loss of consciousness or confusion are notable for being immediate after trauma (not delayed even by seconds) and for being entirely reversible. This is the sense in which concussion was used to mean a *reversible traumatic paralysis of nervous function* and any physiologic explanation of the syndrome would have to incorporate this temporal sequence. However, the effects of concussion on brain function may last for a variable time (seconds, minutes, hours, or longer) and to set arbitrary limits on the duration of loss of consciousness, i.e., to consider a brief loss as indicative of concussion and a prolonged loss as indicative of contusion or other traumatic cerebral lesion, is unsound physiologically. As pointed out by Symonds, any such difference is quantitative, not qualitative. It is true that in the more prolonged states of stupor or coma, there is a far greater chance of finding hemorrhage and contusion, which undoubtedly contribute to the persistence of coma and the likelihood of irreversible change. Finally, the optimal condition for the production of concussion, demonstrated originally by Denny-Brown and Russell, is a sudden change in the momentum of the head; i.e., either movement is imparted to the stationary head by a blow or movement of the head is arrested by a hard, unyielding surface.

Rotational movements of the brain also provide a reasonable explanation for the occurrence of surface injuries in specific locations, i.e., where the swirling brain comes into contact with bony prominences on the inner surface of the skull (petrous and orbital ridges, sphenoid wings), and of injuries to the corpus callosum, which is flung against the falx. Not well explained by any of these mechanisms are concussions after *blast injuries*, a serious problem in military medicine. This syndrome possibly resurrects the notion that a shock wave travels through the brain and disrupts neural function throughout the cerebral hemispheres or in the reticular formation of the midbrain.

These views on the site and mechanism of concussion are not fully accepted but have been supported by a number of additional physiologic observations. Foltz and Schmidt, in 1956, suggested that the reticular formation of the upper brainstem was the anatomic site of concussive injury. They showed that in the concussed monkey, lemniscal sensory transmission through the brainstem was unaltered, but its effect in activating the reticular formation was blocked and that the electrical activity of the medial reticular formation was depressed for a longer time and more severely than that of the cerebral cortex.

What was further noteworthy in most of these cases, and in those reported by Jellinger and Seitelberger, was the presence of additional lesions in the region of the reticular activating system and small hemorrhagic softening in the corpus callosum, superior cerebellar peduncles, and dorsolateral tegmentum of the midbrain. As discussed further on, Strich (1956) interpreted the extensive white matter lesions, both in the hemispheres and in the upper brainstem, to represent a degeneration of nerve fibers that had been stretched or torn by the shear stresses set up during rotational acceleration of the head, as had been postulated earlier by Holbourn. She suggested that

if nerve fibers are stretched rather than torn, the lesions may be reversible and may play a part in the mechanism of concussion. Symonds elaborated on this view and saw in the shearing stresses, which are maximal at the point where the cerebral hemispheres rotate on the relatively fixed upper brainstem, the explanation of concussion.

Clinical Manifestations of Concussion

In its fullest form, the characteristic clinical signs of concussive brain injury are the immediate abolition of consciousness, suppression of supportive reflexes (falling to the ground if standing), transient arrest of respiration, a brief period of bradycardia, and fall in blood pressure following a momentary rise at the time of impact. Rarely, if these abnormalities are sufficiently intense, death may occur at the moment of impact, presumably from respiratory arrest. In its mildest form, there is no apparent loss of consciousness or collapse, only a brief period of stunned disorientation, staggering, and subsequent amnesia during which the individual appears outwardly normal. The vital signs usually return to normal and stabilize within a few seconds even if the patient remains unconscious.

Brief tonic extension of the limbs, clonic convulsive movements lasting up to approximately 20 s, and other peculiar movements may occur immediately after the loss of consciousness (see McCrory et al). These “concussive convulsions” are probably of little prognostic significance and have not been shown to confer an increased risk of later seizures. McCrory and colleagues noted an association between motor and convulsive movements and facial impact, and we have seen this feature several times in teenagers who collided while pursuing a ball.

In the period during which the patient is unconscious and for a few moments afterwards, the plantar reflexes are extensor. After a variable period of time, the patient begins to stir and opens his eyes. Corneal, pharyngeal, and cutaneous reflexes, originally depressed, return, and the limbs withdraw from painful stimuli. Gradually, contact is made with the environment and the patient begins to obey simple commands and respond slowly to questions. Memories are not formed during this period; the patient may even carry on a conversation, which he cannot later recall. Finally, there is ostensibly full neurologic recovery corresponding to the time when the patient can form consecutive memories of current experiences.

The time required for the patient to pass through these stages of recovery may be only a few seconds or minutes, several hours, or possibly a limited number of days; but again, between these extremes there seem to be only quantitative differences. To the observer, such patients are comatose only from the moment of injury until they open their eyes and begin to speak; however, for the patient, the period of unconsciousness in one limited perspective extends from a point before the injury occurred (*retrograde amnesia*) until the time when he is able to form consecutive memories at the end of the period of anterograde amnesia. The duration of the amnesic period, particularly of *anterograde amnesia*, is but one index of the severity of the concussive injury. Although momentary “stunning” without loss of consciousness represents the mildest degree of concussion,

it is not known if it shares the same mechanism as overt loss of consciousness. The aftereffects of concussion in causing anxiety, sleep disturbance, mental fogging and cognitive difficulty, and dizziness are common to both and are discussed further on.

Athletic Concussion

This is a topic of current interest and various guidelines regarding return to play have been published. A recent summary from the American Academy of Neurology can be consulted (authored by Giza and colleagues). The later-life development of dementia and other neurodegenerative conditions in professional athletes is discussed further on. Many useful observations have emerged from study of athletes after head injury. Foremost among these observations is that athletes who have had concussion are more likely than other players to have another concussion in the same playing season (Guskiewicz et al); whether this is a reflection of constitutional incoordination or the person’s style of play, or another factor is not known. Second, most prospective studies show a decline in reaction time and in other neuropsychologic tests after concussion, which returns to baseline over several days or weeks. Third, there is an indication from several series of concussions in National Collegiate Athletic Association and National Football League players that the number of recollected concussions is proportional to the degree of impairment on neuropsychologic tests (McCrea et al). Similar results have been found in other pursuits such as jockeying (Wall et al), but there are few adequate prospective studies.

The appropriate duration of removal from play has been the subject of numerous and largely arbitrary systems. The basis of most rules has been an appropriate conservatism that requires the absence of cerebral symptoms both at rest and under physical stress testing such as running or repetitive squatting. The duration of loss of consciousness and of amnesia was formerly a major component of the decision about return to play. More current guidelines focus instead on slowness in answering questions, uncertainty about plays or game assignments, and clumsiness, with or without loss of consciousness or amnesia. All such players are removed from the game. After medical evaluation, which may include imaging and neuropsychologic testing, a program of physical and cognitive “rest” is followed by graduated physical and mental activity under observation and a return to a lower level if symptoms occur (McCrory et al). Specifically, light aerobic exercise is followed by sport-specific training and noncontact, then contact, drills.

Pathologic Changes Associated With Severe Head Injury

In contrast to concussion, in cases of traumatic brain injury that are fatal or very serious, the brain is usually bruised (contused), swollen, or lacerated, and there are hemorrhages, both meningeal and intracerebral, as well as hypoxic-ischemic lesions. A majority of patients who remain in a coma for more than 24 h after a head injury

are found to have intracerebral hematomas and contusions. Of these lesions, the most frequent are contusions of the surface of the brain beneath the point of impact (*coup lesion*) and the sometimes more extensive lacerations and contusions on the side opposite the site of impact (*contrecoup lesion*), as shown in Fig. 35-4. Blows to the front of the head may produce mainly coup lesions, whereas blows to the back of the head may cause mainly contrecoup lesions. Blows to the side of the head produce either coup or contrecoup lesions, or both. Irrespective of the site of the impact, the common sites of cerebral contusions are in the frontal and temporal lobes, as illustrated in Figs. 35-4 and 35-5. The inertia of the malleable brain—which causes it to be flung against the side of the skull that is struck, to be pulled away from the contralateral side, and to be impelled against bony promontories within the cranial cavity, explains these coup–contrecoup patterns. Relative sparing of the occipital lobes in coup–contrecoup injury has been explained by the smooth inner surface of the occipital bones and subadjacent tentorium, as pointed out by Courville.

The contused cortex is diffusely swollen and hemorrhagic, most of the blood being found around parenchymal vessels. On CT scanning, the lesions appear as edematous regions of cortex and subcortical white matter admixed with areas of increased density representing leaked blood (Fig. 35-6). The bleeding points may coalesce and give the appearance of a unitary clot in the cortex and immediately adjacent white matter.

The predilection of these lesions for the crowns of convolutions attests to their traumatic origin (being thrown against the overlying skull) and distinguishes them from cerebrovascular and other types of cerebral lesions. There may be ball hemorrhages within the hemispheres that are independent of contusions as discussed below. Not surprisingly, such deep areas of bleeding are common in patients receiving anticoagulant or antiplatelet medications.

Of equal importance are axonal lesions that occur at the time of impact or evolve soon afterwards. Strich (1961) described the neuropathologic findings in patients who died months after severe closed head injuries that had caused immediate and protracted coma. In all of her cases, in which there were no signs of skull fracture, raised intracranial pressure, or gross subarachnoid hemorrhage, she observed an uneven but diffuse degeneration of the cerebral white matter that has become the basis of all subsequent work on diffuse axonal shearing (*diffuse axonal injury, DAI*). In cases of shorter survival (up to 6 weeks), she observed ballooning and interruption of axis cylinders. These findings were subsequently confirmed and expanded by Nevin, by Adams and colleagues (1982), and by Gennarelli and coworkers, the last of these groups also working with monkeys.

The extension of Strich's concept, that postulates diffuse axonal injury throughout the cerebral white matter as the main cause of persistent unconsciousness, has been widely adopted. In relation to concussion, shearing

Figure 35-5. Distribution of contusions emphasizing the frontal and frontotemporal distribution in 40 consecutive autopsy cases collected by Courville. (From Courville.)

lesions are also seen in the midbrain and lower thalamus in severe injury, providing some evidence for this neuronal dysfunction in these regions as the cause of concussion.

In most cases of severe head injury, there is damage to the corpus callosum by impact with the falx; necrosis

and hemorrhage are sometimes visible by CT and can be seen to spread bilaterally to adjacent white matter (Fig. 35-7). There may also be scattered hemorrhages in the white matter along lines of force from the point of impact to the contralateral side. The degeneration of white matter from diffuse axonal injury can be remarkably diffuse, with no apparent relationship to focal destructive lesions, although differentiating it from secondary wallerian change that originates in a surface or callosal contusion can be difficult. Investigations using MRI, such

Figure 35-6. CT scan without contrast infusion showing areas of hemorrhagic contusion adjacent to bony prominences. There is also slight subarachnoid blood along the tentorium and in the insular cisterns, both of which are typical of traumatic bleeding.

Figure 35-7. Coronal MRI showing small hemorrhages in the callosum and midbrain that are considered part of the spectrum of diffuse axonal shearing injuries.

as the series by Kampfl and colleagues, suggest that diffuse axonal injury may be the substrate of the persistent vegetative state. However, in most cases of severe cranial injury and protracted coma, there have been major sites of injury in the midbrain and subthalamus, i.e., in the zones subjected to the greatest torque, and these latter lesions may be the critical ones in persistent coma and vegetative state (Adams et al 2000, Ropper and Miller). This was true of the cases of persistent coma described by Jellinger and Seitelberger. Notable, again, was that these deep lesions coincided with the postulated locus of reversible concussive paralysis.

Primary brainstem hemorrhages due to torsion and tearing of tissue at the time of impact are distinguished from the secondary hemorrhages that are a result of the effects of downward displacement of the brainstem. Duret originally emphasized the medullary location of these secondary hemorrhages, but the term *Duret hemorrhage* has come to signify all brainstem hemorrhages when there is mass effect that distorts the brainstem.

In addition to contusions and extradural, subdural, subarachnoid, and intracerebral hemorrhages, closed head injury induces variable degrees of vasogenic edema that increases during the first 24 to 48 h and sometimes, small zones of infarction that have been attributed to vascular spasm caused by subarachnoid blood surrounding basal vessels. The frequency and importance of this type of secondary cerebral infarction have been debated. A retrospective imaging study by Marino and colleagues found that 17 of 89 patients had regions of stroke after moderate or severe head injury. Most were in the distribution of a major branch or penetrating cerebral vessel or in a watershed territory.

The presence of intracranial hypertension has also been associated with a higher incidence of infarction. Marmarou and colleagues demonstrated that *brain swelling* after head injury is essentially the result of edema and not of an increase in cerebral blood volume, as has long been postulated. In children, and in some cases in adults, the cerebral edema may be massive and lead to secondary brainstem compression.

Cerebral Fat Embolism

With fractures of large bones in cases of generalized trauma, with or without head injury, after 24 to 72 h there may be an acute onset of pulmonary symptoms (dyspnea and hyperpnea) followed by coma with or without focal signs or seizures. This sequence is a result of systemic fat embolism, first of the lungs and then of the brain. Cranial trauma is not required. In some cases the onset of pulmonary symptoms is associated with a petechial rash over the thorax, especially in the axillae and also in the conjunctivae and 1 in 3 cases is said to show fat globules in the urine. The specificity of the last of these findings has been questioned. Respiratory distress is the most important and often the only feature of the fat embolism syndrome, evident in the chest film as fluffy infiltrates in both lungs. In the brain, multiple small fat emboli cause

widespread petechial hemorrhages and small infarctions, involving both white and gray matter and a few larger infarcts. Most patients with fat embolism recover spontaneously in 3 or 4 days, although a mortality rate of up to 10 percent is cited, usually related to underlying systemic and bony injuries. Treatment, aside from respiratory support, is supportive. Heparin, which had been used in the past, is not considered effective.

APPROACH TO THE PATIENT WITH HEAD INJURY

The physician first called on to examine a patient who has had a closed head injury will generally find one of three clinical conditions as indicated by the headings below, each of which is dealt with differently. It is usually possible to categorize the patient by assessing the mental and neurologic status when first seen and at intervals after the accident. The *Glasgow Coma Scale* is used as a rapid reference to accomplish this purpose (Table 35-1) but does not substitute for a fuller neurologic examination. The scale registers three aspects of neurologic function: eye opening, verbal response, and motor response to various stimuli. The scale uses a summed score with a maximum of 15; a score of 7 or less is considered to reflect severe trauma and a poor clinical state, 8 to 12, moderate injury,

Table 35-1

GLASGOW COMA SCALE (TOTAL SCORE IS USED FOR SERIAL ASSESSMENT AND PROGNOSIS)

EYES OPEN

Extension (decerebrate rigidity)	2
Flexion abnormal (decorticate rigidity)	3
Flexion withdrawal	4
Localizes pain	5
Obeys	6
Total	3-15

and higher scores, mild injury. The scores provided by this scale correspond roughly with the outcome of the head injury as discussed further on, but its main utility is in recording sequential changes in the patient's clinical state with an easily learned and reproducible tool.

Patients Who Are Conscious or Rapidly Regaining Consciousness (Concussion and Minor Head Injury)

This is the most frequently encountered clinical situation. Roughly, two degrees of disturbed function can be recognized within this category. In one, the patient was not unconscious at all but only stunned momentarily, "saw stars," or was briefly disoriented. This injury is insignificant when judged in terms of life or death and brain damage, although, as we point out further on, there is still the small possibility of a skull fracture or the later development of an epidural or subdural hematoma. Moreover, some patients are liable to a troublesome posttraumatic syndrome consisting of headache, giddiness, fatigability, insomnia, and nervousness that can appear soon after or within a few days of the injury. This problem is discussed in a later section. In the instance of consciousness that was temporarily abolished for a few seconds or minutes, recovery may already be complete, or the patient may be in one of the stages of partial recovery described earlier. Even though mentally clear, there is amnesia for events immediately preceding and following the injury. The latter produces a circumscribed confusional state that is usually confined to inattention and may be ongoing when the patient is first examined. It is characterized by a dazed appearance and repetitive questions from the patient about the circumstances that led to his being found.

In most such mild cases, a brief assessment for mental clarity, weakness, ocular abnormalities, and Babinski signs is appropriate, but there is little need of extensive neurologic consultation and hospitalization is not required, provided that a responsible family member is available to report any change in the clinical state. In only a small group of these patients, mainly in those who are slow in regaining consciousness or who have severe headache, vomiting, or a skull fracture, is there significant risk of intracerebral hemorrhage or other delayed complications.

Whether to obtain imaging of the head routinely in such patients is an unresolved problem. In our litigious society, the physician is inclined to obtain a CT scan. If there is no subarachnoid blood (a common finding) or intraparenchymal clot or contusion, and the patient is mentally clear there is little chance of developing an extradural hemorrhage. The presence of a fracture may increase these odds but most studies, such as the one by Lloyd and colleagues have found that the presence of a skull fracture in children proves to be a relatively poor indicator of intracranial injury. The exception is a fracture through the squamous bone and the groove of the middle meningeal artery, which represents a risk for arterial bleeding and epidural hemorrhage.

With the current focus on the cost-effective use of ancillary studies, criteria that justify obtaining a cranial

CT following minor forms of head trauma have been developed. We have generally advised a CT in cases of head injury that was associated with prolonged loss of consciousness (more than 1 min), severe and persisting headache, nausea and vomiting, a confusional state, and any new, objective neurologic signs, but these are admittedly arbitrary criteria. The CT scan may be particularly important in elderly patients with minor head trauma, in whom the presence of an intracranial lesion (mainly subdural hematoma) may not be predicted by clinical signs. However, in children, it may be advisable to perform the scans more liberally. This is underscored by the results of a study of 215 children with minor head trauma conducted by Simon and colleagues: 34 children with no known loss of consciousness and a Glasgow Coma Scale score of 15 nonetheless displayed intracranial lesions, 3 of whom required surgery.

Several studies in adults have given broad guidance in choosing which patients to scan ("New Orleans Criteria" and "Canadian CT Head Rule"; Table 35-2). They include features that are sensitive but not specific for intracranial injury, such as age above 60 years, intoxication, more than 30 min of retrograde amnesia, suspected skull fracture, seizure, anticoagulation, and dangerous mechanism of injury, (see Smits et al and Stiell et al). These two validated schemes for assisting in the determination of need for CT scanning in the emergency department are included for the reader's reference but they should be viewed as broad guidelines with fairly

Table 35-2

THE NEW ORLEANS AND CANADIAN CLINICAL DECISION RULES FOR CT AFTER CONCUSSION

New Orleans Criteria^a—Glasgow Coma Scale score of 15

- Headache
- Vomiting
- Age >60 y
- Drug or alcohol intoxication
- Persistent anterograde amnesia (deficits in short-term memory)
- Evidence of traumatic soft-tissue or bone injury above clavicles
- Seizure

Canadian CT Head Rule^b—Glasgow Coma Scale score of 13–15 for patients age 16 y and older

- High risk of neurosurgical intervention
 - Glasgow Coma Scale score <15 within 2 h after surgery
 - Suspected open or depressed skull fracture
 - Any sign of basal skull fracture
 - Two or more episodes of vomiting
- Age >54 y
- Moderate risk of brain injury detected by CT
 - Retrograde amnesia for ≥30 min
 - Dangerous mechanism

^aAdapted from Haydel et al.

^bAdapted from Stiell et al.

high sensitivity for important lesions on the CT, but low specificity so that most CT scans done under these advisories can be expected to be normal. These issues are addressed in a review by Ropper and Gorson.

Minor and seemingly trivial head injuries may sometimes be followed by a number of puzzling and worrisome clinical phenomena, some insignificant, others serious and indicative of a pathologic process other than concussion. The latter are described below. When they occur, a neurologic or neurosurgical evaluation is indicated.

Drowsiness, Headache, and Confusion These symptoms occur most often in children, who, minutes or hours after a concussive head injury, seem not to be themselves. They lie down, are drowsy, complain of headache, and may vomit—symptoms that suggest the presence of an intracranial hemorrhage. Mild focal edema near the point of impact may be seen on MRI. There is usually no skull fracture but, as Nee and colleagues point out, vomiting is associated with an increase in the incidence of skull fracture and the New Orleans and Canadian CT rules found vomiting to be a factor associated with intracranial bleeding (Table 35-2). The symptoms subside after a few hours, attesting to the benign nature of the condition in most cases but some form of cerebral imaging is required.

Transient Paraplegia, Blindness, and Migrainous Phenomena With falls or blows on top of the head, both legs may become temporarily weak and numb, with wavering bilateral Babinski signs and sometimes with sphincteric incontinence. Impact over the occiput may cause temporary blindness. The symptoms disappear after a few hours. It seems possible that these transient symptoms represent a direct localized concussive effect, caused either by indentation of the skull or by impact on these parts of the brain against the inner table of the skull, but a vascular mechanism cannot be excluded. The blindness and paraplegia are usually followed by a throbbing, vascular type of headache. Transient migrainous visual phenomena, aphasia, or hemiparesis, followed by a headache, are observed sometimes after minimal concussion in athletes who participate in competitive contact sports. Possibly all of these phenomena are the result of an attack of migraine induced by a blow to the head. These focal syndromes can be perplexing for a few hours, especially if it is the first such attack of migraine in a child. Possibilities to be remembered, particularly in cases of acute quadriplegia, is traumatic cord compression or the rarer cartilaginous embolism of the cervical cord (see “Fibrocartilaginous Embolism” in Chap. 44). A concussion of the cervical portion of the spinal cord is another potential mechanism of transient paraplegia.

Episodes of transient global amnesia after minor head injury have been described by Haas and Ross, as mentioned in Chap. 21. The problem in interpreting these spells is their similarity to posttraumatic amnesia and the repetitive stereotyped questioning regarding orientation that is common to both processes. A duration of 2 to 24 h and the feature of repetitive querying were suggested by Haas and Ross as differentiating the two conditions but the separation on this basis is not compelling.

Delayed Hemiplegia The main causes of delayed hemiplegia are a late-evolving epidural or subdural hematoma and, in more severe injuries, an intracerebral hemorrhage. Most of these are associated with a diminution in the level of consciousness from the outset but there are exceptions.

Dissection of the internal carotid artery should always be considered in cases of delayed hemiplegia. The dissection may occur in the extracranial or the intracranial portion of the carotid artery and should be sought by vascular imaging study if the hemiparesis has no other explanation. In other instances, the hemiplegia has no clear explanation other than the blow to the head, perhaps related to the migraine phenomenon described earlier.

Serious Cerebral Damage Following a Lucid Interval

This group is smaller than the other two but is of importance because it includes a disproportionate number of patients who are in urgent need of surgical treatment. The initial loss of consciousness from concussion may have lasted only a few minutes or, exceptionally, there may have been no period of unresponsiveness at all, in which instance one might wrongly conclude that there was no concussion and little possibility of traumatic hemorrhage or other type of brain injury. Patients who display this sequence of events, in the past referred to vividly as “talk and die” by Marshall and associates (1983), have late deterioration because of the expansion of a subdural hematoma, worsening brain edema around a contusion, or the delayed appearance of an epidural clot. Among 34 such patients in the Traumatic Coma Data Bank who had this type of lucid interval, the majority showed substantial degrees of midline shift on the initial CT scan, reflecting the presence of early brain edema and contusion (Marshall et al, 1983). A somewhat related condition of delayed intracerebral hematoma (*spät apoplexie*), discussed further on, is a feature of a more severe initial head injury that usually produces coma from the onset. The problem of cerebral fat embolism, mentioned earlier, should be considered in these cases of delayed deterioration, especially if there is interposed respiratory failure.

Patients Who Remain Comatose from the Time of Head Injury

Here, the central problem, set forth by Symonds, is the relationship between concussion and contusion and other forms of persisting structural brain damage. Because consciousness is abolished at the moment of injury, one can hardly doubt the existence of concussion in such cases; but when hours pass without consciousness being regained, the second half of the usual definition of concussion—that the disruption of cerebral function be transitory—is not satisfied. Pathologic examination of such cases usually discloses evidence of increased intracranial pressure and of cerebral contusions, subarachnoid hemorrhage, zones of infarction, and scattered intracerebral hemorrhages both at the point of injury (coup) and on the opposite side (contrecoup), in the corpus callosum,

and between these points, along the line of force of the impact. In some patients, the diffuse axonal type of injury is prominent or, as mentioned, there are separate but strategically placed ischemic and hemorrhagic lesions in the upper midbrain and lower thalamic region. Varying amounts of blood in the subarachnoid and subdural spaces are present. Displacement of the thalamus and midbrain may be present, with compression of the opposite cerebral peduncle against the free margin of the tentorium as well as secondary midbrain hemorrhages and zones of necrosis; in some cases, there is transtentorial herniation.

Severe head injury is often associated with an immediate arrest of respiration and sometimes with bradyarrhythmia and cardiac arrest. The immediate effects on the brain of these systemic changes may in themselves be sufficiently profound to cause coma. Intracranial pressure is almost always elevated and imaging of the brain shows various degrees of brain swelling, ventricular compression, and displacement of midline structure. Also, head injury often complicates alcohol and drug ingestion, so the possibility of a toxic or metabolic encephalopathy as the cause (or a contributing cause) of stupor must always be considered.

In all of these patients, following the initial period of stabilization, the matter of interest is the clinical and imaging assessment, with the purpose of uncovering a surgically remediable lesion, namely a subdural or epidural hematoma or a treatable intraparenchymal hematoma. In most cases, the discovery of such a mass lesion leads to surgical removal. But unless it is the only lesion, the procedure often proves to be insufficient and coma is likely to persist because of the associated cerebral damage. The recognition and management of these hematomas are described further on.

In the Traumatic Coma Data Bank, which included 1,030 gravely injured patients with Glasgow Coma Scale scores of 8 or less, 21 percent had subdural hematomas, 11 percent had intracerebral clots, and 5 percent had epidural hematomas. Notable, however, half the patients had no mass lesions on the CT scan. On this basis, these patients were thought to have diffuse axonal injury. However, in 50 consecutive autopsies of severely injured patients, summarized in an earlier era by Rowbotham, all but 2 showed macroscopic changes, suggesting the relative unreliability of CT analysis. The lesions in these cases consisted of surface contusions (48 percent), lacerations of the cerebral cortex (28 percent), subarachnoid hemorrhage (72 percent), subdural hematoma (15 percent), extradural hemorrhage (20 percent), and skull fractures (72 percent). As these figures indicate, several pathologic entities were found in the same patient.

There is that relatively small, distressing group of severely brain-injured patients in whom the vital signs become normal but who never regain full consciousness. As the weeks pass, the prospects become bleaker. Such a patient, especially if a child, may still emerge from coma after 6 to 12 weeks or longer and make a relatively good, although usually incomplete, recovery. Some of those who survive for long periods open their eyes and move their heads and eyes from side to side but betray no evidence

of seeing or recognizing even the closest members of their families. They do not speak and are capable of only primitive postural or reflex withdrawal movements. Jennett and Plum referred to this as the "persistent vegetative state" (see Chap. 17 for a full discussion of this subject). Fourteen percent of the patients in the Traumatic Coma Data Bank remained in this state. Hemiplegia or quadriplegia with varying degrees of decerebrate or decorticate posturing are usually present. Life is terminated after several months or years by some medical complication but some of our patients have survived for decades. Our colleague R.D. Adams has examined the brains of 14 patients who remained in coma and in vegetative states from 1 to 14 years. All showed extensive zones of necrosis and hemorrhage in the upper brainstem. Among patients who survived and remained vegetative until death, Adams and colleagues (2000) found that 80 percent had thalamic damage and 71 percent had findings of diffuse axonal injury. Moreover, trauma of extracranial organs and tissues is frequent and obviously contributes to the fatal outcome. Recent functional studies have shown that a limited proportion of patients who are in a vegetative or minimally conscious state can be trained to purposefully engage parts of the cerebrum.

In generalizing about this category of head injury, the effects of contusion, hemorrhage, and brain swelling often become evident within 18 to 36 h after the injury and then may progress for several days. If a patient survives this period, his chances of dying from complications of these effects are greatly reduced. The mortality rate of those who reach the hospital in coma is approximately 20 percent, and most of the deaths occur in the first 12 to 24 h as a result of direct injury to the brain in combination with other nonneurologic injuries. Of those alive at 24 h, the overall mortality falls to 7 to 8 percent; after 48 h, only 1 to 2 percent of patients succumb. There is some evidence that transfer of such patients to an intensive care unit, where personnel experienced in the handling of head injury can monitor them, improves the chances for survival (see further on).

One modest advance in the medical treatment of traumatic unresponsiveness has come from a randomized trial by Giacino and colleagues. Amantadine accelerated slightly the emergence from the vegetative or minimally conscious state; it was given for 4 weeks between the fourth and twelfth weeks after injury, 100 mg twice per day and increasing to 200 mg twice per day. The effects were less evident by 6 weeks but this seems like a promising approach. In cases of longer standing, deep brain stimulation of thalamic nuclei has been explored intermittently in past decades and has had some notable successes.

SPECIFIC TRAUMATIC CRANIAL LESIONS (Table 35-3)

The following lesions are considered in all cases of serious initial injury. They each have characteristic clinical and imaging features but they may be admixed and the contribution of each to the clinical state must be assessed before deciding on a course of action.

Table 35-3

CLINICAL AND RADIOGRAPHIC CHARACTERISTICS OF THE MAIN TRAUMATIC BRAIN LESIONS

	EPIDURAL HEMATOMA	ACUTE SUBDURAL HEMATOMA	CHRONIC SUBDURAL HEMATOMA	CONTUSION/PARENCHYMAL HEMORRHAGE	INTRAVENTRICULAR HEMATOMA	SUBARACHNOID HEMORRHAGE	SUBDURAL HYGROMA	DIFFUSE AXONAL INJURY
<i>Causative factor</i>	Laceration of middle cerebral artery or dural sinus	Tearing of bridging pial veins and arteries	Trauma (may be absent or minimal) Risk factors: coagulopathy and severe brain atrophy	Shearing of parenchymal vessels Risk factors: coagulopathy and amyloid vasculopathy	Shearing of parenchymal vessels; rule out vascular defects	Exclude underlying aneurysmal rupture	Arachnoid tear, following meningitis	Deceleration or rotational forces
<i>Typical location</i>	Lateral cerebral convexities	Lateral cerebral convexities	Lateral cerebral convexities, may be bilateral	Inferior frontal and temporal lobes	Lateral and third ventricles blood filled	Basilar cisterns	Lateral cerebral convexities	Deep white matter, corpus callosum, dorsolateral pons
<i>Evolution</i>	Hours	Many hours	Days to weeks	Expand over 12–48 h	Rapid	Minutes to hours	Days to weeks	From time of injury
<i>Clinical profile</i>	Typically, lucid interval then coma, but more variable; pupillary dilatation with contralateral then bilateral limb weakness; slowly evolving stupor then coma	Drowsiness, coma; pupillary dilatation with contralateral then bilateral limb weakness; progressive stupor then coma	Headache, progressive alteration in mental status ± focal neurologic signs	Stupor → coma, dilated pupil, progressive hemiplegia, spasticity	Progressive signs of hydrocephalus	Headache, meningismus, delayed manifestations, vasospasm	Mimics chronic subdural hematoma	Coma, posturing, normal intracranial pressure
<i>Age at risk</i>	Children, young adults	Any	Elderly	Any	Any	Any	Infants, children, adults	Any
<i>Radiologic features</i>	Acute bulging epidural clot bounded by cranial sutures; lenticular in shape	Acute blood rimming broad region of cerebral convexity	Hyper- or isodense, unilateral or bilateral	Multiple, confluent regions of edema intermixed with focal, acute blood	Focal, acute blood within ventricles; may layer with gravity	Acute blood lining cortex in subarachnoid space	Focal, CSF density, fluid collection	CT may be normal; MRI shows evolving small deep contusions
<i>Surgical intervention</i>	Urgent evacuation	Urgent evacuation if large enough to cause symptoms	Evacuation in some circumstances	Evacuate if large	Shunting	May cause secondary vasospasm or late hydrocephalus	Aspiration of fluid	None

Acute Epidural Hemorrhage

As a rule, epidural hematoma arises with a temporal or parietal fracture and laceration of the middle meningeal artery or vein. Less often, there is a tear in a dural venous sinus. The injury, even when it fractures the skull, may not have produced coma initially, or it may be part of a devastating craniocerebral injury. A typical example is that of a child who has fallen from a bicycle or swing or has suffered some other hard blow to the head and was unconscious only momentarily. A few hours later (exceptionally, with venous bleeding the interval may be several days or a week), headache of increasing severity develops, with vomiting, drowsiness, confusion, aphasia, seizures (which may be one-sided), hemiparesis with slightly increased tendon reflexes, and a Babinski sign. As coma develops, the hemiparesis may give way to bilateral spasticity of the limbs and Babinski signs. The heart rate is often slow (below 60 beats/min) and bounding, with a concomitant rise in systolic blood pressure (Cushing effect). The pupil may dilate on the side of the hematoma. Physicians need not be reminded that lumbar puncture is contraindicated in this setting, particularly now that CT and MRI are available. Death, which is almost invariable if an expanding clot is not removed surgically, comes at the end of a comatose period and is a result of respiratory arrest. The visualization of a fracture line across the groove of the middle meningeal artery and knowledge of which side of the head was struck (the clot is on that side) are of aid in diagnosis and lateralization of the lesion. However, meningeal vessels may occasionally be torn without fracture. The CT scan is definitive and reveals a lens-shaped clot with a smooth inner margin (Fig. 35-8).

Treatment of Epidural Hematoma The surgical procedure consists of placement of burr holes in an emergency

situation or, preferably, a craniotomy, drainage of the hematoma, and identification and ligation of the bleeding vessel. The operative results are excellent except in cases with extended fractures and laceration of the dural venous sinuses, in which the epidural hematoma may be bilateral rather than unilateral. If coma, bilateral Babinski signs, spasticity, or decerebrate rigidity supervene before operation, it usually means that displacement of central structures and compression of the midbrain have already occurred; prognosis is then poor, but a few patients do well if surgery is not greatly delayed. Small epidural hemorrhages can be followed by serial CT scanning and will be seen to enlarge gradually for a week or two and then be absorbed. There is controversy about the benefit of removing these smaller clots in a patient who has no symptoms; with careful clinical and imaging surveillance, most can be left alone.

Acute and Chronic Subdural Hematomas

The problems created by acute and chronic subdural hematomas are so different that they must be considered separately. In *acute subdural hematoma*, which may be unilateral or bilateral, there may be a brief lucid interval between the blow to the head and the advent of coma. More often, the patient is comatose from the time of the injury and the coma deepens progressively. Acute subdural hematoma may be combined with epidural hemorrhage, cerebral contusion, or laceration. The clinical effects of these several lesions are difficult to distinguish and there are a few patients in whom it is impossible to state before operation whether the clot is epidural or subdural in location. Subdural clots more than a few millimeter in thickness can be accurately visualized by the CT scan in more than 90 percent of cases, but the window settings must be appropriate to avoid obscuring of the clot by adjacent bone (Fig. 35-9). A large acute clot causes a shift of midline structure as well as marked compression of one lateral ventricle; but if there are bilateral clots, there may be no shift and the ventricles may appear symmetrically compressed.

Rapidly evolving subdural hematomas are usually a result of tearing of bridging veins, and symptoms are caused by compression of the adjacent brain and of deep structures. Unlike epidural arterial hemorrhage, which is steadily progressive, the rising intracranial pressure usually arrests the venous bleeding.

Exceptionally, the subdural hematoma forms in the *posterior fossa* and gives rise to headache, vomiting, pupillary inequality, dysphagia, cranial-nerve palsies, and, rarely, stiff neck, and ataxia of the trunk and gait if the patient is well enough to be tested for these functions. Because of their apposition to bone or an axial orientation along the tentorial dura, posterior fossa clots are likely to be overlooked in CT scans.

In *chronic subdural hematoma*, the traumatic etiology is often less clear. The head injury, especially in elderly persons and in those taking anticoagulant drugs, may have been trivial and forgotten. A period of weeks then follows when headaches (not invariable), light-headedness, slowness in thinking, apathy and drowsiness, unsteady gait,

Figure 35-9. Acute subdural hematoma over the right convexity, with substantial mass effect (displacement) of brain tissue but little edema.

and occasionally a seizure are the main symptoms. The initial impression may be that the patient has a vascular lesion or brain tumor or is suffering from drug intoxication, a depressive illness, or Alzheimer disease. Gradual expansion of the hematoma by one of several mechanisms discussed further on is believed to cause the progression of symptoms. As with acute subdural hematoma, the disturbances of mentation and consciousness (drowsiness, inattentiveness, and confusion) are more prominent than focal or lateralizing signs, and they may fluctuate. Focal signs, when present, consist of mild hemiparesis and, rarely, an aphasic disturbance. Homonymous hemianopia is seldom observed, probably because the geniculocalcarine pathway is deep and not easily compressed; similarly, hemiplegia, i.e., complete paralysis of one arm and leg, is usually indicative of a lesion within the cerebral hemisphere rather than a compressive lesion on its surface. Hemiparesis from subdural hematoma may sometimes be ipsilateral to the clot, the result of compression of the contralateral cerebral peduncle against the free edge of the tentorium (Kernohan-Woltman sign; see "Pathoanatomy of Brain Displacement and Herniations" in Chap. 17). If the condition progresses, the patient becomes stuporous or comatose. But this course is often interrupted by striking fluctuations of awareness.

With both large acute and chronic hematomas, dilatation of the ipsilateral pupil is a fairly reliable indicator of the side of the hematoma, although this sign may be misleading, occurring on the opposite side in 10 percent of cases, according to Pevehouse and coworkers. Convulsions are seen occasionally, most often in alcoholics or in patients with cerebral contusions, but they cannot be regarded as a cardinal sign of subdural hematoma. Rare cases of internuclear ophthalmoplegia and of chorea

have been reported but have not occurred in our material. Presumably they are a result of distortion of deep structures. Also, brief and self-limited disturbances of neurologic function simulating transient ischemic attacks (TIAs) may occur with chronic hematomas; their mechanism is uncertain, but they do not appear to represent seizures. In infants and children, enlargement of the head, vomiting, and convulsions are prominent manifestations of subdural hematoma.

CT scanning with contrast infusion and MRI are the most reliable diagnostic procedures. On CT scans, the acute clot is initially hyperdense but becomes slowly more isodense after a period of 1 or more weeks (Fig. 35-10). At that stage it may be difficult to detect except by the tissue shifts it causes. The fluid collection then becomes progressively hypodense (with respect to the cortex) over 2 to 6 weeks. The evolution of signal changes in the MRI is similar to the sequential imaging changes found with parenchymal hematomas. The acute clot is hypointense on T2-weighted images, reflecting the presence of deoxyhemoglobin. Over the subsequent weeks, all image sequences show it as hyperintense as a result of methemoglobin formation. Eventually the chronic clot again becomes hypointense on the T1-weighted images. With contrast infusion, both imaging procedures usually reveal the vascular and reactive border surrounding the clot. Usually, by the fourth week, sometimes later, the hematoma becomes very hypodense, giving rise to a chronic subdural hygroma that is indistinguishable from idiopathic ones that are presumably caused by a rent in the arachnoid that allows CSF to escape to the subdural compartment, as discussed further on.

Figure 35-10. Subacute subdural hematoma on the left (reader's right). CT scans after administration of intravenous contrast material. The lesion is isodense to the adjacent brain tissue, but its margin can be appreciated with contrast enhancement. Note displacement of cerebral structures.

Figure 35-11. Chronic subdural hematomas over both cerebral hemispheres without shift of the ventricular system. Chronicity results in hypodense appearance of the clots. Some old blood can still be seen on the right side. The bilaterally balanced masses result in an absence of horizontal displacement, but they may compress the upper brainstem.

The chronic subdural hematoma becomes gradually encysted by fibrous membranes (pseudomembranes) that grow from the dura. Some hematomas, probably those in which the initial bleeding was slight (see below), resorb spontaneously. Others expand slowly and act as space-occupying masses (Fig. 35-11). Gardner, in 1932, first postulated that the gradual enlargement of the hematoma was a result of the accession of fluid, particularly CSF, which was drawn into the hemorrhagic cyst by its increasing osmotic tension as red blood cells (RBCs) hemolyzed and protein was liberated. This hypothesis, which came to be widely accepted, is not supported by the available data. Rabe and colleagues demonstrated that the breakdown of RBCs contributes little, if at all, to the accumulation of fluid in the subdural space. According to the latter authors, the most important factor in the expansion of subdural fluid is a pathologic permeability of the developing capillaries in the outer pseudomembrane of the hematoma. The CSF plays no discernible role in this process, contrary to the original view of Munro and Merritt. The experimental observations of Labadie and Glover suggested that the volume of the original clot is a critical factor: The larger its initial size, the more likely it will be to enlarge. An inflammatory reaction, triggered by the breakdown products of blood elements in the clot, appears to be an additional stimulus for growth as well as for neomembrane formation and its vascularization. In any event, as the hematoma enlarges, the compressive effects increase gradually.

Treatment of Subdural Hematoma In most cases of acute hematoma it is sufficient to place burr holes and evacuate the clot before coma has developed. Treatment

of larger hematomas, particularly after several hours have passed and the blood has clotted, consists of craniotomy to permit control of the bleeding and removal of the clot. As one would expect, the interval between loss of consciousness and the surgical drainage of the clot is perhaps the most important determinant of outcome in serious cases. Thin, crescentic clots can be observed and followed over several weeks and surgery undertaken only if focal signs or indications of increasing intracranial pressure arise (headache, vomiting, and bradycardia). Small subdural hematomas causing no symptoms and followed by CT scans will self-absorb, leaving only a deep yellow, sometimes calcified membrane attached to the inner dural surface. If the acute clot is too small to explain the coma or other symptoms, there is probably extensive contusion of the cerebrum or another lesion.

To remove the more chronic hematomas a craniotomy must be performed and an attempt made to strip the membranes that surround the clot. This diminishes the likelihood of reaccumulation of fluid but it is not always successful. Other causes of operative failure are postoperative swelling of the compressed hemisphere or failure of the hemisphere to expand after removal of a large clot. The difficulty of managing these patients surgically should not be underestimated. Elderly patients may be slow to recover after removal of the chronic hematoma or may have a prolonged period of confusion. Postoperative expansion of the brain can be followed by serial CT scans and may take weeks. Small, asymptomatic chronic collections are usually left alone and followed serially by clinical and CT examination, first at several weeks and then longer intervals.

Although no longer a common practice, the administration of corticosteroids was an alternative to surgical removal of subacute and chronic subdural hematomas in patients with minor symptoms or with contraindications to surgery. This approach, reviewed by Bender and Christoff decades ago, has not been studied systematically but has been successful in a few of our patients (of course, they may have improved independent of the steroids).

Subdural Hygroma

This is a thinly encapsulated collection of clear or slightly xanthochromic fluid in the subdural space; such collections form after an injury, as well as after meningitis (in an infant or young child). As often, subdural hygromas appear without precipitant, presumably because of a ball-valve effect of an arachnoidal tear that allows cerebrospinal fluid to collect in the space between the arachnoid and the dura; brain atrophy is conducive to this process. Occasionally a hygroma originates from a tear in an arachnoidal cyst. It may be difficult to differentiate a long-standing subdural hematoma from hygroma, and some chronic subdural hematomas are probably the result of repeated small hemorrhages that arise from the membranes of hygromas. Shrinkage of the hydrocephalic brain after ventriculoperitoneal shunting is also conducive to the formation of a subdural hematoma or hygroma, in which case drowsiness, confusion, irritability, and low-grade fever are relieved when the subdural fluid is aspirated or drained. Intracranial hypotension is

another cause of subdural hygromas. In adults, hygromas are usually asymptomatic and do not require treatment; they only are infrequently the cause of seizures.

Cerebral Contusion and Traumatic Intracerebral Hemorrhage

Severe closed head injury is almost universally accompanied by cortical contusions and surrounding edema. The mass effect of contusional swelling, if sufficiently large, becomes a major factor in the genesis of tissue shifts and raised intracranial pressure. The CT appearance of contusion was already described (see Figs. 35-4 and 35-5). In the first few hours after injury, the bleeding points in the contused area may appear small and innocuous. The main concern, however, is the tendency for a contused area to swell or to develop into a hematoma during the first several days after injury. This may give rise to delayed clinical deterioration, sometimes abrupt in onset and concurrent with the appearance of swelling of the damaged region on the CT scan. It has been claimed, on uncertain grounds, that the swelling in the region of an acute contusion is precipitated by excessive administration of intravenous fluids (fluid management is considered further on in this chapter). Craniotomy and decompression of the swollen brain may be of benefit in selected cases with elevated intracranial pressure but it has no effect on the focal neurologic deficit.

One or several intracerebral hemorrhages may be apparent immediately after head injury, or hemorrhage may be infrequently delayed in its development by several days (the earlier mentioned *spät apoplexie*). The bleeding is in the subcortical white matter of one lobe of the brain or in deeper structures such as the basal ganglia or thalamus. The injury had nearly always been severe; blood vessels as well as cortical tissue are torn.

The clinical picture of traumatic intracerebral hemorrhage is similar to that of hypertensive brain hemorrhage with deepening coma with hemiplegia, a dilating pupil, bilateral Babinski signs, and stertorous and irregular respirations. The additional mass may be manifest by an abrupt rise in blood pressure and in intracranial pressure.

Craniotomy with evacuation of an acute or delayed clot has given a successful result in some cases but the advisability of surgery is governed by several factors including the level of consciousness, the time from the initial injury, and the associated damage (contusions, subdural and epidural bleeding) shown by imaging studies. Application of intracranial pressure monitoring and of CT scans at intervals after the injury facilitates diagnosis. Boto and colleagues found that basal ganglia hemorrhages were prone to enlarge in the day or two after closed head injury and that those greater than 25 mL in volume were fatal in 9 of 10 cases.

It should be mentioned again that subarachnoid blood of some degree is very common after all degrees of head injury. A problem that sometimes arises in cases that display both contusions and subarachnoid blood is the possibility that a ruptured aneurysm was the initial event and that a resultant fall caused the contusions. In cases where the subarachnoid blood is concentrated around one

of the major vessels of the circle of Willis, an angiogram is justified to exclude the latter possibility. Also in elderly patients, it has been difficult to determine whether a fall had been the cause or the result of a subarachnoid or an intracerebral hemorrhage. These subjects are addressed further in Chap. 34.

Acute Brain Swelling in Children

This condition is seen in the first hours after injury and may prove rapidly fatal. The CT scan shows enlargement of both hemispheres and compression of the basal cisterns and ventricles. There is usually no papilledema in the early stages, during which the child hyperventilates, vomits, and shows extensor posturing. The assumption has been that this represents a loss of regulation of cerebral blood flow and a massive increase in the blood volume of the brain. The administration of excessive water in intravenous fluids may contribute to the problem and should be avoided. Inappropriate secretion of antidiuretic hormone (ADH) also exaggerates the swelling in some children. We have not observed this complication in adults. Fear of massive brain swelling from a second impact after a concussion has been raised as a rationale for keeping youngsters from returning to athletic activity, but there is little evidence for the existence of this entity in adults as noted by McCrory and Berkovic.

“Shaken Baby” Syndrome

This form of craniocerebral trauma in infants is well known in large emergency practices and is now missed less frequently than in the past as practitioners have been sensitized to specifically consider it when an infant or child is injured. As the name implies, the inciting trauma is typically violent shaking of the body or head of an infant, resulting in rapid acceleration and deceleration of the cranium. The presence of this type of injury must often be inferred from the distribution and types of lesions on imaging studies or autopsy examination, but precision in examination is paramount because of its forensic and legal implications. The diagnosis is suspected from the combination of subdural hematomas and retinal hemorrhages, as summarized by Bonnier and colleagues. Sometimes there are occult skull fractures, but more often, there is little or no direct cranial trauma. Additional lesions may be evident on diffusion-weighted MRI, particularly in the white matter of the corpus callosum and the temporo-occipito-parietal region. This syndrome confers a high risk for slowing of cognitive development; in extreme cases there may be acquired microcephaly reflecting brain atrophy consequent to both contusions and infarctions. A low initial Glasgow Coma Scale score, severe retinal hemorrhages, and skull fractures are associated with poor outcomes. Old and recent fractures in other parts of the body should arouse suspicion of this syndrome.

Penetrating Wounds and Blast Injuries

Missiles and Fragments

The descriptions in the preceding pages apply to blunt, nonpenetrating injuries of the skull and their effects on

the brain. In the past, the care of penetrating craniocerebral injuries was mainly the interest of the military surgeon, but—with the persistence of violent crime in society—such cases have also become commonplace on the emergency wards of general hospitals.

In civilian life, *missile injuries* are essentially caused by bullets fired from rifles or handguns at high velocities. Air is compressed in front of the bullet so that it has an explosive effect on entering tissue and causes damage for a considerable distance around the missile track. *Missile fragments*, or *shrapnel*, from exploding shells, mines, grenades, or bombs are the usual causes of penetrating cranial injuries in wartime. The cranial wounds that result from missiles and shrapnel have been classified by Purvis as tangential, with scalp lacerations, depressed skull fractures, and meningeal and cerebral lacerations; penetrating, with in-driven metal particles, hair, skin, and bone fragments; and through-and-through wounds.

In most penetrating injuries from high-velocity missiles, the object (such as a bullet) causes a high-temperature coagulative lesion that is sterile and does not require surgery if the projectile exits the skull. In these instances, the main considerations are the development of infection or CSF leaks or, in the long term, epilepsy or aneurysms in distal blood vessels. The latter are considered to be the result of disruption of the vessel wall by the local high-energy shock wave.

If the brain is penetrated at the lower levels of the brainstem, death is instantaneous because of respiratory and cardiac arrest. Even through-and-through wounds at higher levels, as a result of energy dissipated in the brain tissue, may damage vital centers sufficiently to cause death immediately or within a few minutes.

Once the initial complications are dealt with, the surgical problems, as outlined by Meirovsky, are reduced to three: prevention of infection by debridement accompanied by the administration of broad-spectrum antibiotics; control of increased intracranial pressure and shift of midline structures by removal of clots of blood and the administration of mannitol or other dehydrating agents, and the prevention of life-threatening systemic complications.

When first seen, the majority of patients with penetrating cerebral lesions are comatose. A small metal fragment may have penetrated the skull without causing concussion, but this is usually not true of high-velocity missiles. In a series of 132 patients analyzed by Frazier and Ingham, consciousness was lost initially in 120. The depth and duration of coma seemed to depend on the degree of cerebral necrosis, edema, and hemorrhage. In the series of the Traumatic Coma Data Bank, the mortality rate in 163 patients who were initially comatose from a cranial gunshot wound is 88 percent—more than twice the rate from severe blunt head injury. On emerging from coma, the patient passes through states of stupor, confusion, and amnesia, not unlike those following severe closed head injuries. Focal or focal and generalized seizures occur in the early phase of the injury in some 15 to 20 percent of cases.

Recovery may take many months. Frazier and Ingham commented on the “loss of memory, slow cerebration, indifference, mild depression, inability to concentrate,

sense of fatigue, irritability, vasomotor, and cardiac instability, frequent seizures, headaches, and giddiness, all reminiscent of the residual symptoms from severe closed head injury with contusions.” Every possible combination of focal cerebral symptoms may be caused by such lesions. The excellent older articles by Feiring and Davidoff, by Russell, and by Teuber are still very useful references on this subject.

Epilepsy is the most troublesome sequela and is described further on. Ascroft and also Caviness, in reviewing World War II cases, found that approximately half of all patients with bullet or shrapnel wounds that had penetrated the dura eventually developed seizures, most focal in nature; the figures reported by Caviness for Korean War veterans are about the same.

CSF *rhinorrhoea*, discussed earlier and in Chap. 30, may occur as an acute manifestation of a penetrating injury that produces a fracture through the frontal, ethmoid, or sphenoid bones. Cairns listed these acute cases as a separate group in his classification of CSF rhinorrhoeas, the others being (1) a delayed form after craniocerebral injury, (2) a form that follows sinus and cranial surgery, and (3) a spontaneous variety. *Pneumoencephalocele (aerocele)*—i.e., air entering the cerebral subarachnoid space or ventricles spontaneously or as a result of sneezing or blowing the nose—is evidence of an opening from the paranasal sinus through the dura, as mentioned earlier in relation to skull fracture (see Fig. 35-3).

Blast Injuries

The shock wave of an explosive device such as bomb can propel objects into the cranium but there is also a direct form of organ damage from the dissipation of energy that occurs at the interfaces of tissues of different densities. This form of barotrauma invariably ruptures the tympanic membranes, a sign that is a marker of blast injury (Xydakis et al). Deafness, tinnitus, and vertigo are common accompaniments from cochlear concussion. The lung is next most often affected.

Loss of consciousness may occur but there is little understanding of the mechanism aside from the more conventional flinging of the skull from the pressure wave. As summarized in an editorial by one of the authors, the initial shock wave is followed by a supersonic blast wind and a reverse and prolonged front of underpressure. Tissues are damaged when energy is dissipated at the interface between air and liquid that presents a change in acoustic impedance. The subsequent blast wind is the source of separate injury, throwing people against fixed objects and dispersing projectiles that penetrate the body. Potential modes of conduction of the force of the blast to the cranial contents include the acceleration and deceleration of the head as a wave passes by, which essentially results in concussion; skull deformation which squeezes the brain; the indirect passage of the shock wave through the lungs; and the entry of the wave through the openings in the cranial vault, specifically, the acoustic and optic canals and the foramen magnum.

Acute gas embolism of the brain vessels has also been reported in the military medical literature. DePalma and colleagues have thoroughly reviewed blast injuries

but the neurologic literature is quite deficient and does not settle whether the percussion wave can produce unconsciousness by direct “concussion” of brain tissue in the original meaning of the term.

SEQUELAE OF HEAD INJURY

Posttraumatic Epilepsy (See also Chap. 16)

Seizures are the most common delayed sequela of craniocerebral trauma, with an overall incidence of approximately 5 percent in patients with closed head injuries and 50 percent in those who had sustained a compound skull fracture and direct wounds of the brain. The basis is nearly always a contusion or laceration of the cortex. As one might expect, the risk of developing posttraumatic epilepsy is also related to the overall severity of the closed head injury. In a civilian cohort of 2,747 head-injured patients described by Annegers and colleagues (1980), the risk of seizures after severe head injury (defined by loss of consciousness or amnesia for more than 24 h, including subdural hematoma and brain contusion) was 7 percent within 1 year and 11.5 percent in 5 years. If the injury was only moderate (unconsciousness or amnesia for 30 min to 24 h or causing only a skull fracture), the risk fell to 0.7 and 1.6 percent, respectively. After mild injury (loss of consciousness or amnesia of less than 30 min), the incidence of seizures was not significantly greater than in the general population. In a subsequent study, Annegers and colleagues (1998) expanded the original cohort to include 4,541 children and adults with cerebral trauma. The results were much the same as those of the first study except that in patients with mild closed head injuries, there was only a slight excess risk of developing seizures—a risk that remained elevated only until the fifth year after injury. The likelihood of epilepsy is said to be greater in parietal and posterior frontal lesions, but it may arise from lesions in any area of the cerebral cortex. Also, the frequency of seizures is considerably higher after penetrating cranial injury, as cited earlier.

The interval between the head injury and the first seizure varies greatly. A small number of patients have convulsive movements within moments of the injury (*immediate epilepsy*). Usually this amounts to a brief tonic extension of the limbs, with slight shaking movements immediately after concussion, followed by awakening in a mild confusional state. Whether this represents a true epileptic phenomenon or, as appears more likely, is the result of arrest of cerebral blood flow or a transient brainstem dysfunction is unclear. Some 4 to 5 percent of hospitalized head-injured individuals are said to have one or more seizures within the first week of their injury (*early epilepsy*). The immediate seizures have a good prognosis and we tend not to treat them as if they represented epilepsy; on the other hand, late seizures are significantly more frequent in patients who had experienced epilepsy in the first week after injury (not including the convulsions of the immediate injury; Jennett). Seizures occurring minutes or hours after the injury in an otherwise

fully awake patient have sometimes turned out to be factitious in our experience.

The term *posttraumatic epilepsy* usually refers to late epilepsy, i.e., to seizures that develop several weeks or months after closed head injury (1 to 3 months in most cases). Approximately 6 months after injury, half the patients who will develop epilepsy have had their first episode; by the end of 2 years, the figure rises to 80 percent (Walker). Data derived from a 15-year study of military personnel with severe (penetrating) brain wounds indicate that patients who escape seizures for 1 year after injury can be 75 percent certain of remaining seizure-free; patients without seizures for 2 years can be 90 percent certain; and for 3 years, 95 percent certain. For the less-severely injured (mainly closed head injuries), the corresponding times are 2 to 6 months, 12 to 17 months, and 21 to 25 months (Weiss et al). Despite this, there is no doubt that seizures in adulthood occur for which there is no other explanation than a small scarred cortical contusion that had been acquired decades before. The interval between head injury and development of seizures is said to be longer in children.

Posttraumatic seizures (both focal and generalized) tend to decrease in frequency as the years pass, and a significant number of patients (10 to 30 percent, according to Caviness) eventually stop having them. Status epilepticus is uncommon. Individuals who have early attacks (within a week of injury) are more likely to have a complete remission of their seizures than those whose attacks begin a year or so after injury. A low frequency of attacks is another favorable prognostic sign. Alcoholism is considered to have an adverse effect on this seizure state, but there are no systematic studies of this subject. Our colleague, M. Victor, observed some 25 patients with posttraumatic epilepsy in whom seizures had ceased altogether for several years, only to recur in relation to drinking. In these patients the seizures were precipitated by a weekend or even one evening of heavy drinking and occurred, as a rule, not when the patient was intoxicated but in the withdrawal period.

The nature of the epileptogenic lesion has been a cortical scar in most instances, but in some cases, particularly in alcoholics, it has been elusive. From the examination of old cortical contusions (*plaques jaunes*), one cannot, on morphologic grounds, determine whether a lesion had or had not been epileptogenic. Electroocortigrams of the brain in regions adjacent to old traumatic foci reveal a number of spontaneously electrically active zones adjacent to the scars.

Treatment and Prophylaxis The use of antiepileptic drugs to prevent a posttraumatic seizure and subsequent epilepsy after closed or penetrating cranial injury has its proponents and skeptics. In one study, patients receiving phenytoin developed fewer seizures at the end of the first year than a placebo group, but a year after medication was discontinued, the incidence was the same (and quite low) in the two groups. An extensive randomized study by Temkin and colleagues demonstrated that when administered within a day of injury and continuing for 2 years, phenytoin reduced the incidence of seizures in the first week, but not thereafter. Also, in a study of a large

number of patients with penetrating head injuries, the prophylactic use of antiepileptic medications was ineffective in preventing early seizures (Rish and Caviness), and this is reflected in current guidelines (Chang and Lowenstein).

Usually, persistent seizures can be controlled by a single antiepileptic medication, and relatively few seizure disorders are recalcitrant to the point of requiring excision of the epileptic focus. In this small group, the surgical results vary according to the methods of patient selection and techniques of operation. Under the neurosurgical conditions of four decades ago, with careful selection of cases, Rasmussen (also Penfield and Jasper) was able to eradicate seizures in 50 to 75 percent of cases by excision of the focus; the results currently are somewhat better.

Autonomic Dysfunction (“Storm”) Syndrome

A worrisome consequence of severe head injury, which is observed in some comatose patients and particularly in the vegetative state, is a syndrome of episodic vigorous extensor posturing, profuse diaphoresis, hypertension, and tachycardia lasting minutes to an hour. A slight fever may accompany the spells. Families and staff are greatly disturbed by the display, particularly when the patient’s grimacing suggests suffering. These spells of excessive sympathetic activity and posturing may be precipitated by painful stimuli or by distention of a viscus, but often they arise spontaneously. The syndrome is often mistakenly identified as a seizure and in many texts is still referred to as “diencephalic epilepsy” but it is more likely the result of the removal of suppressive cortical influences on autonomic structures, allowing the hypothalamus to function independently of normal inhibitory mechanisms. A survey of 35 such patients by Baugley and colleagues identified diffuse axonal injury and a period of hypoxia as being the main associated injuries and this has been our experience as well.

Narcotics such as morphine and benzodiazepines have a slightly beneficial effect but bromocriptine, which may be used in combination with sedatives or with small doses of morphine, has been most effective according to Rossitch and Bullard.

Extrapyramidal and Cerebellar Disorders Following Trauma

The question of a causative relationship between cerebral trauma and the development of Parkinson disease has been a controversial issue for many years—usually with the conclusion that the condition does not exist and that any apparent relationship, particularly after a single brain injury, is coincidental. Some such patients probably had early symptoms of Parkinson disease brought to light by the head injury. There are, however, cases such as the one reported by Doder and colleagues, in which traumatic necrosis of the lenticular and caudate nuclei was followed after a period of 6 weeks by the onset of predominantly contralateral parkinsonian signs, including tremor, which progressed slowly and were unresponsive to L-dopa. There are also undoubted

instances of parkinsonism following severe closed head injury and the vegetative state (Matsuda et al). An exception to these statements may be a parkinsonian syndrome in ex-boxers and in others who had frequent minor head injuries, as a manifestation of the “punch-drunk” syndrome. There remains the possibility that cranial trauma incites a series of cellular events that lead to the deposition of abnormal structural proteins such as synuclein (see below).

Cerebellar ataxia is another rare consequence of cranial trauma, often unexplained but also in cases complicated by cerebral anoxia (causing ataxia with myoclonus) or a by a hemorrhage strategically placed in the deep midbrain or cerebellum. When cerebellar ataxia is caused by the trauma itself, it is frequently unilateral and the result of injury to the superior cerebellar peduncle. We have experience with a severely ataxic patient who had only small lesions in the cerebellum after bilateral acute subdural hematomas from an assault with head trauma. An “apraxia” of gait may also reflect the presence of a communicating hydrocephalus (see below and Chap. 30).

Acute and Chronic Traumatic Encephalopathy

Acute Traumatic Encephalopathy In almost all patients with cerebral concussive injury, there remains a gap in memory (traumatic amnesia) spanning a variable period from before the accident to some point following it. This gap is permanent and is filled in only by what the patient is told. In addition, as stated in the introduction to this section, some degree of impairment of higher cortical function may persist for weeks (or be permanent) after moderate to severe head injuries, even after the patient has reached the stage of forming continuous memories. During the period of reduced mentation, the memory disorder is the most prominent feature; in that respect, the state resembles the alcoholic form of the Korsakoff amnesic state and has some resemblance to the state of transient global amnesia (see Chap. 21).

With more careful testing, other cognitive disorders are usually evident. Concussed patients, during the period of posttraumatic amnesia, rarely confabulate. Apart from disorientation in place and time, the head-injured patient also shows defects in attention, as well as showing distractibility, perseveration, and an inability to synthesize perceptual data. Judgment and executive function may be mildly impaired, rarely severely, during the amnesic epoch. A perseverative tendency interferes with both action and thought. Leininger and associates, for example, found that most of their 53 patients who suffered minor head injury in traffic accidents performed less well than controls on psychologic tests (category test, auditory verbal learning, copying of complex figures). The fact that those who were merely dazed did as poorly as those who were concussed and that litigation was involved in some cases would lead one to question these results. Perhaps most affected, and most evident to high-functional individuals, is a problem with overall planning and coherence that is attributable to a defect in frontal lobe executive functioning.

As a general rule, the lower the score on the Glasgow Coma Scale immediately after injury (see Table 35-1) and

the longer the posttraumatic gap in the formation of new memories (anterograde amnesia), the more likely the patient is to suffer some permanent cognitive and personality changes. According to Jennett and Bond, patients with good recovery achieved their maximum degree of improvement within 6 months. Others have found that detailed and repeated psychologic testing over a prolonged period, even in patients with relatively minor cerebral injuries, discloses measurable improvement for as long as 12 to 18 months.

There are other mental and behavioral abnormalities of a more subtle type that remain as sequelae to serious cerebral injury. As the stage of posttraumatic dementia recedes, the patient may find it impossible to work or to adjust to his family situation. Such patients are often abnormally abrupt, argumentative, and suspicious. Unlike the postconcussion syndrome described above, in which there is a certain uniformity, these traits vary with the patient's age, past experience, and environmental stresses. Extremes of age have been particularly important in our experience. The most prominent behavioral abnormality in children, described by Bowman and colleagues, is a change in personality. They become impulsive, impatient, unable to sit still, or may become heedless of the consequences of their actions and lacking in appreciation of social norms—much like those who in the past had recovered from encephalitis lethargica. Some adolescents or young adults show the general lack of inhibition and impulsivity that one associates with frontal lobe disease. In the older person, it is the impairment of intellectual functions that assumes greater prominence. In most instances, these more serious behavioral changes can be traced to contusions in the frontal and temporal lobes. In cases without obvious structural brain damage, cognitive deficiency after trauma has been widely attributed to diffuse axonal injury. Attempts to validate this by modern techniques such as diffusion tensor imaging have met with some success, such as the series described by Kraus and colleagues.

The tendency is for many such symptoms to subside slowly although not always completely, even in those in whom an accident has provoked a frank outburst of psychosis (as may happen to a person who is bipolar or a paranoid schizophrenic). These forms of what had colorfully in the past been called "traumatic insanity" were analyzed for the first time by Adolf Meyer.

Chronic Traumatic Encephalopathy The cumulative effects of repeated or even single cerebral injuries, constitute a type of head injury that until recently was difficult to classify. The subject of a delayed neurodegenerative cerebral disease that follows mild traumatic brain injury after many years is best introduced by an exposition of the long-appreciated condition in boxers who had engaged in many bouts over a long period of time. This refers to the development, after many years in the ring, of dysarthric speech and a state of forgetfulness, slowness in thinking, and other signs of dementia. Movements are slow, stiff, and uncertain, especially those involving the legs, and there is a shuffling, wide-based gait. In other words, a parkinsonian and dementing syndrome emerges and sometimes a moderately disabling ataxia, but there is no mistaking these for idiopathic Parkinson or Alzheimer

disease. The plantar reflexes may be extensor on one or both sides. The clinical syndrome was reanalyzed by Roberts and colleagues, who found it present to some degree in 37 of the 224 professional boxers they examined. More recent studies show that in about one-half of all professional boxers, both active and retired, the CT scan discloses ventricular dilatation and sulcal widening and a cavum septi pellucidi (why the latter, which is ostensibly a developmental anomaly, would be overrepresented in boxers is unclear). These anatomic abnormalities had been demonstrated many years before by pneumoencephalography and were found to be related to the number of bouts (Ross et al; Casson et al).

A pathologic study of this disorder specific to boxers was made by Corsellis and associates. They examined the brains of 15 retired boxers who had shown the punch-drunk syndrome and identified a group of cerebral changes that appeared to explain the clinical findings. Mild to moderate enlargement of the lateral ventricles and thinning of the corpus callosum were present in all cases. Also, as mentioned, practically all of them showed a greatly widened cavum septi pellucidi and fenestration of the septal leaves. Readily identified areas of glial scarring were situated on the inferior surface of the cerebellar cortex. In these areas, and well beyond them, Purkinje cells were lost and the granule cell layer was somewhat thinned. Surprisingly, cerebral cortical contusions were found in only a few cases. Notably absent also was evidence of previous hemorrhage. Of the 15 cases, 11 showed varying degrees of loss of pigmented cells of the substantia nigra and locus ceruleus, and many of the remaining cells showed Alzheimer neurofibrillary change but not Lewy bodies. Neurofibrillary changes were scattered diffusely through the cerebral cortex and brainstem but were most prominent in the mediotemporal gray matter. Noteworthy was the absence of discrete amyloid plaques in this material by the usual staining methods; however, all cases showed extensive immunoreactive deposits of beta-amyloid ("diffuse plaques").

However, these studies were performed before the advent of modern immunohistochemistry techniques. McKee and coworkers have drawn attention to the deposition of tau protein in autopsy material that has come to define chronic traumatic encephalopathy. They have found a fairly consistent neuropathologic pattern consisting mainly of perivascular hyperphosphorylated tau protein embedded in astrocytic or neurofibrillary tangles with a predilection for the depths of sulci of the frontal and temporal lobes but also in other areas of cortex, thalamus, and brainstem, and eventually appearing extensively in the medial temporal lobes. Among 85 subjects with repetitive mild traumatic brain injury they found these changes to varying degrees in 68. The majority had headaches, depression, impulsivity and aggression, to some extent independent of the severity of pathologic changes. As evident in others was poor cognitive performance in the spheres of executive function and memory. Only those with the most widespread and densest deposition of tau were overtly demented and many of those had gait difficulty. A few of these also had parkinsonian manifestations. A putative relationship to motor neuron disease has also been raised. This form of

chronic encephalopathy and tau deposition has evinced great interest in relation to concussion sustained during athletics at all levels.

Posttraumatic Hydrocephalus

This is an uncommon complication, but one that is frequently imputed to severe head injury. It conforms to the category of normal pressure hydrocephalus, as discussed in Chap. 30. Intermittent headaches, vomiting, confusion, and drowsiness are the initial manifestations. Later on, mental dullness, apathy, and psychomotor retardation are seen; by this time the CSF pressure may have fallen to a normal level (normal-pressure hydrocephalus). Postmortem examinations in some cases have demonstrated an adhesive basilar arachnoiditis. Early subarachnoid hemorrhage may be involved in the mechanisms. The response to ventriculoperitoneal shunt may be dramatic. Zander and Foroglou have written informatively about this condition.

Postconcussion Syndrome

This troublesome and common problem has been mentioned earlier, as well as in Chap. 10 in relation to headache. When the syndrome is protracted, neurologists are vexed by the condition—a problem intensified by worried patients and family. It has some similarities to the *posttraumatic stress disorder*, and had in the past been termed *posttraumatic nervous instability syndrome* and *traumatic neurasthenia* by Sir Charles Symonds, among many other names. Headache, dizziness, poor endurance, and lack of mental clarity are the central symptoms.

The cranial pain is either generalized or localized to the part that had been struck and variously described as aching, throbbing, pounding, stabbing, pressing, or band-like; it is remarkable for its variability in an individual patient. The intensification of the headache and other symptoms by mental and physical effort, straining, stooping, and emotional excitement is characteristic; rest and quiet tend to relieve it. Headaches may present a major obstacle to convalescence.

Dizziness, another prominent symptom, is usually not a true vertigo but a giddiness or light-headedness. The patient may feel unsteady, dazed, weak, or faint. However, a certain number of patients describe symptoms that are at least consonant with labyrinthine disorder; objects in the environment move momentarily, and looking upward or to the side may cause a sense of imbalance. Labyrinthine tests may show hyporeactivity of one side of the vestibular apparatus but more often they disclose no abnormalities. McHugh found a high incidence of minor abnormalities by electronystagmography, both in concussed patients and in those suffering from whiplash injuries of the neck; but we find much of the data difficult to interpret. Exceptionally, vertigo is accompanied by diminished excitability of both the labyrinth and the cochlea (deafness), and one may assume the existence of direct injury to the eighth nerve or end organ. Intolerance of alcohol is reported by some patients.

These physical symptoms resolve in several weeks in the majority of patients. When the symptoms persist, the patient becomes intolerant of noise, emotional

excitement, and crowds. Tenseness, restlessness, fragmentation of sleep, inability to concentrate, feelings of nervousness, fatigue, worry, apprehension, and an inability to tolerate the usual amount of alcohol complete the clinical picture. The resemblance of these symptoms to those of anxiety and depression and to other forms of “posttraumatic stress disorder” is apparent.

The postconcussion syndrome complicates all types of head injury, mild and severe. Once established, it may persist for months or even years, and it tends to resist all varieties of treatment. Any relationship to the earlier described CTE is uncertain. Strangely, this syndrome is almost unknown in children. Characteristic also is the augmentation of both the duration and intensity of this syndrome by problems with compensation and litigation, suggesting a psychologic factor. In countries where these matters are a less-prominent part of the social fabric, the occurrence of posttraumatic syndrome is far less frequent. Environmental stress assumes importance as well, for if too much is demanded of the patient soon after injury, irritability, insomnia, and anxiety are enhanced. In this connection, an interesting experiment was conducted by Mittenberg and colleagues (1992). A group of subjects with no personal experience or knowledge of head injury was asked to select from a list of those symptoms that they would expect after a concussive head injury. They chose a cluster of features virtually identical to that of the postconcussion syndrome. The high background rates of various components of the postconcussion syndrome make it appear to be more prevalent than it truly is. The prospective study by Meares and coworkers found that, when compared to a group of patients who had noncranial trauma, the rates of the features of the syndrome were the same and that the strongest predictor of its occurrence was a previous anxiety disorder. However, the symptoms undoubtedly occur in well-adjusted, high-functioning individuals and should not be dismissed as simply anxiety.

An approach to treating postconcussion symptoms is given below. It has also been reported that military personnel who experience head injuries of any degree have a higher incidence of posttraumatic stress disorder (PTSD) than those with other somatic injuries but again, the disorder is not easily predicated on psychologic factors. The same disorder can be detected in civilians after injury and it then blends clearly into the earlier-described postconcussion syndrome.

Hysterical symptoms that develop after head injury, both cognitive and somatic, appear to be more common than those following injury to other parts of the body. These symptoms are discussed in Chap. 51. They may be immediate or delayed and vary from amnesia to blindness, paralysis, stuttering, inability to stand, and even to catatonia.

TREATMENT OF HEAD INJURY

Patients With Concussion and Transient Symptoms

Patients with an uncomplicated concussive injury who have already regained consciousness by the time they are

seen in a hospital and have a normal neurologic examination pose few difficulties in management. They should not be discharged until the appropriate examinations (CT scans, skull films, if necessary) have been obtained and the results prove to be negative. Also, the patient should not be released until the capacity for consecutive memories has been regained and arrangements have been made for observation by the family of signs of possible, although unlikely, delayed complications (subdural and epidural hemorrhage, intracerebral bleeding, and edema). A program instituted by Mittenberg and colleagues (2001) has shown that reassurance and explanation of the concussive injury and anticipated aftereffects reduce the incidence of postconcussive symptoms at 6 months. Most such patients become mentally clear, have mild or no headache, and are found to have a normal neurologic examination. They do not require hospitalization or special testing, but in the current litigious climate of the United States, some form of brain imaging is nonetheless often performed as discussed in an earlier section.

Acetaminophen may be prescribed for headache. Any increase in headache, vomiting, or difficulty arousing the patient should prompt a return to the emergency department. A written instruction sheet with symptoms to be expected and clear advice about returning for examination is very helpful.

Patients with persistent complaints of headache, dizziness, and nervousness, are the most difficult to manage. The main approach is to counsel patients while the symptoms resolve, coupled with a reduction in mental and physical effort that is commensurate with the patient's level of endurance. A program must be planned in accordance with the basic problem. If work or school work precipitate headaches, for example, plans should be made to have them curtailed. Half-time work may be suitable for some individuals but not for others. Similarly, some physical activity is to be encouraged but exertion that causes headaches or mental confusion to occur or worsen should be reduced. At the same time, a bedbound or homebound state is discouraged and the patient may walk, use the internet, watch television, or read up to the level of causing fatigue. Each of these activities is then increased at a gradual rate. In all instances, reassurance that these symptoms improve over weeks or more should be offered in order not to allow the individual to internalize the notions of chronic dementia after head injury that pervade the popular press. Some hard-driving patients return to work, only to find headache, confusion, and fatigue recur in a disabling way and must start the cycle of reduced effort over again.

If there is mainly an anxious depression, antidepressant medications—such as in a fluoxetine, paroxetine, or a tricyclic—may be useful, but their effects are often disappointing. Simple analgesics, such as acetaminophen or nonsteroidal antiinflammatory drugs, should be prescribed for the headache. Litigation should be settled as soon as possible. To delay settlement usually works to the disadvantage of the patient. Long periods of observation, repetition of a multitude of tests, and waiting only reinforce the patient's worries and fears and reduce the motivation to return to work. Neuropsychologic tests

may be useful in the group with persistent cognitive difficulty, but the results should be interpreted with caution, as depression and poor motivation will degrade performance.

Patients With Severe Head Injury

If the physician arrives at the scene of an accident and finds an unconscious patient, a rapid examination should be made before the patient is moved. First it must be determined whether the patient is breathing and has a clear airway and obtainable pulse and blood pressure, and whether there is hemorrhage from a scalp laceration or injured viscera. Severe head injuries that arrest respiration are soon followed by cessation of cardiac function. Injuries of this magnitude are often fatal; if resuscitative measures do not restore and sustain cardiopulmonary function within 4 to 5 min, the brain is usually irreparably damaged. Bleeding from the scalp can usually be controlled by a pressure bandage unless an artery is divided; then a suture becomes necessary. Resuscitative measures (artificial respiration and cardiac compression) should be continued until they are taken over by ambulance personnel. Oxygen should then be administered.

The likelihood of a cervical fracture–dislocation, which may be associated with any severe head injury, is the reason for taking precautions in immobilizing the neck and in moving the patient. In the awake patient, neck pain calls attention to this complication. It should be recalled that even in the absence of a spinal fracture, the spinal cord may be threatened by the instability resulting from ligamentous injuries (posing the risk of subluxation). In the study of 292 patients with traumatic cervical injuries by Demetriades and colleagues, 31 (11 percent) showed subluxations without fracture and 11 (4 percent) had cord injuries with neither fracture nor subluxation. The combined use of standard cervical spine films and cervical CT scanning detected all cervical injuries. After severe head or neck injury, even without direct impact to the neck, it is advisable to obtain standard anteroposterior, lateral, and oblique neck films, with additional gentle flexion (20 degrees) and extension (30 degrees) views of the neck and a neck CT scan. If these are normal and there is little or no neck pain, the cervical collar is no longer required. If after these studies, or if they cannot be obtained, or if there is significant persistent pain or other neurologic findings induced by head movement, a cervical MRI is advisable. If there are signs of a myelopathy such as flaccid legs or incontinence, urgent MRI is advisable.

In the hospital, the first step is to clear the airway and ensure adequate ventilation by endotracheal intubation if necessary. A search for other injuries must be made, particularly of the abdomen, chest, spine, and long bones. Chestnut et al, in analyzing the data from the Traumatic Coma Data Bank, found that sustained early hypotension (systolic blood pressure <90 mm Hg) was associated with a doubling of mortality. If shock was present on admission to the emergency ward, the mortality was 65 percent. Although the hypotension that follows most injuries is a vasodepressor response and usually comes under control within approximately an hour without pressor drugs, a

large, unimpeded intravenous line should be inserted. Persistent hypotension because of head injury alone is an uncommon occurrence and should always raise the suspicion of thoracic or abdominal internal bleeding, extensive fractures, or trauma to the cervical cord, or diabetes insipidus. Initially, the infused fluid should be normal saline, avoiding the administration of excessive "free water" because of its adverse effect on brain edema. Oxygen should continue to be administered until it can be shown that the arterial oxygen saturation is normal.

A rapid neurologic survey can then be made, with attention to the depth of coma, size of the pupils and their reaction to light, ocular movements, corneal reflexes, facial movements during grimace, swallowing, vocalization, gag reflexes, muscle tone and movements of the limbs, predominant postures, reactions to pinch, and reflexes. Bogginess of the temporal or postauricular area (Battle sign), bleeding from the nose or ear, and extensive conjunctival edema and hemorrhage are useful signs of an underlying basal skull fracture. However, it should be remembered that rupture of an eardrum or a blow to the nose may also cause bleeding from these parts. Fracture of the orbital bones may displace the eye, with resulting strabismus; fracture of the jaw results in malocclusion and discomfort on attempting to open the mouth. If urine is retained and the bladder is distended, a catheter should be inserted and kept there. Temperature, pulse, respiration, blood pressure, arterial oxygen saturation, and state of consciousness should be checked and charted every hour. The Glasgow Coma Scale, mentioned earlier, has provided a practical means by which the state of impaired consciousness can be evaluated at frequent intervals (see Table 35-1), but it should not be considered a substitute for a more complete neurologic examination.

CT and MRI scanning of the cranium have assumed central importance at this juncture. A sizable epidural, subdural, or intracerebral blood clot is an indication for immediate surgery. The presence of contusions, brain edema, and displacement of central structures calls for measures to monitor progression of these lesions and to control intracranial pressure. These measures are best carried out in a critical care unit.

Management of Raised Intracranial Pressure

There has been a presumption, not unreasonable, that high levels of intracranial pressure are deleterious after head injury, much as it is in other processes that involve an intracranial mass. At issue has been the precise pressure at which damage occurs, whether lowering ICP improves outcome, which treatments are best, and the role of monitoring in guiding treatment. Certainly there are many biologic processes in neurons and astrocytes that greatly influence outcome after traumatic brain injury, many set in motion at the time of impact and not referable to raised ICP. At times, these overwhelm the changes induced by intracranial pressure but they are not particularly remediable, producing an emphasis on reducing intracranial pressure as a means of preventing secondary brain damage. An approach to intracranial pressure treatment is given here and also addressed in Chap. 17 on coma and Chap. 31 on brain tumors.

ICP Monitoring In cases of moderate and severe head injury it has been the practice on most ICU services to insert one of several available devices that continuously record intracranial pressure (ICP). The rationale is ostensibly to gain control over a remediable cause of secondary brain damage, particularly if the patient's neurologic examination is reduced to a few sentinel signs such as pupillary enlargement or because sedating medications have obscured the examination. The ventricular catheter has been considered a "gold standard" of pressure measurements as it is directly coupled to the CSF compartment, which should best reflect the summated pressures within the cranium. It has the additional advantage of affording therapeutic drainage of CSF in order to reduce ICP. In comatose patients, monitoring of ICP could avoid excessive fluid administration, refine the amount of osmotic agent and hypertonic saline used to reduce pressure, and establishes the ideal level of hyperventilation. In these respects, monitoring can be helpful by guiding treatment and avoiding detrimental effects on ICP of treatments for head trauma.

However, there are few critical data to support the routine use of ICP monitoring. Certainly in the patient who is only drowsy or shows only minimal mass effect on CT, it is usually not necessary. Guidelines given by the American Association of Neurological Surgeons and allied groups have been that monitoring is appropriate if Glasgow Coma Scale is between 3 and 8 and there are abnormalities on CT scan, or if there is no abnormality on the CT but the patient has any two of age over 40, posturing, or has systolic blood pressure below 90 mm Hg. They set a desirable level of ICP of below 20 mm Hg and this has reinforced the role of ICP monitoring in head trauma management.

A reassessment of the effectiveness of ICP monitoring in a randomized trial reached the contrary conclusion that the information gained offers no advantage over clinical observation and imaging with CT scan. This trial was carried out by Chesnut and colleagues in developing countries and defined raised intracranial pressure at a level that has been criticized as too low (20 mm Hg). Nonetheless the study has demonstrated that the use of a clinical approach to management of raised ICP is as feasible as a program based on direct ICP measurement. This does not negate the desirability of keeping ICP controlled at some arbitrary level; it merely questions the need for direct monitoring as a guide to management.

As a practical matter, we use ICP monitoring in our unit to warn of impending deterioration from brain edema or hemorrhage if the patient cannot be effectively examined or shows poor responsiveness with evidence of mass effect on a CT scan. Although the risk of infection with a ventricular catheter is low, less than 3 percent, prolonged use may be complicated by bacterial meningitis. The catheter may be left in place for 3 to 5 days, or fewer if the clinical state and ICP are stable for 24 to 48 h. The current generation of ICP monitors employs fiberoptic strain gauges that can be inserted directly into the cerebral cortex without apparent damage.

General Measures The first step in lowering elevated ICP is to control the incidental factors that are known to

raise pressure, such as hypoxia, hypercarbia, particularly hyperthermia, awkward head positions that compress the jugular veins, and high mean airway pressures from positive pressure ventilation (see the monograph by Ropper and colleagues [2004] and Chap. 30 for further details). The avoidance of hyponatremia and serum hypoosmolarity that would allow water to enter the brain and increase its volume is accomplished by infusing only isoosmolar or hyperosmolar solutions such as normal saline. Elevations in serum osmolality as a consequence of excessive concentrations of diffusible solutes such as glucose are not useful in reducing intracranial volume because they do not create gradient for water and solutes across the cerebral vasculature. Consequently, fluids such as 5 percent dextrose in water, 0.5 normal saline, and 5 percent dextrose in 0.5 normal saline are avoided; lactated Ringer solution is permissible; normal saline, with or without added dextrose, is ideal. In a post hoc study of a cohort of severely injured patients, resuscitation with albumin was found to have a detrimental effect compared to saline (SAFE Investigators).

Hyperosmolar Therapy The basis for this class of treatments is the creation of a gradient of water concentration from the brain to the blood that reduces brain volume. Mannitol, glycerol, and urea are effective in lowering ICP by producing serum hyperosmolarity initially and then causing a diuresis that sustains this state and secondarily causes hypernatremia and hypovolemia. Hyperosmolar saline, in contrast, raises serum sodium directly and expands intravascular volume.

The effects of mannitol have been of great interest to those who treat head trauma, but the ideal plan for its use has never been established. If intracranial pressure exceeds a predetermined level, for example 20 mm Hg as recommended by aforementioned guidelines for the treatment of traumatic brain injury, mannitol 20 percent, 0.25 to 1.0 g/kg is given every 3 to 6 h to maintain serum sodium above approximately 142 mEq/L and osmolality of 290 to 315 mOsm/L. Even if ICP monitoring is not used, an attempt may be made to maintain this level of serum osmolality for the first days after injury if contusion and brain swelling are detected on the CT scan.

Mannitol in large amounts may cause renal failure, almost always reversible, though an uncertain mechanism perhaps having to do with renal blood flow. Limited evidence suggests that this complication occurs only with the use of more than 200 g of mannitol daily.

The relative merits of hypertonic saline and mannitol are frequently discussed and have been reviewed by one of us (Ropper, 2012). Several small series comparing the agents, referenced in the review, have shown too little difference to allow a choice between the two agents. Local experience and an overall assessment of the side effects of each typically dominate practice. Hypertonic saline (concentrations of 3 percent to 23 percent) has a comparable effect to mannitol in the treatment of raised ICP and has the advantage of avoiding severe dehydration because it increases osmolality directly rather than through diuresis. The opposite also pertains, namely that patients with poor cardiac output may be subject to congestive heart failure with hypertonic saline in high

volumes. Diuretics have been used to mitigate this effect. Either agent can produce a hyperglycemic, hyperosmolar state in diabetics, particularly in the elderly and in those receiving corticosteroids.

Hypertonic saline, 3 percent, can be used in boluses of 150 mL; a 7.5 percent solution, in 75 mL boluses; and 23 percent, in volumes of approximately 30 mL. All but the lowest concentration of saline require a central venous catheter to prevent sclerosis of veins. The same levels of sodium concentration as noted for mannitol are used as a reference to guide graduated increments of sodium administration, with serum sodium higher than about 156 mEq/L infrequently providing additional reductions in ICP.

Hypocarbia Hypocarbia, induced by hyperventilation, produces alkalosis of the CSF and cerebral vasoconstriction with a corresponding reduction in cerebral blood volume and ICP. It is effective for a limited period of time, as the pH of the spinal fluid equilibrates over hours by the elaboration of ammonium ions in the choroids plexus, allowing cerebral blood volume to return to its previous level. A single-step reduction in P_{CO_2} typically lowers ICP for approximately 20 to 40 min. Attempts to prolong the effect of hypocarbia and the alkalosis by the intravenous administration of ammonium buffers have met with mixed success.

It has been suggested that hyperventilation may be harmful to some head-injured patients because of a reduction in cerebral blood flow, but the risk, if any, appears to be minimal, at least in adults. In children, reductions in cerebral blood flow have been demonstrated by Skippen and colleagues at even modest levels of hypocarbia and three-quarters show slight brain ischemia when P_{CO_2} is below 25 mm Hg. For these reasons, hypocarbia is used in cases of head trauma mainly in acute circumstances and has been eschewed for chronic use. If the ICP continues to rise and brain swelling progresses despite these measures, the outlook for survival is poor. It should be mentioned that many patients, particularly children, hyperventilate spontaneously after head trauma.

Hypothermia Hypothermia and barbiturate anesthesia fairly consistently reduce ICP but relatively few patients respond to such measures for long and their clinical outcome is not improved. The main problem, aside from the difficulty maintaining lower body temperatures, is that rewarming induces substantial brain swelling and a return of ICP to prior levels or higher. A randomized controlled trial of cooling adult patients with severe closed head injury (Glasgow Coma Scale scores of 3 to 7) to 33°C (91.4°F) for 24 h appeared to hasten neurologic recovery and may have modestly improved outcome (Marion et al), but a larger and better-conducted study led by Clifton showed that attaining hypothermia of 33°C (91.4°F) within 8 h of injury failed to improve outcome and this approach cannot be endorsed except in special circumstances. The same lack of effect has been shown in studies with children (Hutchinson et al).

Although barbiturates lower ICP, they lower the blood pressure as well; hence they may diminish cerebral perfusion. However, an uncontrolled series by Marshall and coworkers (1979) claimed improved survival by using barbiturates even in cases where the ICP exceeded 40 mm Hg.

The more definitive randomized study by Eisenberg and associates showed no benefit from barbiturate-induced anesthesia in head-injured patients, and this class of drugs has been largely abandoned except for brief, acute control of ICP while other measures are being instituted.

Corticosteroids Several controlled studies have established that the administration of high-dose steroids does not improve the clinical outcome of severe head injury. Eclipsing smaller prior studies was the well-designed Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH) trial, conducted in more than 10,000 adults and controlled for varying degrees of injury as judged by the Glasgow Coma Scale and imaging features. The effect of the infusion of methylprednisolone 2 g, followed by 0.4 g/h for 48 h, favored survival in the untreated patients by a small but clear margin, leading to the current recommendation that steroids not be used routinely following head injury.

Blood Pressure Management The management of posttraumatic systemic hypertension represents a difficult problem. Within hours after head injury, the sympathoadrenal response and elevation of blood pressure recedes spontaneously in a matter of a few hours or days. Unless the blood pressure elevation is extreme (greater than 180/95 mm Hg), it can be disregarded in the early stages. In animal experiments, it has been found that severe hypertension leads to increased perfusion of the brain and an augmentation of the edema surrounding contusions and hemorrhages. As mentioned earlier, edema is the main element in the genesis of brain swelling and of raised ICP in most head-injured patients (Marmarou et al). This reflects a failure of autoregulatory vascular mechanisms, with resulting transudative edema in damaged areas of the brain. The control of high blood pressure must be balanced against the risk of reducing cerebral perfusion pressure and the observation that even a brief period of mild hypotension may provoke a cycle of cerebral vasodilatation, increased cerebral blood volume, and elevated ICP in the form of plateau waves (Rosner and Becker). Observations such as these emphasize the need for immediate correction of hypotension in severely head-injured patients.

Because most therapies for elevated ICP dehydrate the patient or reduce cardiac filling pressures, thereby leading to hypotension, a middle course of avoiding both severe hypertension and any degree of hypotension seems the best compromise. In lowering high levels of blood pressure, diuretics, beta-adrenergic blocking agents, or angiotensin-converting enzyme inhibitors are generally used, rather than agents that potentially dilate the cerebral vasculature (nitroglycerin and nitroprusside, hydralazine, and some of the calcium channel blockers may present this risk). Hypotension should be corrected by vasopressor agents such as phenylephrine or norepinephrine. The precise level of blood pressure that requires treatment must be judged in the context of the ICP and the presence of plateau waves, the goal being to maintain normal cerebral perfusion pressure of 60 to 80 mm Hg, as well as the patient's previous blood pressure level; evidence of organ failure from either hyper- or hypotension, such as cardiac or renal ischemia, must also be considered.

General Medical Measures

If coma persists for more than 48 h, a nasogastric tube should be passed and fluids and nutrition should be given by this route. A basilar skull fracture, especially if there is a CSF leak, may preclude this route and compel a directly situated gastric tube. Agents that reduce gastric acid production—or the equivalent, antacids by stomach tube to keep gastric acidity at a pH above 3.5—are of value in preventing gastric hemorrhage. The prophylactic use of antiepileptic drugs, as discussed earlier, under "Posttraumatic Epilepsy," recently has been favored, but there is no evidence that delayed epileptic seizures are reduced (see Chang and Lowenstein). Only if there has been a seizure are antiepileptics given.

Restlessness is controlled by diazepam, propofol, or a similar drug, but only if careful nursing fails to quiet the patient and provide sleep for a few hours at a time. Etomidate and dexmedetomidine may be preferable for reducing agitation because they are minimally sedating. Fever is counteracted by antipyretics such as acetaminophen and, if necessary, by a cooling blanket. The use of morphine or bromocriptine to quiet episodes of vigorous extensor posturing and accompanying adrenergic activity already has been mentioned.

Surgical Decompression

The need for surgical intervention during the acute posttraumatic period is decided by two factors: the clinical status of the patient and the findings on imaging. The presence of a subdural or epidural clot that is causing a shift of central brain structures calls for evacuation of the collection. The approach to these lesions has been discussed earlier. Should the elevated ICP not respond to this procedure or to the standard osmotic agents and other medical measures outlined earlier, or should the condition of the patient and vital signs then begin to deteriorate (heart rate rising, temperature rising or falling below normal, state of consciousness worsening, hemiplegia, plantar reflexes more clearly extensor), a renewed search must be undertaken for a late-occurring cerebral hemorrhage. Usually in these clinical circumstances, CT scanning will disclose a new or enlarged epidural, subdural, or intracerebral hematoma, or worsened cerebral edema. If death or severe disability is to be avoided, operation in these cases must be undertaken before the advanced signs of brainstem compression—decerebrate or decorticate posturing, hypertension, bradycardia—have appeared.

The use of *decompressive craniectomy* in patients with progressive and intractable traumatic brain swelling has been a subject of renewed interest, after having been practically abandoned several decades ago. Guerra and colleagues reported on 57 such patients, mostly young adults, who underwent wide frontotemporal craniectomy, unilateral in 31 and bilateral in 26. Of these, 58 percent attained surprisingly good states of rehabilitation. These authors were of the opinion that these results represented a significant improvement over the expected outcome in this particular group of patients. A similar open trial conducted by Aarabi and colleagues described

40 percent with good outcome. Similar results in children were reported by Polin and associates. The few cases with which we have been involved, mostly children operated late, have not been as encouraging.

However, these generally favorable results could not be validated in the randomized “DECRA” trial carried out by Cooper and colleagues. Decompression did indeed reduce ICP, as expected, when the intracranial contents are exposed to atmospheric pressure, but surgery did not improve outcome. The details of the operation and choice of ICP level that were chosen to trigger operation have been criticized, but this study remains the best information to date until further trials with different designs, some ongoing, clarify the issue of surgical decompression. Further trials of decompressive craniectomy after severe traumatic brain injury are being undertaken.

The treatment of the general medical diseases relating to protracted coma was outlined in Chap. 17. Each patient presents unique problems.

PROGNOSIS

As has been intimated, the outcome in severe injury is particularly discouraging, more so with increasing age. Some aspects of prognosis were mentioned earlier but the following general comments serve to frame the problem. In the survey of the large European Brain Injury Consortium, comprising 10,005 adult patients, the injury proved fatal in 31 percent; 3 percent were left in a persistent vegetative state, and 16 percent remained severely disabled neurologically (Murray et al). Data from the extensively analyzed Traumatic Coma Data Bank are comparable, as reported by Marshall and coworkers (1983). The signs of focal brain disease, whether because of closed head injuries or open and penetrating ones, tend always to ameliorate as the months pass. A hemiplegia is often reduced to a minimal hemiparesis or to ineptitude of voluntary motor function with exaggerated reflexes and an equivocal Babinski sign on that side, and aphasia is gradually transformed into a stuttering or hesitant paraphasia or dysnomia that is not disabling. Many of the signs of brainstem disease (cranial nerve dysfunction and ataxia) improve also, usually within the first 6 months after injury (Jennett and Bond) and often to a surprising extent. Most patients who had been in coma for many hours or days—i.e., those with severe brain injuries—are left with memory impairment and other cognitive

defects and with personality changes. These may be the only lasting sequelae as detailed earlier. According to Jennett and Bond, these mental and personality changes are a greater handicap than focal neurologic ones as far as social adjustment is concerned. In open head wounds and penetrating brain injuries, Grafman and coworkers found that the magnitude of tissue loss and location of the lesion were the main factors affecting the outcome.

The prognosis of head injury is influenced by several other factors as mentioned. The *age of the patient* is the most important factor (Vollmer et al). Increasing age reduces the chances of survival and of good recovery. Older patients often remain disabled, especially when compensation is involved. Young and middle-aged patients do better, particularly if they are not entitled to compensation.

As a general statement, children recover more completely than adults. Russell pointed out long ago that the severity of the injury as measured by the duration of *traumatic amnesia* is a useful prognostic index. Of patients with a period of amnesia lasting less than 1 h, 95 percent were back at work within 2 months; if the amnesia lasted longer than 24 h, only 80 percent had returned to work within 6 months. However, approximately 60 percent of the patients in his large series still had symptoms at the end of 2 months, and 40 percent at the end of 18 months. Of the most severely injured (those comatose for several days), many remained permanently disabled. However, the degree of recovery was often better than one had expected; the motor impairment, aphasia, and dementia tended to lessen and sometimes cleared. Improvement could continue over a period of 3 or more years. Obviously, multiple-organ injury and, particularly, hypotension in the hours immediately after injury, have major effects, not just on survival, but in some studies, with neurocognitive and behavioral outcome.

The remarkable findings of voluntary activation of parts of the cerebral cortex in patients who are in a vegetative or minimally conscious state was mentioned earlier and in Chap. 17. These serve as a caution to the neurologist to assign the diagnostic labels of vegetative and minimally conscious state only after careful and preferably, repeated examinations and then to temper communication with the family and other physicians by an appropriate degree of uncertainty as to outcome. Nonetheless, most patients who are vegetative for 6 or more months after cranial trauma will not recover to a meaningfully independent life.

Multiple Sclerosis and Other Inflammatory Demyelinating Diseases

It has long been the practice to set apart a group of diseases of the brain and spinal cord in which destruction of myelin, termed *demyelination*, is a prominent feature. To define these diseases precisely is difficult, for the simple reason that there is probably no disease in which myelin destruction is the exclusive pathologic change. The idea of a demyelinating disease is an abstraction that serves primarily to focus attention on one of the more striking and distinctive features of one group of pathologic processes. Another unifying feature of most of these processes is the participation of an inflammatory reaction in proximity to demyelination. The most common and important inflammatory demyelinating disease is multiple sclerosis (MS).

The generally accepted pathologic criteria of a demyelinating disease are (1) destruction of the myelin sheaths of nerve fibers with *relative* sparing of the other elements of nervous tissue, i.e., of axons, nerve cells, and supporting structures, which are less affected; (2) infiltration of inflammatory cells, particularly in a perivenous distribution; (3) lesions that are primarily in white matter, either in multiple small disseminated foci or in larger foci spreading from one or more centers. In most of the demyelinating diseases, it has been known since the early descriptions that there is some degree of neuronal and axonal degeneration, but it is the preferential effect on myelin that defines this group of disorder. In the language of neurology, therefore, the term *demyelination* has acquired a special meaning.

A broad classification of the inflammatory demyelinating diseases is given in Table 36-1. Like all classifications that are not based on etiology, this one has its limitations. For example, in some of the diseases here classified as demyelinating, notably, in necrotizing hemorrhagic leukoencephalitis and even in some cases of multiple sclerosis, the inflammatory process may be sufficiently intense so much so that there is destruction of all tissue in a region including vessels and axons.

In contrast, a number of diseases in which demyelination is a prominent feature are considered part of this category, as mentioned earlier. In some cases of anoxic encephalopathy, for example, the myelin sheaths of the radiating nerve fibers in the deep layers of the cerebral cortex or in ill-defined patches in the convolutional and central white matter are destroyed, while most of the axis

cylinders are spared. A relatively selective degeneration of myelin may also occur in some small ischemic foci as a result of vascular occlusion or in larger confluent areas, as is the case in Binswanger disease (see Chap. 34). In subacute combined degeneration (SCD) of the spinal cord associated with pernicious anemia and in tropical spastic paraparesis (TSP), a demyelinating spinal cord disease, myelin may be affected earlier and to a greater extent than axons. The same is true of progressive multifocal leukoencephalopathy (PML), osmotic demyelination (also known as central pontine myelinolysis), and Marchiafava-Bignami disease. Some of these disorders and several others are not classified as demyelinating because the effects of the process are not primarily on myelin; furthermore, they are not based on an inflammatory component. In addition, for reasons that will become clear in subsequent discussion, the chronic progressive leukodystrophies of childhood and adolescence (e.g., globoid body, metachromatic, and adrenal leukodystrophies), although clearly diseases of myelin, are set apart and called *dysmyelinating* because of their unique genetic and morphologic features, and are discussed in Chap. 37. Occupying an uncertain place in this nosology are demyelinating lesions associated with connective tissue diseases or with autoantibodies directed against DNA or phospholipids. The central nervous system (CNS) lesions may be multiple and cannot easily be distinguished by imaging features from multiple sclerosis. But, as noted further on, their nature is uncertain, while some are clearly caused by a vasculopathy.

MULTIPLE SCLEROSIS

History Multiple sclerosis, called MS by most physicians, was referred to by the British as *disseminated sclerosis* and by the French as *sclérose en plaques*. The broad nature of disseminated lesions was known to pathologists in the early nineteenth century particularly as described by Carswell, Cruveilhier and later, Frerichs, but J.M Charcot at the Salpêtrière later in the century is justly credited with the first serious study of the clinical and pathologic aspects of the disease. He collected 34 cases and set a foundation for understanding the disease. With neurosyphilis, multiple sclerosis formed much of

Table 36-1

CLASSIFICATION OF THE INFLAMMATORY DEMYELINATIVE DISEASES

- I. Multiple sclerosis
 - A. Relapsing-remitting form
 - B. Secondary progressive form
 - C. Primary progressive form
 - D. Acute multiple sclerosis (Marburg disease and tumefactive multiple sclerosis)
 - E. Diffuse cerebral sclerosis (Schilder disease and concentric sclerosis of Balo)
- II. Neuromyelitis optica (Devic disease, NMO) and progressive necrotic myelopathy
- III. Acute disseminated encephalomyelitis (ADEM) and acute hemorrhagic encephalitis (Weston Hurst disease)
- IV. Demyelination in association with autoimmune disease (SLE, Sjögren disease, and related conditions)
- V. Sarcoid-related demyelination
- VI. Graft-versus-host disease

the basis of early clinicopathologic correlation and the clinical method in neurology. It is therefore among the most venerable of neurologic diseases and one of the most important by virtue of its frequency, chronicity, and tendency to affect young adults. Cruveilhier (circa 1835), in his original description of the disease, attributed it to suppression of sweat, and since that time there has been endless speculation about the etiology. While many of the early theories are anachronistic in the light of present-day concepts, others are still of interest. There is little point in enumerating them here. The historical aspects can be found in the corresponding chapter of the text by Compston and colleagues.

Introductory Remarks Multiple sclerosis is a chronic condition characterized clinically by episodes of focal disorders of the optic nerves, spinal cord, and brain, which remit to a varying extent and recur over a period of many years and are usually progressive. The neurologic manifestations are protean, being determined by the varied location and extent of the demyelinating foci. Nevertheless, the lesions have a predilection for certain parts of the CNS, resulting in complexes of symptoms and signs and imaging appearances that can often be recognized as distinctive of MS as discussed in detail further on.

Typical features include weakness, paraparesis, parasthesias, loss of sight, diplopia, nystagmus, dysarthria, tremor, ataxia, impairment of deep sensation, and bladder dysfunction. The diagnosis may be uncertain at the onset and in the early years of the disease, when symptoms and signs point to a lesion in only one locus of the nervous system. Later, as the disease recurs and disseminates throughout the central nervous system, the diagnosis becomes quite certain. There may be a long period of latency (1 to 10 years or longer) between a minor initial symptom, which may not even come to medical attention, and the subsequent development of more characteristic symptoms. In most cases, there is initially a *relapsing-remitting* pattern, i.e., the signs and symptoms improve partially or completely, followed after a variable interval by the recurrence of the same abnormalities or the appearance of new ones in other parts of the nervous system. However, in fewer than half of patients, the disease takes the form a steadily progressive course, especially in patients older than 40 years of age at the time of onset

(*primary progressive MS*). Or, as happens more often, an initially relapsing profile later becomes steadily progressive (*secondary progressive MS*).

A rule that had in the past guided clinicians is that the diagnosis of MS was not secure unless there was a history of remission and relapse and evidence on examination of more than one discrete lesion of the CNS. The advent of MRI and its capacity to identify clinically invident lesions has replaced the exclusive dependence on clinical criteria for the diagnosis.

Pathologic Findings

Before being sectioned, the brain and spinal cord generally show no evidence of disease, but the surface of the spinal cord may appear and feel uneven. Sectioning of the brain and cord discloses numerous scattered patches where the tissue is slightly depressed below the cut surface and stands out from the surrounding white matter by virtue of its pink-gray color (a result of loss of myelin). The lesions may vary in diameter from less than a millimeter to several centimeters; they principally affect the white matter of the brain and spinal cord, and do not extend beyond the root entry zones of the cranial and spinal nerves. It is because of their sharp delineation that they were called *plaques* by French pathologists.

The topography of the lesions is noteworthy. A periventricular localization is characteristic, but only where subependymal veins line the ventricles (mainly adjacent to the bodies and atria of the lateral ventricles). Other favored structures are the optic nerves and chiasm (but rarely the optic tracts) and the spinal cord, where pial veins lie next to or within the white matter. The lesions are distributed randomly throughout the brainstem, spinal cord, and cerebellar peduncles without reference to particular systems of fibers, but always confined predominantly to the white matter. In the cerebral cortex and central nuclear and spinal structures, the acute lesions destroy myelin sheaths but leave the nerve cells mostly intact. Severe and more chronic lesions, however, may destroy axons and neurons in the affected region, but the dominant lesion is still demyelinating.

The histologic appearance of the lesion depends on its age. Relatively recent lesions show a partial or complete destruction and loss of myelin throughout a zone formed by the confluence of many small, predominantly

perivenous foci; the axons in the same region are relatively spared or less affected. There is a variable but usually slight degeneration of oligodendroglia, a variable astrocytic reaction, and perivascular and para-adventitial infiltration with mononuclear cells and lymphocytes as discussed in detail further on. Later, large numbers of microglial phagocytes (macrophages) infiltrate the lesions and astrocytes in and around the lesions increase in number and size. Long-standing lesions, on the other hand, are composed of thickly matted, relatively acellular glial tissue, with only occasional perivascular lymphocytes and macrophages; in such lesions, a few intact axons may still be found. In old lesions with interruption of axons, there may be descending and ascending wallerian degeneration of long fiber tracts in the spinal cord. Partial remyelination is believed to take place on undamaged axons and to account for incompletely demyelinated "shadow patches" (Prineas and Connell). A few of the most severe older lesions will have undergone cavitation, indicating that the disease process has affected not only myelin and axons but also supporting tissues and blood vessels. All gradations of histopathologic change between these two extremes may be found in lesions of diverse size, shape, and age, consistent with the extended clinical course.

The relatively ineffective remyelination of the MS plaque leaves in its wake denuded axons that are thinly myelinated, creating the just mentioned shadow plaques. Histologic evidence suggests that some of the oligodendrocytes are destroyed in areas of active demyelination but also that the remaining ones have little ability to proliferate. Instead, there is an influx of oligodendroglial precursor cells, which mature into oligodendrocytes and provide the remaining axons with new myelin. Probably the astrocytic hyperplasia in regions of damage and the persistent inflammatory response account for some of the inadequacy of the reparative process (see Prineas et al).

An insight into the complexity of the immunopathologic process can be appreciated in the analyses by Lucchinetti and colleagues (2000) of autopsy and brain biopsy specimens from patients with MS. They separated the lesions into four histologic subgroups: inflammatory lesions made up of T cells and macrophages alone (pattern I); an autoantibody lesion mediated by immunoglobulin and complement (pattern II); those characterized by apoptosis of oligodendrocytes and absence of immunoglobulin, complement, and with partial remyelination (pattern III); and those showing only oligodendrocyte dystrophy and no remyelination (pattern IV). Two features are of interest here. First, each case demonstrated only one pattern of pathology, suggesting that perhaps different pathophysiologic processes operated in each patient. Moreover, the last two histopathologic types were considered to represent a primary oligodendroglial cell degeneration. Some confirmation of a primary process in oligodendrocytes is the material from newly symptomatic lesions reported by Barnett and Prineas, in which there was loss of these cells. In addition, early lesions have been found to contain areas of demyelination within the cerebral cortex and these are often in contiguity with meningeal inflammatory infiltrates, or lymphoid follicles (Lucchinetti et al 2011, Howell et al).

The overall implication is that the pathologic characteristics of the chronic progressive type of MS may differ from those of the typical relapsing type (see further on). Most data suggest that antibody and complement-mediated myelin phagocytosis are the dominant mechanism of demyelination in MS. At the moment, we continue to conceptualize MS as mainly an inflammatory-immune process that targets central myelin along the lines of the observations of Adams and Kubik in their earlier studies, who were aware of the axonal and cortical changes in pathologic material they collected in the 1940s.

Etiology and Epidemiology

The incidence of MS is two or three times higher in women than in men but the basis of this fact is unclear, the best current explanation being that women are generally more susceptible to immune and inflammatory conditions. The incidence in children is very low; only 0.3 to 0.4 percent of all cases appear during the first decade. In an analysis of a small number of childhood-onset cases, Hauser and colleagues (1982) found no phenotypic differences between childhood and adult cases, but Renoux and colleagues analyzed a cohort of 394 patients who had MS with an onset at 16 years or younger and found that these patients took longer to reach states of irreversible disability, but did so at a younger age than patients with adult-onset MS. Beyond childhood, the risk of first developing symptoms of the disease rises steeply with age, reaching a peak at about 30 years, remaining high in the fourth decade, then falling off sharply and becoming low in the sixth decade. On this basis it has been pointed out that MS has a unimodal age-specific onset curve, similar to that of infectious and connective tissue diseases.

In a smaller number, the disease appears to develop in late adult life (late fifties and sixties). In such patients, early symptoms may have been forgotten or may never have declared themselves clinically (we have several times found the typical lesions of MS in aged autopsied individuals who had no history of neurologic illness). Gilbert and Sadler report five such cases and from their pathologic findings suggest that the true incidence of MS may be three times higher than the stated figures.

Although the cause of MS remains undetermined, a number of epidemiologic facts have been established and will eventually have to be incorporated in any hypothesis. The disease has a prevalence of less than 1 per 100,000 in equatorial areas; 6 to 14 per 100,000 in the southern United States and southern Europe; and 30 to 80 per 100,000 in Canada, northern Europe, and the northern United States. Mayr and colleagues reported an incidence of 8 and a prevalence of 177 cases per 100,000 in Olmstead County, Minnesota; this prevalence has been stable for approximately 30 years. A less-well-defined gradient exists in the southern hemisphere. Kurland's studies indicated that there is a threefold increase in prevalence and a fivefold gradient in mortality rate between New Orleans (30 degrees north latitude) and Boston (42 degrees north) and Winnipeg (50 degrees north). In Japan, there is a similar although less distinct latitudinal gradient (the prevalence

of MS there is much lower than in corresponding latitudes of North America and northern Europe).

The increasing risk of developing MS with higher and lower latitude has been confirmed by many epidemiologists following the work of Kurtzke (1975). In the United States, African Americans are at lower risk than whites at all latitudes, but both races show the same south-to-north gradient in risk, findings that invoked an environmental factor regardless of genetic predisposition. Supporting this view are the descriptions, by Kurtzke and Hyllested, of an "epidemic" of MS in the Faroe Islands of the North Atlantic. They found a much-higher-than-expected incidence of the disease, occurring as three separate outbreaks of decreasing extent between the years 1943 and 1973. (It should be pointed out that the largest outbreak consisted of only 21 cases.) It was their contention, confirmed by Poskanzer and colleagues, that the disease was the result of an unidentified infection introduced by British troops who occupied the islands in large numbers in the years immediately preceding the outbreak. Kurtzke and colleagues (1982) described a similar postwar epidemic in Iceland. The cause of these geographic distributions has been reinterpreted in terms of migration and population genetics rather than a number of other imputed causes, but they remain interesting (see Compston and Confavreux for a complete discussion).

The role of Vitamin D and of sun exposure has become an area of related epidemiologic research. Some data suggest that the risk of MS is in part a result of a lack of exposure to these two related environmental features (Munger et al and van der Mei et al). Whether this partly explains the latitudinally graded risk is unclear. An observed seasonal fluctuation in the activity of established MS lesions may have a similar basis.

Several studies indicate that persons who migrate from a high-risk to a low-risk zone carry with them at least part of the risk of their country of origin and genetic makeup, even though the disease may not become apparent until 20 years after migration. Such a pattern has been demonstrated in both South Africa and Israel. Dean determined that the prevalence of MS in native-born white South Africans was 3 to 11 per 100,000, whereas the rate in immigrants from northern Europe was approximately 50 per 100,000, only slightly less than among the nonimmigrating natives of those countries. The data of Dean and Kurtzke indicate further that in persons who had immigrated before the age of 15, the risk was similar to that of native-born South Africans; whereas in persons who had immigrated after that age, the risk was similar to that of their birthplace. Alter and colleagues found that in the descendants of European immigrants born in Israel, the risk of MS was low, similar to that of other native-born Israelis, whereas among recent immigrants the incidence in each national group approached that of the land of birth. Again, the critical age of immigration appeared to be about 15 years. These older epidemiologic studies and others have suggested that MS is associated with particular localities rather than with a particular ethnic group in those localities, and implicate environmental factors but not to the exclusion of genetic susceptibility.

However, more current studies suggest the opposite; that genetic factors in a population predominate.

A familial aggregation of MS is now well established. Approximately 15 percent of MS patients have an affected relative, with the highest risk of concurrence being observed in the patient's siblings (Ebers, 1983). In a large population-based study carried out in British Columbia by Sadovnick and colleagues (1988), it was found that almost 20 percent of index cases had an affected relative, again with the highest risk in siblings. In a subsequent study, Sadovnick and colleagues (1996) sought to determine the degree of heritability of MS by comparing the risk of disease in the half-sibs (one biologic parent in common) of affected individuals with the risk in full sibs; the risk for full sibs was two to three times greater than for half-sibs and they interpreted these results as clearly genetic in basis.

The case for heritability is further supported by studies of twins in whom one of each pair is known to have MS. In the most extensive of these studies (Ebers et al), the diagnosis was verified in 12 of 35 pairs of monozygotic twins (34 percent) and in only 2 of 49 pairs of dizygotic twins (4 percent). Furthermore, in two additional sets of monozygotic twins who were clinically normal, lesions were detected by MRI. The concordance rate in dizygotic pairs is similar to that in nontwin siblings. Despite these provocative findings, no consistent pattern of mendelian inheritance has emerged. Of course, one must not assume that all diseases with an increased familial incidence are hereditary in that instances of the same condition in several members of a family may simply reflect an exposure to a common environmental agent. Paralytic poliomyelitis, for example, was about eight times more common in immediate family members than in the population at large.

Further evidence of a genetic factor in the causation of MS is the finding that certain histocompatibility locus antigens (HLAs) are more frequent in patients with MS than in control subjects. The strongest association is with the DR locus on chromosome 6. Other HLA haplotypes that are overrepresented in MS (HLA-DR2 and, to a lesser extent, -DR3, -B7, and -A3) are thought to be markers for an MS "susceptibility gene"—possibly an immune response gene. The presence of one of these markers increases the risk that an individual will develop MS by a factor of 3 to 5. These antigens may indeed prove to be related to the frequency of the disease, but their presence is not invariable and their exact role is far from clear. A genome-wide association study identified several alleles, interleukin (IL)-2R α , and IL7R α in addition to the previously established HLA loci, as heritable risk factors for MS (International Multiple Sclerosis Genetics Consortium). These findings, although they apply to a small number of individuals, support the concept that dysregulation of the immune response is a factor in the risk for developing MS.

The low conjugal incidence of MS, on the other hand, indicates that any common exposure to an inciting infection or environmental agent must occur early in life. To test this hypothesis, Schapira and coworkers determined

the periods of common exposure (common habitation periods) in members of families with two or more cases. From this they calculated the mean common exposure to have happened before 14 years of age, with a latency of about 21 years—figures that are in general agreement with those derived from the migration studies quoted above.

Several studies from northern Europe and Canada suggest that the likelihood of developing MS is somewhat greater among rural than among urban dwellers; studies of American army personnel indicate the opposite (Beebe et al). A number of surveys in Great Britain intimate that the disease is more frequent in the higher socioeconomic groups than in the lower ones. Yet in the United States, no clear relationship has been established to the poverty or social deprivations that are part of a low socioeconomic status. Numerous other environmental factors (surgical operations, trauma, anesthesia, exposure to household pets [small dogs], cobalamin deficiency or resistance, mercury in silver amalgam fillings in teeth), and Lyme disease have been proposed but are unsupported by firm evidence and probably are mostly spurious associations.

Pathogenesis

These epidemiologic data point to both a genetic susceptibility and some environmental factor that is encountered in childhood that, after years of latency, evokes the disease. Over the years, data favoring an infection, most often viral as the triggering factor, have had periods of support (see above). A body of indirect evidence has been marshaled in support of this idea, based largely on alterations in humoral and cell-mediated immunity to viral agents. To this day, however, no virus (including all known members of the human retrovirus family) has been seen in, or isolated from, the tissues of patients with MS despite innumerable attempts to do so. Moreover, no satisfactory viral model of MS has been produced experimentally. The bacterial agents *Chlamydia pneumoniae* and *Borrelia burgdorferi* (the agent of Lyme disease) and herpesvirus type 6 have been similarly implicated by the finding of their genomic material in MS plaques, but the evidence for their direct participation in the disease is, at the moment, not compelling.

If, indeed, some obscure infection is the initial event in the genesis of MS, then a secondary factor must be operative in later life to reactivate the disease and cause exacerbations. One view is that this secondary mechanism is an autoimmune reaction attacking some component of myelin and, in its most intense form, destroying all tissue elements, including axons. Several lines of argument have been advanced in support of this view. One is inclined to draw an analogy between the lesions of MS and those of acute disseminated encephalomyelitis, which is almost certainly an autoimmune disease of delayed hypersensitivity type (see further on). Also in support of this possibility is the finding of antibodies to specific myelin proteins—for example, myelin basic protein (MBP)—in both the serum and cerebrospinal fluid (CSF) of MS patients, and these antibodies, along with T cells that are reactive to MBP and to other myelin

proteolipids, increase with disease activity; moreover, MBP cross-reacts to some extent with measles virus antibodies. The arguments that a chronic viral infection reactivates and perpetuates the disease are, however, less convincing than those proposing a role for viruses in the initiation of the process in susceptible individuals.

The relative roles of humoral and cellular factors in the production of MS plaques are not fully understood. The deposition of immunoglobulin in the plaques of patients with acute and relapsing–remitting disease, but not in the plaques of those with progressive MS, was alluded to earlier. That the humoral immune system is involved is evident from the presence in the CSF of most patients of oligoclonal immune protein antibodies, which are produced by B lymphocytes within the CNS. Sera from patients with MS (and some normal controls), when added to cultures of nervous system tissue from newborn mice in the presence of complement, can damage myelin, inhibit remyelination, and block axonal conduction. Antibodies to oligodendrocytes are present in the serum of up to 90 percent of patients in some studies, but far less frequently in others.

Autoantibodies have been found inconsistently that are directed against myelin oligodendrocyte glycoprotein (MOG) and MBP. It has also been demonstrated that subsets of T cells (CD41 Th2 cells) are activated by MBP and MOG to activate B cells, the production of oligoclonal bands and membrane attack complexes, and the release of cytokines (tumor necrosis factor- α [TNF- α], interleukins, interferon-gamma [IFN- γ]). The inflammatory process erodes the blood–brain barrier and ultimately destroys both oligodendroglia and axons. The eventual functional outcome reflects both the activity of this inflammatory cascade and the degree of axonal damage. In other cases, there may be a compromise of oligodendroglial function and axonal degeneration in the absence of prominent inflammation. Many times, one or another putative antigenic target has been found by immunologic techniques in one laboratory, only to fail to be replicated by another group. None of these provide a unifying etiology for the disease but the humoral aspects may provide insights particularly into the pauci-inflammatory type of oligodendrocyte degeneration that characterizes some lesions, as discussed in the section on pathology.

Nevertheless, most immunologists currently subscribe to the notion that MS is mediated by a T-cell sensitization to some component of myelin. This idea is supported by numerous lines of evidence, including the observation that T cells initiate the lesions of experimental allergic encephalomyelitis (EAE), which is assumed to be an approximate animal model of MS, as suggested originally by Waksman and Adams. It has been difficult, however, to produce a relapsing experimental form of the illness that would simulate MS. Although the entry of autoreactive T cells into the CNS results in a perivascular inflammatory reaction, its relationship to MS is unclear. Conceivably, intense T-cell stimulation is in itself sufficient to induce demyelination but it is also possible that the primary target of the immune reaction is the myelin sheath or some component thereof and that

the T-cell infiltration is a reaction to demyelination. Most investigators believe that an additional insult is required, as illustrated by the EAE animal model, in which myelin alone is not a sufficient factor but always requires an adjuvant immune stimulus. EAE is clearly an imperfect model; it is not a naturally occurring disease but one in which a demyelination of the CNS is induced in susceptible animals in a single episode by autologous myelin antigens. The inducing antigen in EAE is known, whereas the putative antigens in MS are not.

Also incorporated into most theories of the immune pathogenesis is an alteration of the blood–brain barrier, represented by adhesion of lymphocytes to endothelial cells in the nervous system. Whether this is an active interaction or a passive event triggered by antigenic attraction is not clear; nonetheless, these cell–vascular interactions have been incorporated into pathogenic theories and are the basis of newer treatments for MS. Always in the background is the element of genetic susceptibility, presumably making certain individuals prone to these immunologic events as noted in the earlier sections.

The foregoing data notwithstanding, the immune mechanisms in MS are not fully specified and the autoimmune hypothesis is not beyond challenge. It is noteworthy that the prevalence of other diseases of presumed autoimmune origin in some series is no higher in MS patients than in the general population (De Keyser). However, various epidemiologic studies differ on this point and some have found an increase in autoimmune diseases in affected patients and in their families.

Physiologic Effects of Demyelination

The main physiologic effect of demyelination is to impede saltatory electrical conduction of nerve impulses from one node of Ranvier, where sodium channels are concentrated, to the next node. The resulting failure of electrical transmission is thought to underlie most of the abnormalities of function resulting from demyelinating diseases of both the central and peripheral nerves. As an example, the delay in electrical conduction in the optic nerve (found by using pattern-shifting visual stimuli in MS patients) raises a number of points about the pathophysiology of demyelination. When the demyelinating process is acute and reversible within a few days, the block in nerve fiber conduction is obviously physiologic rather than pathologic; in such a brief period, recovery is unlikely to have been a result of remyelination; recovery is probably a result of subsidence of the edema and acute inflammatory changes in and around the lesion. Remyelination probably does occur, but it is a slower process and partial at best, and its functional effects in the CNS are possibly expressed as a slowing of nerve conduction, which, if present in an eye with normal vision, may account for the reduction in flicker fusion and in the perception of multiple visual stimuli (Halliday and McDonald). It also explains one of the typical symptoms of optic neuritis—reduction in the intensity (desaturation) of the color red. It is clear, however, that many of the plaques in the cerebral hemispheres that are visualized on MRI are unaccompanied by corresponding symptoms.

Either there has been complete remyelination in these plaques, sufficient to support clinical functioning, or, in the acute stage, the plaque may represent edema rather than demyelination.

Another typical feature of MS is the temporary induction, by heat or exercise, of symptoms such as unilateral visual blurring (the Uhthoff phenomenon) or tingling and weakness of a limb (the basis of the hot-tub test used in previous years). This has been shown experimentally to represent an extreme sensitivity of conduction in demyelinated nerve fibers to an elevation in temperature. A rise of only 0.5°C (0.9°F) can block electrical transmission in thinly myelinated or demyelinated fibers. Likewise, hyperventilation slows conduction of the visual evoked response, an effect that is rarely perceived by the patient. The remarkable sensitivity of demyelinated and remyelinated regions to subtle metabolic and environmental changes provides an explanation for the rapid onset of symptoms in some patients and the apparent fluctuations of MS that show no laboratory evidence of active inflammatory changes in the CNS. Smoking, fatigue, hyperventilation, and a rise in environmental temperature are all capable of briefly worsening neurologic functioning and are easily confused with relapses of disease.

Clinical Manifestations

Early Symptoms and Signs

Weakness or numbness, sometimes both, in one or more limbs is the initial symptom in about half the patients. Symptoms of tingling of the extremities and tight bandlike sensations around the trunk or limbs are commonly associated and are probably the result of involvement of the posterior columns of the spinal cord. The symptoms generally appear over hours or days, at times being so trifling that they are ignored, and less often, coming on so acutely and prominently as to bring the patient urgently to the doctor. The resulting clinical syndromes vary from a mere dragging or poor control of one or both legs to a spastic or ataxic paraparesis. The tendon reflexes are retained and later become hyperactive with extensor plantar reflexes; varying degrees of deep and superficial sensory loss may be associated. It is a useful adage that *the patient with MS presents with symptoms in one leg but with signs in both*; the patient will complain of weakness, incoordination, or numbness and tingling in one lower limb and prove to have bilateral Babinski signs and other evidence of bilateral corticospinal and posterior column disease.

There are, in addition, several syndromes that are typical of multiple sclerosis and may be the initial manifestations. These common modes of onset are: (1) optic neuritis, (2) transverse myelitis, (3) cerebellar ataxia, and (4) brainstem syndromes (vertigo, facial pain or numbness, dysarthria, diplopia). When these are unaccompanied by other features of MS, they are termed “clinically isolated syndrome” (CIS) but they are often aspects of the established disease as well. In the initial phases of the illness, they may pose diagnostic questions, as they also certainly occur with numerous diseases other than MS.

Flexion of the neck may induce a tingling, electric-like feeling down the shoulders and back and, less commonly, down the anterior thighs. This phenomenon is known as the *Lhermitte sign*, although it is more a symptom than a sign and was originally described by Babinski in a case of cervical cord trauma. Lhermitte's contribution was to draw attention to the frequent occurrence of this phenomenon in MS. It is probably attributable to an increased sensitivity of demyelinated axons to the stretch or pressure on the spinal cord induced by neck flexion, but it occurs in other conditions such as cervical spondylosis.

McAlpine and coworkers (1972) analyzed the mode of onset in 219 patients and found that in 20 percent the neurologic symptoms were fully developed in a matter of minutes, and, in a similar number, in a matter of hours. In approximately 30 percent the symptoms evolved more slowly, over a period of a day or several days, and in another 20 percent more slowly still, over several weeks to months. In the remaining 10 percent the symptoms had an insidious onset and slow, steady, or intermittent progression over months and years. The typical relapsing–remitting pattern of disease is more likely to appear in patients who are younger than 40 years of age. Certain paroxysmal symptoms and signs may occur in the established phase of the disease and discussed further on. The inflammatory process of MS affects no organ system other than the CNS.

Optic Neuritis (Retrobulbar Neuritis; Papillitis) (See “Optic Neuritis” in Chap. 13)

In approximately 25 percent of all MS patients (and possibly in a larger proportion of children), the initial manifestation is an episode of *optic neuritis*. It will be recalled that the optic nerve is in fact a tract of the brain, and involvement of the optic nerves is therefore consistent with the rule that lesions of MS are confined to the CNS. Characteristically, over a period of several days, there is partial or total loss of vision in one eye. Many patients, for a day or two before the visual loss, experience pain within the orbit, worsened by eye movement or palpation of the globe. Rarely, the visual loss is steadily progressive for several weeks, mimicking a compressive lesion or intrinsic tumor of the optic nerve (Ormerod and McDonald). Usually a scotoma involving the macular area and blind spot (cecocentral) can be demonstrated, but a wide variety of other field defects may occur, rarely even hemianopic involvement (sometimes homonymous). In some patients, both optic nerves are involved, either simultaneously or, more commonly, within a few days or weeks of one another, and at least one in eight patients will have repeated attacks.

Serial examinations may disclose evidence of swelling or edema of the optic nerve head (papillitis) in about a tenth of the patients. The occurrence of papillitis depends on the proximity of the demyelinating lesion to the nerve head. As emphasized in Chap. 13, papillitis can be distinguished from the papilledema of increased intracranial pressure by the severe and acute visual loss that accompanies only the former. More often, the optic nerve head appears normal or nearly so; this represents

retrobulbar neuritis. Subtle manifestations of optic nerve affection, such as an afferent pupillary defect, atrophy of retinal nerve fibers, or sheathing of retinal veins and abnormalities of the visual evoked response (Chap. 2), should be sought in patients who have no visual complaints but are suspected of having MS. In cases of substantial visual loss, there is a diminished pupillary response to light (afferent pupillary paralysis) and instability of the direct pupillary response but the pupil is not dilated in ambient light. If the optic neuritis is unilateral, the consensual light reflex from the normal eye is retained. (Demyelination of the third nerve in its brainstem course, however, may be associated with a fixed enlargement of the pupil.) Visual evoked potentials and optical coherence tomography (OCT) may be useful in detecting optic neuritis, as discussed in a later section and in Chap. 2.

As noted in Chap. 13, about half of patients with optic neuritis recover completely, and most of the remaining ones improve significantly, even those who present initially with profound visual loss and, later, pallor of the optic disc (Slamovitis et al). Any pain in the globe is short-lived and persistent pain should prompt an evaluation for local disease. In a cohort of 397 patients enrolled in the Optic Neuritis Treatment Trial and examined 5 years after the initial attack of optic neuritis, visual acuity had returned to 20/25 or better in 87 percent of patients and to 20/40 or better in 94 percent—even if there had been a recurrence of optic neuritis during the 5-year period. Moreover, the mode of treatment did not appear to influence the outcome. Dyschromatopsia, generally taking the form of a perceived desaturation of colors, frequently persists as does the Pulfrich effect, wherein an object such as a pendulum that is swinging perpendicular to the patient's line of sight, appears to moving in a three-dimensional, circular motion.

When improvement occurs, it usually begins within 2 weeks of onset, as is true of most acute manifestations of MS, perhaps sooner with corticosteroid treatment. Once improvement in neurologic function begins, it may continue for several months.

More than one-half of adult patients who present with optic neuritis will eventually develop other signs of MS. The prospective investigation of Rizzo and Lessell showed that MS developed in 74 percent of women and 34 percent of men by the fifteenth year after onset of visual loss; similar results were reported by the Optic Neuritis Study Group (Beck et al, 2003). The risk is much lower if the initial attack of optic neuritis occurs in childhood (26 percent developed after 40 years of followup [Lucchinetti et al 1997]); this suggests that some instances of the childhood disease may be of a different type, perhaps viral or postinfectious. The longer the period of observation and the greater the care given to detection of mild cases, the greater the proportion of patients who are found to develop signs of MS; however, most do so within 5 years of the original attack (Ebers, 1985; Hely et al). In fact, in many patients with clinically isolated optic neuritis, MRI has disclosed lesions of the cerebral white matter—suggesting that dissemination, albeit asymptomatic, had already occurred and thereby establishing the diagnosis of MS (Jacobs et al, 1986; Ormerod et al). The Optic Neuritis

Study Group has made the point, well known to neurologists, that the *recurrence* of optic neuritis greatly increases the chances of developing MS. Of practical value is the observation, in the study by Beck and colleagues (2003), that the risk of relapsing-remitting MS is also considerably lower (22 percent at 10 years) if the cranial MRI fails to reveal demyelinating lesions.

It is unclear whether optic neuritis that occurs alone and is not followed by other evidence of demyelinating disease is simply a restricted form of MS or a manifestation of some other disease process, such as postinfectious encephalomyelitis. By far the most common pathologic basis for optic neuropathy is demyelinating disease, although it is known that a vascular lesion or compression of an optic nerve by a tumor or mucocele may cause a central or cecentral scotoma that is indistinguishable from the defect of optic neuritis. Also, there may be a special form of chronic relapsing optic neuritis that is the result of an undefined granulomatous process such as sarcoid, as suggested by Kidd and colleagues. Uveitis and sheathing of the retinal veins are other ophthalmic disorders that occur with higher than expected incidence in patients with MS. The retinal vascular sheathing is caused by T-cell infiltration, identical to that in typical plaques, but this is an unusual finding, because the retina usually contains no myelinated fibers (Lightman et al). Optic neuritis is, of course, a common feature in neuromyelitis optica (Devic disease), discussed in a later section.

The treatment of optic neuritis is discussed further on.

Acute Myelitis (Transverse Myelitis)

(See Chap. 44)

This is the common designation for an acutely evolving inflammatory–demyelinating lesion of the spinal cord, which proves in many, but not all, instances to be an expression of MS. In this sense, the myelitic lesion is analogous to that of optic neuritis. The term *transverse* in relation to the myelitis is somewhat imprecise, implying that all of the elements in the cord are involved in the transverse plane, usually over a short vertical extent. Instead, in MS, the spinal cord signs are asymmetrical and incomplete and involve only a part of the long ascending and descending tracts, i.e., paraplegia and complete sensory loss are unusual.

Clinically, the illness is characterized by a rapidly evolving (several hours or days) symmetrical or asymmetrical paraparesis or paraplegia, ascending paresthesia, loss of deep sensibility in the feet, a sensory level on the trunk, sphincteric dysfunction, and bilateral Babinski signs. The CSF shows a modest number of lymphocytes and increase in total protein but both may be normal early in the illness. As many as one-third of patients report an infectious illness in the weeks preceding the onset of neurologic symptoms, in which case a monophasic postinfectious demyelinating disease rather than MS is the likely cause of the myelitis. The MRI usually shows indications of focal demyelination in the spinal cord at the appropriate level and there may be enhancement with gadolinium infusion, but neither of these findings is

invariable. The lesions, as shown in Fig. 36-1 (*lower right panel*), are almost indistinguishable from those of postinfectious myelitis. In those instances associated with existing MS, even if not previously symptomatic, MRI of the cerebral hemispheres will show lesions consistent with demyelination; the absence of such lesions, however, does not ensure that the myelitic illness is monophasic and will not evolve to MS. Some cases progress to a necrotic myelopathy, with or without optic neuropathy, that is an expression of neuromyelitis optica, as discussed in a later section.

Fewer than half the patients have evidence of an asymptomatic demyelinating lesion elsewhere in the nervous system or develop clinical evidence of dissemination within 5 years of the initial attack of acute myelitis (Ropper and Poskanzer). Not entirely in accord with our experience is the analysis of subgroups in a trial of interferon therapy conducted by Beck and colleagues (2002), in which the cumulative probability of developing MS after 2 years was similar after either optic neuritis or transverse myelitis. Our sense has been that acute transverse myelitis is somewhat less often an initial expression of MS than is optic neuritis.

A special problem is presented by patients with *recurrent myelitis* at one level of the spinal cord but in whom no other signs of demyelinating disease can be found by careful clinical examination or MRI. Some of them may even have oligoclonal bands in the CSF, which are commonly associated with MS (see further on). Enough cases of this limited nature have come to our attention to permit the conclusion that there is a recurrent form of spinal cord MS in which cerebral dissemination is infrequent (Tippett et al). Isolated recurrent myelitis or myelopathy occurs also with lupus erythematosus, sarcoidosis, Sjögren syndrome, mixed connective tissue disease, and the antiphospholipid antibody syndrome or in the presence of other autoantibodies, as well as with dural and cord vascular fistulas and arteriovenous malformations. An analogous situation pertains in respect to some instances of optic neuritis—repeated attacks that remain confined to the optic nerve.

Other aspects of transverse myelitis are discussed in Chap. 44, and later in this chapter.

Other Clinical Features of Acute Attacks

Like the modes of onset cited above, other early manifestations of MS are unsteadiness in walking, brainstem symptoms (diplopia, vertigo, vomiting), paresthesias or numbness of an entire arm or leg, facial pain often simulating tic douloureux, and disorders of micturition. Vertigo of central type is also a frequent initial sign of MS, but it more often appears in established cases. Discrete manifestations such as hemiplegia, pain syndromes, facial paralysis, deafness, or seizures occur in an only small proportion of cases. Most often the disease presents with more than one of the aforementioned symptoms almost simultaneously or in rapid succession. Another relatively isolated syndrome, occurring mainly in older women, is a slowly progressive cervical myelopathy with weakness and ataxia. This is particularly difficult to differentiate from cervical spondylosis.

Figure 36-1. MRI in multiple sclerosis. *Upper left*, axial T2-FLAIR image showing multiple discrete periventricular hyperintense plaques, as well as two subcortical plaques in the right frontal and parietal lobes. *Upper right*, coronal T1-post gadolinium image showing abnormal enhancement of the right optic nerve in a case of acute optic neuritis (arrow). *Lower left*, sagittal T2-FLAIR image showing two hyperintense plaques emanating radially from the body of the corpus callosum (“Dawson fingers”). *Lower right*, sagittal T2 MRI showing multiple discrete hyperintense plaques within the cervical spinal cord. The lesion at C3 is acute with accompanying expansion of the cord. The lesion at the T1 level of the cord is chronic and shows cord atrophy.

Not infrequently a prominent feature of the disease is *nystagmus and ataxia*, with or without weakness and spasticity of the limbs, a syndrome that reflects involvement of the cerebellar and corticospinal tracts. Ataxia of cerebellar type can be recognized by scanning speech, rhythmic instability of the head and trunk, intention tremor of the arms and legs, and incoordination of voluntary movements and gait, as described in Chap. 5.

The combination of nystagmus, scanning speech, and intention tremor is known as the *Charcot triad*. While this group of symptoms is often seen in the advanced stages of the disease, most neurologists would agree that it is not a common mode of presentation. The most severe forms of cerebellar ataxia, in which the slightest attempt to move the trunk or limbs precipitate a violent and uncontrollable ataxic tremor, are observed

among patients with long-standing MS. The responsible lesion probably lies in the tegmentum of the midbrain and involves the dentatorubrothalamic tracts and adjacent structures. Cerebellar ataxia may be combined with sensory ataxia, owing to involvement of the posterior columns of the spinal cord or medial lemnisci of the brainstem. In most cases of this type, the signs of spinal cord involvement ultimately predominate; in others, the cerebellar signs are more prominent.

Diplopia is another common presenting complaint. It is most often a result of involvement of the medial longitudinal fasciculi, producing an internuclear *ophthalmoplegia* (see Chap. 14). The signs are characterized by paresis of the medial rectus on attempted lateral gaze, with a coarse nystagmus in the abducting eye; in MS, this abnormality is usually bilateral (unlike small pontine infarcts, which cause a unilateral internuclear ophthalmoplegia [INO]). As a corollary, *the presence of bilateral internuclear ophthalmoplegia in a young adult is virtually diagnostic of MS*. Occasionally, internuclear ophthalmoplegia in one direction is combined with a horizontal gaze paresis in the other, although this “one-and-a-half syndrome” is more typical of brainstem stroke. Other palsies of gaze (a result of interruption of supranuclear connections) or palsies of individual ocular muscles (because of involvement of the ocular motor nerves in their intramedullary course) also occur, but less frequently. Additional manifestations of brainstem involvement include myokymia or paralysis of facial muscles, deafness, tinnitus, vertigo—as noted above, vomiting (vestibular connections), and, rarely, stupor and coma. The occurrence of *transient facial hypesthesia or anesthesia or of trigeminal neuralgia* in a young adult should always suggest the diagnosis of MS implicating the intramedullary fibers of the fifth cranial nerve.

Dull, aching, but otherwise nondescript *pain* in the low back is a common complaint, but its relation to the lesions of MS is uncertain. Infrequently, there is sharp, burning, poorly localized, or lancinating radicular pain, localized to a limb or discrete part of the trunk. Nevertheless, these types of pains, presumably caused by demyelinating foci involving the dorsal root entry zones, have a few times been the presenting feature of the disease or have appeared at a later time in established cases (see Ramirez-Lassepas et al for a discussion of pain in MS).

Symptoms and Signs in the Established Disease

When the diagnosis of MS has become virtually certain, a number of clinical syndromes are observed to occur with regularity. Approximately one-half of the patients will manifest a clinical picture of *mixed or generalized type* with signs pointing to involvement of the optic nerves, brainstem, cerebellum, and spinal cord—specifically signs relating to the posterior columns and corticospinal tracts. Another 30 to 40 percent will exhibit only varying degrees of spastic ataxia and deep sensory changes in the extremities, i.e., essentially a *spinal form of the disease*. In either case, an asymmetrical spastic paraparesis with some degree of impaired joint position and vibration sense in the legs is probably the most common manifestation of

progressive MS. A predominantly *cerebellar or brainstem-cerebellar form* occurs in approximately 5 percent of cases. Thus the mixed and spinal forms together have made up at least 80 percent of our clinical material.

It has become evident that some degree of cognitive impairment, and probably a progressive decline, is present in perhaps one-half of patients with long-standing MS. The process is characterized by reduced attention, diminished processing speed and executive skills, and memory decline, while language skills and other intellectual functions are preserved, features that have been subsumed under “subcortical dementia,” as discussed in Chap. 21. Other mental disturbances, such as a loss of retentive memory, a global dementia, or a confusional-psychotic state, also occur in limited cases in the advanced stages of the disease, but we have found this degree of deterioration to be exceptional. The decline in cognitive functions correlates with quantifiable MRI measurements, particularly loss of white matter volume, thinning of the corpus callosum, and brain atrophy (reviewed by Bobholz and Rao).

Traditional teaching has probably overemphasized the frequency of euphoria, a pathologic cheerfulness or elation that seems inappropriate in the face of the obvious neurologic deficit. (Charcot spoke of this phenomenon as “stupid indifference” and Vulpian as “morbid optimism.”) It has often been referred to as “la belle indifférence.”) Some patients do show this abnormality, usually in association with other signs of cerebral impairment. In some instances, it is manifestly a part of the syndrome of pseudobulbar palsy. A much larger number of patients, however, are depressed, irritable, and short-tempered, sometimes as a reaction to the disabling features of the disease but also apparently as a primary effect of the brain disease; the incidence of depression has been estimated to be as high as 25 to 40 percent in some series. Dalos and coworkers, in comparing MS patients with a group of traumatic paraplegics, found a significantly higher incidence of emotional disturbance in the former group, especially during periods of relapse. As mentioned above, the cognitive impairment is in keeping with what has been ascribed to “subcortical dementia” (see Chap. 21) but demyelination in the cortical layers is increasingly being recognized as a possible basis for dementia in MS. Loss of the volume of gray matter, for example, appears to be predictive of dementia as much as loss of central white matter. Either can give rise to global cerebral atrophy.

Symptoms of *bladder dysfunction*, including hesitancy, urgency, frequency, and incontinence, occur commonly with spinal cord involvement. Urinary retention, as a result of damage to sacral segments of the cord is less frequent (see Fig. 26-4). These symptoms are often associated with erectile dysfunction, a symptom that the patient may not report unless specifically questioned in this regard.

Paroxysmal attacks of neurologic deficit, lasting a few seconds or minutes and sometimes recurring many times daily, are relatively infrequent but well-recognized features of MS (see Mathews and also Osterman and Westerby). Usually the attacks occur during the course of relapsing and remitting phase of the illness, rarely as an

initial manifestation. These clinical phenomena are referable to any part of the CNS but tend to be stereotyped in an individual patient. The most common phenomena are dysarthria and ataxia, paroxysmal pain and dysesthesia in a limb, flashing lights, paroxysmal itching, or tonic "seizures", taking the form of flexion (dystonic) spasm of the hand, wrist, and elbow with extension of the lower limb. The paroxysmal symptoms, particularly the tonic spasms, may be triggered by sensory stimuli or can be elicited by hyperventilation. On a few occasions we have seen dystonic hand and arm spasms as the first symptoms; an acute plaque was detected in the opposite internal capsule. In advanced cases, the spasms may involve all four limbs and even a degree of opisthotonos. The cause of paroxysmal phenomena is uncertain. They have been attributed by Halliday and McDonald to ephaptic transmission ("cross-talk") between adjacent demyelinated axons within a lesion.

These transitory symptoms appear suddenly, may recur frequently for several days or weeks, sometimes longer, and then remit completely, i.e., they exhibit the temporal profile of a relapse or an exacerbation. It is sometimes difficult to determine whether they represent an exacerbation or a new lesion. Years ago, Thygesen pointed out, in an analysis of 105 exacerbations in 60 patients, that there were new symptoms in only 19 percent; in the remainder there was only a recurrence of old symptoms. Another problem is that the original lesion may have been asymptomatic. This is most obviously reflected in the many patients who are found to have impaired visual evoked responses but have never had symptomatic visual changes. Thus, new symptoms and signs may be manifestations of previously formed but asymptomatic plaques. However, the observations of Prineas and Connell indicate that symptoms and signs may progress without the appearance of new plaques. These and other factors need to be taken into consideration in evaluating the clinical course of the illness and the effects of a therapeutic program (see Poser, 1980). Carbamazepine is usually effective in controlling such spontaneous attacks, and acetazolamide blocks the painful tonic spasms that are elicited by hyperventilation.

Unusually severe *fatigue* is another peculiar symptom of MS; it is often transient and more likely to occur when there is fever or other evidence of disease activity but it can be a persistent complaint and a source of considerable distress. Depression may play a role in these recalcitrant cases, although the response to pharmacologic agents suggests that these two aspects of the disease are dissociable. Thus, antidepressants often do not improve fatigue, whereas drugs that alleviate fatigue, such as modafinil and amantadine, do not function as antidepressants.

A number of other interesting manifestations of MS have come to attention over the years and have given rise to difficulties in diagnosis. The occurrence of typical *tic douloureux* in young patients has already been mentioned; only their young age and the bilaterality of the pain in some of them raised the suspicion of MS, confirmed later by sensory loss in the face and other neurologic signs. It is notable, however, that facial palsy along the lines of Bell's

palsy is almost never a sign of MS. Brachial, thoracic, or lumbosacral *pain* consisting mainly of thermal and algic dysesthesias was a source of puzzlement in several of our patients until additional lesions developed. Other types of pain in MS have been addressed earlier.

In two of our cases, the relatively acute occurrence of a right hemiplegia and aphasia first raised the probability of a cerebrovascular lesion; in still others, a more slowly evolving hemiplegia had led to an initial diagnosis of a cerebral glioma. The dystonic and paroxysmal symptoms are mentioned earlier; they do not typically bring the diagnosis of MS to mind.

There may be a slightly increased incidence of seizures in patients with MS but the frequency of the problem varies greatly among studies. It should be emphasized that seizures are usually in relation to an obvious cerebral lesion and advanced disease of many years duration. Seizures at an early stage of illness are almost always attributable to previous head injury, idiopathic epilepsy, or withdrawal of sleep medication, but not to MS.

Several times we have seen coma during relapse of longstanding MS, and in each instance it continued to death. In one case it occurred in a 64-year-old woman who had had two previous episodes of nondisabling spinal MS at 30 and 44 years of age. A confusional state with drowsiness was the initial syndrome in another patient whom we saw later with a relapse involving the cerebellum and spinal cord. Another unusual syndrome is one of slow intellectual decline with slight cerebellar ataxia. The chronic progressive form of MS is addressed below.

Precipitating Factors for Acute Attacks

A variety of events occurring immediately before the initial symptoms or exacerbations of MS have been invoked as precipitating factors. The most common are infection, trauma, and pregnancy. However, in our view, none of these has been convincingly related to an increased risk of new attacks of MS, but there is little question that some febrile illnesses such as urinary infections can exaggerate the existing symptoms. The issue of truly precipitating a relapse as a result of a nondescript febrile illness is not resolved. Nonetheless, we have had experience with two patients who regularly had acute exacerbations of MS following each outbreak of labial genital herpes. The incidence of respiratory, urinary, or gastrointestinal viral infections that precede the onset or exacerbations of the disease varies greatly in different series, from 5 to 50 percent. The swine influenza vaccine, which was given to 45 million persons in the United States in late 1976, caused a slight increase in the incidence of Guillain-Barré disease but not of MS (Kurland et al), and more recent surveys of immunization programs, such as the one by Confavreux and colleagues (2001), have had similar results.

The possible role of trauma in precipitating MS is more difficult to assess. McAlpine and Compston found that the incidence of trauma within a 3-month period preceding the onset of MS was slightly greater than in a control group of hospital patients. Furthermore, there appeared to be a relationship between the site of the injury

and the site of initial symptoms, particularly in patients who developed symptoms within a week of injury. We do not find this evidence convincing, particularly when given as an explanation for a large number of attacks. Other forms of trauma (including lumbar puncture and general surgical procedures) that occur after the onset of the neurologic disorder have not been shown to have an adverse effect on the course of the illness. Matthews, who has extensive personal experience with survivors of penetrating head wounds, did not find a single instance of MS among them. One of the most meaningful prospective studies of the relation of physical injury to MS is that of Sibley and colleagues, who followed 170 MS patients and 134 controls for an average of 5 years, during which they recorded all (1,407) instances of trauma and measured their effects on exacerbation rate and progression of the disease. With the possible exception of a case or two of electrical injury, there was no correlation between traumatic episodes and exacerbations. The current authoritative view on this subject is that the coincidence of trauma and new or exacerbated MS is incidental.

Certain other epidemiologic data have a bearing on this subject. There are, in the United States, 250,000 to 350,000 cases of physician-diagnosed MS (Anderson et al). Also, a study from the National Center for Health Statistics has determined that trauma sufficiently severe to be recalled at a periodic health examination occurs in one-third of the population of the United States (some 83 million persons) each year. Moreover, MS patients suffer physical injuries two or three times more often than normal persons (Sibley et al). In light of these data, it is perhaps not surprising that a traumatic event and an exacerbation should sometimes coincide, quite by chance.

Issues related to MS and pregnancy are addressed in a later section.

Variants of Multiple Sclerosis

Several variants of MS present special problems that are addressed in this and in later section.

Acute and Tumor-Like (Tumefactive) Multiple Sclerosis (Marburg Variant)

Rarely, MS takes a rapidly progressive and highly malignant form; Marburg's name has been attached to this variant. A combination of cerebral, brainstem, and spinal manifestations evolves over a few weeks, rendering the patient stuporous, comatose, or decerebrate with prominent cranial nerve and corticospinal abnormalities. Death may end the illness within a few weeks to months without any remission having occurred, or there may be partial recovery, as noted below. At autopsy the lesions are of macroscopic dimensions, in essence very large acute plaques of MS. The only difference from the usual form of MS is that many plaques are of the same age and the confluence of many perivenous zones of demyelination is more obvious. Two of our most striking examples of this rapidly fatal form were in a 6-year-old girl and a 16-year-old boy, both of whom died within 5 weeks of the onset of symptoms. Another was a 30-year-old man who lived 2 months. In none of them had there been a preceding exanthem or inoculation or any symptoms suggestive of demyelinating disease. Usually the CSF shows a cellular response but no oligoclonal bands. Some have made an astonishing recovery after several months, and a few have then remained well for 25 to 30 years. Others have relapsed, and the subsequent clinical course was typical of MS.

Among these cases are occurrences of large acute plaques with associated mass effect and enhancement that simulate a tumor on imaging (*tumefactive MS*, as described in the series by Kepes and shown in Fig. 36-2).

Figure 36-2. Left Axial T2-FLAIR image of a tumefactive MS lesion in the left temporal lobe. Right T1-post gadolinium showing an “open ring” of abnormal contrast enhancement, a common imaging feature of acute demyelinating plaques that is less typical of tumors or abscesses.

The tumefactive lesion also occurs independently in cases of new or established disease that evolve in a manner that is more consistent with typical MS.

Balo and Schilder Diseases

The *concentric sclerosis of Balo* has as its distinguishing feature the occurrence of alternating bands of destruction and preservation of myelin in a series of concentric rings that represent alternating areas of myelin loss, and preservation. The configuration of lesions in this pattern suggests the centrifugal diffusion of some factor that is damaging to myelin. While usually a part of an acute illness, a similar pattern of lesions, although less extensive, is seen in occasional cases of chronic relapsing MS. Some studies have found a high incidence in the Philippines.

A related but confusing entity, which had been the subject of much discussion in the earlier part of the last century, is that of *diffuse sclerosis*, or Schilder disease. Exceptionally, the cerebrum is the site of diffuse and massive demyelination. Such cases are more frequent in childhood and adolescence than in adult life. Despite the undoubted occurrence of such cases, to call them "Schilder disease" is to refer to a clinical entity of ambiguous standing.

The term *diffuse sclerosis* was first used by Strümpell (1879) to describe the hard texture of the freshly removed brain of an alcoholic; later the term was applied to widespread cerebral gliosis of whatever cause. In 1912, Schilder described an instance of what he considered to be "diffuse sclerosis." The case was that of a 14-year-old girl with progressive mental deterioration and signs of increased intracranial pressure, terminating fatally after 19 weeks. Postmortem examination disclosed large, well-demarcated areas of demyelination in the white matter of both cerebral hemispheres, as well as a number of smaller demyelinating foci, resembling the common lesions of MS. Because of the similarities of the pathologic changes to those of MS (prominence of the inflammatory reaction and relative sparing of axons), Schilder called this disease *encephalitis periaxialis diffusa*, bringing it in line with *encephalitis periaxialis scleroticans*, a term that Marburg had used to describe a case of acute MS. Unfortunately, in subsequent publications, Schilder applied the same term to two other conditions of different types. One appears to have been a familial leukodystrophy (probably adrenoleukodystrophy) in a boy, and the other, quite unlike either of the first two cases, was suggestive of an infiltrative lymphoma. The last two reports seriously confused the subject, and for many years the terms *Schilder disease* and *diffuse sclerosis* were indiscriminately attached to quite different conditions.

If one sets aside the hereditary metabolic leukodystrophies and other childhood disorders of cerebral white matter, there remains a characteristic group of cases allied with multiple sclerosis that does, indeed, correspond to Schilder's original case description. They are most frequently encountered in children or young adults. As with the case reported by Ellison and Barron, the disease may follow the course of MS, either steady and unremitting or punctuated by a series of episodes of rapid worsening. The CSF may show changes similar to those in chronic

relapsing MS. Death occurs in most patients within a few months or years, but some survive for a decade or longer. In the differential diagnosis, a diffuse cerebral neoplasm (gliomatosis or lymphoma), adrenoleukodystrophy, and progressive multifocal leukoencephalopathy (Chap. 33) are the main considerations. Histologically, the large single focus, as well as the smaller disseminated ones, shows the characteristic features of MS. These features were elaborated by Poser and colleagues in a subsequent (1986) review of this subject.

Multiple Sclerosis in Conjunction With Peripheral Neuropathy

From time to time there have been patients with MS who also have a polyneuropathy or mononeuropathy multiplex. This relationship always invites speculation and controversy especially as several autopsy cases have shown a coexistent demyelinating lesions in the central white matter and scattered in peripheral nerves but there are reasons for skepticism as vitamin deficiency polyneuropathy or multiple pressure palsies may be responsible. The rarity of the combination suggests a purely coincidental occurrence, perhaps with another underlying disease as an explanation (e.g., Lyme disease, AIDS). Another view, expressed by Thomas and colleagues and by Mendell et al, is that an autoimmune demyelination has been incited in both spinal cord and peripheral nerve, the latter taking the form of a chronic inflammatory polyradiculoneuropathy. Of course, radicular and neuropathic symptoms, motor and/or sensory, can result from the involvement of myelinated fibers in the root entry zone of the cord or fibers of exit in the ventral white matter. At the moment, we consider the two components to be most often different in origin.

Laboratory Findings in Typical Multiple Sclerosis

Cerebrospinal Fluid

In about one-third of all MS patients, particularly those with an acute onset or an exacerbation, there may be a slight to moderate mononuclear pleocytosis (usually in the range of 6 to 20 and in any case, less than 50 cells/mm³). In rapidly progressive cases of neuromyelitis optica (see further on) and in certain instances of severe demyelinating disease of the brainstem, the total cell count may reach or exceed 100, and rarely in the hyper-acute cases 1,000, cells/mm³ and in the last of these processes, the greater proportion of cells may be polymorphonuclear leukocytes. This pleocytosis may in fact be the only measure of activity of the disease.

It has been shown that the gamma globulin proteins in the CSF of patients with MS are synthesized in the CNS (Tourtellotte and Booe) and that they migrate in agarose electrophoresis as abnormal discrete populations, called *oligoclonal bands*. This is currently the most widely used CSF test for the confirmation of the diagnosis. Determination for oligoclonal IgG bands will show several bands in the CSF in more than 90 percent of cases of MS. A lower proportion of patients in Asian countries

demonstrate bands. Such bands also appear in the CSF of patients with syphilis, Lyme, and subacute sclerosing panencephalitis, disorders that should not be difficult to distinguish from MS on clinical grounds. The demonstration of oligoclonal bands in the CSF and not in the blood is particularly helpful in confirming the diagnosis of MS, but they are not always found with the first attack or even in the later stages of the disease. The presence of bands in a first attack of MS is predictive of a chronic relapsing course, according to Moulin and coworkers and others. Oligoclonal bands are usually reported as being present if there is more than one band; the meaning of a single band is not clear, and we have treated this result as a negative test. As will be pointed out, the conditions of necrotic myelopathy and Devic disease generally lack oligoclonal bands.

Also, in approximately 40 percent of patients, the total protein content of the CSF is increased. The increase is slight, however, and a concentration of more than 100 mg/dL is so unusual that the possibility of another diagnosis should be entertained. Less used as a diagnostic test currently is measurement of IgG and the IgG index in the CSF. The latter refers to proportion of gamma globulin (mainly IgG) in reference to the total protein in CSF; a positive test is considered to be greater than 12 percent of the total protein. The same diseases mentioned above as being associated with oligoclonal bands can also increase the IgG index.

It has also been shown, by the use of a sensitive radio-immunoassay, that the CSF of many patients contains high concentrations of MBP during acute exacerbations of MS and that these levels are lower or normal in slowly progressive MS and normal during remissions of the disease. Other lesions that destroy myelin (e.g., infarction) can also increase the level of MBP in the spinal fluid. Thus the assay is not particularly useful as a diagnostic test and probably simply reflects the destruction of central myelin.

When cells, total protein, gamma globulin, and oligoclonal bands are all taken into account, some abnormality of the spinal fluid will be found in the great majority of patients with established MS. At present, the oligoclonal bands in the CSF is the most widely used of the CSF tests for MS, particularly when taken some interval after an acute exacerbation or during the chronic progressive phase of disease. The more complicated laboratory procedures, such as CSF measurements of globulin production or MBP provide little additional sensitivity.

Imaging

It is now widely appreciated that MRI is the most helpful ancillary examination in the diagnosis of MS, by virtue of its ability to reveal symptomatic and asymptomatic plaques in the cerebrum, brainstem, optic nerves, and spinal cord (Fig. 36-1). Most experience indicates that the incidence of lesions, if the cerebrum and spinal cord are imaged, is greater than 90 percent in established cases of MS. It is remarkable that even when there are a multitude of cerebral lesions, they tend to be asymptomatic; by contrast, spinal cord lesions are almost always symptomatic.

Several MRI features are characteristic of the MS lesion. In general, MS plaques are hyperintense (white) on T2-weighted images and even more obvious on T2 fluid-attenuated inversion recovery (T2-FLAIR) images. The T2 sequence is particularly sensitive in detecting lesions in the brainstem, cerebellum, and spinal cord. Acute lesions tend to demonstrate tissue expansion due to edema that is evident as T1 hypointensity and T2 hyperintensity. Chronic lesions, in distinction, are usually contracted and hyperintense on T2 sequences. The presence of T1 hypointensity depends on the extent of remyelination of the lesion. If there is no or scant remyelination, the center of the chronic lesion gives the appearance of a "black hole." As assessed histologically with both autopsy and MRI studies, T1 hypointensity was inversely proportional to the degree of remyelination (Barkhof et al).

The individual cerebral lesions on MRI do not always ensure the diagnosis of MS, but the finding of multifocal, well-demarcated, oval or linear, radially oriented lesions adjacent to the ventricular surface usually denotes the typical relapsing-remitting form of MS. When viewed in sagittal images, they extend from the corpus callosum in a filiform pattern and have been termed "Dawson fingers." The radial orientation of these lesions corresponds to the course of venules embedded within the cerebral white matter. In addition to these periventricular lesions, subcortical and infratentorial lesions are frequently seen, most often in white matter tracts such as the cerebral and cerebellar peduncles and the medial longitudinal fasciculus. Lesions in MS do not conform to cerebral vascular territories and lack the wedge shape of typical embolic cerebral infarctions. Further assisting in distinguishing an MS lesion from an infarction, diffusivity in MS is variable.

Early in the evolution of an MS lesion, there is disruption of the blood-brain barrier, presumably as a consequence of inflammation. The MRI correlate of this inflammation is abnormal T1 hyperintensity (enhancement) following the administration of gadolinium. Gadolinium enhancement, may last for many weeks. One characteristic pattern is of a C-shaped partial or open ring of abnormal enhancement; which assists in differentiating a MS lesion from other lesions such as abscess and neoplasm. The open segment of the ring is most often medially situated. Many of these imaging characteristics are listed in Table 2-3 and displayed in Fig. 36-1.

In advanced cases of MS, the periventricular lesions may become confluent, usually at the poles of the ventricles. Infrequently, a large acute lesion may have a mass effect and a ring-like contrast-enhancing border, then resembling a glioblastoma or an infarct—the previously referred to "tumefactive" lesion (see Fig. 36-2).

As discussed below, in recent criteria for diagnosis, and in keeping with the traditional notion of MS as a disease that is "disseminated in time and space," the MRI is invaluable for demonstrating asymptomatic lesions. It is the discovery of these additional lesions in a patient with a single clinical episode that can establish the diagnosis of MS. Similarly, the unsuspected diagnosis of MS may be revealed on a single MRI by detecting one

or more acute (enhancing) lesions with additional non-enhancing ones. Some of these asymptomatic lesions may be found in the spinal cord as discussed by Bot and colleagues. Furthermore, serial MRIs showing accumulating T2 hyperintense lesions over time are consistent with the diagnosis. As with other laboratory procedures, MRI changes assume maximal significance when they are consistent with the clinical findings.

Less evident than the focal lesions of MS is the progressive cerebral atrophy that accompanies most cases. This change probably reflects both the loss of glial cells and, importantly, wallerian degeneration and loss of axons triggered acutely by inflammation and more chronically by other neurodegenerative stimuli (Miller et al, 2002). Several studies document that slowly progressive brain atrophy, as gauged by volumetric MRI measurements of the cortical mantle, deep nuclei, and white matter, is a feature of MS. This is demonstrable both early and late in the disease and correlates particularly with cognitive disability.

The spinal lesions of MS occupy only a portion of the transverse surface of the cord, most commonly being situated in white matter tracts in a subpial location. The lesions infrequently extend longitudinally beyond three contiguous vertebral segments (Fig. 36-1), in contrast to those of neuromyelitis optica as discussed further on. As described above, acute lesions may cause focal expansion of the cord and enhance with contrast, while chronic lesions tend to produce atrophy.

It should be stressed that foci of periventricular T2 hyperintensity are observed with a variety of pathologic processes and even in normal persons, particularly older ones. Unlike the lesions of MS, these periventricular lesions are usually oriented parallel to the ventricular surfaces, are smoother in outline than the lesions of MS, and have been attributed to microvascular changes as discussed in Chapter 34. The same lack of specificity of cerebral lesions pertains to those in the spinal cord.

CT may also demonstrate cerebral lesions, sometimes unexpectedly, but with far less sensitivity than MRI. Two points worth noting about the CT are that acute plaques can appear as contrast-enhanced ring lesions, simulating abscess or tumor, and that some contrast-enhanced periventricular lesions become radiologically invident after steroid treatment.

Evoked Potentials and Other Tests

When the clinical data point to only one lesion in the CNS, as often happens in the early stages of the disease or in the spinal form, a number of other sensitive physiologic and radiologic tests may establish the existence of additional asymptomatic lesions. These include visual, auditory, and somatosensory-evoked responses and the less standardized and infrequently tested perceptual delay on visual stimulation; electro-oculography; altered blink reflexes; and a change in flicker fusion of visual images. Abnormalities of visual evoked responses have been found in approximately 70 percent of patients with the clinical features of definite MS and 60 percent of patients with probable

or possible MS. The corresponding figures for somatosensory evoked responses have been 60 percent and 40 percent, and for brainstem auditory evoked responses (usually prolonged interwave latency or decreased amplitude of wave 5), approximately 40 percent and 20 percent, respectively (see Chap. 2). These tests had been used with greater frequency in the past and have been largely supplanted by MRI to detect dispersed demyelinating lesions.

Optical coherence tomography (OCT) is a technique for creating two- and three-dimensional images of the optic nerve and retina. By using near-infrared interferometry, it displays axonal loss and thinning of the retina that assists in the evaluation of optic neuritis and subsequent optic atrophy. It is used mainly to follow the course of optic neuritis.

Whether tests for serum antibodies against oligodendrocytes and myelin have the predictive value remains to be seen. Berger and colleagues published provocative findings in which 23 percent of patients who lacked such antibodies had further attacks after their first one, whereas 95 percent of those who had both antibodies suffered a relapse. Attempts to reproduce these findings by Kuhle and colleagues did not meet with success and there is no serum test for multiple sclerosis that has proven consistent, nor is there a predictive test for relapse. The importance of anti-aquaporin (NMO) antibodies in Devic disease will be discussed further on.

Diagnostic Criteria for Multiple Sclerosis

The clinician is well advised to make the diagnosis of MS on the firmest grounds possible and to withhold judgment unless the combination of clinical and laboratory features allows certainty. In the past, the passage of time was necessary to clarify the situation but presently, it is considered preferable to use MRI and other tests to attempt to establish the diagnosis at the time of the first symptoms. Certainly, the disease is likely when one of the usual syndromes, such as optic neuritis, bilateral brainstem symptoms, or transverse myelitis, occurs in a younger person. However, the time-honored—and still valid—criteria for diagnosis proposed by McAlpine and colleagues (1972), requiring several lesions that were “separated in time and space,” have been broadened greatly by the ability to detect demyelinating lesions by nonclinical means. This approach, in essence, predicts the likelihood that a clinically isolated syndrome (“CIS”) will disseminate over time and space and conform to the diagnosis of MS.

Polman and colleagues in 2011 have provided a diagnostic scheme based on previous consensus (2001, 2005 and 2010) that incorporates MRI changes into the criteria and further revisions have increased sensitivity (Table 36-2). These criteria are provided for the reader because they are often cited but they may prove unwieldy for routine clinical work. Our colleague Kurtzke apocryphally is said to have quipped “MS is what the experienced neurologist says it is.” All such criteria are also relevant to predicting the course of illness, which is discussed below.

Table 36-2

DIAGNOSTIC CRITERIA FOR MS^a

CLINICAL FEATURES	LABORATORY FEATURES
Two or more typical attacks of central nervous system demyelination with objective evidence on examination for both lesions (see text)	—
Two clinical attacks with objective evidence on examination for only one lesion	Lesions or T2 hyperintensity located in at least two of four typical locations (periventricular, juxtacortical, infratentorial, or spinal cord)
One attack with objective evidence on examination of two or more lesions	Dissemination over time: simultaneous enhancing and nonenhancing lesions in the above locations, or interval development of new T2 hyperintense lesions
One attack with objective evidence on examination for only one lesion (clinically isolated syndrome, CIS; see text)	Dissemination in space: lesions or T2 hyperintensity located in at least two of four typical locations (periventricular, juxtacortical, infratentorial, or spinal cord), and dissemination in time demonstrated by simultaneous enhancing and nonenhancing lesions in the above locations, or interval development of new T2 hyperintense lesions
Progressive, nonrelapsing, deficits suggestive of MS	One year of disease progression and dissemination in space as above and oligoclonal bands or elevated IgG index in the CSF

^aAdapted from Polman 2011.

Clinical Course and Prognosis

The intermittency of the clinical manifestations—the disease advancing in a series of attacks, each permitting remission—is perhaps the most important clinical attribute of most cases of MS. Some patients will have a complete clinical remission after the initial attack, or, there may be a series of exacerbations, each with complete remission; rarely, such exacerbations may be severe enough to have caused quadriplegia and pseudobulbar palsy. The average relapse rate is 0.3 to 0.4 attacks per year according to the calculations of McAlpine and Compston, but the interval between the opening symptom and the first relapse is highly variable. It occurred within 1 year in 30 percent of McAlpine's cases and within 2 years in another 20 percent. A further 20 percent relapsed in 5 to 9 years, and another 10 percent in 10 to 30 years. Not only the length of this interval is remarkable, but also the fact that the basic pathologic process can remain potentially active for such a long time.

Weinshenker and colleagues (1989), on the basis of observations in 1,099 MS patients over a 12-year period, have identified a number of features of the early clinical course that were predictive, in a general way, of the outcome of the illness. Perhaps not surprisingly, they found that a high degree of disability, as measured by the Kurtzke Disability Status Scale, was reached earlier in patients with a higher number of attacks, a shorter first interattack interval, and a shorter time to reach a state of moderate disability. Kurtzke had earlier reported that the feature most predictive of long-term disability was the degree of disability at 5 years from the first symptom. Confavreux and colleagues (2000) analyzed a cohort of 1,844 patients with multiple sclerosis and found, somewhat surprisingly, that relapses did not significantly influence the progression of irreversible disability. Furthermore, large population studies (Pittock et al 2004; Tremlett et al) have shown that many patients develop only mild disability after long follow-up (so-called benign

MS). Regardless of the age of onset, approximately 20 percent of patients do not become disabled, even after many decades of illness. These data should inform the use of the long-term disease-modifying therapies discussed in a later section but, as pointed out by Sayao and colleagues, reliable criteria for identifying patients who are destined to accumulate minimal or no disability are not available but are being sought.

After a number of years there is an increasing tendency for the patient to enter a phase of slow, steady, or fluctuating deterioration of neurologic function, attributable to the cumulative effect of increasing numbers of lesions (*secondary progressive MS* as described in the introductory section). However, in approximately 10 percent of cases, the clinical course lacks periodic relapses and is almost evenly progressive from the beginning (*primary progressive MS*; see Thompson et al). In these latter cases, the disease usually takes the form of a chronic asymmetrical spastic paraparesis and probably represents the most frequent type of difficult to diagnose as MS. In Thompson's review of primary progressive MS, there was little change over time in the MRI findings, a negligible response to therapy, and a poor outcome. The frequency with which acute MS blends into the progressive variety has already been emphasized. (See earlier comments regarding the pathologic distinctions between types of MS.)

Pregnancy is typically associated with clinical stability or even with improvement (as it is in a number of autoimmune diseases). The average relapse rate in established cases declines in each trimester, reaching a level less than one-third of the expected rate by the third trimester. However, there appears to be an increased risk of exacerbations, up to twofold, in the first few months postpartum (Birk and Rudick). An extensive study of 269 pregnancies by Confavreux and colleagues (1998) established a rate of relapse of 0.7 per woman per year before pregnancy and rates of 0.5 in the first, 0.6 in the second, and 0.2 in the third trimester, the rate then increasing substantially to 1.2 in the first 3 months postpartum.

The duration of the disease is exceedingly variable. A small number of patients die within several months or years of the onset, but the average duration of the illness is in excess of 30 years. A 60-year appraisal of the resident population of Rochester, Minnesota, disclosed that 74 percent of patients with MS survived 25 years, as compared with 86 percent of the general population. At the end of 25 years, one-third of the surviving patients were still working and two-thirds were still ambulatory (Percy et al). Other statistical analyses have given a less optimistic prognosis; these were reviewed by Matthews. Patients with mild and quiescent forms of the disease are, of course, less likely to be included in such surveys. Although exceptional, one of our patients relapsed and developed massive brainstem demyelination and coma after 30 years (confirmed by postmortem examination) and cases of an aggressive myelopathy that appears after years are well known.

No environmental, dietary, or activity-related changes are known to alter the course of the illness.

Differential Diagnosis

In the usual forms of MS—that is, in those with a relapsing and remitting course and evidence of disseminated lesions in the CNS—the diagnosis is rarely in doubt. Vascular malformations such as cavernous angiomas of the brainstem or spinal cord with multiple episodes of bleeding, brain lymphoma, lupus erythematosus, the antiphospholipid antibody syndrome, and Behçet disease all may simulate relapsing MS, and each has its own characteristic and diagnostic features. The list can be expanded by the inclusion of corticosteroid-responsive intravascular lymphoma and the other numerous causes of multiple, well-demarcated white matter abnormalities on MRI, such as embolic infarcts, progressive multifocal leukoencephalopathy, migraine-associated white matter lesions, Lyme disease, sarcoidosis, and tumors. Difficulties are most likely to arise when the standard clinical criteria for the diagnosis of MS are lacking, as occurs in the acute initial attack of the disease and in cases with an insidious onset and slow, steady progression. Other features that call for caution in diagnosis of MS are an absence of symptoms and signs of optic neuritis, the presence of widespread amyotrophy, entirely normal eye movements, a hemianopic field defect, pain as the predominant symptom, or a progressive nonremitting illness that begins in youth. Other points against MS are fever and nonneurologic features such as joint inflammation, skin rash, sicca syndrome, or evidence of peripheral neuropathy. The differentiation from Devic disease is discussed further on.

As has been stated, *the initial attack of MS* may mimic acute labyrinthine vertigo or tic douloureux (trigeminal neuralgia). Careful neurologic examination of such patients usually discloses other signs of a brainstem lesion; the CSF examination may be particularly helpful in these circumstances. Extensive brainstem demyelination of subacute evolution, involving tracts and cranial nerves sequentially, may be mistaken for a pontine glioma. With brainstem symptoms of acute onset, there

may be difficulty in distinguishing an MS plaque from a small infarction because of a basilar branch occlusion. In several patients who we have observed, recurrent bleeding from cavernous vascular malformations and small brainstem arteriovenous malformations simulated MS clinically. Only with MRI, visualization of blood products surrounding the small vascular lesions may the diagnosis be clarified. Sequential MRIs and the course of the illness usually settle the matter.

Acute disseminated encephalomyelitis (ADEM; see further on) is an acute illness with widely scattered small demyelinating lesions but it is self-limited and monophasic. Furthermore, fever, stupor, and coma, which are characteristic of severe cases, rarely occur in MS. The encephalomyelitis may, however, progress for several weeks, making the distinction from MS difficult.

White Matter Lesions Associated With Systemic Autoimmune and Inflammatory Diseases

In systemic lupus erythematosus and less often in other autoimmune diseases (mixed connective tissue disease, Sjögren syndrome, scleroderma) there may be multiple lesions of the CNS white matter. These may parallel the activity of the underlying immune disease or the level of autoantibodies, particularly those against native DNA or phospholipids but myelitis or lesions in the cerebral hemispheres are known to occur before other organ systems are affected. Conversely, between 5 and 10 percent of MS patients have antinuclear or anti-double stranded DNA antibodies without signs of lupus, but the significance of this finding is not at all clear. In addition, as discussed in the introductory section relatives of patients with MS in some series have a higher than expected incidence of autoantibodies of various types, suggesting an as yet unproved connection between systemic autoimmune disease and MS.

On MRI, the lesions of lupus and of antiphospholipid antibody syndrome appear similar to plaques, and both the optic nerve (rarely) and the spinal cord may be involved, even repeatedly, in a succession of attacks resembling MS. The lesions may be small and single, multiple, or confluent in large regions (Akasbi). Nevertheless some of the lesions represent small zones of infarct necrosis rather than demyelination and are traceable to small-vessel occlusion. Others may be autoimmune and demyelinating and this group of processes that affect the cerebral white matter remains difficult to understand. In a few instances, inflammatory demyelination without vascular changes may be seen. It is best for the moment to consider these as special manifestations of lupus or related diseases that mimic MS. The neurologist should be cautious in initiating some of the treatments for MS, such as β -interferon, as they may worsen the systemic autoimmune illness.

Periarteritis nodosa or vasculitis confined to the nervous system may produce multifocal lesions simulating MS. The distinction may be particularly difficult in rare instances of the vasculitic process in which the neurologic manifestations take the form of a relapsing or steroid-responsive myelitis. In these cases, the CSF may

contain 100 or more white blood cells/mm³ and there may be no evidence of disease elsewhere in the nervous system. Occasionally, a young person with Lyme disease may have complaints of inordinate fatigue and vague neurologic symptoms coupled with hyperintense lesions on the T2-weighted cranial MRI. Close attention to the characteristic history (rash, arthritis, etc.) and serologic findings permit the distinction between MS and systemic diseases. The distinguishing features of Behçet disease are recurrent iridocyclitis and meningitis, mucous membrane ulcers of mouth and genitalia, and symptoms of articular, renal, lung, and multifocal cerebral disease. The chronic forms of brucellosis in the Mediterranean regions and Lyme borreliosis throughout North America and Europe may cause myelopathy or encephalopathy with multiple white matter lesions on imaging studies, but in each case the history and other features of the disease help to identify the infectious illness (see Chap. 32).

Spinal Multiple Sclerosis

The *purely spinal form of MS*, presenting as a progressive spastic paraparesis, hemiparesis, or, in several of our cases, spastic monoparesis of a leg with varying degrees of posterior column involvement, is a special source of diagnostic difficulty. A tendency to affect older women has already been mentioned. Such patients require careful evaluation for the presence of spinal cord compression from neoplasm or cervical spondylosis. Dural arteriovenous fistula is also a consideration as mentioned below. Radicular pain at some point in the illness is a frequent manifestation of these disorders and is much less frequent in MS. Pain in the neck, restricted mobility of the cervical spine, and severe muscle wasting as a result of spinal root involvement, as is sometimes seen in spondylosis, are almost unknown in MS. However, atrophy of the first dorsal interosseus muscles, a frequent finding in spondylosis, is also in MS. As a general rule, loss of abdominal reflexes, erectile dysfunction, and disturbances of bladder function occur early in the course of demyelinating myelopathy but late or not at all in cervical spondylosis. The CSF protein in cervical spondylosis is often elevated, but oligoclonal bands and elevated IgG are not found.

A special problem arises when imaging procedures reveal a regional swelling of the spinal cord suggestive of a tumor. In a patient with this finding and a subacute, saltatory myelopathy restricted to several adjacent levels (usually thoracic), a search for an arteriovenous malformation or fistula may be required. In several of our patients, this finding has led to an ill-advised attempt at spinal cord biopsy. Sarcoidosis affecting the cord presents similar problems; steroid-responsive granulomatous lesions of sarcoid that follow a venous pattern in the cerebrum may cause confusion with MS when viewed by MRI. A subpial pattern of enhancement with gadolinium is helpful in identifying sarcoid.

The problem of differentiating chronic spinal MS from tropical spastic paraparesis (human lymphotropic virus, myelitis of the HTLV-1 type) and progressive familial spastic paraplegia may also arise occasionally. Amyotrophic lateral sclerosis (ALS) and subacute combined

degeneration (SCD) may be confused with MS, but ALS can be identified by the presence of muscle wasting, fasciculations, and the absence of sensory involvement, whereas SCD is characterized by symmetrical involvement of the posterior and then lateral columns of the spinal cord. Reports that vitamin B₁₂ levels are marginally low in a proportion of MS patients have suggested an underlying disturbance of homocysteine metabolism but this has not been confirmed (Vrethem et al).

Platybasia and basilar impression of the skull should also be considered in the differential diagnosis, but patients with these conditions usually have a characteristic shortening of the neck; images of the base of the skull are diagnostic. Neurologic syndromes resulting from the Chiari malformation, syringomyelia, rheumatoid destruction of the upper cervical segments, and tumors of the foramen magnum, cerebellopontine angle, clivus, and other parts of the posterior fossa have been misdiagnosed clinically as MS. In each of these instances, a solitary, strategically placed lesion may give rise to a variety of neurologic symptoms and signs referable to the lower brainstem and cranial nerves, cerebellum, and upper cervical cord, giving the impression of dissemination of lesions. It is a dependable clinical dictum that a diagnosis of MS should be made with caution when all of the patient's symptoms and signs can be explained by a single lesion in one region of the neuraxis.

Occasionally, the chronic progressive form of MS may be confused with the hereditary ataxias, particularly the spinocerebellar types. The latter are generally distinguished by their familial incidence and other associated genetic traits; by their insidious onset and slow, steady progression; and by their relative symmetry and stereotyped clinical pattern. Intactness of abdominal reflexes and sphincter function and the presence of pes cavus, kyphoscoliosis, and cardiac disease are other features that favor the diagnosis of a heredodegenerative disorder (see Chap. 39).

Treatment of Multiple Sclerosis

As one might expect, numerous forms of treatment have been proposed over the years, and many were thought to be successful, no doubt because of the remitting nature of the disease. The many therapeutic trials of recent years, using mainly anti-inflammatory and immunosuppressive are summarized below. Typical relapsing-remitting MS that is associated with episodic inflammation is most responsive to immunomodulatory therapy; on the other hand, these measures may be ineffective for chronic progressive subtypes. Therefore, as discussed earlier, therapy should be guided by the nature of the disease in each individual and with consideration of the side effects and risks of each of the expanding group of available therapies. A current list of clinical trials is maintained by the National Multiple Sclerosis Society: <http://www.nationalmssociety.org/research/clinical-trials/clinical-trials-in-ms/index.aspx>

Although many writers on the subject indicate that virtually all patients with proven MS should be treated

soon after the diagnosis is established, the long-term effects on the illness still remain to be clarified. From the numerous studies cited below, a concept has emerged that subclinical lesions may be of importance and that, over time, cognitive decline and neurologic deficits are more likely to occur if progression is not reduced by treatment. There are few circumstances where such treatment is mandated immediately, and we allow enough time for the patient to consider the alternatives and sometimes encourage serial examinations and MRI to determine the course of illness. With all of these treatments it should be acknowledged that there is no certain correlation between the number of relapses and the ultimate disability despite authoritative statements to the contrary (as expressed by Confavreux et al [2000]).

Corticosteroids Under the influence of corticosteroids, recovery from an acute attack, including an attack of optic neuritis, appears to be hastened. However, a substantial group of patients with acute exacerbations fails to respond; in others, benefit is not apparent for a month or longer after the course of treatment has been completed and therefore may reflect the natural course of disease. There is no evidence that steroids have a significant effect on the ultimate course of this disease or that they prevent recurrences. Accordingly, there is limited justification for steroid treatment over a period of many months or years except in those infrequent cases where withdrawal of the medication consistently leads to relapse (alternative diagnoses should be considered in this event). In a study of intravenous methylprednisolone administered at 1 g/d for 5 days per month over 5 years, there was a reduction in disability as well as in the degree of brain atrophy and total volume of hypodense lesions on T1-weighted MRI (Zivadinov et al).

As to the dosage of corticosteroids for an acute attack, it seems that initially a high dose is more effective but this has been disputed, as noted below. A randomized trial comparing oral and intravenous methylprednisolone in acute relapses of MS demonstrated no clear advantage of the intravenous regimen (Barnes et al), but many MS experts dispute this finding. The administration of adrenocorticotropic hormone (ACTH), which was popular during the 1970s, has been abandoned.

The intravenous administration of massive doses of methylprednisolone (a bolus of 500 to 1,000 mg daily for 3 to 5 days) followed by high oral doses of prednisone (beginning with 60 to 80 mg daily and tapering to a lower dosage over a 12- to 20-day period) is generally effective in aborting or shortening an acute or subacute exacerbation of MS or of optic neuritis. Whether the tapering oral course is necessary is unclear. When it is impractical to administer parenteral methylprednisolone, one may substitute oral methylprednisolone (48 mg in a single daily dose for 1 week, followed by 24 mg daily for 1 week, and finally 12 mg daily for 1 week) or the equivalent amount of prednisone (Barnes et al).

A brief period of corticosteroid administration generally produces few adverse effects but some patients complain of insomnia and a few will develop depressive or manic symptoms. Patients who, because of clinical relapse

on withdrawal of the medication, require oral treatment for more than several weeks are subject to the effects of hypercortisolism, including the facial and truncal cosmetic changes of Cushing syndrome, hypertension, hyperglycemia and erratic diabetic control, osteoporosis, avascular necrosis of the head of the femur, and cataracts; less often, there may be gastrointestinal hemorrhage and activation of tuberculosis or pneumocystis. It must be acknowledged that the corticosteroid regimens and dosages in common use are derived from anecdotal experience (the Optic Neuritis Treatment Trial being an exception) and that certain patients appear, at least for a period of time, to respond better to one or another method of treatment.

As mentioned under "Acute Multiple Sclerosis," there may be a role for *plasma exchange* (see Weinschenker et al, 1999; Rodriguez et al) and perhaps immunoglobulin in fulminant cases, but these have not been tested rigorously. One limited trial has shown some benefit, in patients with relapsing–remitting disease, of monthly infusions of intravenous immunoglobulin (0.2 g/kg) for 2 years (Fazekas et al).

Treatment of Optic Neuritis (See Chap. 13) The Optic Neuritis Treatment Trial, reported by Beck and colleagues, cautioned against the use of oral prednisone in the treatment of acute optic neuritis (see also Lessell). In this study, it was found that the use of intravenous methylprednisolone followed by oral prednisone did, indeed, speed the recovery from visual loss, although at 6 months there was little difference between patients treated in this way and those treated with placebo. They reported that treatment with oral prednisone alone slightly increased the risk of new episodes of optic neuritis. In a subsequent randomized trial conducted by Sellebjerg and colleagues, it was found that methylprednisolone 500 mg orally for 5 days had a beneficial effect on visual function at 1 and 3 weeks. However, at 8 weeks, no effect could be shown (compared with the placebo-treated group), nor was there an effect on the subsequent relapse rate.

Interferon-Beta Interferon and glatiramer modestly alter the natural history relapsing–remitting MS. IFN- β -1b, a nonglycosylated bacterial cell product with an amino acid sequence identical to that of natural IFN- β , was the first of these agents to be tested (Arnason). Several trials have shown that the subcutaneous injection of this agent every second day for up to 5 years decreases the frequency and severity of relapses by almost one-third and also the number of new or enlarging lesions ("lesion burden") in serial MRIs. A large-scale trial (European Study Group, PRISMS Study Group) has extended the observations with IFN- β -1b to patients with the secondarily progressive type of MS; progression of the disease was delayed for 9 to 12 months in a study period of 2 to 3 years. The treatment of relapsing–remitting MS with IFN- β -1a is probably equally effective but was tested in a once weekly intramuscular regimen, making direct comparisons to the -1b preparation difficult. The dose currently used is 30 mcg, or 6.6 million units.

One issue with the longer term administration of interferon is the development of antibodies to the drug. The rate of such antibody emergence increases with the

frequency of use of interferon. After a period of years, 30 percent of patients demonstrate antibodies with daily administration, 18 percent with alternate-day use, and less than 5 percent with weekly use. More recent changes in the preparation of interferon have led to reported rates of only 2 percent with antibodies after 1 year of use. There is some evidence that the presence of these antidrug antibodies diminishes the effectiveness of interferon.

Overall, the side effects of these interferon agents are modest, consisting mainly of flu-like symptoms, sweating, and malaise beginning several hours after the injection and persisting for up to 14 h; they are reduced by pre- and post-treatment with nonsteroidal anti-inflammatory drugs and tend to abate with continued use of the agents. In severe cases, prednisone 10 mg taken an hour before, a few hours after, and again 6 to 8 hours after injection may be effective. Nevertheless, some patients cannot tolerate interferon. A few migraineurs complain of exacerbation of their headaches. There may also be a tendency to depression in susceptible patients treated with interferon, and in our experience, this information, when openly discussed with the patient, has sometimes influenced the decision regarding choice of treatment. A rare but notable problem is the induction of a "systemic capillary leak syndrome" in patients with a monoclonal gammopathy who receive interferon. With more than weekly use, there may be an increase in liver function enzymes.

The need to treat patients with optic neuritis alone with interferon has not been satisfactorily resolved. We have generally avoided this approach except in a few patients with repeated episodes involving both eyes at various times. Some guidance is given by the Controlled High Risk Subjects Avonex Multiple Sclerosis Prevention Study (CHAMPS), which examined the effect of interferon (weekly) in patients with a first episode of optic neuritis and at least two lesions on MRI that were compatible with MS. Over 3 years, there was a modest reduction in clinical progression or relapse from 37 percent to 28 percent; if further MRI lesions were used as evidence of clinical progression, the difference from placebo treatment was even greater. If nothing else, this points to the value of a cerebral MRI in patients who have their first optic attack.

Glatiramer Copolymer I (glatiramer acetate), which was synthesized to mimic the actions of myelin basic protein, a putative autoantigen in MS, is given daily in subcutaneous doses of 20 mg. Antibodies do not develop to glatiramer, and this has been emphasized as a relative advantage of the drug. The salutary effects of treatment are definite though limited. Patients receiving glatiramer acetate should be warned of a reaction consisting of flushing, chest tightness, dyspnea, palpitations, and severe anxiety. Injection site reactions occur with both classes of drugs but are rarely troublesome if the sites are rotated. Trials that combine interferon and glatiramer have not produced benefit over either agent alone (Lublin and colleagues).

Conventional Immunosuppressive Drugs A number of agents that modify immune reactivity have been tried with, until recently, limited success. Drugs such as azathioprine and cyclophosphamide, as well as total lymphoid irradiation and bone marrow transplantation, have

been given to small groups of patients and seem to have improved the clinical course of some (Aimard et al; Hauser et al, 1983; Cook et al). However, the risks of prolonged use of immunosuppressive drugs, including a chance of neoplastic change and infection, will probably preclude their widespread use. The study by the British and Dutch Multiple Sclerosis Azathioprine Trial Group attributed no significant advantage to treatment with this drug.

For the chronic, progressive phase of the disease, an MS study group has reported a modest delay in the advance of the disease after a 2-year trial of prednisolone and cyclophosphamide. The group cautions, however, that the "burdensome and potentially serious toxicity must temper consideration of its use in this disease." At least one subsequent blinded, placebo-controlled study with cyclophosphamide has failed to show any benefit but many groups continue to use it for recalcitrant and severe acute cases. In one trial involving patients with chronic progressive MS, weekly low-dose oral methotrexate resulted in slight improvement difference and produced some reduction in the volume of cerebral lesions on the MRI compared with control cases (Goodkin et al, 1996). Because this regimen is well tolerated, it may still have some use in otherwise untreatable progressive cases. Among these more aggressive agents, mitoxantrone, a drug with broad immunosuppressant and cytotoxic activity, has attracted interest because one study has shown a slight beneficial effect on the progressive form of the disease (Hartung et al). Some have disputed the interpretation of these results; additionally, there is little effect on the number of MRI lesions. Mycophenolate and similar drugs have been tried with varying success.

These drugs, as a class, are being used less frequently, particularly as new oral agents become available.

Monoclonal Antibodies One novel approach to treatment has been the use of monoclonal antibodies to various components of the inflammatory response. Natalizumab is directed against alpha-integrin in order to block lymphocyte and monocyte adhesion to endothelial cells and their migration through the vessel wall. It has been used in rheumatoid arthritis and fistulizing Crohn disease. In a study that ran for 6 months, Miller and colleagues (2003) were able to demonstrate a reduction in the number of relapses and a slowing of the accumulation of MRI lesions. A double-blind, placebo-controlled study of 942 patients with relapsing-remitting MS (Polman et al; the AFFIRM study) showed a 68 percent reduction in relapses, an 80 percent reduction in new or enlarging T2 cerebral lesions and a 96 percent reduction in gadolinium-enhancing lesions on MRI after a year. This represents a twofold improvement in efficacy compared to what has been reported with interferon and glatiramer acetate. There was a 2 percent rate of anaphylactic reactions. Another study suggested that the use of interferon and natalizumab may give better results (Rudick et al, 2006; the SENTINEL study) but these two are no longer combined in practice.

The advantages of this drug are once monthly intravenous treatment and a virtual lack of acute side effects. However, the appearance of cases of progressive multifocal

leukoencephalopathy (PML as discussed in Chap. 33) has led to a restriction on its use. As of the time just prior to this writing, there were over 300 cases of PML recorded in relation to the use of natalizumab for MS. Programs are in place to facilitate the early detection of PML since recovery may be possible if the drug is stopped promptly and removed by plasma exchange. However, the methods to detect the infection and to predict which patients will become symptomatic are imperfect. It can be stated that the absence of both JC virus in the urine and of serum antibodies to JC virus makes it very unlikely that PML will occur but there still may be rare cases. In those who have anti-JC virus antibodies, the risk is dependent on the duration of use of natalizumab (particularly if over 24 months) and the prior or concurrent use of other immunosuppressive medications. With both of these factors present, the risk of PML is approximately 11 per 1000 patients (Bloomgren et al).

One remarkable observation has been that the use of plasma exchange to rapidly clear natalizumab has reversed PML and led to disappearance of JC virus from the cerebrospinal fluid. There may be an *immune reconstitution inflammatory syndrome* (IRIS) soon after the exchanges, which may be ameliorated by corticosteroids (Wenning et al; Lindå et al). Some patients have survived PML using this approach, 71 percent in one series reported by Vermersch and colleagues, in distinction to the almost uniform fatality in other circumstances.

Alemtuzumab is a monoclonal antibody that targets CD-52 antigen expressed on T and B lymphocytes, reduces the number of circulating B cells and, for a longer period, T cells. It is used in an annual cycle of intravenous administration for 5 consecutive days. A randomized trial conducted over 36 months comparing the drug to interferon- β 1a found it to be superior in preventing relapses and in the accumulation of disability (CAMMS223 Trial Investigators). A series of subsequent trials have confirmed its effectiveness in comparison to interferon (Cohen et al). The drug can produce idiopathic thrombocytopenic purpura and autoimmune thyroiditis that results in either hyper- or hypothyroidism. At the time of this writing, it is being used in Europe but has not yet been approved in the United States.

Rituximab, a B-cell-depleting monoclonal antibody that targets CD20 lymphocytes, has been tested in several trials and found to be effective in reducing relapses and the accumulation of MRI lesions in a trial of relapsing-remitting cases over 4 years, but long-term safety is still being established (Hauser et al, 2008). Numerous other drugs in this class have been explored for MS with varying but generally positive results. The limiting factors have been infection, later development of lymphoma, and a number of effects that are particular to each drug. A similar anti-CD20 drug, ocrelizumab, is effective in reducing new MRI lesions (Kappos 2011).

Oral Therapies Several novel oral agents have become available for the treatment of MS. Similar to the drugs described above, they each have particular idiosyncratic side effects, but it is patient preference in avoiding injections and infusions that is driving the development of this class.

One immunosuppressive drug that interferes with egress of lymphocytes from lymph nodes, fingolimod, has had a short-term effect on MRI lesion burden and relapse rate that is comparable or slightly superior to injectable agents in a randomized trial reported by Kappos and colleagues. The drug stands out because it is administered orally, once daily, and ostensibly has tolerable side effects. It causes a lymphopenia by restricting lymphocytes to the lymph nodes and causes adenopathy. Discontinuation of the drug is sometimes required because of extremes of bradycardia or atrioventricular block, macular edema, herpes infections and elevations in liver function tests, the last of these, in approximately 10 percent of patients.

Other oral drugs under study and in clinical use include: teriflunomide, laquinimod, cladribine, and dimethyl fumarate, not all of which have been accepted by various national drug approval agencies. The last of these has an interesting history and is perhaps notable because its mechanism of action in MS and psoriasis, the other main disease in which it is used, is not clear (Ropper 2012). Which of these orally administered drugs will be widely used remains to be determined.

General Measures Fatigue, a common complaint of MS patients, particularly in relation to acute attacks, responds to some extent to amantadine (100 mg morning and noon), modafinil (200 to 400 mg/d), or pemoline (20 to 75 mg each morning), methylphenidate, or dextroamphetamine. Confirmation of their benefit will be required before they come into general use. A number of agents exist that improve conduction through demyelinated central fibers and have been suggested as improving fatigue and gait (e.g., 4-aminopyridine).

Disorders of bladder function may raise serious problems in management. Where the major disorder is one of urinary retention, bethanechol chloride is helpful. In this situation, monitoring and reducing the residual urinary volume are important means of preventing infection; volumes up to 100 mL are generally well tolerated. Some patients with severe bladder dysfunction, particularly those with urinary retention, benefit from intermittent catheterization, which they can learn to do themselves and which lessens the constant risk of infection from an indwelling catheter. More often the problem is one of urinary urgency and frequency (spastic bladder), in which case the use of propantheline (Pro-Banthine) or oxybutynin (Ditropan) may serve to relax the detrusor muscle (Chap. 26). These drugs are best used intermittently. Severe constipation is best managed with properly spaced enemas. Often a program of bowel training can be successfully undertaken. Sexual dysfunction has been treated with sildenafil and similar drugs. When pain is a prominent symptom, its management follows the general principles of pain management outlined in Chap. 8. Carbamazepine or gabapentin are often helpful to reduce paroxysmal symptoms in MS.

In patients with severe spastic paralysis and painful flexor spasms of the legs, if local injection of botulinum toxin fails, oral and then intrathecal infusion of baclofen through an indwelling catheter and implanted pump, as

in other spastic states, is sometimes of value. The selective injection of botulinum toxin into the most hypertonic muscles is an early resort. Patients with lesser degrees of spasticity have benefited from the oral administration of baclofen. An alternative to oral baclofen is tizanidine. Failing this measure, intrathecal baclofen infusion by pump may give relief for a prolonged period.

The severe and disabling tremor that is brought out by the slightest movement of the limbs, if unilateral, can be managed surgically by ventrolateral thalamotomy or implanted stimulator of the type used for the treatment of Parkinson disease. Most surgical series report that about two-thirds of patients achieve a satisfactory reduction in their intention tremor (Critchley and Richardson; Geny et al). In the experience of others, the results have not been quite this reliable. In the series of Hooper and Whittle, only 3 of 10 MS patients who underwent thalamotomy for a severe tremor had sustained improvement. Hallett and colleagues have reported that severe postural tremor of this type can be improved by the administration of isoniazid (300 mg daily, increased by weekly increments of 300 mg to a dose of 1,200 mg daily) in combination with 100 mg of pyridoxine daily. How isoniazid produces its beneficial effects is not known, and careful monitoring of liver tests is required. Variable success may also be achieved with carbamazepine or clonazepam. For the depression associated with the disease, there does not seem to be any superior antidepressant and donepezil has not been found to be helpful for cognitive problems.

There are no valid studies to substantiate claims that have been made for the value of synthetic polypeptides other than copolymer, for hyperbaric oxygen, low-fat and gluten-free diets, or linoleate supplementation of the diet. Necessary vaccinations are not prohibited in patients with MS.

The importance of an understanding and sympathetic physician in the care of patients with a chronic and potentially incapacitating neurologic disease that requires choices among many medications of this kind cannot be overemphasized. Enlisting the support of physical and occupational therapists, visiting nurses, and social workers can be equally important. From the beginning, when patients first inquire about the nature of their illness, they require advice about their daily routine, marriage, pregnancy, the use of drugs, inoculations, and so on. As indicated earlier, the term *MS* should not be introduced until the diagnosis is certain, and then it should be qualified by a balanced explanation of the symptoms, stressing always the optimistic aspects of the disease. Most patients desire an honest appraisal of their condition and prognosis; some consider the uncertainty of their prognosis worse than their actual disability.

Neuromyelitis Optica (Devic Disease, Necrotic Myelopathy) (See also Chap. 44)

This disease is characterized by a simultaneous or successive and usually severe involvement of optic nerves and spinal cord. The combination was remarked upon by Clifford Albutt in 1870, and Gault (1894), stimulated by his teacher Devic, devoted his thesis to the subject.

Devic subsequently endeavored to crystallize medical thought about a condition that has come to be known as neuromyelitis optica. Its principal features are the acute to subacute onset of blindness in one or both eyes, preceded or followed within days or weeks by a severe transverse or ascending myelitis (Mandler et al, 1993). The singular modern insight in Devic disease has been the discovery by the group at the Mayo Clinic of a fairly specific circulating autoantibody to the aquaporin-4 water channel protein. After decades of debate, this has largely settled the controversy about Devic disease as an independent entity from MS.

In certain parts of the world, this form of aggressive and usually monophasic demyelinating disease is more common than is typical MS. The disease termed "Asian optic-spinal MS" almost certainly represents Devic disease and displays this antibody in the majority of cases. Most cases of neuromyelitis optica stand apart from MS by virtue of distinctive clinical and pathologic features, mainly, a failure to develop cerebral demyelinating lesions typical of MS even after years of illness; the absence of oligoclonal bands in the CSF; a tendency to CSF pleocytosis more so than in MS, and the necrotizing and cavitory nature of the spinal cord lesion, affecting white and gray matter alike with prominent thickening of vessels but with minimal inflammatory infiltrates. It is also quite unusual for MS to involve several contiguous longitudinal segments of the spinal cord, and this is a frequent finding in Devic disease (Fig. 36-3). It is not clear if events such as pregnancy that alter the course of MS have the same relationship to NMO (Bourre et al).

The spinal cord lesions in cases of neuromyelitis optica are often necrotizing, centrally located in the cord, and occupying several contiguous vertebral segments, leading eventually to cavitation. As would be expected, the clinical effects are more likely to be permanent than those of typical demyelination. A few affected patients have been children; in a number of instances, they have suffered only a single episode of neurologic illness. Despite the now clear distinction between Devic disease and MS, there remains a group of patients with the clinical syndrome of simultaneous or sequential optic neuritis and myelitis, who probably have the latter condition. The presence of the anti-aquaporin antibody (see below) and the MRI appearance of the cord lesion are able to differentiate most instances. In one memorable example, where hemiplegia and aphasia were followed within 2 weeks by a necrotizing myelitis from which there was no recovery, the patient later developed typical attacks of MS, including retrobulbar neuritis. Elsewhere in the brain and cord, the lesions were typically demyelinating.

Most compelling, the separation of Devic disease from MS is supported by evidence of a specific serum immunoglobulin (Ig) G antineural antibody directed against aquaporin-4, (*NMO antibody*) that binds complement. This has led to the conclusion that the Devic process is a humoral disease in contrast to the cellular mechanism that is proposed for MS (see Lucchinetti et al, 2002). Pittock and coworkers have explored the distribution of the antibody and found it to be located in astrocytic end feet adjacent to capillaries, pia, and Virchow-Robin spaces

Figure 36-3. MRI of the spinal cord in neuromyelitis optica. Sagittal T2 image showing a hyperintense, longitudinally extensive, confluent cervico-thoracic lesion.

all in the periventricular region and surrounding the central canal of the spinal cord. This is concordant with the distribution of the lesions and many of the clinical characteristics such as the extensive myelitis but also unusual features such as *vomiting* and *hiccoughs*, which reflects damage in the area postrema.

Lennon and colleagues reported that the antibody is a marker for neuromyelitis optica in the majority of cases, and that it is virtually absent in MS. In the material of Wingerchuk and colleagues, the presence of the antibody was 76 percent sensitive and 94 percent specific. By using the additional criteria of the presence of two of the following, the sensitivity and specificity were 99 and 90 percent: longitudinally extensive myelopathy, positive antibodies and an initial MRI that is not characteristic for MS.

Occasionally, neuromyelitis optica occurs in the context of a connective tissue disease such as Sjögren syndrome or lupus, and many of these patients have this same circulating anti-aquaporin antibody. Pittock and colleagues (2008) give the frequency of these antibodies as approximately one-third in patients with systemic autoimmune disease and clinical features of

Devic disease. It should also be noted that acute disseminated encephalomyelitis, discussed further on, may present as a neuromyelitis optica syndrome.

Differential Diagnosis There is in addition to the myelitis described earlier a progressive and sometimes saltatory *subacute necrotic myelopathy* without optic neuritis that shares all the features of Devic disease but not the optic neuropathy and, in our view, they probably represent the same entity (Katz and Ropper). The differential diagnosis is broader and includes vascular malformations of the cord or dura and infarction or neoplasm of the cord. Also, a rare isolated vasculitis of the cord may cause a necrotic myelopathy; it is associated with an active CSF pleocytosis (Ropper et al). The cord in the cases we have studied was swollen on MRI in the early stages, often with edema extending many segments above and below the area of primary disease, and later became atrophic, similar to what has been reported in Devic disease. Up to 50 cells are typical in the CSF and the protein is elevated but the spinal fluid may be normal during periods of clinical stability. Several, but not all, of these cases have had positive NMO IgG antibodies (see above), further supporting the notion that most of these aggressive, purely spinal cases are allied with Devic disease.

Treatment The treatment of neuromyelitis optica and of subacute necrotic myelopathy has been largely unsuccessful, most cases progressing despite aggressive therapy, including high-dose corticosteroids, plasma exchange, intravenous immunoglobulin, azathioprine, and cyclophosphamide. A study of several patients by Mandler and colleagues (1998) suggested that perhaps a combination of high-dose methylprednisolone and azathioprine led to clinical improvement; we cannot affirm this approach, but most other treatments have given poor results in our experience. Because a few individuals respond to them, it may be appropriate to try one or more of these therapies. A provocative approach that is being explored by Tradtrantip and colleagues is the use of blocking antibodies to the aquaporin antibody. A summary of treatment has been given by Collongues and de Seze.

ACUTE DISSEMINATED ENCEPHALOMYELITIS (ADEM); POSTINFECTIOUS, POSTEXANTHEM, POSTVACCINAL ENCEPHALOMYELITIS

Some of these terms, used originally to refer to the neurologic sequelae of infectious fevers, were introduced into medicine in the late nineteenth century but it was not until the late 1920s that Perdrau, Pette, Greenfield, and others identified a type of pathologic reaction common to a number of exanthems and vaccines. The current view of this entity is that it represents an acute inflammatory and demyelinating disease, distinguished pathologically by numerous foci of demyelination scattered throughout the brain and spinal cord. These lesions vary from 0.1 to several millimeters (when confluent) in diameter and invariably surround small and medium-sized veins. The

axons and nerve cells remain more or less intact. Equally distinctive is the perivenular inflammatory reaction of lymphocytes and mononuclear cells. The adjacent regions of white matter are invaded by monocytes and microglia corresponding to the zones of demyelination. Multifocal meningeal infiltration is another invariable feature but is rarely severe. With the exception of this last feature, ADEM is indistinguishable on histopathologic grounds from acute MS. It is the postinfectious setting, temporal course, and certain special features of each that set them apart. Indeed, even the monophasic nature of ADEM and its clear separation from MS on clinical grounds has been questioned by Schwarz and colleagues, who found that 14 of 40 adults later developed clear signs of MS, usually within a year.

An acute encephalitic, myelitic, or encephalomyelitic process of this type is observed in a number of clinical settings and is more common in children. In our experience, the disease in children follows a febrile illness by days or infrequently up to 2 weeks; this is less often the case in adults. In the originally described form, it occurred within a few days of onset of the exanthem of measles, rubella, smallpox, or chickenpox. Prior to widespread immunization against measles, an epidemic in a large city might have resulted in 100,000 cases of measles and clinically evident neurologic complications in 1 in 800 to 1 in 2,000 cases. The mortality among patients with such complications ranged from 10 to 20 percent; about an equal number were left with persistent neurologic damage. The neurologic complications of measles alone provide sufficient justification for immunization against the disease. The incidence of encephalomyelitis was less following chickenpox and rubella, and much less following mumps (the latter never seen in our pathologic material). In the past, a similar illness was observed to follow vaccination against rabies and smallpox and, reportedly, after administration of tetanus antitoxin (rare), as discussed further on. Now, however, most cases, clinically and pathologically indistinguishable from these two categories of ADEM, appear to develop after seemingly banal respiratory infections and after documented infections with Epstein-Barr, cytomegalovirus, and *Mycoplasma pneumoniae* and even HIV (Narisco et al); occasionally there is no clearly defined preceding illness or inoculation. Many, if not most, instances of acute transverse myelitis may represent the same postinfectious process. The neurologic illness may coincide with the later stages of the manifestations of the infection, in which case the term *parainfectious* may be appropriate.

Irrespective of the clinical setting in which it occurs, disseminated encephalomyelitis in its severe form is of grave import because of the significant rate of neurologic defects in patients who survive. In children, recovery from the acute stage is sometimes followed by a permanent disorder of behavior, mental retardation, or epilepsy; paradoxically, most adults make good recoveries. The *cerebellitis* and acute ataxia that follow chickenpox and other infections are more benign, normally clearing over several months, and may represent a different process, as discussed further on.

Pathogenesis

The pathogenesis of disseminated encephalomyelitis is still unclear despite its obvious association with viral infections. In the postexanthem cases, a definite interval usually separates the onset of disseminated encephalomyelitis from the onset of the rash; also, the pathologic changes are quite different from those of viral infections and virus is rarely if ever recovered from the CSF or brains of patients with disseminated encephalomyelitis. For these reasons, it is believed that the disorder represents an immune-mediated complication of infection rather than a direct infection of the CNS, a process comparable to the Guillain-Barré syndrome. However, as discussed in Chap. 33, new molecular techniques have been able to detect fragments of DNA from varicella zoster virus, *Mycoplasma*, and other organisms in the CSF, so that the question of pathogenesis cannot be answered with finality. Nevertheless, Waksman and Adams found the pathologic changes in these two circumstances—postinfectious demyelination and direct viral infection of the CNS—to be quite different.

A laboratory model of the disease, EAE, has been produced by inoculating animals with a combination of sterile brain tissue and adjuvants. The experimental disease appears most commonly between the eighth and fifteenth days after sensitization (see below) and is characterized by the same perivenular demyelinating and inflammatory lesions that one observes in the human disease. Presumably the lesions are the result of a T-cell-mediated immune reaction to components of myelin or oligodendrocytes. Recently, evidence of antibody binding, complement activation, and eosinophilic infiltration has led to the notion that ADEM is a humoral disease, in contrast to the cellular mechanism that has been proposed for MS, but further confirmation of this notion is required (see Lucchinetti et al, 2000 and 2002).

The notion that EAE and disseminated encephalomyelitis have a similar pathogenesis has received support from the observations of R.T. Johnson and colleagues. They studied 19 patients with postinfectious encephalomyelitis complicating natural measles virus infections. Early myelin destruction was demonstrated by the presence of MBP in the CSF, and lymphocyte proliferative responses to MBP were found in 8 of 17 patients tested. Similar responses were observed in patients with encephalomyelitis after rabies vaccine and after varicella and rubella virus infections, suggesting a common immune-mediated pathogenesis. Moreover, the patients with postmeasles encephalomyelitis showed a lack of intrathecal synthesis of antibody against measles virus, indicating that the neurologic disease was not dependent on viral replication within the CNS.

Clinical Features

The encephalitic form is expressed more fully in children than in adults. As an acute infectious illness is resolving or after a latency of several days or longer, there is the abrupt onset, over hours or a day or two, of confusion,

somnolence, and sometimes convulsions with headache, fever, and varying degrees of neck stiffness. Ataxia is common, but myoclonic movements and choreoathetosis are observed less frequently. In more severe cases, stupor, coma, and at times decerebrate rigidity may occur in rapid succession. In many cases, the disease is less severe and the patient suffers a transient encephalitic illness with headaches, confusion, and slight signs of meningeal irritation.

The latency between infection and the first neurologic symptoms that it is acceptable for this diagnosis is a matter of debate, but there are convincing cases (post-exanthematous) in which the two phases of illness are separated by 3 or 4 weeks; several days is more typical, as noted below. Curiously, in the encephalitic form, new signs may continue to appear for up to 2 or 3 weeks from the onset. This is emphasized in the series of affected children collected by Hynson and colleagues. The imaging changes may also display delayed or continued evolution. These authors note that ataxia was the most common initial feature in their cases, which is not entirely in accordance with our experience.

In the myelitic form (*postinfectious myelitis, acute transverse myelitis*), there is partial or complete paraplegia or quadriplegia, diminution or loss of tendon reflexes, sensory impairment, and varying degrees of paralysis of bladder and bowel. A syndrome that simulates anterior spinal artery occlusion (spastic paraplegia and loss of pain sensation below a level on the trunk but tending to spare large-fiber sensibility) is not uncommon in our experience. Also, we have cared for a few patients with a limited sacral form of postinfectious myelitis. Midline back pain may be a prominent symptom at the onset.

In both the encephalitic and myelitic types, there may be slight fever, particularly in the more aggressive cases and in younger individuals, where we have seen temperatures reaching 39.4°C (103°F), but the peripheral white blood cell count is normal if the initiating infection has resolved. A few of our patients have had elevated sedimentation rates, but it is not possible to know whether this reflects the precipitating infection. Nonetheless, separating these two entities may be difficult, especially in children who have a greater tendency to develop fever and convulsions with ADEM. Either process may be associated with aseptic meningitis.

The CSF shows a slight increase in lymphocytes and protein content, but these are highly variable, with a few of our patients having only an increase in protein and no cells and others having up to several hundred cells. The MRI shows several bilateral confluent white matter lesions in both cerebral hemispheres early in the course of ADEM (Fig. 36-4); when these are large and numerous, the diagnosis is more certain. The lesions all appear to be of similar age, but we cannot account for several cases we have seen in which serial MRIs show new lesions accumulating over 2 or 3 weeks, as already noted. Moreover, as pointed out by Honkaniemi and colleagues, there may be a delay of several days between the clinical manifestations and the first appearance of changes in the MRI, a situation to which we can attest. Whether a single lesion on MRI can be considered compatible with ADEM is unclear.

In the case of postexanthem encephalomyelitis, the syndrome generally begins 2 to 4 days after the appearance of the rash. Usually the rash is fading and other symptoms are improving when the patient, typically a

Figure 36-4. Acute (postinfectious) disseminated encephalomyelitis (ADEM). Axial T2-FLAIR images showing left inferior frontal (*left*) and right anterior temporal (*right*) edematous lesions.

child, suddenly develops a recrudescence of fever, convulsions, stupor, and sometimes coma. Less commonly, the patient may develop hemiplegia or a virtually pure cerebellar syndrome, as noted below (particularly after chickenpox), and occasionally a transverse myelitis, sphincteric disturbance, or other signs of spinal cord involvement. Choreoathetotic movements are seen infrequently. Likewise, optic neuritis is uncommon, but it does occur.

A variant of postinfectious encephalomyelitis that involves solely or predominantly the cerebellum deserves special comment. Typically, a mild ataxia with variable corticospinal or other signs appears within days of one of the childhood exanthems as well as after Epstein-Barr virus, *Mycoplasma*, *Legionella*, and cytomegalovirus infections, and after a number of vaccinations and nondescript respiratory infections. It is described in detail in Chap. 33 because it has a close relationship to certain viruses, particularly varicella, suggesting that some, if not most, cases are caused by an infectious meningoencephalitis. Others—for example, following mycoplasmal infection—occur after a long latency and show pathologic changes that are consistent with a postinfectious demyelination. Thus it is possible that there may be two types of acute cerebellitis, one para- or postinfectious and the other caused by a direct infection of the brain and meninges. The benign nature of the illness has precluded adequate pathologic examination; hence some of these statements are speculative.

Not all the neurologic complications of measles and other exanthems and acute viral infections are examples of postinfectious encephalomyelitis. As already noted, the illness is at times difficult to distinguish from viral meningoencephalitis. Infectious mononucleosis, herpes simplex, mycoplasmal infection, and other forms of encephalitis may all mimic the postinfectious variety. The Reye syndrome is usually not difficult to separate from postinfectious encephalomyelitis, even when it follows chickenpox or viral influenza, because of the normal CSF and high serum concentrations of liver enzymes and ammonia (see Chap. 33). In a child, the first attack of febrile seizures in the course of an exanthematous illness may raise the suspicion of encephalitis or postinfectious encephalomyelitis.

The MRI finding of large or multifocal areas of white matter damage can also be produced by intravascular lymphoma and progressive multifocal leukoencephalopathy (Chap. 31) and a rare leukoencephalopathy that follows inhaling heroin vapor (Chap. 43).

Postvaccinal ADEM Since late in the nineteenth century, it has been known that a severe form of encephalomyelitis may complicate the injection of rabies vaccine (“neuroparalytic accident”). Until quite recently, the rabies vaccine in common use consisted of killed virus that had been grown in rabbit brain tissue. Encephalomyelitis occurred in about 1 in 750 patients inoculated with this vaccine, and approximately 25 percent of cases with this complication proved fatal. Alternative vaccines, made from embryonated duck eggs (and later from human diploid cells) infected with fixed viruses, contain very little

or no nerve tissue and are almost free of neurologic complications. In developing countries, where less-expensive brain-based vaccines are still in use, neuroparalytic accidents continue to occur. The observations of Hemachudha and colleagues indicate that the altered immune mechanism that is operative in the neuroparalytic accident is the same as that in postmeasles encephalomyelitis and experimental allergic encephalomyelitis.

There are numerous recorded instances in which the old rabies vaccine (with neural tissue) induced an attack of what subsequently appeared to be MS. Shiraki and Otani reported such examples from Japan. The evolution of symptoms was subacute, over a period of 2 to 4 weeks, and the demyelinating lesions were macroscopic—up to 1 to 2.0 cm in diameter—but composed of confluent perivenous lesions. The disease could be reproduced in dogs—persuasive evidence that one form of acute MS is a variant of ADEM. Encephalomyelitis following vaccination against smallpox has been known since 1860, having occurred about once in 4,000 vaccinations. That disease is now of historical interest only, insofar as smallpox has disappeared as a human illness.

The association of the neurologic disorder with vaccination usually leaves the diagnosis in little doubt, and the characteristic combination of encephalitic and myelitic features will help to distinguish the condition from meningitis, viral encephalitis, and poliomyelitis. Rarely, an atypical case may mimic any one of these disorders. On occasion, the disease may suggest involvement of nerve roots and peripheral nerves and resemble acute inflammatory polyneuritis (Guillain-Barré syndrome). In fact, the rabies vaccine produced in South America from suckling mouse brain causes this type of peripheral nerve disease more often than encephalomyelitis.

Mundane inoculations such as those for influenza or hepatitis must have a very small rate of ADEM, judging from surveillance studies; Ascherio and colleagues were unable to find any increase in cases among two large studies of nurses who received hepatitis B vaccine. The absence of a clear connection of MS to vaccination has already been mentioned.

The mortality rate of postvaccinal encephalomyelitis is high, between 30 and 50 percent. If recovery occurs, it may be surprisingly complete. However, a significant proportion of patients show residual neurologic signs, mainly in the form of seizures, intellectual impairment, or behavioral abnormalities.

Treatment

Corticosteroids given soon after the appearance of neurologic signs may modify the severity of experimental allergic encephalomyelitis; this provides the logic for their use in the human counterpart of this disease but controlled trials have not been carried out. We usually administer methylprednisolone in high doses intravenously for 3 to 5 days. Plasma exchange and intravenous immune globulin have also been successful in some fulminant cases (Kanter et al; Stricker et al) but only in a few we have observed.

Acute Necrotizing Hemorrhagic Encephalomyelitis (Acute Hemorrhagic Leukoencephalitis of Weston Hurst)

This, the most fulminant form of demyelinating disease, almost certainly the severe end of the spectrum of ADEM, affects mainly young adults and children. It is usually preceded by a respiratory infection of variable duration (1 to 14 days), sometimes caused by *M. pneumoniae* but more often following a mundane infection or of indeterminate cause. The neurologic symptoms appear abruptly, beginning with headache, fever, stiff neck, and confusion. These are followed in short order by signs of disease of one or both cerebral hemispheres and brainstem—focal seizures, hemiplegia or quadriplegia, pseudobulbar paralysis, and progressively deepening coma. Peripheral leukocytosis is usually present, sometimes reaching 30,000 cells/mm³, and the sedimentation rate is elevated. The CSF is often under increased pressure; cells vary in number from a few lymphocytes to a polymorphonuclear pleocytosis of up to 3,000 cells/mm³; red cells may be present in variable numbers; protein content is increased, but glucose values are normal. Diagnosis is greatly facilitated by CT scanning and MRI, which reveal bilateral but asymmetrical large, confluent, edematous lesions in the cerebral white matter with a myriad of punctate hemorrhages in gray and white matter (Fig. 36-5). The

Figure 36-5. Acute necrotizing hemorrhagic leukoencephalitis. Axial T2-FLAIR MRI shows extensive abnormal hyperintensity throughout the hemispheric white matter as well as within the deep gray nuclei. Additional signal abnormality in the cortical sulci is due to subarachnoid hemorrhage.

size of the lesions, their hemorrhagic character, and the extent of the surrounding edema distinguish them from the typical postinfectious ADEM. In many other ways they are similar, except for their severity. Many cases terminate fatally in 2 to 4 days, but in others, survival is longer. Patients with a similar clinical picture who are thought to have the same disease on the basis of brain biopsy examinations have recovered with almost no residual symptoms. In one of the fatal cases reported by Adams and colleagues, the illness evolved more slowly—over a period of 2 to 3 weeks—while another patient died with temporal lobe herniation within 12 h. A single recurrence of the disease after an interval of 2 years was observed in one of our patients.

Brain abscess, subdural empyema, focal embolic encephalomalacia, and acute encephalitis, especially as a result of type 1 herpes simplex virus, are the important considerations in the differential diagnosis.

The *pathologic findings* are distinctive. On sectioning of the brain, the white matter of one or both hemispheres is destroyed almost to the point of liquefaction. The involved tissue is pink or yellow-gray and flecked with multiple petechial hemorrhages. Similar changes are often found in the brainstem and cerebellar peduncles and probably in the spinal cord (one form of acute necrotizing myelitis and Devic disease). On histologic examination, one finds widespread necrosis of small blood vessels and brain tissue around the vessels, with intense cellular infiltration, multiple small hemorrhages, and an inflammatory reaction in the meninges of variable intensity. The pathologic picture resembles that of disseminated encephalomyelitis in its perivascular distribution, with the added features of a more widespread necrosis and a tendency of lesions to form large foci in the cerebral hemispheres. The vascular lesions result in a characteristic exudation of fibrin into the vessel wall and surrounding tissue. It is possible that certain patients who are showing an explosive myelitic illness are suffering from a necrotizing lesion of similar type, but pathologic evidence in support of this view has been difficult to obtain. Fibrin exudation in an acute fatal hemorrhagic myelitis was present in a case examined by Adams and colleagues. We also have experience with a case of this nature that evolved in steps over several months, resulting in death, with a cellular reaction in the spinal fluid on each of several lumbar punctures. There was partial steroid responsiveness.

The etiology of this condition remains obscure, but its resemblance to other demyelinating diseases should be emphasized. The similarities of the histologic changes to those of disseminated encephalomyelitis, noted above, suggest that the two diseases are related forms of the same fundamental process. In fact, cases combining both types of pathologic changes have been described (Fisher et al). It is noteworthy that, among the small number of patients who have recovered from what appeared to be a typical necrotizing hemorrhagic encephalitis, a few have gone on to develop typical MS.

Treatment of Hurst Disease

High-dose intravenous corticosteroids should be used in the treatment of acute necrotizing hemorrhagic encephalopathy; in several personally observed patients, we had the impression that corticosteroids produced a favorable result. The use of plasma exchange and intravenous immunoglobulin, as for acute disseminated encephalomyelitis, is being explored and has had success in single reported cases when instituted early.

Graft-Versus-Host Disease

This form of brain inflammation, pertinent to the special circumstance of bone marrow transplantation, is included here for lack of a better category with which to align it. Months or years after transplantation, subacute hemiparesis, seizures, behavioral changes, or ataxia arise and may be attributed to PML, a viral infection of the white matter (Chap. 33), or another viral process that is known to occur with circumstances of immunosuppression. The MRI shows white matter lesions that conform to an MS-like periventricular orientation or a more confluent leukoencephalopathy. A recent patient under our care demonstrated lesions in the splenium of the corpus callosum that extended into the adjacent centrum semiovale (Fig. 36-6). Several reports emphasize a mild vasculitis in the territory of the white matter lesions (Padovan et al). Almost all affected patients have concurrently displayed a tender erythematous, macular rash that is typical of acute graft-versus-host disease. There are also rare, but

Figure 36-6. Abnormal T2 hyperintensity in the splenium of the corpus callosum in a patient with graft-versus-host disease 2 years following allogeneic bone marrow transplantation.

well-characterized, neuromuscular complications of graft-versus-host disease.

Inherited Metabolic Diseases of the Nervous System

Advances in biochemistry and molecular genetics have led to the discovery of such a large number of metabolic diseases of the nervous system that it taxes the mind just to remember their names. As the causes and mechanisms of the diseases included in this chapter are increasingly being expressed in terms of molecular genetics, it seems appropriate, by way of introduction, to consider briefly some basic facts pertaining to the genetics of neurologic disease. The reader is referred to the continuously updated database, *Online Mendelian Inheritance in Man* (<http://www.ncbi.nlm.nih.gov/omim>), to the four-volume text by Scriver and colleagues, which still serves as an excellent source, and to recent general reviews by Feero and colleagues, and on mitochondrial genetics, by Koopman and coauthors.

The brain is more frequently affected by a genetic abnormality than any other organ, probably because of the large number of genes implicated in its development (an estimated one-third of the human genome). Approximately one-third of all inherited diseases are neurologic in some respect; if one adds the inherited diseases affecting the musculature, skeleton, eye, and ear, the number rises to 80 to 90 percent. Approximately 7 percent of diseases in hospitalized children are estimated to be attributable to single-gene defects and 0.4 to 2.5 percent to a chromosomal abnormality. Another 22 to 31 percent have a disease putatively due to polymorphisms, most of which are yet to be specified. Mitochondrial inheritance of mutations is much less frequent but gives rise to several distinctive diseases.

Although only a minority of inherited diseases is identified as an enzymopathy, this group represents the most direct translation of mendelian disorders to primary defects in proteins. These constitute only one-third of the known recessive (autosomal and X-linked) disorders. Most enzymopathies become manifest in infancy and childhood; only a few appear as late as adolescence or adult life. Many damage the nervous system so severely that survival to adult years and reproduction are impossible, and some cause death in utero. As a group, these diseases—along with congenital anomalies (see Chap. 38), birth injuries, epilepsy, disharmonies of development, and learning disabilities (see Chap. 28)—make up the bulk of the clinical problems with which the pediatric neurologist must contend.

PATTERNS OF GENETIC ABERRATIONS AND INHERITANCE

The diseases grouped in this chapter, and many in the next, represent four particular categories of genetic abnormality: (1) monogenic disorders determined by a single mutation that follow a mendelian pattern of inheritance. These mutations can be of a single base pair (point mutation), an insertion or deletion of nucleotides, or structural rearrangements of a sequence of DNA, such as translocations or inversions; because the most important of these involve the coding (exonic) portion of DNA, they are likely to disrupt the structure and function of enzymes or cellular structural proteins. *Most of the diseases discussed in this chapter are of this variety;* (2) a type of monogenic mutation characterized by duplications or deletions of genes or parts of chromosomes, termed *copy number variations*; these account for some proportion the heritability of common diseases; (3) single nucleotide polymorphisms, which are variations from the most common, “wild type,” sequence of a gene and are by convention present with a frequency of greater than 1 percent in the population; these play a role in the genesis of disease but do not obligatorily result in a somatic aberration or alternatively, they interact with exogenous environmental factors; and (4) mitochondrial gene mutations that are inherited in a nonmendelian, mainly maternally inherited pattern.

Autosomal and Sex-Linked Inheritance

Traditionally, the recognition of the broad categories of genetically determined diseases has rested on their pattern of occurrence in families, segregated according to mendelian inheritance into autosomal dominant, autosomal recessive, and sex-linked types. As mentioned, mutations of nuclear DNA account for the heritable autosomal and sex-linked diseases described in this chapter, and they are remarkably diverse in nature. Some are lethal and are therefore not transmitted to successive generations; others are less harmful and may conform to one of the classic mendelian patterns. The mutation may be large and result in duplication of a major part of a chromosome or even of the entire gene (diploidy or triploidy) or a deletion (haploidy). Other mutations are quite small, involving only a single

base pair (“point mutation”). Between these two extremes are deletions or duplications that include a portion of a gene, an entire gene, or contiguous genes, as mentioned above.

The factors conducive to mutations are poorly understood. The parent’s increasing age is important in relation to some mutations; the size, structure, and placement of the gene on the chromosome are important in others. A mutation of the DNA of a germ cell leaves unchanged the somatic phenotype of the individual in whom it occurs, but it may have a devastating effect on the descendants. Conversely, a DNA mutation of a somatic cell affecting only part of the cell population may change the individual harboring it but is not passed on to the descendants. Such an individual, with both normal cells and cells containing the mutant gene, is referred to as a *mosaic*. Mutations of somatic cells appear to be most pertinent to cancer and aging.

In the monogenic inheritance of all three mendelian patterns, the mutation usually causes an abnormality of a single protein. It may involve an enzyme, peptide hormone, immunoglobulin, collagen, membrane channel, or coagulation factor. Such abnormalities of single genes have been isolated in several hundred diseases, but less is known of their protein products. About one-quarter of these diseases are apparent soon after birth and more than 90 percent by puberty. More than half of them affect more than one organ. Of the 10 in every 1,000 live births with monogenic diseases, 7 are dominant, 2.5 are recessive, and the remainder are sex-linked.

Autosomal dominant mutations usually cause manifest disease in heterozygotes, but variations in the size of the gene abnormality can produce any one of several phenotypes. This poses a challenge to the current clinical and pathologic classifications of disease. Moreover, an identical clinical syndrome may be traced to a gene on two different chromosomes. Even more surprising, an estimated 28 percent of all gene loci have polymorphic rather than monomorphic effects—that is, the same mutation has several different phenotypic expressions. Another problem is that of differentiating dominant from recessive inheritance. In small families, in which only one descendant is afflicted and the parent is seemingly normal, one may mistakenly conclude that the inheritance is recessive. Other characteristics of mutational diseases are penetrance, a measure of the proportion of individuals with a given genotype who will show the phenotype, and expressivity, referring to the severity of disease in an affected individual. Variable degrees of penetrance and expressivity are characteristic features of dominant patterns of inheritance but not of recessive ones. There is also a general tendency for dominantly inherited disease to first appear long after birth.

Autosomal recessive forms of inherited metabolic diseases, in contrast to dominant ones, occur only in the homozygous state (both alleles are abnormal). They are usually characterized by an onset soon after birth. The basic abnormality in the recessively inherited diseases discussed in this chapter is more often an enzyme deficiency than an abnormality of some other protein.

In disorders of X-linked genes, in which the mutant gene affects mainly one sex, the female will suffer the same fate as the male if one X chromosome has been inactivated, as happens in most cells during embryonic development (the Lyon phenomenon). However, even if the abnormal

X chromosome is not widely expressed, the female carrier may still exhibit minor abnormalities. In the latter case, sex-linked inheritance becomes difficult to distinguish from dominant inheritance. Also, sex linkage is deceptive when a disease is lethal to one sex. In contrast to autosomal recessive mutations, the abnormality has more often been one of a basic protein than an enzyme deficiency.

Multifactorial genetic diseases may also be familial. They may present as constitutional disorders with gene abnormalities located on several chromosomes (polygenic, or “complex genetics”) or they may arise from single nucleotide polymorphisms or copy number variations. Here, the relative contributions of genetic and environmental influences are highly variable. The occurrence of many disorders that display high degrees of familial incidence, such as schizophrenia and Gilles de la Tourette syndrome, but do not strictly conform to classic genetic principles has been attributed to this type of complex genetics.

The Genetics of Mitochondrial Disease

An entirely different type of genetic transmission relating to the DNA that lies in the mitochondria has been elucidated. Mitochondria contain their own extrachromosomal DNA, distinct from nuclear DNA. Mitochondrial DNA (“the other human genome”) is a double-stranded, circular molecule that encodes the protein subunits required mainly for translation of the proteins located on the mitochondrial inner membrane. Of the 37 mitochondrial genes, small in number by comparison with nuclear DNA, 13 partake in the cellular processes of oxidative phosphorylation and the production of adenosine triphosphate (ATP). A few genes in the cell’s nucleus also code for a considerable number of oxidative enzymes of the mitochondria, but their inheritance follows a mendelian pattern; consequently, a mitochondrial disorder may fail to display maternal inheritance that is characteristic of mitochondrial mutations as described below.

Each mitochondrion contains up to 10 ringed DNA molecules, and each cell, of course, contains numerous mitochondria. In the cell, mitochondria with mutant genes may exist next to normal mitochondria (*heteroplasmy*), a state that permits an otherwise lethal mutation to persist (Johns). The presence of either completely normal or completely mutant mitochondrial DNA is termed *homoplasmy*. The essential feature of mitochondrial genes and the mutations to which they are subject is that they are inherited almost exclusively through *maternal* lineage. This is explained by the transmission of virtually all mitochondria from the ovum at the time of conception. Moreover, mitochondrial DNA does not recombine, thus permitting the accumulation of mutations through maternal lines. Also, the replication and distribution of mitochondrial DNA during cell division do not follow the nuclear mitotic cycle. Instead, there are contributions during cell division from the genes of various mitochondria to the progeny of dividing cells. The combination of a heteroplasmic state and the capricious dispersion of mitochondria to daughter cells (replicative segregation) explains the variable expression of mitochondrial mutations in different tissues and in different regions of the nervous system.

The genetic error in each of the mitochondrial diseases is most often a single-point mutation that leads to the alteration of a single amino acid, but there are also single or multiple deletions or duplications of mitochondrial genes that do not conform to maternal inheritance because they are caused by nuclear DNA defects. It is important to note that approximately 85 percent of the protein components of the respiratory chain are coded in nuclear DNA and are then imported into the mitochondrion; as mentioned above, this allows for a mitochondrial disease with a mendelian pattern of inheritance rather than a maternal one. Another of the general rules of mitochondrial inheritance is exemplified by an infantile myopathy (cytochrome oxidase deficiency) that is usually fatal but may also occur in a less severe form and have a later onset. In cases of earlier onset, there is less of the normal mitochondrial DNA than in the cases of later onset.

Because the unique function of mitochondria is the production of ATP by oxidative phosphorylation, it is not surprising that many of the genes contained in mitochondria code for proteins in the respiratory chain. However, there is not always concordance between the error in the mitochondrial genome and the enzymatic defect that leads to disease. Of the five complexes that make up the respiratory chain, cytochrome-*c* oxidase (complex IV) is the one most often disordered, and its deficient function gives rise to lactic acidosis, a feature common to many of the mitochondrial disorders (see further on). In keeping with the mutable nature of this class of disorders, it is thought that some cases of complex IV defect are autosomally transmitted. Complex I defects, which originate in mitochondrial mutations, are seen, for example, in Leber optic atrophy. A more complete account of the disorders of the mitochondrial respiratory chain can be found in the review by Leonard and Schapira.

As one would expect, aberrant function of the ubiquitous energy-producing mitochondria results in disease of many organs besides skeletal muscle (e.g., diabetes and other endocrinopathies and minor dysmorphic features are seen in several mitochondrial disorders). Nevertheless, most of the mitochondrial disorders affect the nervous system prominently and at times exclusively. Two characteristics traceable to mitochondrial abnormalities are particularly common; one is a special change in muscle fibers termed *ragged red fibers*, a clumping of mitochondria in muscle fibers described in more detail further on, and the other is a systemic lactic acidosis. Other than these, each of the mitochondrial diseases has distinctive features and in their main elements they do not resemble each other. The main syndromes are MELAS and MERRF (acronyms defined further on), Leber hereditary optic atrophy, progressive external ophthalmoplegia, and the Leigh syndrome. These diseases are described in detail in the last part of this chapter.

Diagnostic Features of Hereditary Metabolic Diseases

In clinical practice, one should consider the possibility of a hereditary metabolic disease when presented with the following lines of evidence:

1. A neurologic disorder of similar type in a sibling or close relative

2. Recurrent nonconvulsive episodes of impaired consciousness or intractable seizures in infants or young children or infantile spasms and progressive myoclonic seizures in the absence of neonatal hypoxia-ischemia
3. Some combination of unexplained symmetrical or generalized spastic weakness, cerebellar ataxia, extrapyramidal disorder, deafness, or blindness
4. Progression of a neurologic disease measured in months, or a few years
5. Developmental delay in an individual if there are no congenital somatic abnormalities or developmental delay in a sibling or close relative

In the face of such clinical information, one should obtain appropriate biochemical analyses of blood, urine, and cerebrospinal fluid (CSF); MRI of the brain; and, in certain instances, genetic studies.

In addition to the investigation of symptomatic individuals, the array of available genetic and biochemical tests has made practical the mass screening of newborns for inborn metabolic defects. Innovative tests have also led to the discovery of a number of previously unknown diseases and have clarified the basic biochemistry of old ones. As a consequence, the neurologist's role is changing. No longer must we wait until a disease of the nervous system has declared itself by conventional symptoms and signs, by which time the underlying lesion may have become irreversible. Now it is possible to find patients who, although asymptomatic, are at risk and to introduce dietary and other measures that may prevent injury to the nervous system. This is especially important to families who have already had an affected infant. To assume this new responsibility intelligently requires knowledge of genetics, biochemical screening methods, and public health measures.

The many clinical syndromes by which these inborn errors of metabolism declare themselves vary in accordance with the nature of the biochemical defect and the stage of maturation of the nervous system at which these metabolic alterations become apparent. In phenylketonuria, for example, there is a specific effect on the cerebral white matter, mainly during the period of active myelination; once the stages of myelinogenesis are complete as detailed in Chap. 28, the biochemical abnormality becomes relatively harmless. Even more important from the neurologist's point of view is the level of function that has been achieved by the developing nervous system when the disease strikes. A derangement of function in a neonate or infant, in whom much of the cerebrum is not fully developed, is much less obvious than one in an older child. Moreover, as the disease evolves, the clinical manifestations are always influenced by the ongoing maturation of the untouched elements in the nervous system. These interactions may give the impression of regression of attained neurologic function, lack of progress of development (developmental delay), or even improvement in function that is attributable to continuing maturation of the normal parts of the nervous system. The separation of metabolic-genetic from degenerative diseases (accorded a separate chapter) may disquiet the reader, for there are many overlaps between the two groups. The current division is tenable only until

such time as all the degenerative diseases will have been shown to have a comprehensible pathogenesis.

Because of the overriding importance of the age factor and the tendency of certain pathologic processes to appear in particular epochs of life, it has seemed to the authors logical to group the inherited metabolic diseases not according to their major syndromes of expression, as we have done in other parts of the book, but in relation to the periods of life at which they are most likely to be encountered: the neonatal period, infancy (1 to 12 months), early childhood (1 to 4 years), late childhood, adolescence, and adult life. Only in the last two age periods do we return to the more clinically useful syndromic ordering of diseases.

In adopting this chronological subdivision, we realize that *certain hereditary metabolic defects that most typically manifest themselves at a particular period in life are not necessarily confined to that epoch and may appear, sometimes in variant form, at a later age.* Such variations are noted at appropriate points in the discussion.

METABOLIC DISEASES OF THE NEONATAL PERIOD

A small number of progressive metabolic diseases become evident in the first few days of life. The importance of these diseases relates not to their frequency (they constitute only a small fraction of diseases that compromise nervous system function in the neonate) but to the fact that they must be recognized promptly if the infant is to be prevented from dying or from suffering a lifelong severe developmental delay. This inherent threat introduces an element of urgency into neonatal neurology. Recognition of these diseases is also important for purposes of family and prenatal testing.

Two approaches to the neonatal metabolic disorders are possible—one, to screen every newborn, using a battery of biochemical tests of blood and urine, and the other, to undertake in the days following birth a detailed neurologic assessment that will detect the earliest signs of these diseases. Unfortunately, not all the biochemical tests have been simplified to the point where they can be adapted to a mass screening program, and many of the commonly used clinical tests at this age have yet to be validated as markers of disease. Moreover, many of the biochemical tests are costly, and practical issues, such as cost-effectiveness, insinuate themselves, to the distress of the pediatrician. The introduction of tandem mass spectrometry for the evaluation of blood and urine has allayed some of the latter concerns.

Neurologic Assessment of Neonates With Metabolic Disease

As pointed out in Chap. 28, the neonate's nervous system functions essentially at a brainstem–spinal level. The pallidum and visuomotor cortices are only beginning to be myelinated and their contribution to the totality of neonatal behavior cannot be very great. Neurologic examination, to be informative, must therefore be directed to evaluating diencephalic–midbrain, cerebellar–lower

brainstem, and spinal functions. The integrity of these functions in the neonate is most reliably assessed by noting the following, as was also described in Chap. 28:

1. Control of respiration and body temperature; regulation of thirst, fluid balance, and appetite–hypothalamus–brainstem mechanisms
2. Certain elemental automatisms, such as sucking, rooting, swallowing, grasping—brainstem–cerebellar mechanisms
3. Movements and postures of the neck, trunk, and limbs, such as reactions of support, extension of the neck and trunk, flexion movements, and steppage—lower brainstem (reticulospinal), cerebellar, and spinal mechanisms
4. Muscle tone of limbs and trunk—spinal neuronal and neuromuscular function
5. Reflex eye movements—tegmental midbrain and pontine mechanisms (a modified optokinetic nystagmus can be recognized by the third day of life)
6. The state of alertness and attention (stimulus responsiveness and capacity of the examiner to make contact) as well as sleep–waking and electroencephalographic patterns—mesencephalic–diencephalic mechanisms
7. Certain reflexive reactions such as the startle (Moro) response and placing reactions of the foot and hand—upper brainstem–spinal mechanisms with possible cortical facilitation

Derangements of these functions are manifest as impairments of alertness and arousal, hypotonia, disturbances of ocular movement (oscillations of the eyes, nystagmus, loss of tonic conjugate deviation of the eyes in response to vestibular stimulation, i.e., to rotation of the upright infant), failure to feed, tremors, clonic jerkings, tonic spasms, opisthotonos, diminution or absence of limb movements, irregular or chaotic breathing, hypothermia or poikilothermia, bradycardia, circulatory difficulties, poor color, and seizures.

In most instances of neonatal metabolic disease, the pregnancy and delivery proceed without mishap. Birth at full term is usual. The infant is of a size and weight expected for the duration of pregnancy, and there are no signs of a developmental abnormality (in a few instances the infant is somewhat small, and in G_{M1} gangliosidosis there may be a pseudo-Hurler appearance; see further on). Furthermore, function continues to be normal in the first few days of life. The first hint of trouble may be the occurrence of feeding difficulties: food intolerance, diarrhea, and vomiting. The infant becomes fretful and fails to gain weight and thrive—all of which should suggest a disorder of amino acid, ammonia, or organic acid metabolism.

The first definite indication of disordered nervous system function is likely to be the occurrence of seizures. These usually take the form of unpatterned clonic or tonic contractions of one side of the body or independent bilateral contractions, sudden arrest of respiration, turning of the head and eyes to one side, or twitching of the hands and face. Some of the ill-formed seizures may become generalized. They occur singly or in clusters and in the latter instance, are associated with unresponsiveness, immobility, and arrest of respiration.

The other clinical abnormalities in the motor realm, according to authorities such as Precht and Beintema, can be subdivided roughly into three groups, each of which constitutes a kind of syndrome: (1) hyperkinetic-hypertonic, (2) apathetic-hypotonic, or (3) unilateral or hemisyndromic. Precht and Beintema, from a study of more than 1,500 newborns, found that if clinical examination consistently discloses any one of the 3 syndromes, the chances are 2 in 3 that by the seventh year the child will be manifestly abnormal neurologically. They found also that certain neurologic signs—such as facial palsy, lack of grasping, excessive floppiness, and impairment of sucking—while sometimes indicative of serious disease of the nervous system, are less dependable; also, being rare, these signs will identify but few brain-damaged infants. It is not the single neurologic sign but groups of them that are held to be the most reliable indices of brain abnormality, and the 3 syndromes mentioned above are the important ones, even though their anatomic and physiologic bases are not completely known.

In cases of hypocalcemia-hypomagnesemia, the hyperkinetic-hypertonic syndrome prevails. Although most of the other diseases tend to induce the apathetic-hypotonic state, the hyperactive-hypertonic syndrome may represent the initial phase of the illness and always carries a less ominous prognosis than the apathetic-hypotonic state, which represents a more severe condition regardless of cause. The third putative group of unilateral abnormalities in the metabolic diseases is less common and more difficult to recognize. These syndromes frequently overlap and seizures may occur in all of them. The anatomic correlate for some of these neurologic abnormalities can be observed by MRI. Clearly what is needed is a more definitive neonatal neurologic semiology utilizing numerous stimulus-response tests, including those described by Andre Thomas and Dargassis.

Neonatal Metabolic Diseases and Their Estimated Frequency

In New England, screening of all newborns for metabolic disorders has been practiced for almost 50 years. Data on the diseases with neurologic implications were in the past collated by our colleague, H.L. Levy of Boston

Table 37-1

METABOLIC DISORDERS DETECTED BY NEONATAL SCREENING IN NEW ENGLAND

DISORDERS	CASES PER 100,000
Biotinidase Deficiency	5.4
Galactosemia	1.5
Glutaric aciduria-I	0.4
Propionic aciduria	0.3
Methylmalonic aciduria-mutase	0.5
Cobalamin deficiency	1.3
Maple syrup urine disease	0.4
Isovaleric acidemia	0.8
Phenylketonuria	6.6
Homocystinuria	0.4
Tyrosinemia-type I	0.3
Ornithine transcarbamylase	0.8
Carnitine palmitoyl transferase	0.1
Citrulinemia type I	0.3
Argininosuccinic aciduria	1.0
Glutaric Aciduria-Type II	0.6
Very long chain acyl CoA dehydrogenase	3.3
Carnitine palmitoyl transferase type 2	0.5
Long chain hydroxyacyl CoA dehydrogenase	0.8

Source: Courtesy of Dr. Inderneel Sahai, New England Newborn Screening Program, MA. Screening done by tandem mass spectrometry of dried blood spot. Abnormalities with no neurological significance or with extremely low rates are omitted.

Children’s Hospital, and are summarized in Table 37-1. Some of these disorders can be recognized by simple color reactions in the urine; these are listed in Table 37-2.

To this group should be added the inherited hyperammonemic syndromes and vitamin-responsive aminoacidopathies (such as pyridoxine dependency and bipterin deficiency), as well as certain nonfamilial metabolic disorders that make their appearance in the neonatal period—hypocalcemia, hypothyroidism and cretinism, hypomagnesemia with tetany, and hypoglycemia.

URINARY SCREENING TESTS FOR METABOLIC DEFECTS

DISEASE	FERRIC CHLORIDE	DNPH	BENEDICT REACTION	NITROPRUSSIDE REACTION
Phenylketonuria	Green	+	–	–
Maple syrup urine disease	Navy blue	+	–	–
Tyrosinemia	Pale green (transient)	+	–	+
Histidinemia	Green-brown	±	–	–
Propionic acidemia	Purple	+	–	–
Methylmalonic aciduria	Purple	+	–	–
Homocystinuria	–	–	–	+
Cystinuria	–	–	–	+
Galactosemia	–	–	+	–
Fructose intolerance	–	–	+	–

DNPH, diaminoxyphenylhydrazine.

It is important to note that the three most frequently identified hereditary metabolic diseases—*phenylketonuria* (PKU), *hyperphenylalaninemia*, and *congenital hypothyroidism*—do not become clinically manifest in the neonatal period and are therefore discussed in a later portion of this chapter and in Chap. 40 (in the discussion of congenital hypothyroidism). This is fortunate, for it allows time to introduce preventive measures before the first symptoms appear. A number of other metabolic disorders, which can be recognized either by screening or by early signs, are synopsized below.

Vitamin-Responsive Aminoacidopathies

Included under this heading is a group of diseases that respond not to dietary restriction of a specific amino acid but to the oral supplementation of a specific vitamin. Some 30 vitamin-responsive aminoacidopathies are known (they are all rare, but the more frequent ones are listed in Table 41-3), and many of them result in injury to the central nervous system (CNS).

Pyridoxine-Dependent Seizures Pyridoxine dependency is the prototypic example of a genetic, vitamin-dependent biochemical disorder, albeit a rare disease. It is inherited as an autosomal recessive trait and is characterized by the early onset of convulsions, sometimes occurring in utero; failure to thrive; hypertonia-hyperkinesia; irritability; tremulous movements (“jittery baby”); exaggerated auditory startle (hyperacusis); and later, if untreated, by psychomotor retardation. The specific laboratory abnormality is an increased excretion of xanthurenic acid in response to a tryptophan load. There are decreased levels of pyridoxal-5-phosphate and gamma-aminobutyric acid (GABA) in brain tissue. The mutation is of the *ALDH7A1* gene.

The neuropathology has been studied in only a few cases. One patient of our colleague R.D. Adams, a 13.5-year-old boy affected in the neonatal period, was left in a state of mental retardation, with pale optic discs and spastic legs; the brain weight was 350 g below normal. There was a decreased amount of central white matter in the cerebral hemispheres and a depletion of neurons in the thalamic nuclei and cerebellum, with gliosis (Lott et al). Most importantly, in pyridoxine deficiency, the administration of 50 to 100 mg of vitamin B₆ suppresses the seizure state, and daily doses of 40 mg permit normal development.

Biopterin Deficiency

Some patients with increased concentrations of serum phenylalanine in the neonatal period are unresponsive to measures that lower phenylalanine. They are usually found to have a defect in biopterin metabolism. If this condition is unrecognized and not treated promptly, it leads to seizures of both myoclonic and, later, grand mal types, combined with a poor level of responsiveness and generalized hypotonia. Swallowing difficulty is another prominent symptom. Within a few months, developmental delay becomes prominent. Unlike in PKU, phenylalanine hydroxylase enzyme levels are normal, but there is a lack of tetrahydrobiopterin, which is a cofactor of phenylalanine hydroxylase. Treatment consists of administration of tetrahydrobiopterin in a dosage of 7.5 mg/kg/d in combination with a low-phenylalanine diet. It is

important to recognize this condition early in life by the measurement of urine pterins and to institute appropriate therapy before irreversible brain injury occurs. A later onset form with diurnally fluctuating dystonia has also been described but its nature is not certain.

Galactosemia

Inheritance of this disorder is autosomal recessive. The biochemical abnormality consists of a defect in galactose-1-phosphate uridyl transferase (GALT), the enzyme that catalyzes the conversion of galactose-1-phosphate to uridine diphosphate galactose. Several forms of galactosemia have been described, based on the degree of completeness of the metabolic block and some of these are due to mutations in other galactose pathway genes. In the typical (severe) form, the onset of symptoms is in the first days of life, after the ingestion of milk; vomiting and diarrhea are followed by a failure to thrive. Drowsiness, inattention, hypotonia, and diminution in the vigor of neonatal automatisms then become evident. The fontanels may bulge, the liver and spleen enlarge, the skin becomes yellow (in excess of the common neonatal jaundice), and anemia develops. In a small number, there is thrombocytopenia with cerebral bleeding. Cataracts form as a result of the accumulation of galactitol in the lens. Studies of the outcome of surviving infants have shown delayed psychomotor development (IQ about 85), visual impairment, osteoporosis, ovarian failure, and residual cirrhosis, sometimes with splenomegaly and ascites. This seems to happen even with treatment. However, it is not known whether, in such patients, the treatment is always maintained through a critical developmental period. In one such patient, who died at age 8 years, the main change in the brain was slight microcephaly with fibrous gliosis of the white matter and some loss of Purkinje and granule cells in the cerebellum, and also gliosis (Crome). The diagnostic laboratory findings are an elevated blood galactose level, low glucose, galactosuria, and deficiency of GALT in red and white blood cells and in liver cells. The treatment is essentially dietary, using milk substitutes; if this is instituted early, the brain should be protected from injury.

A late-onset neurologic syndrome has also been observed by Friedman and colleagues in galactosemic patients who had survived the infantile disease. By late adolescence, they were cognitively delayed; some showed cerebellar ataxia, dystonia, and apraxia. One of these patients was middle-aged.

Organic Acidurias of Infancy

These have been divided into ketotic and nonketotic types. Among the *ketotic types*, the main one is *propionic acidemia*. This is an autosomal recessive disease caused by a primary defect in organic acid metabolism that is expressed clinically by episodes of vomiting, lethargy, coma, convulsions, hypertonia, and respiratory difficulty. The onset is in the neonatal or early infantile period; in time, psychomotor retardation becomes evident. Death usually occurs within a few months despite dietary treatment. Propionic acid, glycine, various forms of fatty acids, and butanone are elevated in the serum. As with other ketotic organic acidurias, high protein intake induces

ketotic attacks. Marked restriction of dietary protein (specifically leucine) may prevent attacks of ketoacidosis and permit relatively good psychomotor development.

A number of other ketotic acidurias also occur in infancy. The most important of these are *methylmalonic acidemia*, *isovaleric acidemia*, *beta-keto acidemia*, and *lactic acidemia*. Each of these disorders can become manifest with profound metabolic acidosis and intermittent lethargy, vomiting, tachypnea, tremors, twitching, convulsions, and coma, with early death in about half the patients and developmental retardation in those who survive. Rare subtypes of methylmalonic acidemia respond to vitamin B₁₂. Isovaleric acidemia is characterized by a striking odor of stale perspiration, which has given it the sobriquet "sweaty foot syndrome." Numerous metabolic defects, most commonly of pyruvate decarboxylase and pyruvate dehydrogenase, are responsible for the accumulation of lactic and pyruvic acids. The enzymatic defect of isovaleric acidemia also has been demonstrated in a recurrent form of episodic cerebellar ataxia and athetosis and in a persistent form in mitochondrial encephalopathies (Leigh disease), as described further on in this chapter.

A separate and rare deficiency of aromatic L-amino acid decarboxylase has been described; the chemical signature is low levels of almost all catecholamines. This defect is associated with a peculiar movement disorder of oculogyric crises, dystonia and athetosis, and autonomic failure (see Swoboda et al).

A type II glutaric acidemia has also been observed in the neonatal period and causes episodes of acidosis with vomiting and hyperglycemia. Multiple congenital anomalies of brain and somatic structures and cardiomyopathy are conjoined. A diet low in the specific toxic amino acid and supplements of carnitine and riboflavin are recommended, but the effects are unclear.

In the *nonketotic form of hyperglycinemia*, there are high levels of glycine but no acidosis. The notable diagnostic finding is an elevation of the CSF glycine, several times higher than that of the blood. The effects on the nervous system are more devastating than in the ketotic form. In reported cases (the authors and our colleagues have seen several), the neonate is hypotonic, listless, and dyspneic, with dysconjugate eye movements, opisthotonic posturing, myoclonus, and seizures. A few such neonates survive to infancy but are extremely cognitively impaired and helpless. Spongy degeneration of the brain has been reported both in this disease and in the ketotic form (Shuman et al). No treatment has been effective in severe cases. In an atypical milder form, with neurologic abnormalities that appear in later infancy or childhood, reduction of dietary protein and administration of sodium benzoate in doses up to 250 mg/kg/d have been beneficial. The use of dextromethorphan, which blocks glycine receptors, is said to be effective in preventing seizures and coma.

Inherited Hyperammonemias

These are a group of six diseases caused by inborn deficiencies of the enzymes of the Krebs-Henseleit urea cycle; they are designated as *N-acetyl glutamate synthetase*, *carbamoyl phosphate synthetase* (CPS), *ornithine transcarbamylase* (OTC), *argininosuccinic acid synthetase* (citrullinemia), *argininosuccinase deficiency*, and *arginase deficiency*. Hyperornithinemia-

hyperammonemia-homocitrullinemia (HHH) and intrinsic protein intolerance are closely related disorders. They are identified by the finding of a persistent or episodic elevation of ammonia levels in the blood. A detailed account of these inherited hyperammonemic syndromes is contained in the review by Brusilow and Horwich.

The pattern of inheritance of each of these disorders is autosomal recessive except for OTC deficiency, which is X-linked dominant. Their clinical manifestations are a common expression of an accumulation of ammonia or of urea cycle intermediates in the brain; they differ only in severity, in accordance with the degree of completeness of the enzymatic deficiency and with the age of the affected individual. The one exception is arginase deficiency, which commonly appears during later childhood as a progressive spastic paraplegia with mental retardation. Clinically, it has been convenient to divide the hyperammonemias into two groups—one that presents in the neonatal period and another that becomes evident in the weeks or months thereafter. This division is somewhat artificial, the clinical presentation being more in the nature of a continuous spectrum governed by the biologic factors mentioned above and even extending to rare cases that have their first symptoms during adulthood.

In the most severe forms of the hyperammonemic disorders, the infants are asymptomatic at birth and during the first day or two of life, after which they refuse their feedings, vomit, and rapidly become inactive and lethargic, soon lapsing into an irreversible coma. Profuse sweating, focal or generalized seizures, rigidity with opisthotonos, hypothermia, and hyperventilation have been observed in the course of the illness. These symptoms constitute a medical emergency, but even with measures to reduce serum ammonia, the disease is usually fatal.

In less severely affected infants, hyperammonemia develops some months later, when protein feeding is increased. There is a failure to thrive, and attempts to enforce feeding or during periods of constipation (both of which increase ammonia production in the bowel) may result in bouts of vomiting, lethargy, hyperirritability, and screaming. Respiratory alkalosis is a consistent feature. Other manifestations are periods of alternating hypertonia and hypotonia, seizures, ataxia, blurred vision, and of confusion, stupor, and coma. During episodes of stupor, often precipitated by dehydration, an alimentary protein load, or minor surgery, brain edema may be seen by CT and MRI; with repeated relapses, the brain edema gives way to atrophy, which appears as symmetrical areas of decreased attenuation in the cerebral white matter. Between attacks, some patients with partial deficiency may be normal or show only a slight hyperbilirubinemia (DiMagno et al; Rowe et al). With decompensation, the bilirubin rises, as does ammonia, but neither reaches exceedingly high levels. After repeated attacks, signs of developmental delay with motor and mental retardation become evident, and the patient is vulnerable to recurrent infections. Two adult male patients in our care, who were married (but with azoospermia, which is common) and working at technically demanding jobs, came to medical attention because of bouts of visual blurring followed by stupor that evolved over hours (Shih et al, 1999). They had displayed an aversion to protein and

milk products as children; in later life, after meals high in protein, they became encephalopathic, one with severe brain swelling. There are few phenotypic differences among the late-onset hyperammonemias except for *argininosuccinic aciduria*, in which excessive dryness and brittleness of the hair (trichorrhexis nodosa) are notable features, and the aforementioned *arginase deficiency* with spastic diplegia.

Diagnosis is established by the finding of *hyperammonemia*, often as high as 1,500 mg/dL. The precise biochemical diagnosis requires testing of blood and urine for amino acids or assays for specific enzymes in red cells, liver, or jejunal biopsies. The primary hyperammonemias must be distinguished from the organic acidurias, including *methylmalonic aciduria* (see above), in which hyperammonemia can occur as a secondary metabolic abnormality.

In all the neonatal hyperammonemic diseases, the liver is often enlarged and liver cells appear to be inadequate in their metabolic functions, but how the enzymatic deficiencies or other disorders of amino acid metabolism affect the brain remains uncertain. It must be assumed that in some the saturation of the brain by ammonia impairs the oxidative metabolism of cerebral neurons, and when blood levels of ammonium increase (from protein ingestion, constipation, etc.), episodic coma or a more chronic impairment of cerebral functions occurs—as it does in adults with cirrhosis of the liver and portal-systemic encephalopathy. In the acutely fatal cases, the brain is swollen and edematous, and the astrocytes are diffusely increased in number and enlarged. The neurons are normal. Astrocytic swelling has been attributed to the accumulation of glutamate secondary to a suppression of glutamate synthetase. These changes have been reproduced in animals by the injection of ammonium chloride. When the hyperammonemia is abrupt in onset and severe, the resulting combination of encephalopathy, brain swelling, and respiratory alkalosis simulates the *Reye syndrome* (see “Reye-Johnson Syndrome” in Chap. 40).

As in all forms of liver disease, valproic acid and other hepatic toxins may cause hepatic coma by further impairing the urea cycle enzymes. Notable are a few cases of inherited hyperammonemia that come to light in childhood or adulthood only after the administration of one of these drugs.

Ornithine Transcarbamylase Deficiency and Argininosuccinic Aciduria Most cases present in the neonatal period with hyperammonemia but milder forms may appear later in life with episodic symptoms such as episodic stupor, ataxia, and seizures. The other features have been mentioned above.

Treatment of the Hyperammonemic Syndromes The treatment of acute hyperammonemic syndromes is directed at lowering ammonia levels by hemodialysis, exchange transfusions, and administration of arginine and certain organic acids. With subsidence of the acute symptoms, a systematic form of management should be undertaken, as outlined by Brusilow and colleagues and by Msall and colleagues. Sodium benzoate should be given in doses up to 250 mg/d, supplemented by sodium phenylacetate or sodium phenylbutyrate, which, on theoretical grounds, should divert nitrogen from the ureagenesis cycle. Arginine (50 to 150 mg/kg) should be

added to the diet, as a deficiency of this substance may be responsible for the mental retardation and skin rashes. In more chronic cases, treatment consists of decreasing the ammonium load by the use of dietary protein restriction and by administration of oral antibiotics and lactulose. In infants with inborn errors of ureagenesis, there is a constant danger of recurrent episodes of hyperammonemia and coma, particularly in response to infections. In a few instances, careful management of the metabolic error has resulted in normal psychomotor development.

Liver transplantation may prove to be a therapeutic option.

Branched-Chain Aminoacidopathies (Maple Syrup Urine Disease)

These conditions are caused by a deficiency of α -keto acid dehydrogenase, resulting in the accumulation of the branched-chain amino acids leucine, isoleucine, and valine and the corresponding branched-chain α -keto acids. Maple syrup urine disease may be taken as the prototype. The pattern of inheritance is autosomal recessive. With the most-severe neonatal type, the infant appears normal at birth, but toward the end of the first week, poor feeding, intermittent hypertonicity, opisthotonos, and respiratory irregularities appear. These are followed by diminished neonatal automatisms, convulsions, severe ketoacidosis, and often coma and death toward the end of the second to fourth week. This disease is one of the causes of the malignant epileptic syndrome of early infancy (Brett). Four milder forms of the disease have been described. In these more chronic cases, feeding difficulties begin somewhat later in the early infantile period. They are manifest as recurrent infections, episodic acidosis, coma, and retarded growth and psychomotor development. Some of these patients, toward the end of the first year, may become quadriparetic or ataxic; or there may be only a nonspecific mental retardation. The disease derives its name from the maple syrup odor of the child's urine that tests positively for 2,4-dinitrophenylhydrazine (DNPH).

Other important laboratory findings are increased plasma and urine concentrations of leucine, isoleucine, valine, and keto acids. Secondary accumulation of a derivative of α -hydroxybutyric acid probably accounts for the maple syrup odor. The neuropathologic findings are uncertain. In the first acute case described, only interstitial edema was observed; but in more chronic cases, pallor and loss of myelin and gliosis of parts of the cerebral white matter that myelinate after birth may be found. This can be visualized in CT and MRI scans.

Treatment by restriction of foods containing branched-chain amino acids (leucine, isoleucine, and valine) allows reasonably normal mental development, but only if such restriction is begun in the neonatal period and maintained lifelong. A thiamine-responsive variant with a slightly different pattern of keto acids described by Prensky and Moser responds variably to 30 to 300 mg of thiamine. The acute episodes, which threaten life, may require peritoneal dialysis to remove the putative toxic metabolites; they respond to the administration of glucose amino acid mixtures that are free of branched-chain keto acids.

Other Organic Acidemias

In addition to maple syrup urine disease, there are a number of other metabolic disturbances, some of them of mitochondrial origin, that appear in the neonatal period or later and are marked by an organic acidemia. If they are severe, the infant develops a metabolic (lactic) acidosis soon after birth, with lethargy, feeding problems, rapid respirations, and vomiting. Or there may be irritability, jerky limb movements, and hypertonia. Later presentations take the form of feeding difficulties, repeated vomiting, hypotonia, and failure to thrive. With the passage of time, psychomotor retardation and drug-resistant seizures become evident. Metabolic stress—e.g., intercurrent infection or surgical procedures—may precipitate an episode of lactic or ketoacidosis.

Biochemical studies may disclose a biotinidase deficiency, methylmalonic aciduria, glutaric acidemia, methylglutaconic acidemia, or any number of other organic acid abnormalities. The precise abnormality is determined by measuring enzyme activity in white blood cells or cultured skin fibroblasts. As remarked above, some of these enzymes act in conjunction with a specific vitamin cofactor, so that exact diagnosis is imperative. The biotinidase deficiency may respond to 10 mg of biotin per day; the methylmalonic acidemia to 1 to 2 mg of vitamin B₁₂ per day; maple syrup urine disease to 10 to 20 mg of thiamine per day; and glutaric acidemia types I and II to 300 mg of riboflavin per day. The administration of carnitine may increase the elimination of toxic metabolites.

The care of these patients during an acute illness is of extreme importance. See Lyon and colleagues for a more complete description.

Sulfite Oxidase Deficiency With or Without Molybdenum Cofactor Deficiency (See also "Sulfite Oxidase Deficiency")

These are extremely rare autosomal recessive disorders of sulfur metabolism, manifest clinically during the neonatal period by seizures, axial hypotonia, reduced level of responsiveness, and spasms with opisthotonos. There may be added dislocation of lenses, blindness, coloboma, and enophthalmos in combination with severe mental retardation and dysmorphic facial features (widely spaced eyes, long face and philtrum, puffy cheeks). There are no differences between pure sulfite oxidase deficiency and that associated with molybdenum cofactor deficiency. With survival into infancy, episodic confusion and stupor give way to seizures, mental retardation, and ataxia. In one of our cases, described by Shih and colleagues (1977) a stroke-like syndrome of hemiplegia and aphasia appeared during a relapse at the age of 4.5 years, and in one case, subluxation of the lenses and choreoathetosis appeared at 8 months of age.

The biochemical abnormality is the accumulation of sulfite and possibly sulfatase as a result of the enzyme deficiency. Shih and colleagues (1977) have identified sulfite, thiosulfate, and S-sulfocysteine in the urine. Cerebral atrophy with loss and destruction of white matter and gray matter (cerebral cortex, basal ganglia, and cerebellar nuclei) was observed in one postmortem examination.

Increasing the intake of molybdenum or lowering the dietary intake of sulfur amino acids is a therapeutic possibility not yet fully evaluated.

Diagnosis of Neonatal Metabolic Diseases

An important clue, of course, is provided by the history of a neonatal disease or unexplained death earlier in the same sibship or in a male maternal relative. A history that protein foods are rejected by the infant, or even a history among relatives of a dislike of protein or feeding difficulties in infancy, should raise the suspicion of an inherited hyperammonemic disorder or an organic acidemia. Measurements of blood ammonia and lactate and of the urine for ketones and reducing substances (that react with cupric sulfate) are the key laboratory tests. A wide-spectrum screening program may disclose a biochemical abnormality; this is the optimal state of affairs, especially when this type of screening provides the information before symptoms appear.

A number of nonhereditary metabolic diseases must be distinguished from the hereditary ones in this period of life. *Hypocalcemia* is one of the most frequent causes of neonatal seizures; tetany, spasms, and tremulous movements are usually present. Its cause is unknown, but the disorder is easily corrected, with excellent prognosis. Symptomatic *hypoglycemic reactions* are frequent in neonates. Premature infants are the most susceptible. Seizures, tremulousness, and drowsiness occur with blood sugar levels of less than 30 mg/dL in the mature infant, and less than 20 mg/dL in the premature. Maternal toxemia and diabetes mellitus also predispose to hypoglycemia. Other causes of hypoglycemia are adrenal insufficiency, galactosemia, an idiopathic pancreatic islet-cell hyperplasia, the treatable fatty-acid beta-oxidation disorders, and a congenital deficiency of CSF glucose transport—causing persistent hypoglycorrachia and refractory seizures unless blood glucose levels are kept high. The damaging effects of untreated hypoglycemia were well documented by Koivisto and colleagues. Also now identified is a disorder of CSF serine transport causing failure to thrive, severe developmental disability with spasticity and intractable epilepsy. The diagnosis is made by measuring CSF amino acids; treatment is with high-dose oral serine. *Cretinism* and *idiopathic hypercalcemia* are other recognizable entities that appear during this age period.

Aicardi has described a neonatal myoclonic syndrome, and Ohtahara has described a malignant neonatal seizure disorder. In some of the cases, the neonatal syndrome merged later with the West type of infantile spasms and the Lennox-Gastaut syndrome (see Chap. 16). Some of the cases had developmental abnormalities of the cerebrum, and severe mental retardation was the outcome. In other cases of this type, a familial coincidence was a feature; a metabolic defect has been suspected in these cases but never proved.

The hereditary metabolic diseases must also be distinguished from a number of other catastrophic disorders that occur at or soon after birth, such as asphyxia, perinatal ventricular hemorrhage with the respiratory distress syndrome of hyaline membrane disease, other

hypotensive–hypoxic states, erythroblastosis fetalis with kernicterus, neonatal bacterial meningitis, meningoencephalitis (herpes simplex, cytomegalic inclusion disease, listeriosis, rubella, syphilis, and toxoplasmosis), and hemorrhagic disease of the newborn. These are described in Chap. 38, on the developmental diseases.

HEREDITARY METABOLIC DISEASES OF INFANCY

The hallmark of all the hereditary metabolic diseases is *psychosensorimotor regression*. However, those that have their onset in the first year of life pose extraordinary problems in neurologic diagnosis. If the onset is in the first postnatal months, before the infant has had time to develop the normal complex repertoire of behavior, the first signs of disease may take the form of subtle delays in maturation rather than of psychomotor regression. Departures from normalcy include a lack of interest in the surroundings, a lack of visual engagement, poor head control, inability to sit up at the usual time, poor hand–eye coordination, and persistence of infantile automatisms. Of course, embryologic maldevelopment of the brain may have similar effects, and systemic diseases and other visceral malformations—such as cystic fibrosis, renal disease, biliary atresia and congenital heart disease, chronic infection, malnutrition, and seizures (with drug therapy)—may appear to impede psychomotor development. Diagnosis becomes somewhat easier in the second half of the first year, especially if development in the first half had proceeded normally. Then an observant mother, usually one with older children, can perceive a loss of certain early acquisitions, attesting to the progressive nature of a disease.

The most distinctive members of this category of neurologic disease are the *leukodystrophies* and the *lysosomal storage diseases*. The leukodystrophies are a group of inherited metabolic diseases of the nervous system characterized by progressive, symmetrical, and usually massive destruction of the white matter of the brain and sometimes of the spinal cord; each type of leukodystrophy is distinguished by a specific genetic defect in myelin metabolism. In the *lysosomal storage diseases*, there is a genetic deficiency of the enzymes (usually one or more of the acid hydrolases) necessary for the degradation of specific glycosidic or of peptide linkages in the intracytoplasmic lysosomes, causing nerve cells to become engorged with material that they would ordinarily degrade. These metabolites eventually damage the nerve cell or its myelin sheath.

Most of these diseases are classed as *sphingolipidoses*. Brady in 1966 made the observation that in each of these disorders an increased quantity of sphingolipid accumulated in the brain and other tissues. The sphingolipids are a class of intracellular lipids that all have ceramide as their basic structure, but each has a different attached oligosaccharide or phosphorylcholine. The rate of synthesis of the sphingolipids is normal and their accumulation results from a defect of a specific lysosomal enzyme that

normally degrades each of the glycoproteins, glycolipids, and mucopolysaccharides by removing a monosaccharide or sulfate moiety. It is the type of enzyme deficiency and accumulated metabolite, as well as the tissue distribution of the nondegradable substrate, that impart a distinctive biochemical and clinical character to each of the diseases in this category.

The concept of lysosomal storage diseases, introduced by Hers in 1965, excited great interest at the time because it provided the potential for prenatal diagnosis and the detection of carriers. The diagnosis of this group of diseases has also been facilitated by the use of CT, MRI, and evoked response techniques, which confirm the existence of leukodystrophies and by the electron microscopic examination of skin, rectal, or conjunctival biopsies, circulating lymphocytes, and cultured amniotic fluid cells, which discloses the lysosomal storage material in nonneural cells.

There are now more than 40 lysosomal storage diseases in which the biochemical abnormalities have been determined. The main ones are listed in Table 37-3, which was adapted originally from the review of Kolodny and Cable and updated by our colleague, E. Kolodny. In addition to the sphingolipidoses, which are the lysosomal storage diseases most likely to be encountered in the first year of life, the table includes the storage diseases that may not appear clinically until a later age (in childhood and adolescence)—to be considered later in this chapter. The frequency of each of the various types, as detected in a comprehensive study of the Australian population, is given by Meikle and colleagues and generally accords with the ordering below. A broad perspective on the frequency of the lysosomal disorders can be appreciated from the report of the Australian national referral laboratory. There were 545 cases (75 detected prenatally) over a 16-year period, a calculated frequency of 1 case per 7,700 live births. This is close to the estimate in the United States, which is approximately 1 per 5,000 births.

The more frequent types of lysosomal storage diseases are as follows:

1. Tay-Sachs disease (G_{M2} gangliosidosis) and variants such as Sandhoff disease
2. Infantile Gaucher disease
3. Infantile Niemann-Pick disease
4. Infantile G_{M1} generalized gangliosidosis
5. Krabbe globoid-body leukodystrophy
6. Farber lipogranulomatosis
7. Pelizaeus-Merzbacher and other sudanophilic leukodystrophies
8. Spongy degeneration (Canavan-van Bogaert-Bertrand disease)
9. Alexander disease
10. Zellweger encephalopathy
11. Lowe oculorenal-cerebral disease

In the following descriptions, we have summarized the clinical and pathologic features of each of the diseases listed above and have italicized the characteristic clinical signs and corroborative laboratory tests. Leigh disease, which may appear in this age group, is described with the mitochondrial diseases, further on in this chapter.

Table 37-3

LYSOSOMAL STORAGE DISEASES^a

DISORDER	PRIMARY DEFICIENCY	ACCUMULATED METABOLITE
Sphingolipidoses		
G _{M1} gangliosidosis	β-Galactosidase	G _{M1} ganglioside, galactosyl oligosaccharides, keratan sulfate
G _{M2} gangliosidosis	N-acetylhexosaminidase α subunit	G _{M2} ganglioside
Tay-Sachs disease	N-acetylhexosaminidase β subunit	G _{M2} ganglioside, oligosaccharides, glycosaminoglycans
Sandhoff disease		G _{M2} ganglioside
Activator deficiency	G _{M2} activator	Galactosylsulfatide, lactosylsulfatide
Metachromatic leukodystrophy	Arylsulfatase A (sulfatidase), sulfatide activator (saposin B)	
Krabbe disease	Galactocerebrosidase	Galactosylceramide
Fabry disease	α-Galactosidase A	Ceramide trihexoside
Gaucher disease	Glucocerebrosidase	Glucosylceramide, glycopeptides
Niemann-Pick disease		
Types A and B	Sphingomyelinase	Sphingomyelin, cholesterol
Type C	Cholesterol esterification	Free cholesterol, bis-monoacylglycerophosphate
Farber disease	Ceramidase	Ceramide
Schindler disease	α-Galactosidase B	α-N-acetylgalactosaminyl oligosaccharides and glycopeptides
Neuronal ceroid lipofuscinoses		
Infantile form (Haltia-Santavuori)	Palmitoyl-protein thioesterase	Granular osmiophilic deposits
Late infantile form (Jansky-Bielschowsky)	Tripeptidyl peptidase I	Curvilinear bodies, subunit C of mitochondrial ATP synthase
Juvenile form (Spielmeyer-Sjögren)	438-amino acid membrane protein	Curvilinear and laminated (fingerprint) bodies, subunit C of mitochondrial ATP synthase
Adult form (Kufs disease)	Unknown	Mixed-type osmiophilic deposits and lamellar inclusions
Glycoproteinoses		
Aspartylglycosaminuria	Aspartylglycosaminidase	Aspartylglycosamine
Fucosidosis	α-L-Fucosidase	Fucosyloligosaccharides, fucosylglycosphingolipids
Galactosialidosis	Protective protein (β-galactosidase and α-neuraminidase)	Sialyloligosaccharides, galactosyloligosaccharides
α-Mannosidosis	α-Mannosidase	α-Mannosyl oligosaccharides
β-Mannosidosis	β-Mannosidase	β-Mannosyl oligosaccharides
Mucopolipidoses		
Sialidosis (mucopolipidosis I)	α-Neuraminidase	Sialyloligosaccharides, sialylglycopeptides
Mucopolipidosis II (I-cell disease)	UDP-N-acetylglucosamine: lysosomal enzyme, N-acetylglucosamine-1-phosphotransferase	Sialyloligosaccharides, glycoproteins, glycolipids
Mucopolipidosis III (pseudo-Hurler polydystrophy)	Same phosphotransferase as above	Sialyloligosaccharides, glycoproteins, glycolipids
Mucopolipidosis IV	Mucopolipin-1	Gangliosides, phospholipids, mucopolysaccharides
Other lysosomal diseases		
Acid lipase deficiency		
Wolman disease	Acid lipase	Cholesterol esters, triglycerides
Cholesterol ester storage disease	Acid lipase	Cholesterol esters, triglycerides
Glycogenosis type II (Pompe disease)	α-Glucosidase (acid maltase)	Glycogen
Sialic acid storage disease		
Infantile form	Sialic acid transport	Free sialic acid
Salla disease	Sialic acid transport	Free sialic acid
Mucopolysaccharidoses (see Table 37-7)		

^aSee text for genetic designation.

Tay-Sachs Disease (G_{M2} Gangliosidosis, Hexosaminidase A Deficiency, HEXA Mutation)

This is an autosomal recessive disease, mostly of Jewish infants of eastern European (Ashkenazic) background. The first description came from Tay, a British ophthalmologist, in 1881, and Sachs, an American neurologist, in 1887; they called it amaurotic family idiocy. The disease becomes apparent in the first weeks and months of life, almost always by the fourth month. The first manifestations are a regression of motor activity and an abnormal startle to acoustic stimuli, accompanied by listlessness, irritability, and poor reactions to visual stimuli. These are followed by a progressive *delay in psychomotor development* or regression (by 4 to 6 months), with inability to roll over and sit. At first, axial hypotonia is prominent, but later spasticity and other corticospinal tract signs and visual failure become evident. Degeneration of the macular cells exposes the underlying red vascular choroid surrounded by a whitish gray ring of retinal cells distended with ganglioside. The resulting appearance is of the *cherry-red spot* with optic atrophy (Fig. 37-1). These are observed in the retinas in more than 90 percent of patients (but are also characteristics of other storage diseases—see Table 37-4). In the second year, there are tonic-clonic or minor motor seizures and an increasing size of the head and diastasis of sutures with relatively normal-size ventricles; in the third year, the clinical picture is one of dementia, decerebration, and blindness. Cachexia becomes increasingly severe and death occurs at 2 to 4 years. The electroencephalogram (EEG) becomes abnormal in the early stages (paroxysmal slow waves with multiple spikes). Occasionally, one can find basophilic granules in leukocytes and vacuoles in lymphocytes. There are no visceral, skeletal, or bone marrow abnormalities by light microscopy.

Figure 37-1. Retinal cherry-red spot in a patient with Tay-Sachs disease. The whitish ring surrounds the dark macula. In this dark-skinned child, the macular spot is dark rather than reddish. (Courtesy of Dr. Shirley Wray.)

Table 37-4

DISEASES DISPLAYING A CHERRY-RED MACULAR SPOT

G_{M1} gangliosidosis
G_{M2} gangliosidosis (Tay-Sachs and Sandhoff type)
Sialidosis
Niemann-Pick disease types A to D (not E and F); ring may be diffuse and indistinct
Farber lipogranulomatosis
Metachromatic leukodystrophy
Neuronal ceroid lipofuscinosis, late infantile form ("bull's-eye" maculopathy, not true cherry-red spot)

The basic enzymatic abnormality is a *deficiency of beta hexosaminidase A*, which normally cleaves the *N*-acetylgalactosamine from gangliosides. As a result of this deficiency, G_{M2} ganglioside accumulates in the cerebral cortical neurons, Purkinje cells, retinal ganglion cells, and, to a lesser extent, larger neurons of the brainstem and spinal cord. The enzymatic defect can be found in the serum, white blood cells, and cultured fibroblasts from the skin or amniotic fluid, the latter giving parents the option of abortion to prevent a presently untreatable and fatal disease. Testing for hexosaminidase A also permits the detection of heterozygote carriers of the gene defect. Detection of this enzyme defect is complicated by the fact that more than 50 mutations of the *HEXA* gene have been isolated, coding for alpha subunit of the beta hexosaminidases and the enzyme itself is normal in one form of activator enzyme deficiency. Fortunately, only three mutations account for 98 percent of the form that is common in individuals of Jewish ancestry.

The brain is large, sometimes twice the normal weight. In addition, there is a loss of neurons and a reactive gliosis; remaining nerve cells throughout the CNS are distended with glycolipid. Biopsies of the rectal mucosa disclose glycolipid distention of the ganglion cells of the Auerbach plexus, but the need for this procedure has been obviated by enzyme analysis of white blood cells. Under the electron microscope, the particles of stored material appear as membranous cytoplasmic bodies. Retinal ganglion cells are distended with the same material and, together with fat-filled histiocytes, cause the whitish gray rings around the fovea, where there are no nerve cells, as noted above.

Tay-Sachs disease is untreatable but can be prevented by testing all individuals of Jewish origin for the recessive trait. Where screening has been instituted the disease has become virtually extinct.

In *Sandhoff disease*, which affects infants of non-Jewish origins, there is a deficiency of both hexosaminidase A and B, moderate hepatosplenomegaly, and coarse granulations in bone marrow histiocytes. The clinical and pathologic picture is the same as in Tay-Sachs disease except for the additional signs of visceral lipid storage. Occasionally, these visceral organs are not enlarged.

In recent years numerous variants of hexosaminidase A and B deficiency have been identified. They differ clinically from Tay-Sachs disease in having a later onset, less-extensive brain involvement (cortical neurons relatively spared and intense affection of basal ganglia, as well as

cerebellar and spinal neurons). Accordingly, the clinical expression of the variants appearing in childhood, adolescence, and adult life takes the form of athetosis, dystonia, ataxia, and motor neuron paralysis; mental function can be normal. The process has also been found in a few congenital cases in which there was a rapidly progressive decline of a microcephalic infant.

Infantile Gaucher Disease (Type II Neuronopathic Form, Glucocerebrosidase Deficiency, GBA Mutation)

This is an autosomal recessive disease without ethnic predominance, first described by Gaucher in 1882. The onset of the neuronopathic form is usually before 6 months and frequently before 3 months. The clinical course is more rapid than that of Tay-Sachs disease (most patients with infantile Gaucher disease do not survive beyond 1 year and 90 percent not beyond 2 years). Oculomotor apraxia and bilateral strabismus are early signs and are accompanied by rapid loss of head control, of ability to roll over and sit, and of purposeful movements of the limbs—along with apathy, irritability, frequent crying, and difficulty in sucking and swallowing. In some cases progression is slower, with acquisition of single words by the first year, bilateral corticospinal signs (Babinski signs and hyperactive tendon reflexes), *persistent retroflexion of the neck*, and *strabismus*. Laryngeal stridor and trismus, diminished reaction to stimuli, smallness of the head, rare seizures, normal optic fundi, *enlarged spleen* and slightly enlarged liver, poor nutrition, yellowish skin and scleral pigmentation, osteoporosis, vertebral collapse and kyphoscoliosis, and sometimes lymphadenopathy complete the clinical picture. The CSF is normal; the EEG is abnormal, but nonspecifically so.

The important laboratory findings are an *increase in serum acid phosphatase and characteristic histiocytes (Gaucher cells)* in marrow smears and liver and spleen biopsies. A *deficiency of glucocerebrosidase* in leukocytes and hepatocytes is diagnostic; glucocerebrosidase accumulates in the involved tissues. The characteristic pathologic feature is the Gaucher cell, 20 to 60 μm in diameter, with a wrinkled appearance of the cytoplasm and eccentricity of the nucleus. These cells are found in the marrow, lungs, and other viscera; neuronal storage is seldom evident. In the brain, the main abnormality is a loss of nerve cells—particularly in the bulbar nuclei, but also in the basal ganglia, cortex, and cerebellum—and a reactive gliosis that extends into the white matter.

In contrast to the type II form described above, type I Gaucher disease is a nonneuronopathic and relatively benign form. A less-frequent type III Gaucher disease is neuronopathic. It expresses itself in late childhood or adolescence by a slowly progressive mental decline, seizures, and ataxia, and, later, by spastic weakness and splenomegaly. Vision and retinae remain normal. Highly diagnostic is the defect in voluntary lateral gaze, with full movements on the oculocephalic (“doll’s-head”) maneuver. These signs help to differentiate Gaucher from Niemann-Pick disease, in which vertical eye movements are lost (see below). The nucleotide sequence of the cloned glucocerebrosidase gene of type I Gaucher disease was found by

Tsuji and associates (1987) to be different from that of types II and III. There is no treatment for the latter types.

Infantile Niemann-Pick Disease (Sphingomyelinase Deficiency, NPC Mutation)

This is also an autosomal recessive disease. Two-thirds of the affected infants have been of Ashkenazi Jewish parentage. The onset of symptoms in the usual type A disease is between 3 and 9 months of age, frequently beginning with marked *enlargement of liver, spleen, and lymph nodes and infiltration of the lungs*; rarely, there is jaundice and ascites. Cerebral abnormalities are definite by the end of the first year, often earlier. The usual manifestations are loss of spontaneous movements, lack of interest in the environment, axial hypotonia with bilateral corticospinal signs, blindness and amaurotic nystagmus, and a macular cherry-red spot (in about one-quarter of the patients). Seizures may occur, but are relatively late. There is no acoustic-induced startle or myoclonus, and head size is normal or slightly reduced. Loss of tendon reflexes and slowed conduction in peripheral nerves have been recorded but are rare. Protuberant eyes, mild hypertelorism, slight yellowish pigmentation of oral mucosa, and dysplasia of dental enamel have also been reported but are rare. Most patients succumb to an intercurrent infection by the end of the second year.

Vacuolated histiocytes (“foam cells”) in the bone marrow and vacuolated blood lymphocytes are the important laboratory findings. A *deficiency of sphingomyelinase* in leukocytes, cultured fibroblasts, and hepatocytes is diagnostic. Pathologic examination reveals a decrease in the number of neurons; many of the remaining ones are pale and ballooned and have a granular cytoplasm. The most prominent neuronal changes are seen in the midbrain, spinal cord, and cerebellum. The white matter is little affected. The retinal nerve cell changes are similar to those in the brain. The foamy histiocytes (Niemann-Pick cells) that fill the viscera contain sphingomyelin and cholesterol; the distended nerve cells contain mainly sphingomyelin.

There are also less-severe late infantile and juvenile forms of Niemann-Pick disease types C and D. These are discussed in a later section of this chapter.

Infantile Generalized G_{M1} Gangliosidosis (Type I, Beta-Galactosidase Deficiency, Pseudo-Hurler Disease, GLB1 Mutation)

This is probably an autosomal recessive disease without ethnic predominance. The infants appear abnormal at birth. They have *dysmorphic facial features*, like those of the mucopolysaccharidoses: depressed and wide nasal bridge, frontal bossing, hypertelorism, puffy eyelids, long upper lip, gingival and alveolar hypertrophy, macroglossia, and low-set ears. These features, with the bone changes mentioned below, account for the term *pseudo-Hurler*. Other indications of the disease are the onset of impaired awareness and reduced responsivity in the first days or weeks of life; lack of *psychomotor development* after 3 to 6 months; hypotonia, and later hypertonia with lively tendon reflexes and Babinski signs. Seizures are frequent. The head size is variable (microcephaly more often than

macrocephaly). *Loss of vision, coarse nystagmus and strabismus, macular cherry-red spots* (in half the cases), flexion pseudocontractures of elbows and knees, kyphoscoliosis, and enlarged liver and sometimes enlarged spleen are the other important clinical findings. Radiographic abnormalities include subperiosteal bone formation, mid-shaft widening and demineralization of long bones, and hypoplasia and beaking of the thoracolumbar vertebrae. Vacuoles are seen in 10 to 80 percent of blood lymphocytes and foam cells in the urinary sediment.

A *partial or complete deficiency of beta-galactosidase* and accumulation of G_{M1} ganglioside in the viscera and in neurons and glia cells throughout the CNS are the specific biochemical abnormalities. In addition, the epithelial cells of renal glomeruli, histiocytes of the spleen, and liver cells contain a modified keratan sulfate and a galactose-containing oligosaccharide. The changes in the bone are also like those in the Hurler form of mucopolysaccharidosis. *The disease should be suspected in an infant having the facial features of mucopolysaccharidosis and severe early-onset neurologic abnormalities.*

A remarkably benign variant, also inherited as an autosomal recessive trait, begins later in childhood but may advance so slowly as to allow attainment of adult life. Dystonia, myoclonus, seizures, visual impairment, and macular red spots were features of the two cases described by Goldman and coworkers.

Globoid Cell Leukodystrophy (Krabbe Disease, Galactocerebrosidase Deficiency, GALC Mutation)

This is an autosomal recessive disease without ethnic predilection, first described by Krabbe, a Danish neurologist, in 1916. The onset is usually before the sixth month and often before the third month (10 percent after 1 year). Early manifestations are *generalized rigidity*, loss of head control, diminished alertness, frequent vomiting, irritability and bouts of inexplicable crying, and spasms induced by stimulation. With increasing muscular tone, *opisthotonic* recurvation of the neck and trunk develops. Later signs are adduction and extension of the legs, flexion of the arms, clenching of the fists, hyperactive tendon reflexes, and Babinski signs. Later still, the tendon reflexes are depressed or lost but Babinski signs remain, an indication that *neuropathy* is added to corticospinal damage. This finding, shared with some of the other leukodystrophies, is of diagnostic value. Blindness and optic atrophy supervene. Convulsions occur but are rare and difficult to distinguish from tonic spasms. Myoclonus in response to auditory stimuli is present in some cases. The head size is normal or, rarely, slightly increased. In the last stage of the disease, which may occur from one to several months after the onset, the child is blind and usually deaf, opisthotonic, irritable, and cachectic. Most patients die by the end of the first year and survival beyond 2 years is unusual, although a considerable number of cases of later onset have been reported (see below).

The EEG shows nonspecific slowing without spikes, and the CSF protein is usually elevated (70 to 450 mg/dL). Imaging shows symmetrical nonenhancing areas of increased signal in the internal capsules and basal ganglia.

Figure 37-2. Krabbe disease. Axial T2-weighted MRI of a 6 month old with difficulty feeding, irritability, upper extremity hyper-tonia and lower extremity hypotonia, which began at 3 months. Laboratory testing confirmed low levels of leukocyte galactocerebrosidase activity. There is abnormal hyperintensity of the cerebral peduncles (corticospinal tract atrophy) as well as enlargement of the prechiasmatic optic nerves. Thalamic hypointensity, not shown here, is a common finding as well. (Image courtesy of Drs. Edward Yang and Sanjay Prabhu.)

As the disease advances, more of the cerebral white matter and brainstem become involved (Fig. 37-2). An additional feature in many cases is enlargement of the prechiasmatic optic nerves. Neuropathy is a feature in most cases, but clinical signs may be difficult to detect except for a decrease or loss of tendon reflexes; however, there is *evidence of denervation and slowed motor and sensory nerve conduction velocities*, reflecting a demyelinating polyneuropathy (see later comments on late-onset cases).

The deficient lysosomal enzyme in Krabbe disease is *galactocerebrosidase* (GALC; also called galactosylceramide beta-galactosidase); it normally degrades galactocerebroside to ceramide and galactose. The deficiency results in the accumulation of galactocerebroside; a toxic metabolite, psychosine, leads to the early destruction of oligodendrocytes and depletion of lipids in the cerebral white matter. The globoid cell reaction, however, indicates that impaired catabolism of galactosylceramide is also important. Gross examination of the brain discloses a marked reduction in the cerebral white matter, which feels firm and rubbery. Microscopically, there is widespread myelin degeneration, absence of oligodendrocytes, and astrocytic gliosis in the cerebrum, brainstem, spinal cord, and nerves. The characteristic globoid cells are large histiocytes containing the accumulated metabolite.

Schwann cells have tubular or crystalloid inclusions under electron microscopy.

About a dozen variants of globoid cell leukodystrophy have been reported, many of them allowing survival for years. In these, neurologic regression begins in the 2- to 6-year-old period. Visual failure with optic atrophy and a normal electroretinogram is an early finding. Later there is ataxia, as well as spastic weakness of the legs, mental regression, and finally decerebration. In three patients observed by R.D. Adams, a progressive quadriplegia with mild pseudobulbar signs, slowly progressive impairment of memory and other mental functions, dystonic posturing of the arms, and preserved sphincteric control constituted the clinical picture. The patients were alive at ages 9, 12, and 16 years. We have observed another rare variant, beginning in adult years, with spastic quadriplegia (asymmetrical) and optic atrophy. Mentation was essentially normal and, on imaging, the cerebral lesion was restricted. Unlike typical Krabbe disease, these CNS abnormalities are unaccompanied by any change in the spinal fluid. The nerve conduction velocities in the late-onset form may be either normal or abnormal.

Kolodny and colleagues reported 15 cases of even later onset (ages 4 to 73 years); pes cavus, optic pallor, progressive spastic quadriplegia, a demyelinating sensorimotor neuropathy, and symmetrical parietooccipital white matter changes (on imaging studies) were the main features. Galactocerebrosidase levels were not as reduced as in the infantile form; possibly these late-onset variants represent a structural mutation of the enzyme (see Farrell and Swedberg).

In this disease, as well as others described in this chapter, it has become clear that different mutations involving the same enzyme or metabolic pathway can produce strikingly different phenotypes and that there is a wide range in the age of onset in what had been considered, until relatively recently, a disease confined to infancy and early childhood.

Treatment

In what may be considered a possible breakthrough in the treatment of childhood metabolic disease, Escolar and colleagues reported the successful use of transplanted umbilical cord hematopoietic cells in asymptomatic babies with Krabbe disease. Patients who were treated after becoming symptomatic did not benefit, but 14 patients who had been diagnosed prenatally or very soon after birth demonstrated progressive myelination of the nervous system, normalization of blood galactocerebrosidase activity, and attained visual, developmental, and cognitive function. The donors were partially human leukocyte antigen (HLA)-matched and substantial antirejection medication was required.

Vanishing White Matter Disease

This more recently described and peculiarly named disease with variable age of onset is most typically manifest in this age group. After a period of normal development, and sometimes precipitated by infection or fever, there

is a progressive encephalopathy punctuated by episodes of more rapid deterioration. The core syndrome is of irritability, loss of vision, seizures, ataxia, and coma, sometimes with recovery to a disabled state. The denominative feature is a symmetrical leukodystrophy with progressive disappearance of white matter and replacement by CSF or gliosis. The nature of this disease, metabolic, inflammatory, or genetic (mutations in *eIF2B*), has not been resolved despite tentative linkage to certain chromosomal regions. We include it in this section because exacerbation with fever, similar to the case in some mitochondrial diseases, is suggestive of a metabolic disorder (see Leegwater et al).

Lipogranulomatosis (Farber Disease, Ceramidase Deficiency)

This is a rare autosomal disorder that is based on a mutation in *ASAH1*. The onset is in the first weeks of life, with a hoarse cry because of fixation of laryngeal cartilage, respiratory distress, and sensitivity of the joints, followed by characteristic *periarticular and subcutaneous swellings* and *progressive arthropathy*, leading finally to ankylosis. Usually there is severe psychomotor delay, but a few patients have been neurologically normal. Inanition and recurrent infections lead to death in the first 2 years. The diagnostic abnormality is a *deficiency of ceramidase*, leading to accumulation of ceramide. There is widespread lipid storage in neurons, granulomas of the skin, and accumulation of periodic acid-Schiff (PAS)-positive macrophages in periarticular and visceral tissues.

Sudanophilic Leukodystrophies and Pelizaeus-Merzbacher Disease

These are a heterogeneous group of disorders that have in common a defective myelination of the cerebrum, brainstem, cerebellum, spinal cord, and peripheral nerves. Morphologic peculiarities and genetic features separate a certain group called *Pelizaeus-Merzbacher disease*; other types have been artificially delineated; as a result, a relatively meaningless terminology has been introduced.

Pelizaeus-Merzbacher Disease (PLP1 Mutation)

This is predominantly an X-linked disease of infancy, childhood, and adolescence, and includes other closely related pathologic entities with different modes of inheritance. The affected gene encodes proteolipid protein (PLP), one of the two myelin basic proteins. Koeppen and associates have provided evidence of a defective synthesis of this protein. While one group of PLP mutations causes Pelizaeus-Merzbacher disease, another set causes an infantile spastic paraplegia.

The onset of symptoms is most often in the first months of life; other cases begin later in childhood. The first signs are *abnormal movements of the eyes* (rapid, irregular, often asymmetrical pendular nystagmus), jerk nystagmus on extremes of lateral movements, upbeat nystagmus on upward gaze, and hypometric saccades (Trobe et al). There is spastic weakness of the limbs, optic atrophy (often with unexplained retention of pupillary

light reflex), ataxia of limb movement and intention tremor, choreiform or athetotic movements of the arms, and slow psychomotor development with delay in sitting, standing, and walking. Seizures occur occasionally. In later-developing cases, pendular nystagmus, choreoathetosis, corticospinal signs, dysarthria, cerebellar ataxia, and mental deterioration are the major manifestations. There are milder cases of later onset with behavioral peculiarities and loss of tendon reflexes and, rarely, pure spastic paraparesis.

Imaging confirms the extensive and symmetrical white matter involvement. In the most severe cases, Seitelberger has observed an absence of oligodendrocytes and myelinated fibers. It is hypothesized that proteolipids accumulate in the endoplasmic reticulum of the oligodendrocytes, resulting in apoptosis. Patients may survive to the second and third decades. One group of cases resembles the Cockayne syndrome, with photosensitivity of skin, dwarfism, cerebellar ataxia, corticospinal signs, cataracts, retinitis pigmentosa, and deafness. Pathologically, islands of preserved myelin impart a tigroid pattern of degenerated and intact myelin in the cerebrum. Seitelberger has obtained pathologic verification of this lesion in cases beginning as late as adult years. *This disease and Cockayne syndrome are the only leukodystrophies in which nystagmus has been an invariable finding.*

Koeppe and Robitaille, in a thorough review of the subject of the pathogenesis of Pelizaeus-Merzbacher disease, summarized the evidence supporting the concept that misfolding of myelin proteins is the essential cause.

Unclassifiable Sporadic and Familial Sudanophilic Leukodystrophies

There are two types of such disorders, one with early and the other with late onset. In the former, the illness begins before 3 months of age, with survival of less than 2 years; in the latter, onset is between ages 3 and 7 years and the course is only slowly progressive to the point of being chronic. *Psychomotor regression; spastic paralysis; incoordination; blindness and optic atrophy; seizures (rare); severe microcephaly; and absence of skeletal, visceral, and hematologic evidence of the metabolic abnormality are the main features.* No characteristic laboratory abnormalities are known. Diffuse degeneration of myelinated fibers (visible by MRI) with phagocytosis of *sudanophilic degeneration products of myelin* and gliosis are the major changes. In two cases followed by R.D. Adams and T. Rabinowicz, a brother and sister living to adolescence, the destroyed white matter was widely cavitated.

Spongy Degeneration of Infancy (Canavan-van Bogaert-Bertrand or Canavan Disease, ASPA Mutation)

This is an autosomal recessive disease that was described in 1931 by Myrtille Canavan as a form of Schilder disease (see Chap. 36), but later categorized as a special spongy degeneration of the brain by van Bogaert and Bertrand. Of 48 affected families reported by Banker and Victor, 28 were of Jewish ancestry. Onset is early, usually recognizable in the first 3 months of life and sometimes in the first

neonatal weeks. There is either a lack of development or rapid *regression of psychomotor function, loss of sight and optic atrophy, lethargy, difficulty in sucking, irritability, reduced motor activity, hypotonia followed by spasticity of the limbs with corticospinal signs, and an enlarged head (macrocephaly).* There are no visceral or skeletal abnormalities but a variable sensorineural hearing loss has been found (Ishiyama et al). Seizures occur in some cases. An interesting but unexplored aspect of the disease is the occurrence of blond hair and light complexion in affected members, in contrast to the darker hair and complexion of their normal siblings (Banker and Victor).

The CSF is usually normal but the protein is slightly elevated in some cases. The disease is characterized by an increased urinary excretion of *N*-acetyl-L-aspartic acid (NAA), which may be used as a biochemical marker. It reflects the basic enzyme abnormality, a deficiency of aminoacylase II, which catalyzes the breakdown of NAA (Matalon et al). On CT there is *attenuation of cerebral and cerebellar white matter in an enlarged brain with relatively normal-size ventricles.* The MRI appearance (Fig. 37-3) is that of diffuse, somewhat uneven, high signal intensity on T2-weighted images. A leukodystrophy with behavioral regression, an enlarging head, a characteristic MRI abnormality, and a marked elevation of urinary NAA should leave little doubt about the diagnosis.

The characteristic pathologic changes are an increase in brain volume (and weight), spongy degeneration in the deep layers of the cerebral cortex and subcortical

Figure 37-3. Spongy degeneration of infancy (Canavan-van Bogaert-Bertrand disease). Axial T2-weighted MRI of a 5-week old with hypertonia, nystagmus, and macrocephaly. There is abnormal hyperintensity in the globus pallidus, ventrolateral thalamus, and internal capsule. Abnormal white matter hyperintensity extends to the cortex without sparing of the arcuate fibers. MR spectroscopy (not shown) revealed a markedly elevated *N*-acetyl aspartate peak. (Image courtesy of Drs. Edward Yang and Sanjay Prabhu.)

white matter, widespread depletion of myelin involving the convolutional more than the central white matter, loss of Purkinje cells, and hyperplasia of Alzheimer type II astrocytes throughout the cerebral cortex and basal ganglia. Adachi and coworkers have demonstrated an abnormal vacuolar accumulation of fluid in astrocytes and between split myelin lamellae; they have suggested that the loss of myelin is secondary to these changes.

The enlargement of the brain in this disease must be distinguished clinically from G_{M2} gangliosidosis, Alexander disease, Krabbe disease, and nonprogressive megaloccephaly and pathologically from a variety of disorders characterized by vacuolation of nervous tissue. There is no treatment.

Alexander Disease (GFAP Mutation)

This distinctive disease shares certain features with the leukodystrophies and also with gray matter diseases (poliodystrophies), both clinically and pathologically. The onset is in infancy with a *failure to thrive, psychomotor retardation, spasticity of the craniospinal musculature, and seizures*. An early and *progressive macrocephaly* has been a consistent feature. Alexander was the first to call attention to the enlargement of the brain, the extensive loss of cerebral white matter, and highly characteristic inclusions (the so-called Rosenthal fibers noted below) in astrocytes, and subpial and periventricular regions.

Pathologically, there are severe destructive changes in the cerebral white matter, most intense in the frontal lobes. Distinctive eosinophilic hyaline bodies, most prominent just below the pia and around blood vessels, are seen throughout the cerebral cortex, brainstem, and spinal cord. These have been identified as *Rosenthal fibers* and probably represent glial degradation products.

The astrocytic changes have been traced to a mutation in the glial fibrillary acidic protein (GFAP), as described by Gorospe and colleagues. It is usually inherited in an autosomal dominant pattern, and gives rise to the intermediate filament protein in astrocytes and, presumably, to the Rosenthal fiber inclusions. On the basis of this and related gene mutations, apparent milder forms of Alexander disease have been reported in juveniles and adults. They differed clinically in lacking the cerebral leukoencephalopathy. Instead, after a long period of constipation, sleep disorder, and orthostatic hypotension during adolescence, bulbar symptoms (dysarthria, dysphonia, and dysphagia), seizures, and in some cases ataxia gradually emerged during adult years. The myelin changes and atrophy of the medulla seen in MRI were confirmed by postmortem examination and the Rosenthal fibers; GFAP fibers were present in two autopsied cases.

Alpers Disease (POLG Mutation)

This is a progressive disease of the cerebral gray matter, known also as *progressive cerebral poliodystrophy* or *diffuse cerebral degeneration in infancy*. A familial form (probably autosomal recessive) as well many sporadic cases has been reported. In both groups there is a certain uniformity

of clinical features—loss of smile and disinterest in the surroundings, sweating attacks, *seizures*, and *diffuse myoclonic jerks* beginning in early infancy and followed by incoordination of movements; progressive spasticity of limb, trunk, and cranial muscles; blindness and optic atrophy; growth retardation and *increasing microcephaly*; and finally virtual decortication. In some instances, the late onset of jaundice and fatty degeneration or cirrhosis of the liver have been described (Alpers-Huttenlocher syndrome); the hepatic changes are distinctive and probably not related to the use of anticonvulsant drugs, as had been hypothesized (Harding et al). By the age of 4 years, these patients are hypotonic, anemic, and thrombocytopenic. They also show fragile hair follicles that break at thickened nodes (trichorrhexis nodosa).

The nature of this combined hepatic–cerebral degeneration remains unexplained but some instances have been connected to the mitochondrial disorders, as noted below. EEG abnormalities, progressive atrophy (particularly occipital) on the CT, loss of visual evoked potentials, and abnormal liver function tests are diagnostically useful. Neuropathologic examination shows marked atrophy of the cerebral convolutions and cerebellar cortex, with loss of nerve cells and fibrous gliosis (“walnut brain”). The cerebral white matter and basal ganglia are relatively preserved. In some cases, the spongiform vacuolization of the gray matter of the brain resembles that seen in Creutzfeldt-Jakob disease. Hypoglycemic, hypoxic, and hypotensive encephalopathies must always be considered in the diagnosis but can usually be eliminated by knowledge of the clinical circumstances at the onset of the illness.

A number of biochemical abnormalities have been identified in patients with Alpers disease, including pyruvate dehydrogenase deficiency, decreased pyruvate utilization, dysfunction of the citric acid cycle, and decreased cytochromes *a* and *aa₃*. The biochemical and pathologic changes suggest a relationship to Leigh encephalomyelopathy and a mitochondrial transmission. Many authoritative texts classify it with the mitochondrial diseases, but its nosologic status is in our opinion still uncertain.

Congenital Lactic Acidosis

This uncommon disease of the neonatal period or early infancy has many biochemical etiologies. The symptoms have consisted of *psychomotor regression* and *episodic hyperventilation, hypotonia, and convulsions*, with intervening periods of normalcy. *Choreoathetosis* has been observed in a few cases. Death often occurs before the third year. The important laboratory findings are *acidosis with an anion gap and high serum lactate levels* and hyperalaninemia. Defects can be found in the pyruvate dehydrogenase complex of enzymes and the electron transport chain complexes, which function in the oxidative decarboxylation of pyruvate to acetyl coenzyme A (CoA), relating the disease to defects in the mitochondrial respiratory chain enzymes. Indeed, lactic acidosis is a feature of several of the mitochondriopathies discussed later in this chapter. Cases examined postmortem have

shown necrosis and cavitation of the globus pallidus and cerebral white matter. Possibly this is a variant of Leigh disease. It must be distinguished from the several diseases of infancy that are complicated secondarily by lactic acidosis, especially the organic acidopathies. Cases of benign transient infantile lactic acidosis have been reported, but their etiology is unclear.

Cerebrohepatorenal (Zellweger) Disease and the Peroxisomal Disorders (PEX1 and Other Mutations)

This disease, estimated to occur once in every 100,000 births, is inherited as an autosomal recessive trait. It has its onset in the neonatal period or early infancy and as a rule leads to death within a few months. Motor inactivity and hypotonia, *dysmorphic alterations of the skull and face* (high forehead, shallow orbits, hypertelorism, high arched palate, abnormal helices of ears, retrognathia), poor visual fixation, multifocal seizures, swallowing difficulties, fixed flexion posture of the limbs, cataracts, abnormal retinal pigmentation, optic atrophy, cloudy corneas, hepatomegaly, and hepatic dysfunction are the usual manifestations. *Stippled, irregular calcifications of the patellae and greater trochanters are highly characteristic.* Pathologically, there is dysgenesis of the cerebral cortex and degeneration of white matter as well as a number of visceral abnormalities—cortical renal cysts, hepatic fibrosis, intrahepatic biliary dysgenesis, agenesis of the thymus, and iron storage in the reticuloendothelial system.

As to the biochemical abnormality, Moser and coworkers (1984) demonstrated a fivefold increase of very-long-chain fatty acids, particularly hexacosanoic acid, in the plasma and cultured skin fibroblasts from 35 patients with Zellweger disease. A similar abnormality was found in cultured amniocytes of women at risk of bearing a child with Zellweger disease, thus permitting prenatal diagnosis. The findings of Moser and colleagues (1984) are in keeping with current notions about the basic abnormality in Zellweger syndrome, namely, that it is caused by a lack of liver peroxisomes (oxidase-containing, membrane-bound cytoplasmic organelles), in which the very-long-chain fatty acids are normally oxidized (Goldfischer et al).

Currently, a spectrum of at least 12 disorders of peroxisomal function is recognized, all of them characterized by deficiencies in the peroxisomal enzyme of fatty acid oxidation. The most common form of Zellweger syndrome is due to a mutation in *PEX1*. However, the most widely recognized peroxisomal disorders are adrenoleukodystrophy and Refsum disease, but the Zellweger cerebrohepatorenal syndrome can be considered a prototype. Each variant can be identified by its characteristic profile of elevated long- and very-long-chain fatty acids, and the specific diagnosis can be confirmed by enzymology of cultured fibroblasts or amniocytes. Several of them become manifest at a later age and are discussed further on. For an authoritative discussion of peroxisomal biogenesis, the reader is referred to the article by Gould and Valle.

The Oculocerebrorenal (Lowe) Syndrome (OCRL1 Mutation)

Here the mode of inheritance is probably X-linked recessive, although sporadic cases have been reported in girls. The abnormal gene is located on chromosome Xq25.26. The clinical abnormalities comprise *bilateral cataracts* (which may be present at birth), glaucoma, large eyes with megalocornea and buphthalmos, corneal opacities and blindness, pendular nystagmus, hypotonia and absent or depressed tendon reflexes, corticospinal signs without paralysis, slow movements of the hands, tantrums and aggressive behavior, high-pitched cry, occasional seizures, and psychomotor regression. Later the frontal bones become prominent and the eyes sunken. The characteristic biochemical abnormality is a *renal tubular acidosis*, and death is usually from *renal failure*. Additional laboratory findings include demineralization of bones and typical rachitic deformities, anemia, metabolic acidosis, and generalized aminoaciduria. The neuropathologic changes are nonspecific; inconstant atrophy and poor myelination have been described in the brain and tubular abnormalities in the kidneys. The primary genetic defects are in the gene encoding inositol polyphosphate phosphatase of the Golgi complex. The main diagnostic distinction is from Zellweger disease. Treatment programs include anticonvulsant medication, correction of electrolyte disorders, and removal of cataracts.

Menkes Disease (Kinky- or Steely-Hair Disease; Trichopolydystrophy, ATP7A Mutation)

This rare disorder is inherited as a sex-linked recessive trait. In most of the cases known to us, birth was premature. Poor feeding and failure to gain weight, instability of temperature (mainly *hypothermia*), and seizures become apparent in early infancy. The hair is normal at birth but the secondary growth is lusterless and depigmented and feels like steel wool; hairs break easily and under the microscope they appear twisted (*pili torti*). Radiologic examination shows *metaphysial spurring*, mainly of the femurs, and subperiosteal calcifications of the bone shafts. Arteriography discloses *tortuosity and elongation of the cerebral and systemic arteries* and occlusion of some. The combination of intracerebral hemorrhage and metaphysial bone spurs, which may be interpreted as “corner fractures,” has led in some cases to the erroneous diagnosis of child abuse. There is no discernible neurologic development, and rarely does the untreated child survive beyond the second year. Three of our cases were examined postmortem (Williams et al). There was a diffuse loss of neurons in the relay nuclei of the thalamus, the cerebral cortex, and the cerebellum (granule and stellate cells) and of dendritic arborizations of residual neurons of the motor cortex and Purkinje cells.

The manifestations of this disease are attributable to one of numerous known mutations in a copper-transporting adenosine triphosphatase (ATPase), *ATP7A*,

that is attributed to a *failure of absorption of copper from the gastrointestinal tract* and a profound deficiency of tissue copper (Danks et al). Furthermore, because copper fails to cross the placenta, a severe reduction of copper in the brain and liver is evident from birth. In this sense, the abnormality of copper metabolism is the opposite of that in Wilson disease. A relationship between Wilson and Menkes disease is nonetheless evident at a genetic level as they arise from genes encoding two different copper-transporting proteins that are both ATPases. The situation, however, may be more complex, as samples of intestinal tissue show a buildup of copper that indicates the problem is in mobilization of copper from the gut to the bloodstream. Other copper-dependent enzymes show impaired function, such as cytochrome oxidase. For the purposes of early diagnosis, Kaler and colleagues have taken advantage of the reduced activity of another copper-dependent enzyme, dopamine- β -hydroxylase, to detect increased plasma levels of its substrates (dopamine and dihydroxyphenylacetic acid [DOPAC]), as well as reduced levels of the enzyme products (norepinephrine and dihydroxyphenylglycol [DHPG]). The ratio of dopamine to norepinephrine and dihydroxyphenylacetic acid to dihydroxyphenylglycol proved, in their study, to be the most sensitive and specific for early detection. This has allowed the neonatal identification of cases in families with affected children and resulted in normal neurodevelopment in a few children who were treated with copper beginning in the first weeks of life. This same group has suggested that only those mutations in *ATP7A* that allow for some residual copper transport activity are associated with better outcomes.

Parenteral administration of cupric salts, usually in the form of copper histidine administered subcutaneously twice daily by the parents, restores the serum and hepatic copper and may allow normal development in a few children as noted above but it does not materially influence the neurologic symptoms if treatment is started later. However, even early treated cases showing limited neurodevelopment survive and show some neurologic advance, unlike the past experience in which few survived beyond 5 or 6 years.

Diagnosis of Inherited Metabolic Diseases of Infancy

It will be recognized from the foregoing synopses that many of the neurologic manifestations of the inherited metabolic diseases of infancy are nonspecific and are common to most or all of the diseases in this group. In general, in the early stages of all these diseases, there is a loss of postural tone and a paucity of movement without paralysis or loss of reflexes; later there is spasticity with hyperreflexia and Babinski signs. Equally nonspecific are features such as irritability and prolonged crying; poor feeding, difficulty in swallowing, inanition, and retarded growth; failure of fixation of gaze and following movements of the eyes (often misinterpreted as blindness); and tonic spasms, clonic jerks, and focal and generalized seizures.

The differentiation of the inherited metabolic diseases of infancy rests essentially upon four types of data: (1) a few highly characteristic neurologic and ophthalmic signs; (2) the presence of an enlarged liver and/or spleen; (3) special dysmorphic features of the face; and (4) the results of several relatively simple laboratory tests, such as images of the thoracolumbar spine, hips, and long bones; smears of the peripheral blood and bone marrow; CSF examination; and certain urinary tests and other biochemical estimations (serum lactate, glucose, ammonia, and urinary ketones, amino acids, and organic acids). For purposes of differential diagnosis, we have found the flowcharts constructed by our colleague, E. Kolodny, to be very useful. One such schematic, illustrated in Fig. 37-4, is based on the subdivision of patients into three groups: (1) dysmorphic, (2) visceromegalic, and (3) purely neurologic. Only rarely does an inherited metabolic disease fall into more than one of these categories. There is also considerable value in beginning the diagnostic process by classifying the syndrome as a leukodystrophy or a poliodystrophy (disease predominantly affecting neurons, see further on), although this distinction is easier to make in the older child. Once the major category of disease has been identified, correct diagnosis depends on particular clinical and laboratory features tabulated below (Tables 37-5 and 37-6).

Neurologic signs that are more or less specific for certain metabolic diseases are as follows:

1. Acousticomotor obligatory startle: Tay-Sachs disease
2. Abolished tendon reflexes with definite Babinski signs: globoid cell (Krabbe) leukodystrophy, occasionally Leigh disease, and (beyond infancy) metachromatic leukodystrophy
3. Peculiar eye movements, pendular nystagmus, and head rolling: Pelizaeus-Merzbacher disease, Leigh disease; later, hyperbilirubinemia and Lesch-Nyhan hyperuricemia (see below)
4. Marked rigidity, opisthotonos, and tonic spasms: Krabbe, Alpers disease, or infantile Gaucher disease (classic triad: trismus, strabismus, opisthotonos)
5. Intractable seizures and generalized or multifocal myoclonus: Alpers disease
6. Intermittent hyperventilation: Leigh disease and congenital lactic acidosis (also nonprogressive familial agenesis of vermis)
7. Strabismus, hypotonia, seizures, lipodystrophy: carbohydrate-deficient glycoprotein syndrome

Ocular abnormalities of specific diagnostic value in this age group are as follows:

1. Rapid pendular nystagmus: Pelizaeus-Merzbacher disease, rarely Krabbe leukodystrophy, Cockayne syndrome (later age)
2. Macular cherry-red spots: Tay-Sachs disease and Sandhoff variant, some cases of infantile Niemann-Pick disease, and rarely lipofuscinosis (see Table 37-4)
3. Corneal opacification: Lowe disease, infantile G_{M1} gangliosidosis; later, the mucopolysaccharidoses
4. Cataracts: galactosemia, Lowe disease, Zellweger disease (also congenital rubella)

Figure 37-4. A schematic for diagnosis of the inherited metabolic diseases of infancy. (Courtesy of Dr. Edwin Kolodny.)

Several other medical findings are of specific diagnostic value:

1. Dysmorphic facies: generalized G_{M1} gangliosidosis, Lowe and Zellweger syndromes, and some early cases of mucopolysaccharidosis and mucopolipidosis
2. Enlarged liver and spleen: infantile Gaucher disease and Niemann-Pick disease; one type of hyperammonemia; Sandhoff disease; later, the mucopolysaccharidoses and mucopolipidoses
3. Enlarging head without hydrocephalus (macrocephaly): Canavan spongy degeneration of infancy, some cases of Tay-Sachs disease, Alexander disease
4. Beaking of vertebral bodies in radiographs: G_{M1} gangliosidosis (and, at a more advanced age, the mucopolysaccharidoses, fucosidosis, mannosidosis, and the mucopolipidoses)
5. Multiple arthropathies and raucous dysphonia: Farber disease
6. Storage granules and vacuolated lymphocytes: Niemann-Pick disease, generalized G_{M1} gangliosidosis

7. Abnormal histiocytes in marrow smears: Gaucher cells, foamy histiocytes in Niemann-Pick disease, generalized G_{M1} gangliosidosis and closely related diseases, Farber disease
8. Colorless, friable hair: Menkes disease

INHERITED METABOLIC DISEASES OF EARLY CHILDHOOD

Included here are the diseases that become manifest between the ages of 1 and about 4 years. Diagnosis is less difficult than in the neonate and young infant. A pathologic process in the nervous system is reliably ascertained by the obvious progression of a neurologic disorder, such as a loss of ability to walk and to speak, which usually parallels a regression in other high-level (quasi-intellectual) functions. Embryologic anomalies, prenatal diseases, and birth injuries can be excluded with relative certainty if psychomotor development was normal in the

Table 37-5

DIFFERENTIAL DIAGNOSIS OF POLIODYSTROPHIES OF INFANCY

	TAY-SACHS	NIEMANN-PICK	GAUCHER	ALPERS	SUBACUTE NECROTIZING ENCEPHALOPATHY
<i>Age of onset</i>	4-6 mo	Under 6 mo	Under 6 mo	Under 1 y	Under 1 y, rarely late childhood
<i>Rate of progression</i>	Rapid	Rapid	Very rapid	Rapid	Usually rapid
	Death 2-3 y	Death before 3 y	Death before 2 y	Death before 3 y	Death before 3 y
<i>Ethnic group</i>	Almost all Jewish	50% Jewish			
<i>Genetic</i>	Recessive	Recessive	Recessive		Recessive
<i>Head size</i>	Enlarges late	Normal	Normal	Reduces late	Normal
<i>Skin and/or systemic lesions</i>	Normal	Hepatosplenomegaly xanthoma of skin, rare	Hepatosplenomegaly	Normal	Normal
<i>Eye</i>	Cherry-red macula Optic atrophy	Cherry-red macula Optic atrophy	Normal	Normal	Optic atrophy
<i>Seizures</i>	Frequent, but late	Rare	Rare	Onset with seizures Myoclonus and other types	Seizures late and rare
<i>Neurologic signs</i>	Early: flaccid paresis	Spastic paralysis	Early: retroflexion of head, dementia	Spastic paralysis	Bulbar palsy
	Late: spastic paralysis	Early: dementia	Strabismus	Dementia	Weak, infrequent cry
	Dementia: early hyperacusis with myoclonus		Bulbar palsy	Cortical blindness and deafness	Flaccid paresis with immobility
<i>Blood</i>	Absent fructose 1-phosphate-aldolase	↑Serum lipids	↑Total acid phosphatase (prostatic acid phosphatase is normal)	Normal	Normal
	↑SGOT	↑SGOT ↑Vacuolated lymphocytes	Spastic paralysis		
	↑Vacuolated lymphocytes				
<i>Urine</i>	Normal	Normal	Normal	Normal	Normal
<i>CSF</i>	Normal	Normal		Normal	Normal
<i>Biopsy</i>	Rectal	"Foam cells" in bone marrow	Gaucher cells in bone marrow		
<i>X-ray</i>		Diffuse pulmonary infiltrates Demineralization of bone			

Electroretinogram: normal.
Diagnostic biochemical abnormality: see text.

first year or two. Diseases characterized by seizures and myoclonus may prove more difficult to interpret, for the seizures may occur at any age from a variety of distant or immediate neurologic causes and, if frequent, may cause a significant impairment of psychomotor function. The effects of anticonvulsant medications may add to the impairment of cortical function. Unfortunately, most of the slowly advancing metabolic diseases of the second

year may be so subtle in their effects that for a time the physician cannot be sure whether a regression of intellectual functions is taking place or mental retardation or autism is becoming apparent for the first time. An added difficulty arises when, for a number of years, the hereditary metabolic abnormality merely slows development. Repeated examinations and testing will usually settle the matter. Suspicion of a progressive encephalopathy is

heightened by the presence of certain ocular, visceral, and skeletal abnormalities, as described below.

Once a neurologic syndrome is clearly established, there is a particular advantage in determining whether its main characteristics reflect a disorder of the cerebral

white matter (oligodendrocytes and myelin) or of gray matter (neurons). Indicative of predominantly white matter affection (*leukodystrophy* or leukoencephalopathy) are early onset of spastic paralysis of the limbs, with or without ataxia, and visual impairment with optic atrophy but

normal retinae. Seizures and intellectual deterioration are late events. MRI usually confirms the involvement of white matter. Indicative of gray matter disease (*poliodystrophy* or *polioencephalopathy*) are the early onset of seizures, myoclonus, blindness with retinal changes, and mental regression. Choreoathetosis and ataxia, spastic paralysis, and signs of sensorimotor tract involvement occur later. On MRI, only a generalized atrophy and ventricular enlargement may be seen.

Neuronal storage diseases, such as those described in the previous section, as well as neuroaxonal dystrophy and the lipofuscinoses, conform to the pattern of gray matter diseases (see Table 37-5). Metachromatic leukodystrophy, globoid-cell (Krabbe) disease, sudanophilic leukodystrophy, and spongy degeneration of infancy (Canavan disease) exemplify white matter diseases (see Table 37-6). Although this mode of categorization is helpful, there is some degree of overlap; for example, Tay-Sachs disease, a poliodystrophy, also causes white matter changes, and metachromatic leukodystrophy may be accompanied by some degree of neuronal storage.

The following are inherited metabolic diseases that become evident clinically in late infancy and early childhood:

1. Many of the milder disorders of amino acid metabolism
2. Metachromatic and other leukodystrophies
3. Late infantile G_{M1} gangliosidosis
4. Late infantile Gaucher disease and Niemann-Pick disease
5. Neuroaxonal dystrophy
6. The mucopolysaccharidoses
7. The mucopolidoses
8. Fucosidosis
9. The mannosidoses
10. Aspartylglycosaminuria
11. Ceroid lipofuscinosis (Jansky-Bielschowsky disease)
12. Cockayne syndrome

The Aminoacidopathies (Aminoacidurias)

In a group of 48 inherited aminoacidopathies tabulated by Rosenberg and Scriver, at least one-half were associated with recognizable neurologic abnormalities. Twenty other aminoacidopathies result in a defect in the renal transport of amino acids, some of which secondarily damage the nervous system. Usually, when the nervous system is involved, the only clinical manifestation is simply a lag in psychomotor development, which, if mild, does not become apparent until the second and third years or later. Like other inherited metabolic disorders, the aminoacidurias do not impair growth, development, or maturation in utero or interfere with parturition. (This is the result of the maternal blood supply, which defines the amino acid balance in utero.) No physical sign betrays their presence in the early months of life. The only possible means of detection is by the screening of all newborns. Table 37-1 indicates the relative frequency of these diseases and Table 37-2 summarizes the practical tests for their identification.

Three aminoacidopathies of the late infantile and early childhood period—PKU, tyrosinemia, and Hartnup

disease—are described here because of their clinical importance and because they exemplify different types of biochemical defects. Reference is also made to certain other aminoacidurias, described in the first part of this chapter, which, like Hartnup disease, are associated with intermittent ataxia. Only passing comments are made about the other aminoacidurias, which are exceedingly rare or have only an uncertain effect on the nervous system. A detailed account of these disorders can be found in the monograph of Scriver and coworkers.

The Phenylketonurias (Phenylalanine Hydroxylase Deficiency)

Apart from being the most frequent of the aminoacidurias, this entity has a special historical significance. Since its discovery by Følling in 1934, it has remained the classic example of an aminoaciduria and illustrates three principles of medical genetics: first, it is inherited as an autosomal recessive trait; second, it exemplifies Garrod's cardinal principle of gene action, in which genetic factors specify chemical reactions as well as biochemical individuality; third, PKU is expressed only in an environment that contains an abundance of L-phenylalanine. Thus, as predicted by Galton, the ultimate phenotype is a product of "nature and nurture" (Scriver and Clow).

One must refer to the phenylketonurias in the plural, for there are (1) the usual type and several mild and severe variants thereof, in all of which mental retardation is invariable if the disease is not treated early in life; (2) other types, presumably allelic mutations, in which there is hyperphenylalaninemia without PKU and without effect on the nervous system; and (3) a rare adult type with a progressive spastic paraparesis or without neurologic manifestations. Also there are a small number of patients (3 percent in our series) in whom a lowering of the hyperphenylalaninemia does not prevent the progression of the neurologic lesion.

At birth, the typical PKU infant is believed to have a normal nervous system. The disease appears later, only after long exposure of the nervous system to phenylalanine (PA), because the homozygous infant lacks the means of protecting the nervous system. However, if the mother is homozygous with high PA levels in the blood during pregnancy, the CNS is damaged in utero and the heterozygous infant is mentally defective from birth.

In the classic form of PKU, the *impairment of psychomotor development* can usually be recognized in the latter part of the first year, when expected performance lags. By 5 to 6 years in an untreated child, when the IQ can be estimated, it is usually less than 20, occasionally 20 to 50, and exceptionally above 50. *Hyperactivity*, aggressivity, self-injurious behavior—including severe injury to the eyes, clumsy gait, fine tremor of the hands, poor coordination, odd posturings, *repetitious digital mannerisms* and other so-called rhythmicias, and slight corticospinal tract signs stand out as the main clinical manifestations. Athetosis, dystonia, and frank cerebellar ataxia have been described but must be rare. Also, seizures occur in a small minority of severely affected patients, taking the form at first of flexor spasms and later of absence and grand mal attacks.

The majority of PKU patients are blue-eyed and fair in skin and hair color, and their skin is rough and dry and subject to eczema. A musty body odor (because of phenylacetic acid excretion) can often be detected. Two-thirds are slightly microcephalic. The fundi are normal, and there is no visceral enlargement or skeletal abnormality.

There are some people living in the community with asymptomatic PKU and normal intelligence. Instances of PKU in which the symptoms are of adult onset are rare but of interest because of the entirely unexpected diagnosis. The few such cases reported and summarized by Kasim and colleagues, with a case of their own, developed a progressive spastic paraparesis, some with mild dementia. The phenylalanine levels were at values that reflect total or partial enzyme deficiency.

The finding of *high levels of serum phenylalanine* (above 15 mg/dL) and of *phenylpyruvic acid in the blood, CSF, and urine* is diagnostic of PKU. The level is normal at birth and rises only after the first few days. But screening by the Guthrie (ferric chloride) test will reliably identify the patient at risk. The addition of 3 to 5 drops of 10 percent ferric chloride to 1 mL of urine is a simple and informative test. It yields an emerald-green color that reaches peak intensity in 3 to 4 min and fades in 20 to 40 min. In contrast, the green-brown color in the urine of patients with histidinemia is permanent. In maple syrup urine disease, the ferric chloride test gives a navy-blue color; propionic and methylmalonic acidemia and either ketones or salicylates in the urine yield a purple color.

The fundamental biochemical abnormality is a deficiency of the hepatic enzyme PA hydroxylase; the failure of conversion of PA to tyrosine results in the excretion of phenylpyruvic acid by affected individuals. The precise step that is faulty in the complex phenylalanine hydroxylating reaction is still unknown.

Pathologic examination shows poor staining of myelin in the cerebral hemispheres. This can be visualized by MRI in untreated children. Another instructive feature is that the pigmented nuclei (substantia nigra, locus ceruleus, dorsal vagal motor) fail to acquire dark coloration because of a block in the production of neuromelanin. Reduction in size of cortical neurons and their dendritic arborizations is said to be demonstrable in some cases.

Treatment If instituted in infancy, diets low but not totally lacking in PA can improve intellectual development (blood level should be maintained at 5 to 10 mg/dL). Careful dietary management may result in completely normal intellectual development. Once the neurologic picture unfolds, diet has little or no effect on the mental status but may improve behavior. Prolonged dietary treatment has many untoward effects and should be supervised by physicians and nutritionists experienced in its use; if too restricted, it may retard growth. This is particularly important, as it has been shown that intellectual impairment is greatest among children who were the earliest to abandon their diets, permitting the PA concentration to rise above 15 mg/dL, and least in children who maintained dietary control the longest (Holtzman et al). Continued dietary treatment is probably necessary, but the degree of restriction of PA may be relaxed once the nervous system is fully developed. The precise degree of allowed restriction of

dietary PA restriction is not known but many children, having been raised on a low PA diet, will have little or no difficulty in maintaining the restrictions into adulthood.

With the widespread screening for PKU and the initiation of dietary control during early postnatal life, this metabolic brain disease has virtually disappeared in the New England states. Treated women who reach childbearing age should be particularly careful about dietary restriction, because high levels of phenylalanine are harmful to the normal fetus. Mild cases of PKU have been successfully treated with the cofactor tetrahydrobiopterin (Muntau et al).

The late forms of maple syrup urine disease, and hydroxyprolinemia evolve in much the same fashion as PKU and raise similar problems in diagnosis and therapy. Histidinemia can be detected by screening but is now considered a benign biochemical variant.

A small number of infants have a variant of PKU in which a restricted PA diet does not prevent neurologic involvement. In some such infants, a dystonic extrapyramidal rigidity ("stiff-baby syndrome") has appeared as early as the neonatal period, and, according to Allen and coworkers, it responds to biopterin. Such infants have normal levels of PA hydroxylase in the liver. The defect is a failure to synthesize the active cofactor tetrahydrobiopterin, because of either an insufficiency of dihydropyridine reductase or an inability to synthesize biopterin (see "Biopterin Deficiency"). The urinary metabolites of catecholamines and serotonin are reduced and are not responsive to low-PA diets. There is some evidence that the underlying neurotransmitter fault can be corrected by L-dopa and by 5-hydroxytryptophan (Scriver and Clow).

Hereditary Tyrosinemia (Oculocutaneous Tyrosinemia; Richner-Hanhart Disease)

This is a rare, predominantly dermatologic aminoacidopathy, but in approximately one-half of the infants there is a mild to moderate degree of mental retardation. Also, as in some other aminoacidopathies, there may be self-mutilation and incoordination of limb movements. Language defects are prominent. Toward the end of the first or second year of life, lacrimation, photophobia, and redness of the eyes (because of corneal erosions) appear. Neovascularization of the corneas and opacification follow. Palmar and plantar keratosis with hyperhidrosis and pain are frequently present as a result of an inflammatory reaction to deposits of crystalline tyrosine (also the cause of the corneal changes). Elevated tyrosine in the blood (>0.18 mM) and urine is diagnostic. The most severe form (type 1) is caused by a mutation in the gene (*FAH*) that codes for fumarylacetoacetate hydrolase, the final enzymatic step in tyrosine metabolism, a deficiency of which results in the accumulation of tyrosine and its metabolites.

A low-tyrosine and low-PA diet, optimized to allow growth and development, has resulted in rapid amelioration of symptoms but must be started early. Retinoids given orally improve the skin lesions. Neonatal tyrosinemia can cause liver failure and early death. This disease can be distinguished from the Cross syndrome (albinism with mental retardation, growth impairment, spastic weakness, and alkalosis) and from the Waardenburg ocular albinism syndrome (white forelock, hypertelorism,

deafness). For a detailed discussion of the albinism syndromes, see the article by Oetting and King.

Tyrosine Hydroxylase Deficiency (TH Mutation)

This disease causes a progressive infantile encephalopathy; it is of special interest because tyrosine is the precursor of L-dopa and the other catecholamines. Levels of these chemical substances in the brain are greatly reduced. As a result, the encephalopathy takes the form mainly of fluctuating extrapyramidal signs in combination with ocular and vegetative symptoms. L-Dopa causes some improvement in the motor symptoms (see Hoffmann et al). This disease has similarities to juvenile dopa-responsive dystonia, which is exquisitely sensitive to L-dopa treatment (as discussed in Chap. 39) and to the deficiency of L-amino decarboxylase, described above, which also causes low levels of catecholamines and a movement disorder.

Hartnup Disease (SLC6A19 Mutation)

This amino acid disorder, named after the family in which it was first observed, is probably transmitted in an autosomal recessive pattern. The babies are normal at birth. The onset of symptoms is in late infancy or early childhood. The clinical features consist of an *intermittent red, scaly rash over the face, neck, hands, and legs*, resembling that of pellagra. It is often combined with an episodic personality disorder in the form of *emotional lability*, uncontrolled temper, and confusional-hallucinatory psychosis; *episodic cerebellar ataxia* (unsteady gait, intention tremor, and dysarthria); and, occasionally, spasticity, vertigo, nystagmus, ptosis, and diplopia. Attacks of disease are triggered by exposure to sunlight, emotional stress, and sulfonamide drugs and last for about 2 weeks, followed by variable periods of relative normalcy. The frequency of attacks diminishes with maturation, but some children suffer retarded growth and development with a mild persistent mental retardation.

The metabolic faults are the result of a transport error of neutral amino acids across renal tubules, with excretion of greatly increased amounts of these amino acids in the urine and feces. In particular, there is the excretion of large amounts of indicans, mainly indoxyl sulfate, particularly after oral L-tryptophan loading, and an abnormally high excretion of nonhydroxylated indole metabolites. Impaired intestinal transport of tryptophan and loss in the urine reduce its availability for the synthesis of niacin and accounts for the pellagrous skin changes. The pathologic basis of the disease is undetermined. It must be differentiated from the large number of intermittent and progressive cerebellar ataxias of childhood, described below.

Treatment consists of avoiding exposure to sunlight and to sulfonamide drugs. Because of the similarities between pellagra and Hartnup disease, the usual practice is to give nicotinamide in doses of 50 to 300 mg daily. The skin lesions disappear and there are reports of subsidence of ataxia and psychotic behavior. However, the results of treatment are inconsistent. Possibly a better response is obtained by the administration of L-tryptophan ethyl ester in doses of 20 mg/kg tid.

Other Metabolic Diseases With Episodic or Persistent Ataxia, Seizures, and Mental Retardation

In addition to Hartnup disease, a number of other metabolic diseases give rise to intermittent episodes of ataxia during early childhood. These are (1) mild forms of maple syrup urine disease and the congenital hyperammonemias (type II hyperammonemia, citrullinemia, argininosuccinic aciduria, hyperornithinemia), described in an earlier part of the chapter; (2) subacute necrotizing encephalomyelopathy (Leigh disease), described further on; (3) hyperalaninemia and hyperpyruvic acidemia (Lonsdale et al; Blass et al); and (4) autosomal dominant, acetazolamide-responsive ataxia that may have its onset in childhood but usually appears later; and (5) familial hypobetalipoproteinemia—Bassen-Kornzweig disease.

In all of these conditions, the ataxia, which is of cerebellar type, is variable from time to time and may follow a burst of seizures (such as occur in argininosuccinic aciduria). The seizures are treated with antiepileptic drugs, which may at first be held responsible for the ataxia. In time, however, it becomes apparent that the ataxia lasts a week or two and bears no relation to the anticonvulsant therapy. Indeed, seizures and ataxia are both a result of the common biochemical abnormality. Between attacks, in all the intermittent ataxias, the patient's movements are relatively normal, but most of the affected children have learning disabilities to a varying degree.

Progressive Cerebellar Ataxia of Early Childhood

The differentiation among the childhood ataxias is difficult. The problem is twofold—first, to be certain that ataxia exists and, second, to differentiate cerebellar ataxia from the sensory ataxia of peripheral nerve disease and from generalized tremor and polymyoclonus. Because cerebellar ataxia is more a disorder of voluntary than of postural movements, its presence usually cannot be determined with certainty until intentional (projected) movements become part of the child's repertoire of motor activity. As indicated in Chap. 28, the earliest signs become manifest in the arms when the infant reaches for an object and brings it to his mouth or transfers it from hand to hand. A jerky, wavering, tremulous movement then appears; in sitting, titubation of the head and a tremor of the trunk may be apparent. Once walking begins, apart from the usual clumsiness of the toddler, there is a similar incoordination of movement. Sensory ataxia is always difficult to distinguish but is rare at this age and usually accompanied by weakness and absence of tendon reflexes. By the fourth or fifth year, when more detailed sensory testing becomes possible, the presence or absence of a proprioceptive disturbance and a Romberg sign can be demonstrated.

The group of persistent and progressive cerebellar ataxias is heterogeneous and of varied etiology; some of them merge with Friedreich ataxia, Levy-Roussy neuropathy, and other adolescent–adult degenerative hereditary ataxias. These disorders are discussed in Chap. 39. There are many other childhood ataxias that probably belong

in the category of degenerative disease, some in which cerebellar ataxia is the most prominent disorder and in which other neurologic abnormalities are more prominent. To describe each in detail would be impractical in a book on the principles of neurology; consequently, the non-Friedreich ataxias are only tabulated here.

1. Cerebellar ataxia with diplegia, hypotonia, and mental retardation (also called *atonic diplegia* of Foerster); this is a form of cerebral palsy.
2. Agenesis of the cerebellum: early cerebellar ataxia (with or without mental retardation) and episodic hyperventilation; this group included the selective agenesis of the vermis—Joubert syndrome.
3. Cerebellar ataxia with cataracts and oligophrenia: onset from childhood (mainly) to as late as adult years (Marinesco-Sjögren disease).
4. Familial cerebellar ataxia and retinal degeneration (Behr disease).
5. Familial cerebellar ataxia with cataracts and ophthalmoplegia or with cataracts and mental as well as physical retardation.
6. Familial cerebellar ataxia with mydriasis.
7. Familial cerebellar ataxia with deafness and blindness and a similar combination, called retinocochleodentate degeneration, involving the loss of neurons in these three structures.
8. Familial cerebellar ataxia with choreoathetosis, corticospinal tract signs, and mental and motor retardation.

In none of the syndromes mentioned above has a biochemical abnormality been established, so their metabolic nature is a matter of speculation. However, disorders of the electron transport chain can, on occasion, present as the Marinesco-Sjögren phenotype, mentioned above.

The persistent cerebellar ataxias of childhood in which a metabolic fault or gene defect has been demonstrated are as follows:

1. Refsum disease
2. Abetalipoproteinemia (Bassen-Kornzweig syndrome)
3. Ataxia-telangiectasia (See Chap. 38)
4. Galactosemia
5. Friedreich ataxia

Bassen-Kornzweig syndrome (onset more often in late than in early childhood) is described in the following section of this chapter. Ataxia-telangiectasia is described below.

Generally, it is not difficult to differentiate these diseases from the acquired postinfectious variety that occurs predominantly in children (see Chap. 36).

Metachromatic Leukodystrophy (MLD, Arylsulfatase Deficiency)

This is another of the lysosomal (sphingolipid) storage diseases (see Tables 37-3 and 37-6). The abnormality is the mutation of the gene for enzyme arylsulfatase A, which prevents the conversion of sulfatide to cerebroside (a major component of myelin) and results in an accumulation of the former. The disease is transmitted as an

autosomal recessive trait and usually becomes manifest between the first and fourth years of life (variants have their onset in the congenital period, in late childhood, and even in adult life). Variability of gene mutation accounts for the different forms. The so-called O-type mutation causes a lack of active gene product and of the corresponding enzyme; the R-type mutation results in low levels. The infantile form is associated with two copies of the O gene, the juvenile form, with either O or R, and the adult form is usually from two copies of R. Another genetic classification system denominates I and A alleles and differentiates the types of diseases by age of onset and residual enzyme activity.

The disease in this age group is characterized clinically by progressive impairment of motor function (gait disorder, spasticity) in combination with reduced output of speech and mental regression. At first the tendon reflexes are usually brisk, but later, as the peripheral nerves become more involved, the tendon reflexes are decreased and eventually lost. Or, there may be variable hypotonia and areflexia from the beginning, or spasticity may be present throughout the illness, but with hyporeflexia and slowed conduction velocities. Signs of mental regression may be apparent from the onset or appear after the motor disorder has become established. Later there is impairment of vision, sometimes with squint and nystagmus; intention tremor in the arms and dysarthria; dysphagia and drooling; and optic atrophy (one-third of patients), sometimes with *grayish degeneration around the maculae*. Seizures are rare, and there are no somatic abnormalities. The head size is usually normal, but rarely there is macrocephaly. Progression to a bedridden quadriplegic state without speech or comprehension occurs over a 1- to 3-year period, somewhat more slowly in late-onset types. The CSF protein is elevated.

There is widespread degeneration of myelinated fibers in the cerebrum (Fig. 37-5), cerebellum, spinal cord, and peripheral nerves. The presence of metachromatic granules in glia cells and engorged macrophages is characteristic and enables the diagnosis to be made from a biopsy of a peripheral nerve. The stored material, *sulfatide*, stains brown-orange rather than purple with aniline dyes. Sulfatides are also PAS-positive in frozen sections.

The diagnostic laboratory findings, in addition to the MRI and histologic changes, are the *elevated CSF protein* (75 to 250 mg/dL) and a *marked increase in sulfatide in urine* and an *absence of arylsulfatase A* in white blood cells, in serum, and in cultured fibroblasts. Assays of arylsulfatase A activity in cultured fibroblasts and amniocytes permit the identification of carriers and prenatal diagnosis of the disease but a pseudodeficiency of the enzyme is known (the *Pd* allelic variant). In this condition, measured enzyme activity is 10 percent of normal, but no clinical manifestations result.

Treatment with enzyme replacement or bone marrow transplantation is being tried. Marrow transplant appears to be of less benefit once the patient becomes symptomatic, but it may be useful early in the disease and in the treatment of an asymptomatic sibling of an index case.

The differential diagnosis of this leukodystrophy includes neuroaxonal dystrophy (see below), cases of early-onset inherited polyneuropathy, late-onset Krabbe

Figure 37-5. Metachromatic leukodystrophy. Axial T2-weighted MRI of a 2-year-old girl with developmental regression and EMG evidence of diffuse motor and sensory demyelination. There is abnormal symmetric central white matter hyperintensity with sparing of the subcortical arcuate fibers. (Image courtesy of Drs. Edward Yang and Sanjay Prabhu.)

disease, and childhood forms of Gaucher disease and Niemann-Pick disease. A *variant of metachromatic leukoencephalopathy*, caused by a deficiency of the isoenzymes of arylsulfatase A, B, and C, was described by Austin in 1973 and called *multiple sulfatase deficiency*. The neurologic manifestations resemble those of metachromatic leukodystrophy but, in addition, there are facial and skeletal changes similar to those of a mucopolysaccharidosis. Deafness, hepatic enlargement, ichthyosis, and beaking of lumbar vertebrae are additional findings in some cases. Metachromatic material is found in the urinary sediment. Pathologically, in addition to metachromasia of degenerating white matter in cerebrum and peripheral nerve, there may be storage material (sulfated glycolipids), like that found in the gangliosidoses in neurons as well as in liver, gallbladder, and kidney. Granules are demonstrable in neutrophilic leukocytes. There has also been described a state of “arylsulfatase pseudodeficiency,” which exists as a polymorphism in approximately 7 percent of Europeans and makes the point that low enzyme levels alone are insufficient to be expressed as a phenotype of metachromatic leukodystrophy.

Forms of metachromatic leukodystrophy developing in adult years are discussed further on.

Neuroaxonal Dystrophy (Degeneration; PLA2G6 Mutation)

This is a rare disease, inherited as an autosomal recessive trait. In the largest group of cases (77 collected by Aicardi and Castelein), the onset was near the beginning of the second year in 50 patients and before the third year in

all instances. The clinical constellation comprised psychomotor deterioration (loss of ability to sit, stand, and speak), marked hypotonia but brisk reflexes and Babinski signs, and progressive blindness with optic atrophy but normal retinae. Seizures, myoclonus, and extrapyramidal signs were rare. Loss of sensation was found later in some cases. Terminally, bulbar signs, spasticity, and decerebrate rigidity often supervened. The course was relentlessly progressive, with fatal issue in a decorticate state in 3 to 8 years. There were no abnormalities of the liver and spleen and no facial or skeletal changes.

Pathologic examination reveals eosinophilic spheroids of swollen axoplasm in the posterior columns and nuclei of Goll and Burdach and in the Clarke column, substantia nigra, subthalamic nuclei, central nuclei of brainstem, and cerebral cortex. There is cerebellar atrophy, affecting the granule cell layer predominantly, and increased iron-containing pigment in the basal ganglia (like that observed in the PANK mutation type of iron deposition discussed in a later section).

The CT and CSF are normal, and there are no biochemical or blood cell abnormalities. MRI may show decreased signal intensity of the pallidum bilaterally corresponding to iron deposition. Some reports are confusing in reporting an area of necrosis around a high signal that is characteristic of the aforementioned PANK mutation, with which it has overlapping clinical and pathologic features. After the age of 2 years, however, the EEG shows characteristic high-amplitude fast rhythms (16 to 22 Hz). Evoked responses may be abnormal. Nerve conduction velocities are normal despite EMG evidence of denervation. The diagnosis can be reliably established during life by electron microscopic examination of skin and conjunctival nerves, which show the characteristic spheroids within axons.

There is a later-onset form of the disease in which the course is more protracted and the neurologic manifestations (rigidity and spasticity, cerebellar ataxia, and myoclonus) are more pronounced. In these cases the mental regression is slow. Vision may be retained but retinal degeneration has been documented. Some of the late-onset cases are indistinguishable from Hallervorden-Spatz disease.

In early infantile forms there is a mutation in a lysosomal hydrolase. The primary mutation in the infantile form is in the *PLA2G6* gene.

Late Infantile and Early Childhood Gaucher Disease

As stated earlier, Gaucher disease usually develops in early infancy, but some cases, so-called Gaucher disease type III, may begin in childhood, between 3 and 8 years of age. The clinical picture is variable and combines features of infantile Gaucher disease—such as abducens palsies, dysphagia, trismus, rigidity of the limbs, and dementia—with features of the late childhood–early adult form, such as palsies of horizontal gaze, diffuse myoclonus, generalized seizures, and a chronic course. The diagnosis is established by the finding of splenomegaly, Gaucher cells, glucocerebroside storage, and deficient activity of glucocerebrosidase in leukocytes or cultured fibroblasts.

Late Infantile–Early Childhood Niemann-Pick Disease

Niemann-Pick disease is a subacute or chronic neurovisceral storage disease with early signs of hepatosplenomegaly and later signs (2 to 4 years) of neurologic involvement. These later-onset types have been termed C and D, and formerly, III and IV, to differentiate them from infantile forms discussed earlier. The neurologic disorder consists of progressive dementia, dysarthria, ataxia, rarely extrapyramidal signs (choreoathetosis), and *paralysis of horizontal and vertical gaze*, the latter being a distinguishing feature of the later-onset types. On attempting to look to the side, some of the patients make head-thrusting movements of the same type that one observes in ataxia-telangiectasia and the oculomotor apraxia of Cogan. Lateral eye movements are full on passive movement of the head (oculocephalic maneuver). Convergence is also deficient. A subtype called *juvenile dystonic lipidosis* is characterized by extrapyramidal symptoms and paralysis of vertical eye movements. The syndrome of the “sea-blue histiocyte” (liver, spleen, and bone marrow contain histiocytes with sea-blue granules)—in which there is retardation in mental and motor development, grayish macular degeneration, and, in rare cases, posterior column and pyramidal degeneration—may be another variant.

The diagnosis is made by bone marrow biopsy, which discloses vacuolated macrophages and sea-blue histiocytes, and by measuring the defect in cholesterol esterification in cultured fibroblasts.

Late Infantile–Childhood G_{M1} Gangliosidosis (GLB1 Mutation)

In type 2 or so-called juvenile G_{M1} gangliosidosis, the onset is between 12 and 24 months, with survival for 3 to 10 years. The first sign is usually *difficulty in walking*, with frequent falls, followed by awkwardness of arm movements, loss of speech, severe mental regression, gradual development of spastic quadriparesis and pseudobulbar palsy (dysarthria, dysphagia, drooling), and seizures. Retinal changes are variable—usually they are absent—but macular red spots may be seen at the age of 10 to 12 years; vision is usually retained, but squints (comitant) are common. There is a facial dysmorphism resembling that of the Hurler syndrome, and the liver and spleen are enlarged. Important laboratory findings are hypoplasia of the thoracolumbar vertebral bodies, mild hypoplasia of the acetabula, and the presence in the bone marrow of histiocytes with clear vacuoles or wrinkled cytoplasm. As noted in the discussion of Tay-Sachs disease, leukocytes and cultured skin fibroblasts show a *deficiency* or absence of *beta-galactosidase* activity. G_{M1} ganglioside accumulates in the cerebral neurons.

The Neuronal Ceroid Lipofuscinoses (Batten Disease)

Four types of lipofuscinoses have been identified, defined largely by the age of onset: Santavuori-Haltia Finnish infantile type, Jansky-Bielschowsky early childhood type,

Vogt-Spielmeyer juvenile type, and Kufs adult type. All except a few adult cases are autosomal recessive. The storage material in neuronal cytoplasm consists of two pigmented lipids, presumably ceroid and lipofuscin, which are cross-linked polymers of polyunsaturated fatty acids and have the property of autofluorescence. At least 20 gene loci are implicated in the ceroid lipofuscinoses, for most of which the mutation has been identified. All the infantile forms and one of the juvenile forms of the disease are due to mutations affecting the lysosomal enzyme palmitoyl-protein thioesterase. Other lysosomal enzymes are abnormal in the remaining juvenile and in the adult forms.

In the *Santavuori-Haltia form* of the disease, infants from 3 to 18 months of age, after a normal period of development, undergo psychomotor regression with ataxia, hypotonia, and *widespread myoclonus*. There are retinal changes with extinction of the electroretinogram, slowing of the EEG with spike and slow-wave discharges, and eventually an isoelectric record. Within a few years these patients become blind, develop spastic quadriplegia and microcephaly, and succumb.

In the *Jansky-Bielschowsky type*, the onset of symptoms is between 2 and 4 years, after normal or slightly slow earlier development, with survival to 4 to 8 years of age. Usually the first neurologic manifestations are seizures (petit mal or grand mal) and *myoclonic jerks* evoked by proprioceptive and other sensory stimuli, including voluntary movement and emotional excitement. Incoordination, tremor, ataxia, and spastic weakness with lively tendon reflexes and Babinski signs, deterioration of mental faculties, and dysarthria proceed to dementia and eventually to mutism. In patients with relatively late onset, a progressive dementia is the cardinal manifestation. Visual failure may occur early in some cases because of *retinal degeneration* (of rods and cones) with pigmentary deposits, but in others vision is normal. The electroretinogram becomes isoelectric if vision is affected. Abnormal inclusions (translucent vacuoles) are seen in 10 to 30 percent of circulating lymphocytes, and azurophilic granules in neutrophils. High-voltage EEG spikes are induced by photic stimuli. Only in early-onset cases is there microcephaly.

Pathologic examination shows neuronal loss in the cerebral and cerebellar cortices (granule and Purkinje cells), and curvilinear storage particles and osmophilic granules are visible in the remaining neurons. Inclusions are also observed in cutaneous nerve twigs and endothelial cells of blood vessels, findings that permit diagnosis during life by electron microscopy of skin, conjunctival, or rectal mucosal biopsies.

In many patients with lipofuscinoses, *diagnosis* can be confirmed by demonstrating the presence of one of several recently identified gene mutations. There are no definite markers for the group in blood or urine, but in some patients a structural component of mitochondria is excreted in excess (the so-called C-fragment).

In the differential diagnosis, one must consider late infantile G_{M1} gangliosidosis, idiopathic epilepsy, Alpers disease, and other forms of neuronal ceroid-lipofuscinosis.

The lipofuscinoses of later onset—the Vogt-Spielmeyer (juvenile) type and the Kufs (adult) type—are

discussed further on. There is no treatment for the basic disease process but approaches involving gene therapy are being explored.

Mucopolysaccharidoses (Table 37-7)

This is a group of diseases in which the storage of lipid in neurons is combined with that of polysaccharides in connective tissues. As a consequence there is a conjunction of neurologic and skeletal abnormalities that is virtually unique. The nervous system may also be involved secondarily as a result of skeletal deformities and thickening and hyperplasia of connective tissue at the base of the brain, leading to obliteration of the subarachnoid space and obstructive hydrocephalus or compression of the cervical cord. The prevalence of mucopolysaccharides as a whole is approximately 1 per 8,000 births, according to Meikle and colleagues. Depending on the degree of visceral-skeletal and neurologic changes, at least 7 distinct clinical subtypes are recognized (see Table 37-7).

The basic abnormality is an enzymatic defect that prevents the degradation of acid mucopolysaccharides (now called *glycosaminoglycans*). The latter can be measured and are increased in serum, leukocytes, or cultured fibroblasts. The storage is, again, within lysosomes in the brain, spinal cord, heart, viscera, bone, and connective tissue. All forms of the disease except the Hunter syndrome, which is sex-linked, are inherited in an autosomal recessive pattern. The studies of Neufeld and Muenzer indicate that each type of mucopolysaccharidosis is caused by a defect in a different enzyme.

Hurler Disease (MPS I, IDUA Mutation)

This, the classic form, also known as MPS I, begins clinically toward the end of the first year. *Mental retardation* is severe, and *skeletal abnormalities* are prominent (dwarfism;

gargoyle facies; large head with synostosis of longitudinal suture; kyphosis; broad hands with short, stubby fingers; flexion contractures at knees and elbows). Conductive deafness and corticospinal signs are usually present. Protuberant abdomen, hernias, *enlarged liver and spleen*, valvular heart disease, chronic rhinitis, recurrent respiratory infections, and *corneal opacities* complete the picture. The biochemical abnormalities consist of the accumulation of *dermatan* and *heparan sulfate* (glycosaminoglycans) in the tissues and their *excretion in the urine*, probably as a consequence of absence of activity of α -L-iduronidase. Also, there is an increase in the ganglioside content in nerve cells of the brains of these patients. In the milder Scheie (MPS V) variant of Hurler disease, intelligence and life span are normal.

Treatment Enzyme replacement therapy (aronidase) is now available. The enzymes are produced with recombinant technology and are successful where previous attempts with enzymes delivered by white cell or other infusions had been ineffective. Hematopoietic stem cell bone marrow transplantation (cord blood from unrelated donors) has also been used (see Staba et al). To be effective, treatment must commence before the accumulation of glycosaminoglycans and neurologic decline. The eye and bone deterioration associated with Hurler disease is not improved. In children with the milder *Scheie form* and those with CNS involvement, bone marrow transplantation is not helpful and enzyme replacement is recommended. Enzyme treatment is also being tried concurrently with bone marrow transplantation in early cases. These approaches have not been effective in the Hunter or the Sanfilippo diseases, discussed below.

Hunter Disease (MPS II, IDS Mutation)

Unlike the Hurler and other types, the Hunter form (MPS II) is transmitted as an *X-linked trait*. The Hurler

Table 37-7

CLASSIFICATION OF THE MUCOPOLYSACCHARIDOSES

NUMBER	Eponym	Clinical Manifestations	Enzyme Deficiency	Glycosaminoglycan
MPS I ^a	Hurler	Corneal clouding, severe skeletal changes and MR, organomegaly, heart disease	α -L-Iduronidase	Dermatan sulfate, heparan sulfate
MPS II	Hunter	Dysostosis, normal corneas, MR, joint stiffness, hydrocephalus, short stature, organomegaly	Iduronate sulfatase	Dermatan sulfate, heparan sulfate
MPS III	Sanfilippo	MR, mild or absent somatic changes, hyperactivity, hepatosplenomegaly	Heparan N-sulfatase	Heparan sulfate
MPS IV	Morquio	Distinctive skeletal abnormalities, slight corneal clouding, odontoid hypoplasia, normal intelligence, hepatomegaly	Galactose 6-sulfatase	Keratan sulfate, chondroitin 6-sulfate
MPS V	No longer used			
MPS VI	Maroteaux-Lamy	Dysostosis, corneal clouding, normal intelligence, spinal cord compression, organomegaly	N-acetylgalactosamine, 4-sulfatase (arylsulfatase B)	Dermatan sulfate
MPS VII	Sly	Dysostosis, hepatosplenomegaly, wide range of severity, corneal clouding	β -Glucuronidase	Dermatan sulfate, heparan sulfate, chondroitin 4-sulfate

^aLess-severe phenotypes are known as Scheie or Hurler-Scheie syndromes. MR, mental retardation.

Source: Modified by permission from Neufeld and Muenzer.

and Hunter syndromes are clinically alike except that the Hunter form is milder: mental retardation is less severe than in the Hurler type, deafness is less common, and *corneal clouding is usually absent*. Probably there are two forms of the syndrome—a more severe one, in which the patients do not survive beyond their midteens, and a less severe form with relatively normal intelligence and survival to middle age. Excessive amounts of dermatan and heparan sulfate are excreted in the urine. The basic abnormality is a *deficiency of iduronate sulfatase*.

Sanfilippo Disease (MPS III, Several Genes Implicated)

This form, or MPS III, expresses itself clinically between 2 and 3 years of age, with progressive intellectual deterioration. The patients are of short stature, but in other respects the physical changes are fewer and less severe than in the Hunter and Hurler syndromes. Three and possibly four types of Sanfilippo disease, designated A, B, C, and D, are distinguished on the basis of their enzymatic defects (Neufeld and Muenzer). All subtypes are phenotypically similar, and all of them may excrete excessive amounts of heparan sulfate in the urine.

Morquio Disease (MPS IV, GALNS and GLB1 Mutations)

This form of the disease, MPS IV, is characterized by marked *dwarfism* and *osteoporosis*. Skeletal deformity and compression of the spinal cord and medulla are constant threats because of hypoplasia of the odontoid process and atlantoaxial dislocation and thickening of the dura around the cervical cord and inferior surface of the cerebellum. Intelligence is affected only slightly or not at all. *Corneal opacities may be present*. Patients excrete large amounts of keratan sulfate in the urine; two types of enzymatic deficiencies have been identified (Neufeld and Muenzer).

Maroteaux-Lamy Disease (MPS VI, ARSB Mutation)

This syndrome, MPS VI, includes severe skeletal deformities (short stature, anteriorly beaked vertebrae) but *normal intelligence*. Several patients observed by our colleagues have had a cervical pachymeningitis with spinal cord compression and hydrocephalus during adult life. Spinal cord function improved with cervical decompression and the hydrocephalus with ventriculoatrial shunting (Young et al). Hepatosplenomegaly is often present. Large amounts of dermatan sulfate are excreted in the urine, as a result of an *arylsulfatase B deficiency*.

β -Glucuronidase Deficiency (Sly Disease, MPS VII, GUSB Mutation)

This (MPS VII) is a rare type of mucopolysaccharidosis, the clinical features of which have yet to be sharply delineated. Short stature, progressive thoracolumbar gibbus, hepatosplenomegaly, and the bony changes of dysostosis multiplex (as in the Hurler type) are the main clinical features. There is excessive excretion of dermatan and heparan sulfate, the result of a deficiency of β -glucuronidase. Attempts to treat the mucopolysaccharidoses by enzyme

replacement therapy, bone marrow transplantation, and gene transfer are in progress. None of these is far enough along to determine its efficacy.

Mucolipidoses and Other Diseases of Complex Carbohydrates (Sialidoses; Oligosaccharidoses) (See Table 37-3)

Several diseases have been described in which there is an abnormal accumulation of mucopolysaccharides, sphingolipids, and glycolipids in visceral, mesenchymal, and neural tissues, because of an α -N-acetylneuraminidase defect. In some types there is an additional deficiency of beta-galactosidase. All are autosomal recessive diseases that manifest many of the clinical features of Hurler disease, but—in contrast to the mucopolysaccharidoses—normal amounts of mucopolysaccharides are excreted in the urine. Frequently, G_{M1} gangliosidosis, described above, is also classified with the mucolipidoses. The other members of this category are synopsisized below and in Table 37-3.

Mucolipidoses

At least three and possibly four closely related forms have been described. In mucolipidosis I (*lipomucopolysaccharidosis*), the morphologic features are those of gargoylism, with slowly progressive mental retardation. Cherry-red spots in the maculae, corneal opacities, and ataxia have been noted in some patients. Vacuolation of lymphocytes, marrow cells, hepatocytes, and Kupffer cells in the liver and metachromatic changes in the sural nerve have been described.

In *mucolipidosis II (I-cell disease)*, the most common of the mucolipidoses, there is usually an early onset of psychomotor retardation, but in some cases this does not appear until the second or third decade of life. *Abnormal facies* and *periosteal thickening (dysostosis multiplex)*, like that of G_{M1} gangliosidosis and Hurler disease) are characteristic. *Gingival hyperplasia* is prominent, and the *liver* and *spleen are enlarged*; but deafness is not found and corneal opacities are slower to develop. Tonic-clonic seizures are frequent in older patients. In most cases, death from heart failure occurs by the third to eighth year. There is a typical vacuolation of lymphocytes, Kupffer cells, and cells of the renal glomeruli. Bone marrow cells are also vacuolated and contain refractile cytoplasmic granules (hence the designation *inclusion-cell*, or *I-cell, disease*). A deficiency of several lysosomal enzymes required for the catabolism of mucopolysaccharides, glycolipids, and glycoproteins have been found.

In *mucolipidosis III (pseudo-Hurler polydystrophy)*, the biochemical abnormalities are like those of I-cell disease, but there are clinical differences. In the pseudo-Hurler type, symptoms do not appear until 2 years of age or later and are relatively mild. Retardation of growth, fine corneal opacities, and valvular heart disease are the major manifestations.

Yet another variant, mucolipidosis IV, has been described (see Tellez-Nagel et al). Here, clouding of the

corneas is noticed soon after birth, and profound developmental retardation is evident by 1 year of age. Skeletal deformities, enlargement of liver and spleen, seizures, or other neurologic abnormalities are notably lacking. Ultrastructural examination of conjunctival and skin fibroblasts has demonstrated lysosomal inclusions of material similar to lipids and mucopolysaccharides that remain to be further characterized.

Mannosidosis

This is another rare hereditary disorder with poorly differentiated symptomatology but with dysmorphic features of broad nose, depressed bridge, thick lips, and protruding tongue. The onset is in the first 2 years, with *Hurler-like facial and skeletal deformities, mental retardation*, and slight motor disability. Corticospinal signs, loss of hearing, variable degrees of gingival hyperplasia, and spoke-like opacities of the lens (but no diffuse corneal clouding) may be present. The liver and spleen are enlarged in some cases. Radiographs show beaking of the vertebral bodies and poor trabeculation of long bones. Vacuolated lymphocytes and granulated leukocytes are present and aid in diagnosis. The urinary mucopolysaccharides are normal. *Mannosiduria is diagnostic*, caused by a defect in α -mannosidase. Mannose-containing oligosaccharides accumulate in nerve cells, spleen, liver, and leukocytes (see Kistler et al).

Fucosidosis

This also is a rare autosomal recessive disorder, with neurologic deterioration beginning usually at 12 to 15 months and progressing to spastic quadriplegia, decerebrate rigidity, severe psychomotor regression, and death within 4 to 6 years. *Hepatomegaly, splenomegaly, enlarged salivary glands, thickened skin, excessive sweating, normal or typical gargoylike facies, beaking of the vertebral bodies*, and vacuolated lymphocytes are the main features. A variant of this disease has been described with slower progression and survival into late childhood and adolescence and even into adult life (Ikeda et al). The latter type is characterized by mental and motor retardation, along with the corneal opacities, coarse facial features, skeletal deformities of gargoylism, and dermatologic changes of Fabry disease (angiokeratoma corporis diffusum), but no hepatosplenomegaly. The basic abnormality in both types is a lack of lysosomal L-fucosidase, resulting in accumulation of fucose-rich sphingolipids, glycoproteins, and oligosaccharides in cells of the skin, conjunctivae, and rectal mucosa.

Aspartylglycosaminuria

This disease is characterized by the early onset of psychomotor regression; delayed, inadequate speech; severe behavioral abnormalities (*bouts of hyperactivity* mixed with apathy and hypoactivity or psychotic manifestations); progressive dementia; clumsy movements; corticospinal signs; corneal clouding (rare); retinal abnormalities and cataracts; coarse facies including low bridge of the nose, epicanthi, thickening of the lips and skin; enlarged

liver; and abdominal hernias in some. Radiographs show minimal *beaking of the vertebral bodies*, and the blood lymphocytes are vacuolated.

The pattern of inheritance in this entire group of diseases, as already stated, is probably autosomal recessive. Diagnostic methods applicable to amniotic fluid and cells are being developed so that prenatal diagnosis will be possible, prompted often by the occurrence of the disease in an earlier child. Neurons are vacuolated rather than stuffed with granules, much like the lymphocytes and liver cells. The specific biochemical abnormalities, as far as they are known, are listed in Table 37-3.

Cockayne Syndrome

This disorder is probably inherited as an autosomal recessive trait. The onset is in late infancy, after apparently normal earlier development. The main clinical findings are *stunting of growth*, evident by the second and third years; *photosensitivity of the skin*; microcephaly; *retinitis pigmentosa, cataracts*, blindness, and pendular nystagmus; nerve deafness; *delayed psychomotor* and speech development; spastic weakness and *ataxia of limbs* and gait; occasionally athetosis; amyotrophy with abolished reflexes and reduced nerve conduction velocities; wizened face, sunken eyes, prominent nose, prognathism, anhidrosis, and poor lacrimation (resembling progeria and bird-headed dwarfism). Some cases show calcification of the basal ganglia. The CSF is normal, and there are no diagnostic biochemical findings.

Pathologic examination reveals a small brain, striatal and cerebellar calcifications, leukodystrophy like that of Pelizaeus-Merzbacher disease, and a severe cerebellar cortical atrophy. The peripheral nerve changes are those of a primary segmental demyelination.

It is now apparent that Cockayne syndrome, like ataxia-telangiectasia, is a consequence of mutations in genes that mediate DNA repair. At least three different forms of Cockayne syndrome have been identified, each with a different underlying gene defect.

Other Metabolic Diseases of Late Infancy and Early Childhood

Globoid cell leukodystrophy (Krabbe), subacute necrotizing encephalomyelopathy (Leigh), and Gaucher disease may also begin in late infancy or early childhood. They are described in the preceding section of this chapter. Familial striatocerebellar calcification (Fahr disease) and Lesch-Nyhan disease may also become manifest in this age period, but they usually have a later onset and are therefore described with the diseases of later childhood in the section that follows.

This group of metabolic disorders presents many of the same diagnostic problems as those of early infancy. The flow chart in Fig. 37-4, which divides these disorders into dysmorphic, visceromegaly, and purely neurologic groups, is equally useful in the differential diagnosis of both age groups. As with the early infantile diseases, certain clusters of neurologic, skeletal, dermal, ophthalmic,

and laboratory findings are highly distinctive and often permit the identification of a particular disease. These signs are listed below:

1. Evidence of involvement of peripheral nerves (weakness, hypotonia, areflexia, sensory loss, reduced conduction velocities) in conjunction with lesions of the CNS—metachromatic leukodystrophy, Krabbe leukodystrophy, neuroaxonal dystrophy, and Leigh disease (rare)
2. Ophthalmic signs
 - a. Corneal clouding—several of the mucopolysaccharidoses (Hurler, Scheie, Morquio, Maroteaux-Lamy), mucopolipidoses, tyrosinemia, aspartylglycosaminuria (rare)
 - b. Cherry-red macular spot— G_{M2} gangliosidosis, G_{M1} gangliosidosis (half the cases), lipomucopolysaccharidosis, occasionally Niemann-Pick disease
 - c. Retinal degeneration with pigmentary deposits—Jansky-Bielschowsky lipid storage disease, G_{M1} gangliosidosis, syndrome of sea-blue histiocytes
 - d. Optic atrophy and blindness—metachromatic leukodystrophy, neuroaxonal dystrophy
 - e. Cataracts—Marinesco-Sjögren syndrome, Fabry disease, mannosidosis
 - f. Ocular apraxia—ataxia-telangiectasia, Niemann-Pick disease
 - g. Impairment of vertical eye movements—late infantile Niemann-Pick disease, juvenile dystonic lipidosis, sea-blue histiocyte syndrome, Wilson disease
 - h. Jerky eye movements, limited abduction—late infantile Gaucher disease
3. Extrapyramidal signs—late-onset Niemann-Pick disease (rigidity, abnormal postures), juvenile dystonic lipidosis (dystonia, choreoathetosis), Rett, ataxia-telangiectasia (athetosis), Sanfilippo mucopolysaccharidosis, type I glutaric acidemia, Wilson disease, Segawa dopa-responsive dystonia
4. Facial dysmorphism—Hurler, Scheie, Morquio, and Maroteaux-Lamy forms of mucopolysaccharidosis, aspartylglycosaminuria, mucopolipidoses, G_{M1} gangliosidosis, mannosidosis, fucosidosis (some cases), multisulfatase deficiencies (Austin), some mitochondrial disorders
5. Dwarfism, spine deformities, arthropathies—Hurler, Morquio, and other mucopolysaccharidoses, Cockayne syndrome
6. Enlarged liver and spleen—Niemann-Pick disease, Gaucher disease, all mucopolysaccharidoses, fucosidosis, mucopolipidoses, G_{M1} gangliosidosis
7. Alterations of skin—photosensitivity (Cockayne syndrome and one form of porphyria); papular nevi and angiokeratoma (Fabry disease, fucosidosis); telangiectasia of ears, conjunctiva, chest (ataxia-telangiectasia); ichthyosis (Sjögren-Larsen disease, caused by fatty alcohol dehydrogenase deficiency); plaque-like lesions in Hunter syndrome
8. Beaked thoracolumbar vertebrae—all mucopolysaccharidoses, mucopolipidoses, mannosidosis, fucosidosis; aspartylglycosaminuria, multiple sulfatase deficiencies

9. Deafness—mucopolysaccharidoses, mannosidosis, Cockayne syndrome
10. Hypertrophied gums—mucopolipidoses, mannosidosis
11. Vacuolated lymphocytes—all mucopolysaccharidoses, mucopolipidoses, mannosidosis, fucosidosis
12. Granules in neutrophils—all mucopolysaccharidoses, mucopolipidoses, mannosidosis, fucosidosis, multiple sulfatase deficiencies

One of the most difficult diagnostic problems in this age period is distinguishing neuroaxonal dystrophy, metachromatic leukodystrophy, subacute necrotizing encephalomyelopathy (Leigh disease), some cases of lipofuscinosis, and the late form of G_{M1} gangliosidosis. In none of these diseases is the clinical picture entirely stereotyped. The clinician is aided in identifying neuroaxonal dystrophy by noting an onset, at 1 to 2 years of age, of severe hypotonia with retained reflexes and Babinski signs, early visual involvement without retinal changes, lack of seizures, normal CSF, physiologic evidence of denervation of muscles, fast-frequency EEG, normal CT, and *N*-acetylgalactosaminidase deficiency in cultured fibroblasts. Metachromatic leukodystrophy can be excluded if the CSF protein is normal and if nerve conduction velocities and enzymatic studies of leukocytes and fibroblasts are normal. Similar criteria enable one to rule out G_{M1} gangliosidosis. Mitochondrial disorders (Leigh disease) may begin at the same age; in many cases lactic acidosis and pyruvate decarboxylase defect will corroborate the diagnosis. Sequencing tests of the mitochondrial genome allow definitive diagnosis in most cases, as described in a later section. Also in Leigh disease, imaging of the brain may disclose hypodense lesions in the basal ganglia and brainstem, in contrast to the normal CT in neuroaxonal dystrophy. In metachromatic leukodystrophy, the cerebral white matter shows a diffusely decreased attenuation and the MR images are striking. Lipofuscinosis cannot always be diagnosed accurately; curvilinear bodies in nerve twigs and in the endothelial cells in skin biopsies and the recently discovered gene mutations are the most informative laboratory tests.

INHERITED METABOLIC ENCEPHALOPATHIES OF LATE CHILDHOOD AND ADOLESCENCE

Unavoidably, one must refer here to certain inherited metabolic diseases already described that permit survival into late childhood and adolescence, as well as to diseases that begin in adolescence or adult life after a normal childhood. There is a tendency for them to be less severe and less rapidly progressive, an attribute shared by many diseases with a dominant mode of inheritance. Nonetheless, there are diseases, such as Wilson disease, in which the onset of neurologic symptoms occurs after the tenth year and in rare instances after the thirtieth year, and the mode of inheritance is recessive in type. However, in the latter instance, the basic abnormality has existed since early childhood in the form of a ceruloplasmin

deficiency with early cirrhosis and splenomegaly; only the neurologic disorder is of late onset. This brings us to another principle: The pathogenesis of the cerebral lesion may involve a factor or factors once removed from the underlying biologic abnormality.

Genetic heterogeneity poses another problem with respect to both the clinical and biochemical findings. It is well established that a single clinical phenotype, such as the one seen in Hurler disease, can be the expression of a number of different alleles of a given gene mutation. Conversely, a number of different clinical phenotypes may be based on different degrees of the same enzyme deficiency. One must, therefore, not rely solely on clinical appearances for diagnosis but always combine them with biochemical tests and molecular genetic studies for confirmation. No one of these lines of data, including genomics, is sufficient for classification of disease.

The diseases in this category are probably of greater interest to neurologists than the preceding ones, for they more consistently cause familiar neurologic abnormalities such as epilepsy, polymyoclonus, dementia, cerebellar ataxia, choreoathetosis, dystonia, tremor, spastic-ataxic paraparesis, blindness, deafness, and stroke. These manifestations appear much the same in late childhood and adolescence as they do in adult life, and the neurologist whose experience has been mainly with adult patients feels quite comfortable with them.

Diseases in this age period have a diversity of manifestations, yet each disease tends to have a certain characteristic pattern of neurologic expression, as though the pathogenetic mechanism were acting more selectively on particular systems of neurons. Such affinities between the disease process and certain anatomic structures raise the question of *pathocllisis*, i.e., specific vulnerability of particular neuronal systems to certain morbid agents. Stated another way, for each disease there is a common and relatively stereotyped clinical syndrome and a small number of variants; conversely, certain other symptoms and syndromes are rarely observed with a given disease. At the same time, however, it is clear that more than one disease may cause the same syndrome.

In deference to these principles, *the diseases in this section are grouped according to their most common mode of clinical expression*, as follows:

1. The progressive cerebellar ataxias of childhood and adolescence
2. The familial polymyoclonias and epilepsies
3. Extrapiramidal syndromes of parkinsonian type
4. The syndrome of dystonia and generalized choreo-athetosis
5. The syndrome of bilateral hemiplegia, cerebral blindness and deafness, and other manifestations of focal cerebral disorder
6. Strokes in association with inherited metabolic diseases
7. Metabolic polyneuropathies
8. Personality changes and behavioral disturbances as manifestations of inherited metabolic diseases

It is advantageous to be familiar with these groupings. Like the age of onset and the distinctions between

gray and white matter diseases of earlier onset, this scheme facilitates clinical diagnosis. One word of caution: It is a mistake to assume that the diseases in these categories affect one and only one particular part of the nervous system or to assume that they are exclusively neurologic. Once the biochemical abnormality is discovered, it is usually found to implicate cells of certain nonneurologic tissues as well; whether or not the effects of such involvement become symptomatic is often a quantitative matter. Also, one encounters mixed neurologic syndromes in which tremor, myoclonus, cerebellar ataxia, seizures, and choreoathetosis are present in various combinations; it is then difficult to decide whether a movement disorder is of one type or another.

The Progressive Cerebellar Ataxias of Late Childhood and Adolescence

In the preceding section it was pointed out that there is a large group of diseases, some with a known metabolic basis, in which an acute, episodic, or chronic cerebellar ataxia becomes manifest in early childhood. Here the discussion of the cerebellar ataxias is continued, with reference to those forms that begin in late childhood and adolescence. In these later age periods, the number of ataxias of proven metabolic type diminishes markedly. Most of them, of chronic progressive type, are part of the late-onset lipid storage diseases. Of the other cerebellar ataxias of late childhood and adolescence, only the Bassen-Kornzweig acanthocytosis, late-onset G_{M2} gangliosidosis, Refsum disease, ataxia-telangiectasia, and a genetic fault in vitamin E metabolism fall into the category of truly metabolic disease. Refsum disease is so clearly a polyneuropathy (cerebellar features only in exceptional cases) that it is presented in Chap. 46. Ataxia-telangiectasia is usually encountered in late childhood, but the ataxia may begin as early as the second year of life; therefore it has been described in the preceding section with the ataxias of early childhood.

There are many other conditions of metabolic type in which cerebellar ataxia figures in the clinical picture. Some of these are associated with polymyoclonus and cherry-red macular spots (mainly sialidosis or α -neuraminidase deficiency; see below). Cerebellar ataxia is a prominent feature of Unverricht-Lundborg (Baltic) disease and Lafora-body disease (see Chap. 16). The Cockayne syndrome and Marinesco-Sjögren disease persist into later childhood and adolescence or may even have their onset in this later period. In cerebrotendinous xanthomatosis (see further on), spastic weakness and pseudobulbar palsy are combined with cerebellar ataxia. Prader-Willi children have a broad-based gait and are clumsy in addition to being obese, genitally deficient, and diabetic. Several diseases associated with hyperuricemia implicate defective purine and pyrimidine metabolism and fit into this category; the enzymatic defect of Lesch-Nyhan disease is not present, however. Marsden and coworkers (1982) have observed cerebellar ataxia beginning in late childhood as an expression of adrenoleukodystrophy (see below). The familial syndrome of neuropathy, ataxia, and retinitis pigmentosa (NARP) caused by a mitochondrial genome mutation that

impairs ATP synthase can cause ataxia and closely mimic the Marinesco-Sjögren syndrome.

Doubtless, many of the progressive forms of cerebellar ataxia now classified as degenerative and described in Chap. 39 will be proved to have an underlying biochemical or similar subcellular pathogenesis and will logically fall in place here, with the metabolic diseases. At present, when faced with a progressive ataxia of cerebellar type, even in a young adult, the reader should consult both this chapter and Chap. 39.

The *acute forms of cerebellar ataxia* that occur in late childhood and adolescence are essentially nonmetabolic, being traceable to postinfectious encephalomyelitis (see Chap. 36) or to postanoxic, postmeningitic, or posthyperthermic states and certain drug intoxications. With relatively pure cerebellar ataxias of this age period, postinfectious cerebellitis, cerebellar tumors (medulloblastomas, astrocytomas, hemangioblastomas, and ganglioneuromas of Lhermitte-Duclos) should be considered in the differential diagnosis. MRI establishes the correct diagnosis.

Bassen-Kornzweig Acanthocytosis (Abetalipoproteinemia)

Bassen and Kornzweig, in 1950, first described this rare metabolic disease of lipoproteins that causes ataxia, sensory neuropathy, and acanthocytic deformity of red cells. It excited great interest, for it gave promise of a breakthrough into a hitherto obscure group of “degenerative” disorders. The inheritance is autosomal recessive.

The initial symptoms, occurring between 6 and 12 years (range: 2 to 20 years), are weakness of the limbs with areflexia and ataxia of sensory (tabetic) type, to which a cerebellar component is added later (the first two aspects relating to a peripheral neuropathy are discussed in Chap. 46). Steatorrhea, raising the suspicion of celiac disease (sprue), often precedes the appearance of a weak and unsteady gait. Later, in more than half the patients, vision may fail because of retinal degeneration (similar to retinitis pigmentosa). Kyphoscoliosis, pes cavus, and Babinski signs are other elements in the clinical picture. The neurologic disorder is relatively slowly progressive—by the second to third decade, the patient is usually bedridden.

The diagnostic laboratory findings are spiky or thorny red blood cells (acanthocytes), low sedimentation rate, and a marked reduction in the serum of low-density lipoproteins (LDL cholesterol, phospholipid, and β -lipoprotein levels are all subnormal). Pathologic study has revealed the presence of foamy, vacuolated epithelial cells in the intestinal mucosa (causing absorption block); diminished numbers of myelinated nerve fibers in sural nerve biopsies, depletion of Purkinje and granule cells in all parts of the cerebellum; loss of fibers in the posterior columns and spinocerebellar tracts; loss of anterior horn and retinal ganglion cells and of muscle fibers and fibrosis of the myocardium. It has been proposed that the basic defect is an inability of the body to synthesize the proteins of cell membranes because of the impaired absorption of fat through the mucosa of the small intestine. Vitamin E

deficiency may be a pathogenic factor, because the administration of a low-fat diet and high doses of vitamins A and E may prevent progression of the neurologic disorder, according to Illingworth and colleagues, but the pathophysiology appears to be more complex.

Often mentioned in the context of acanthocytosis is a related rare condition, McLeod syndrome, in which progressive muscular atrophy, seizures, involuntary movements, and elevated serum creatine kinase (CK) are combined in various configurations. The acanthocytosis in this disease is the result of an abnormality of the red cell surface Kell antigen (Kx, coding for the protein XK).

Familial Hypobetalipoproteinemia

This is another rare but well-defined disease resembling abetalipoproteinemia, in which there is hypocholesterolemia, acanthocytosis of red blood corpuscles, retinitis pigmentosa, and a pallidal atrophy (HARP syndrome). Inheritance is autosomal dominant, and heterozygotes may exhibit some part of the syndrome. Many cases are caused by mutations in the gene encoding β -lipoprotein B. Fat droplets may be seen in the jejunal mucosa, indicating malabsorption. Cases have been reported from Europe, Asia, and the United States. Treatment consists of restriction of dietary fat and supplements of vitamin E.

An adult form of acanthocytosis unrelated to the above several diseases is associated with hereditary chorea and dystonia but evidence of lipid malabsorption is lacking. This disease is described in Chap. 39.

Familial Polymyoclonus

As stated in Chap. 6, the term *myoclonus* is applied to many conditions that are not at all alike but share a single clinical feature—a multitude of exceedingly brief, random, arrhythmic twitches of parts of muscles, entire muscles, or groups of muscles. Myoclonic jerks differ from chorea by virtue of their brevity (15 to 50 ms). Notably, both phenomena are considered to be symptomatic of “gray matter” diseases (“polioencephalopathies”).

Myoclonus or polymyoclonus may, in certain conditions, stand alone as a relatively pure syndrome. In most other cases, it is mixed with epilepsy or athetosis and dystonia, discussed further on. Most often, myoclonus is associated with cerebellar ataxia; thus it is being considered here, with the progressive cerebellar ataxias. The many acquired forms of polymyoclonus, such as subacute sclerosing panencephalitis, were mentioned in Chap. 6. This chapter is concerned only with those of known or presumed metabolic origin.

Myoclonic Encephalopathy of Infants (Infantile Opsoclonus-Myoclonus Syndrome)

Under this title, Kinsbourne originally described a form of widespread, continuous myoclonus (except during deep sleep) affecting male and female infants whose development had been normal until the onset of the disease at the age of 9 to 20 months. The myoclonus evolves over a week or less, affects all the muscles of the body, and interferes seriously with all the natural

muscular activities of the child. The eyes are notably affected by rapid (up to 8/s), irregular conjugate movements ("dancing eyes" of an opsoclonic type). The child is irritable and speech may cease. All laboratory tests are normal.

Treatment Dexamethasone in doses of 1.5 to 4.0 mg/d suppresses the myoclonus and permits developmental progress. Some patients have recovered from the myoclonus but have been left mentally slow and mildly ataxic. Others have required corticosteroid therapy for 5 to 10 years, with relapse whenever it was discontinued. Ordinary anticonvulsants seem to have no effect. The pathology has not been determined.

A similar syndrome has been observed in conjunction with neuroblastoma in children and as a transient illness of unknown cause (probably viral or postinfectious) in young adults (Baringer et al; see Chap. 33). A similar condition is also known in adults as a paraneoplastic disease with ovarian, breast, gastric, and bronchogenic carcinomas and with other occult tumors.

In a broader survey of the pediatric opsoclonus-myoclonus syndrome, Pranzatelli and associates reported their experience with 27 cases, some with neural crest tumors, others with viral infections or hypoxic injury (intention myoclonus). In nearly all of their patients there was cerebellar ataxia and mental disorder, and 10 percent had seizures. The CSF was normal. The investigators have emphasized the pathogenetic heterogeneity and defined a rare serotonergic type (low levels of 5-hydroxytryptophan and homovanillic acid in the CSF) that responds to 5-hydroxyindole acetic acid.

Familial Progressive Myoclonus

Five major categories of familial polymyoclonus of late childhood and adolescence have been delineated: (1) Lafora- or amyloid-body type, (2) juvenile cerebrotretinal degeneration, (3) cherry-red spot myoclonus (sialidosis or α -neuraminidase deficiency), (4) mitochondrial encephalopathy, and (5) a more benign degenerative disease (dyssynergia cerebellaris myoclonica of Hunt). Familial myoclonus may also be a prominent feature of two other diseases— G_{M2} gangliosidosis and Gaucher disease—which occasionally have their onset in this age period.

Lafora-Body Polymyoclonus With Epilepsy This disease, which is inherited as an autosomal recessive trait, was first identified by Lafora in 1911 on the basis of the large basophilic cytoplasmic bodies that were found in the dentate, brainstem, and thalamic neurons. These inclusions have been shown by Yokoi and colleagues to be composed of a glucose polymer (polyglucosan) that is chemically but not structurally related to glycogen. Possibly some of the cases of familial myoclonus epilepsy reported by Unverricht and by Lundborg were of this type, but because these authors provided no pathologic data, one cannot be sure.

Beginning in late childhood and adolescence (11 to 18 years) in a previously normal individual, the disease announces itself by a seizure, a burst of myoclonic jerks, or both. In about half the cases there are focal (often

occipital) seizures. The illness may at first be mistaken for ordinary epilepsy, but within a few months it becomes evident that something far more serious is occurring. The myoclonus becomes widespread and can be evoked as a startle by noise, an unexpected tactile stimulus (even the tap of a reflex hammer), and also by excitement, or certain sustained motor activities. An evoked train of myoclonic jerks may progress to a generalized seizure with loss of consciousness. As the disease advances, the myoclonus interferes increasingly with the patient's motor activities until voluntary function is seriously impaired. Speech may be marred, much as it is in chorea. Close examination may also reveal an alteration in muscle tone and a slight degree of cerebellar ataxia. At this time, or even before the onset of myoclonus and seizures, the patient may experience visual hallucinations or exhibit irritability, odd traits of character, uninhibited or impulsive behavior, and, ultimately, progressive failure in all cognitive functions. Deafness has been an early sign in a few cases. Rigidity or hypotonia, impaired tendon reflexes, acrocyanosis, and rarely corticospinal tract signs are late findings. Finally the patient becomes cachectic and bed-fast and succumbs to intercurrent infection. Most do not survive beyond their twenty-fifth birthday. Nonetheless there are isolated reports of Lafora-body disease in which symptoms began as late as age 40 years, with death as late as age 50 years. These late cases may constitute a separate genetic type.

No abnormalities of the blood, urine, or CSF have been detected. The EEG shows diffuse slow waves and spikes as well as bursts of focal or multifocal discharges. Altered hepatocytes with homogeneous PAS-positive bodies that displace the nuclei have been observed in both the presymptomatic and symptomatic stages of the disease. These inclusions have been seen in skin and liver biopsies, even though liver function tests were normal. Neuropathologic examinations have shown a slight loss of granule and Purkinje cells and loss of neurons in the dentate nuclei, inner segment of globus pallidus, and cerebral cortex in addition to the Lafora bodies. The latter may also be seen in the retina, cerebral cortex, myocardium, and striated muscles. Anticonvulsant drugs, especially methsuximide and valproic acid, help in the control of the seizures but have no effect on the basic process.

Juvenile Ceroid Lipofuscinosis (Cerebrotretinal Degeneration; Batten Disease) As stated earlier, this is one of the most variable forms of the lipidoses. The salient clinical features of the later-onset types are severe myoclonus, seizures, and visual loss. In the juvenile type, the first lesions are seen in the maculae; they appear as yellow-gray areas of degeneration and stand in contrast to the cherry-red spot and the encircling white ring of Tay-Sachs disease. At first, the particles of retinal pigment are fine and dust-like; later they aggregate to resemble more the bone-corpuseular shapes of retinitis pigmentosa. The liver and spleen are not enlarged and there are no osseous changes. The usual development of these and other manifestations of the disease were outlined by Sjögren, who studied a large number of the late infantile and juvenile types of cases in Sweden. He divided the illness into stages, the first of which was visual impairment,

followed approximately sequentially by generalized seizures and myoclonus, often with irritability, poor control of emotions, and stuttering, jerky speech at 2 years, then gradual intellectual deterioration to which were added cerebellar ataxia and intention tremor, in this respect coming to resemble Wilson disease. Finally, the patient lies curled up in bed, blind and speechless, with strong extensor plantar reflexes, occasionally adopting dystonic postures. Life usually ends in 10 to 15 years.

In the early stages, the EEG pattern of random, high-voltage, triphasic waves is diagnostic; later, as the seizures and myoclonic jerks become less frequent and finally cease, only delta waves remain. The electroretinographic waveforms are lost once the retina is affected. The lateral ventricles are slightly dilated on CT and on MRI. The CSF is normal. Diagnosis can be confirmed by the appearance of inclusions of a curvilinear "fingerprint" pattern in electron microscopic study of biopsy material, particularly of the eccrine sweat glands of the skin. A defective membrane protein has been identified that forms the inclusion material in the most common, or classic, juvenile phenotype. The genetics of the lipofuscinoses have been reviewed by Mole.

Late Juvenile and Adult Ceroid Lipofuscinosis (Kufs-Parry or Kufs Disease)

The *type of ceroid lipofuscinosis* that develops later (15 to 25 years of age or older) is often unattended by visual or retinal changes and is even slower in its evolution. It is presented here for ease of exposition, but it becomes relevant mostly in relation to dementing illness in young adulthood. Personality change or dementia is one constellation, the other being myoclonic seizures with subsequent dementia and even later pyramidal and extrapyramidal signs. As the disease progresses, cerebellar ataxia, spasticity, rigidity or athetosis, or mixtures thereof, are combined with dementia. As a reflection of the variability of the clinical presentation, a recent patient of ours had vague visual difficulties at age 51 years and evolved a spastic quadriparesis with disinhibited behavior over 5 years. Additional comments regarding the unusual presentations of this disease can be found further on, under "Adult Forms of Inherited Metabolic Disease." van Bogaert pointed out to our colleague R.D. Adams that relatives of these patients may have retinal changes without neurologic accompaniments. The genetic defect for the adult form has been analyzed (see below).

Of all the lipidoses, these cerebroretinal degenerations had for decades defied unifying biochemical definition. Our understanding of these diseases is difficult because they embody both enzymatic defects and structural protein dysfunctions. In a few of the early childhood types, mutations of one of several lysosomal enzymes have been identified as summarized by Mole and by Wisniewski and colleagues. As mentioned earlier, Zeman and coworkers showed that the cytoplasmic inclusions are autofluorescent and give a positive histochemical reaction for both ceroid and lipofuscin, but this material is not different biochemically from the lipid substance that accumulates in aging cells. In addition to the presence of curvilinear bodies in the cytoplasm of neurons

and other tissues, some in a fingerprint pattern, there is a reduction in type II synapses in the distal parts of the axon. All these changes precede nerve cell loss. The genetic defects have been tentatively determined for some of the subtypes of neuronal ceroid lipofuscinosis (see Wisniewski et al). These genes have been designated CLN 1 through 9 and they embody over 100 different mutations.

Childhood or Juvenile G_{M2} Gangliosidosis Instances of the recessive type of G_{M2} gangliosidosis rarely have their onset at the typical age period. Twenty-four such cases (from 20 kindreds) were collected from the medical literature by Meek and coworkers. Ataxia and dysarthria were frequently the presenting symptoms, followed by dementia, dysphagia, spasticity, dystonia, seizures, and myoclonus. Degeneration of anterior horn cells with progressive muscular atrophy may be a feature, although this is more characteristic of the adult-onset variety (see further on). Atypical cherry-red spots are observed in some patients. The biochemical abnormality, i.e., a deficiency of hexosaminidase A, is the same as in Tay-Sachs disease, but not as severe or as extensive. Progression of the disease is slow, over a period of many years.

Late Gaucher Disease With Polymyoclonus A type of Gaucher disease is occasionally encountered in which seizures, severe diffuse myoclonus, supranuclear gaze disorders (slow saccades, saccadic and pursuit horizontal gaze palsies), and cerebellar ataxia begin in late childhood, adolescence, or adult life. The course is slowly progressive. The intellect is relatively spared. The spleen is enlarged. The pathologic and biochemical abnormalities are the same as those of Gaucher disease of earlier onset.

Cherry-Red Spot-Myoclonus Syndrome (Sialidosis Type 1, α -Neuraminidase Deficiency) This is a genetically distinct class of disease characterized by the storage in nervous tissue of sialylated glycopeptides. It is caused by a neuraminidase deficiency. In some of the patients, the onset was in late childhood or adolescence, and in others, even later. In addition to the patients initially reported by Rapin and coworkers, 24 similar cases have appeared in the medical literature.

In the cases described by Rapin and colleagues the first findings were visual impairment with cherry-red macular spots, similar to those seen in Tay-Sachs disease and less consistently in G_{M1} gangliosidosis, Niemann-Pick disease, and metachromatic leukodystrophy. In one case, there was severe episodic pain in the hands, legs, and feet during hot weather, reminiscent of Fabry disease. Polymyoclonus followed within a few years and, together with cerebellar ataxia, disabled the patients. Mental function remained relatively normal. Liver and spleen were not enlarged, but storage material was found in the Kupffer cells, neurons of the myenteric plexus, and cerebral neurons, and presumably in cerebellar and retinal neurons.

The cases of Thomas and colleagues were young adults, all members of one generation, who had developed dysarthria, intention myoclonus, cerebellar ataxia, and cherry-red macular lesions. Like the cases of Rapin and coworkers, the heredity was autosomal recessive.

There was urinary excretion of sialylated oligosaccharides and a sialidase deficiency in cultured fibroblasts. The two patients described by Tsuji and associates (1982) are noteworthy in that they were of age 50 and 30 years. In addition to the macular lesions, polymyoclonia, and cerebellar ataxia, there were gargoyle-like facial features, corneal opacities, and vertebral dysplasia. These patients also had a neuraminidase (partial beta-galactosidase) deficiency.

Dentatorubral Cerebellar Atrophy With Polymyoclonus This progressive degeneration of the cerebellar-dental efferent system was originally described by Ramsay Hunt under the title of *dyssynergia cerebellaris myoclonica*. The onset is in late childhood; both sexes are vulnerable, and it probably has more than one cause. In Hunt's case, a progressive ataxia was accompanied by a striking degree of action myoclonus. Seizures are infrequent, and the intellect is relatively preserved. The neurons of the dentate nuclei and their ascending and descending brainstem axons gradually disappear. Berkovic and associates studied 84 cases of polymyoclonus, 13 of which conformed to the Hunt syndrome. Of these, 9 proved to have a mitochondrial encephalomyopathy. However, there are other reports (Tassinari et al) in which muscle biopsies showed no mitochondrial abnormalities. In the series of 30 cases reported by Marsden and coworkers (1990) the onset was usually before the age of 21 years. Cortical electrographic discharges were found to precede each myoclonic twitch (cortical myoclonus). A biochemically supported diagnosis could not be made in nearly half of their cases.

Extremely chronic forms of rhythmic myoclonus involving only the facial and bulbar muscles also occur. Although this benign familial polymyoclonia has not been associated with any biochemical abnormality, its association with cellular mitochondrial abnormalities in some cases justifies its inclusion in this chapter rather than with the degenerative diseases. Another mitochondrial disorder, the myoclonic epilepsy ragged red fiber (MERRF) disease, begins in the second decade or later with myoclonus and ataxia and enters into the differential diagnosis of this group of diseases. The mitochondrial diseases as a group are considered in the last part of this chapter.

Epilepsies of Hereditary Metabolic Disease

(See Chap. 16)

Convulsive seizures may complicate nearly all hereditary metabolic diseases. The seizures may occur at all ages but more frequently in the neonate, infant, or young child than in the older child or adolescent. The seizures take many forms, as discussed in Chap. 16. Most often they are generalized grand mal or partial types; typical petit mal probably does not occur. Some diseases may cause focal seizures, simple or complex partial, before becoming generalized. The combination of series of polymyoclonic jerks progressing to a generalized motor seizure is always highly suggestive of one of the hereditary metabolic diseases. Another highly significant form of presentation is with sensory evoked seizures. The subject

of epilepsy and the hereditary metabolic diseases was reviewed by Sansaricq and colleagues.

EXTRAPYRAMIDAL SYNDROMES WITH HEREDITARY METABOLIC DISEASE

Parkinsonian Syndromes

In the typical parkinsonian syndrome, with features of rigidity, tremor, and bradykinesia, strength remains relatively intact and corticospinal signs are absent, but effectiveness of movement is nonetheless impaired by the patient's disinclination to use the affected parts (hypo- or akinesia), by slowness (bradykinesia), and by rigidity and tremor (see Chap. 4). Other clinical syndromes in this category include choreoathetosis, dystonia, and spasms of gaze.

When the parkinsonian syndrome or some component thereof has its onset in middle or late adult life, it usually indicates idiopathic Parkinson disease or related multisystem forms. The development of such an extrapyramidal motor disorder in late childhood and adolescence instead suggests Wilson disease, juvenile Huntington disease, Hallervorden-Spatz disease, and the Segawa type of L-dopa-responsive dystonia as well as other so-called parkin mutations (see Chap. 39).

Hepatolenticular Degeneration (Wilson Disease, Westphal-Strümpell Pseudosclerosis, ATP7B Mutation)

Wilson's description of "Progressive Lenticular Degeneration: A Familial Nervous Disease Associated with Cirrhosis of the Liver" appeared in 1912. A similar neurologic disorder had been described previously by Gowers (1906) under the title of "tetanoid chorea" and by Westphal (1883) and Strümpell (1898), as "pseudosclerosis." None of these authors, however, recognized the association with cirrhosis. The clinical studies of Hall (1921) and the histopathologic studies of Spielmeyer (1920), who reexamined sections from the liver and brain of Westphal's and Strümpell's cases, clearly established that the pseudosclerosis described by these authors was the same disease as the one that had been described by Wilson. Interestingly, none of these authors, including Wilson, noticed the golden-brown (Kayser-Fleischer) corneal ring, the one pathognomonic sign of the disease. Rumpell had demonstrated the greatly increased copper content of the liver and brain as early as 1913, but this discovery was generally ignored until Mandelbrote (1948) found, quite by chance, that the urinary excretion of copper was greatly increased in patients with Wilson disease and that it was increased even more after the intramuscular administration of the chelating agent British anti-Lewisite (BAL). In 1952, Scheinberg and Gitlin discovered that ceruloplasmin, the serum protein that binds copper, is reduced in this disease (see reviews by Scheinberg and Sternlieb for a full historical account and references). Denny-Brown demonstrated a recession of symptoms after prolonged treatment with BAL.

The prevalence of the disease cannot be stated exactly, but is on the order of 1 per 50,000 to 1 per 100,000 of the general population. The disease is transmitted as an autosomal recessive trait. The gene, called *ATP7B* (homologous with the *ATP7A* gene, which is defective in Menkes disease), codes for a membrane-bound, copper-binding ATPase. One of the curious aspects of the genetics of the disease is the multitude of mutations within this gene that give rise to the disease and no one mutation accounts for more than 30 percent of cases. Inadequate functioning of the ATPase enzyme in some way reduces excretion of copper in the bile. As noted further on, liver transplantation halts progression of the disease, indicating that the primary biochemical effect of the mutation is in the liver rather than the nervous system.

The mutation gives rise to two fundamental disturbances of copper metabolism: (1) a reduced rate of incorporation of copper into ceruloplasmin and (2) a reduction in biliary excretion of copper. The deposition of copper in tissues is the cause of virtually all the manifestations of the disease—cirrhosis, hemolytic anemia, renal tubular changes, Kayser-Fleischer rings, and, in all likelihood, the cerebral damage—as discussed below.

Clinical Features

The onset of neurologic symptoms is usually in the second, and less often in the third, decade, but rarely beyond that time. Half of patients are symptomatic by age 15 years, but exceptional cases, including two under our care, had their first clinical manifestations as late as their midfifties. In all instances the initial event is a deposition of copper in the liver, leading to an acute or chronic hepatopathy and eventually to multilobular cirrhosis and splenomegaly (Scheinberg and Sternlieb). In childhood, the liver disorder often takes the form of attacks of jaundice, unexplained hepatosplenomegaly, or hypersplenism with thrombocytopenia and bleeding. Rarely is there clear evidence of cirrhosis alone. The hepatic abnormalities may be asymptomatic (except for elevated serum transaminases), in which case the initial clinical presentation is neurologic. In some instances, a hemolytic anemia or, less often, renal tubular acidosis may first draw attention to the disease.

The first neurologic manifestations are most often extrapyramidal with a proclivity to affect the oropharyngeal musculature. The typical presentations are tremor of a limb or of the head and generalized slowness of movement (i.e., a parkinsonian syndrome); or slowness of movement of the tongue, lips, pharynx, larynx, and jaws, resulting in dysarthria, dysphagia, and hoarseness; or there may be slowness of finger movement and occasionally choreic movements or dystonic postures of the limbs. Often the mouth is held slightly open in the early stage of the disease. Exceptionally, an abnormality of behavior (argumentativeness, impulsiveness, excessive emotionality, depression, delusions) or a gradual impairment of intellectual faculties precedes other neurologic signs by a year or more (see Starosta-Rubinstein et al).

As the disease progresses, the “classic syndrome” evolves: dysphagia and drooling, rigidity and slowness of movements of the limbs; flexed limb postures; fixity

of facial muscles with mouth constantly agape, giving an appearance of grinning or a “vacuous smile”; dysarthria or virtual anarthria (bulbar extrapyramidal syndrome); and a tremor in repose that increases when the limbs are outstretched to a coarse, “wing-beating” movement. Slowed saccadic eye movements and limitation of upgaze are also characteristic. *A notable feature is the tendency for the motor disorders to be concentrated in the bulbar musculature and to spread caudally.* Thus, the syndrome differs from classic parkinsonism. Usually elements of cerebellar ataxia and intention tremor of variable degree are added at some stage of the disease. Approximately 6 percent of patients develop seizures (Denning et al). Gradually the disability increases because of increasing rigidity and tremor. The patient becomes mute, immobile, extremely rigid, dystonic, and slowed mentally, the latter usually being a late and variable effect.

With progression of the neurologic disease, the *Kayser-Fleischer rings* become more evident (see Fig. 37-6). They take the form of a crescentic rusty-brown discoloration of the deepest layer of the cornea (Descemet membrane). In the purely hepatic stage of the disease, the rings may not be evident (in 25 percent of cases), but *they are virtually always present (if properly sought) once the neurologic signs become manifest.* A slit-lamp examination may be necessary for their early detection, particularly in brown-eyed patients, but in the majority of patients with neurologic signs the rings can be visualized with the naked eye or with the aid of an indirect ophthalmoscope focused on the limbus.

The diagnosis is virtually certain when there is a similar syndrome in a sibling or when an extrapyramidal motor disorder of this type is conjoined with liver disease and the corneal rings. Variants of the above syndrome that the authors have seen are an early choreoathetosis (like Sydenham chorea); prominent dystonic postures;

Figure 37-6. Kayser-Fleischer corneal ring in Wilson disease. Brown coloration is seen near the limbus of the cornea and represents copper deposition in Descemet's membrane. (Reproduced from Mackay D, Miyawaki E: Hyperkinetic Movement Disorders. ACP Medicine, Online S12C17, Topic ID 1271. © Decker Intellectual Properties. Courtesy of Drs. Edison Miyawaki and Donald Bienfang.)

a cerebellar ataxia with minimal rigidity; a syndrome of coarse action or action and intention tremor resembling that of dentatorubral degeneration; an immobile mute state with profound rigidity; and a dementia, character change, or psychosis with relatively few extrapyramidal signs. Action myoclonus as a prominent early manifestation has also been described. The parkinsonian features do not respond to L-dopa treatment.

Laboratory Findings In both the typical and variant forms of the disease, the finding of a low serum ceruloplasmin level (less than 20 mg/dL in 80 to 90 percent of patients), low serum copper (3 to 10 mM/L; normal 11 to 24 mM/L), and increased urinary copper excretion (more than 100 mg Cu/24 h) corroborate the diagnosis. Because 90 percent of copper is carried by ceruloplasmin and the latter is generally reduced in Wilson disease, serum copper values alone may be misleadingly normal. Early in the course of the illness, the most reliable diagnostic findings are a high copper content in a biopsy of liver tissue (more than 200 μ g Cu/g dry weight) and a failure to incorporate labeled ^{64}Cu into ceruloplasmin. The latter test, however, fails to dependably differentiate asymptomatic carriers from affected individuals. Measurement of increased cupruresis after the administration of penicillamine has not been shown to be more sensitive than an unenhanced 24-h urine collection for copper. Persistent aminoaciduria, reflecting a renal tubular abnormality, is present in most but not all patients. Liver function tests are usually abnormal; some patients are jaundiced and other signs of liver failure may appear late in the illness. In these patients, the serum ammonia may be elevated and the symptomatology may worsen with increases in dietary protein. The cirrhosis is not always evident in a liver biopsy (some regenerative nodules are large, and the biopsy may be taken from one of them). On the other hand, the diagnosis in children may be revealed when a liver biopsy is taken for the evaluation of cirrhosis. As mentioned earlier, the large number of mutations that give rise to the disease makes it impractical to use genetic analysis for diagnosis, but once the gene abnormality has been established in a given family, linkage studies may be used to identify other affected sibs.

It has been established that copper deposition in the liver is the initial disturbance; over time it leads to cirrhosis, so that, as already mentioned, the hepatic stage of the disease precedes neurologic involvement. Cranial CT is abnormal even in the hepatic stage and are invariably so when the neurologic disorder supervenes. The lateral ventricles and often the third ventricle are slightly enlarged, the cerebral and cerebellar sulci are widened, the brainstem appears shrunken, and the posterior parts of the lenticular nuclei, red nuclei, and dentate nuclei become hypodense (Ropper et al). With treatment, these radiologic changes become less marked (Williams and Walshe). MRI is an even more sensitive means of visualizing the structural changes, particularly those in the subcortical white matter, midbrain, pons, and cerebellum (Starosta-Rubinstein et al). In the MRI survey by Saatci and colleagues, the putamen was involved most frequently (although not invariably), showing a symmetrical T2 signal change in a laminar pattern; there

was also an increase in T1 signal throughout the basal ganglia, particularly in the pallidum. Signal changes are almost universally found in the claustrum and also in the midbrain (pars compacta of the substantia nigra), dentate nucleus of the cerebellum, pons, and thalami. We have been impressed with a glassy diffuse and confluent signal abnormality on T2-weighted and fluid-attenuated inversion recovery (FLAIR) images in the hemispherical white matter in some cases—findings that were mistaken for multiple sclerosis.

Neuropathologic Changes These vary with the rate of progress of the disease. Exceptionally, in the rapidly advancing and fatal form, there is frank cavitation in the lenticular (putaminal and pallidal) nuclei, as observed in Wilson's original cases. In the more chronic form, there is only shrinkage and a light-brown discoloration of these structures. Nerve cell loss and some degree of degeneration of myelinated fibers in lenticular nuclei, substantia nigra, and dentate nuclei are usually apparent. Subcortical myelin degeneration is found in some cases. More striking, however, is a marked hyperplasia of protoplasmic astrocytes (Alzheimer type II cells) in the cerebral cortex, basal ganglia, brainstem nuclei, and cerebellum, almost certainly a reaction to liver failure and hyperammonemia.

Treatment Ideally, treatment should be started before the appearance of neurologic signs; if this can be implemented, neurologic deterioration can be prevented to a large extent. Treatment consists of (1) reduction of dietary copper to less than 1 mg/d, which can usually be accomplished by avoidance of copper-rich foods (liver, mushrooms, cocoa, chocolate, nuts, and shellfish), and (2) administration of the copper chelating agent D-penicillamine (1 to 3 g/d) by mouth, in divided doses. Pyridoxine 25 mg/d should be added in order to prevent anemia. The use of D-penicillamine is associated with a number of problems. Sensitivity reactions to the drug (rash, arthralgia, fever, leukopenia) develop in 20 percent of patients and require a temporary reduction of dosage or a course of prednisone to bring them under control. Reinstitution of drug therapy should then be undertaken, using low dosages (250 mg daily) and, later, small, widely spaced increases. If the patient is still sensitive to D-penicillamine or if severe reactions (lupus-like or nephrotic syndromes or myasthenia gravis) occur, the drug should be discontinued and another chelating agent, triethylene tetramine (trientine) or ammonium tetrathiomolybdate may be substituted. Zinc, which blocks the intestinal absorption of copper, is also a suitable treatment, but ineffective alone. It is given as zinc acetate, 100 to 150 mg daily in 3 to 4 divided doses at least 1 h before meals (Hoogenraad et al). The appropriate drug must then be continued for the patient's lifetime. Some women report improvement in neurologic symptoms during pregnancy, although there is no apparent change in copper metabolism during this time. In most patients, neurologic signs improve in response to decoppering agents. The Kayser-Fleischer rings disappear and liver function tests may return to normal, although the abnormalities of copper metabolism remain unchanged. In moderately severe and advanced cases, clinical improvement may not begin for

several months despite full doses of D-penicillamine, and it is important to resist discontinuing the drug during this latent period.

It is also well known that the institution of treatment with penicillamine may induce an abrupt worsening of neurologic signs, and we have witnessed several such instances, including one that culminated fatally from a cardiac arrhythmia. Furthermore, in many of these patients, the lost function is never retrieved. Presumably this deterioration is a result of the rapid mobilization of copper from the liver and its redistribution to the brain. The slow introduction of penicillamine may avoid this complication. The additional use of zinc or one of the newer agents mentioned above should be instituted as soon as neurologic deterioration becomes evident. In at least one reported case, new lesions of Wilson disease (shown by MRI) developed while the patient was receiving full doses of D-penicillamine and excellent decoppering of the liver had occurred (Brewer et al). In the few patients who develop seizures, they may become apparent soon after therapy is begun.

Many wilsonian patients with advanced liver disease have been subjected to liver transplantation, which is curative for the underlying metabolic defect. The degree of neurologic improvement varies; in some it has been remarkable and sustained, confirming that the hepatic defect is primary and that the brain is involved secondarily. According to Schilsky and coworkers, the main indication for transplantation is severe and progressive liver damage, but the operation has been used successfully in some patients with intractable neurologic deterioration and only mild signs of liver disease.

An important aspect of treatment is the screening of potentially affected relatives for abnormalities of serum copper and ceruloplasmin; if any relative is found to have the disease, penicillamine should be given indefinitely to prevent the emergence of neurologic symptoms. A full explanation of the dangers of ceasing the medication must be given, and compliance may have to be monitored.

Hereditary Deficiency of Ceruloplasmin (Aceruloplasminemia, CP Mutation)

This is a rare illness, similar to Wilson disease, occurring in patients with a recessively inherited deficiency of ceruloplasmin; it is not simply a heterozygous form of Wilson disease (the mutation involves a different gene). Cirrhosis and Kayser-Fleischer rings are not features of the disease but diabetes is common and extrapyramidal signs may or may not arise. Rather than copper, iron is deposited in the brain and liver (see discussion by Logan). Those few cases that have been well studied, mainly Japanese, show mainly an ataxic disorder (Miyajima et al).

Hyprocupric Myeloneuropathy

Noted briefly here and discussed more extensively in Chap. 44, is an idiopathic progressive posterior and lateral column myelopathy that closely simulates subacute combined degeneration of B₁₂ deficiency. It is associated with low serum copper levels, usually idiopathic but

sometimes caused by malabsorption or the intake of zinc as an over-the-counter supplement to prevent colds or to improve the senses of smell and taste; zinc inhibits absorption of copper from the gut.

Neurodegeneration With Brain Iron Accumulation (Formerly, Hallervorden-Spatz Disease, PANK Mutation)

This disease, recently renamed because of ignoble associations of the eponymous Hallervorden and Spatz, is also known as *pigmentary degeneration of the globus pallidus*. It is inherited as an autosomal recessive trait and is caused by, in all classic cases, a defect in the gene encoding pantothenate kinase 2 (*PANK2*), usually in the form of a missense mutation. The onset of symptoms is in late childhood or early adolescence with slow progression over a period of 10 or more years. The early signs are highly variable but are predominantly motor, both corticospinal (spasticity, hyperreflexia, Babinski signs) and extrapyramidal (rigidity, dystonia, and choreoathetosis). General deterioration of intellect is conjoined. In individual cases, ataxia and myoclonus have appeared at some phase of the illness. The spasticity and rigidity are most prominent in the legs, but in some instances they begin in the bulbar muscles, interfering with speech and swallowing, as happens in Wilson disease. We have observed patients who, over a period of years, exhibited only dystonia of the tongue, blepharospasm, or arching of the back. The relationship of this restricted form to the complete syndrome remains unsettled. Eventually, the patient becomes almost completely inarticulate and unable to walk or use his or her arms. Hayflick and colleagues found that only one-third of patients with atypical forms of the disease have mutations of the *PANK2* gene. Moreover, variant cases tended not to show the characteristic changes on MRI described below.

Reduced levels of *PANK2* in the blood corroborate the diagnosis but this test is available only in research laboratories with an interest in the disease. The characteristic deposits of iron in the basal ganglia have not been associated with a demonstrable abnormality of serum iron or of iron metabolism. It has, however, been reported that there is increased uptake of radioactive iron in the region of the basal ganglia following intravenous injection of labeled ferrous citrate (Vakili et al; Szanto and Gallyas). CT reveals hypodense zones in the lenticular nuclei, resembling those of hepatolenticular degeneration (also of sulfite oxidase deficiency, glutaric acidemia and Leigh disease), although high-density lesions have been described in one autopsy-proven case of this disease (Tennison et al). The MRI findings are striking (Fig. 37-7). In T2-weighted images, the rim of the pallidum appears intensely black (iron deposition), with a small white area in its medial part that represents a zone of necrosis ("eye-of-the-tiger" sign; see also Savoirdo et al).

The neuropathologic features prove to be the most distinctive attributes of the disease. There is an intense brown pigmentation of the globus pallidus, substantia nigra (especially the anteromedial parts), and red nucleus. Granules and larger amorphous deposits of iron mixed with calcium stud the walls of small blood vessels or lie

Figure 37-7. Pantothenate kinase-associated neurodegeneration (Hallervorden-Spatz disease). T2-weighted MRI showing areas of decreased signal intensity of the pallidum bilaterally (corresponding to iron deposition) and a central high signal area because of necrosis ("eye-of-the-tiger" sign). (Reproduced by permission from Lyon et al. Courtesy of Dr. C. Gillain.)

free in the tissue. A loss of neurons and myelinated fibers occurs in the most affected regions. Another unique feature is the presence of swollen axon fragments, which resemble those of neuroaxonal dystrophy. The significance of iron deposition is difficult to judge. To some extent, there is an increase of iron in the basal ganglia in other degenerative diseases. In Parkinson disease and striatonigral degeneration, for example, the deposition of iron is two to three times normal, presumably the result of degeneration of those tissues that are known to be rich in iron.

No treatment is known to be effective. Some of our patients responded temporarily to L-dopa, but the effect was slight. The use of chelating agents to reduce iron storage has not helped.

Syndromes of Dystonia and Generalized Chorea and Athetosis

As indicated in Chap. 4, the differences between dystonia and choreoathetosis are not fundamental. If one examines many patients with these involuntary movements, every gradation between the two is seen, and often the quicker, unpatterned involuntary movements of mild ballismus are added. Even tremor and myoclonus may complicate the composite movement disorder. With reference to muscular tone in patients with athetosis and dystonia,

there are unpredictable associations of hypertonia and hypotonia. A number of inherited metabolic diseases, all of them rare, express themselves by this syndrome of chorea, athetosis, and dystonia.

Lesch-Nyhan Syndrome (HPRT1 Mutation)

This rare metabolic disease is inherited as an X-linked recessive trait. Although it carries the names of Lesch and Nyhan, the occurrence of uricemia in association with spasticity and choreoathetosis in early childhood had been described earlier by Cateland Schmidt. Essentially, it is a hereditary choreoathetosis with self-mutilation and hyperuricemia. The affected children appear normal at birth and usually develop on schedule up to 3 to 6 months of age. Maturation delay then sets in, initially with hypotonia that later gives way to hypertonia. Also, the patient's behavior becomes abnormal, with aggressiveness and compulsive actions. The uncontrollable self-mutilation, mainly of the lips, occurs early (during the second and third year), and spasticity, choreoathetosis, and tremor come later. Most of the children learn to walk. Speech is delayed, and once attained, it is dysarthric and remains so throughout life. Mental retardation is moderately severe. In patients more than 10 years of age, gouty tophi appear on the ears, and there is increasing risk from gouty nephropathy. The serum levels of uric acid are in the range of 7 to 10 mg/dL.

A deficiency of the enzyme hypoxanthine-guanine-phosphoribosyl transferase (HPRT) has been found in all typical cases of this disease. The *HPRT* gene lies on the X chromosome (Xq 26-q 27), and accurate diagnosis of affected males and carriers can be made by DNA analysis. As a result of this deficiency, hypoxanthine is either excreted or catabolized to xanthine and uric acid. The details of the biochemical abnormality responsible for CNS dysfunction are unclear.

In the differential diagnosis, one must consider nonspecific mental retardation or autism with hand biting and other self-mutilations, athetosis from birth trauma, and encephalopathies with chronic renal disease. Hyperuricemia has also been reported in a family with spinocerebellar ataxia and deafness and in another with autism and mental retardation, neither of them with the enzymatic defect of Lesch-Nyhan disease. As mentioned earlier, there are several other disorders of purine and pyrimidine metabolism, some of them with hyperuricemia, that present with a neurologic syndrome like that of Lesch-Nyhan.

Treatment This is with the xanthine oxidase inhibitor allopurinol, which blocks the last steps of uric acid synthesis, reduces the uric acid in Lesch-Nyhan disease, and prevents the uricosuric nephropathy, but it seems to have no effect on CNS symptoms. Guanosine 5-monophosphate and inosine 5-monophosphate, both of which are deficient in Lesch-Nyhan disease, have been replaced without benefit to the patient. Transitory success has also been achieved by the administration of 5-hydroxytryptophan in combination with L-dopa. Fluphenazine (Prolixin) is reported to have suppressed the self-mutilation after haloperidol (Haldol) had failed to do so. Behavior modification programs may be of some value.

Calcification of Vessels in Basal Ganglia and Cerebellum

Ferrugination and calcification of vessels in the basal ganglia occur to a slight degree in many elderly persons (and in other mammals) who are otherwise normal. The widespread use of and MRI has brought the condition to light with increasing frequency (see Fig. 37-8). Usually it may be dismissed as an aging phenomenon of no clinical significance. When it occurs early in life and is of such degree as to be visible in plain films of the skull, it must always be regarded as abnormal.

Fahr Disease An adult case of this type was described by Fahr, so that his name is sometimes attached to this disorder. This is an idiopathic form of calcification of the basal ganglia and cerebellum in which choreoathetosis and rigidity are prominent acquired features. The clinical state may also take the form of a parkinsonian syndrome or bilateral athetosis. In two of our patients there was unilateral choreoathetosis, which was replaced gradually by a parkinsonian syndrome, and in another of our sporadic cases, the initial abnormality was a unilateral dystonia responsive to L-dopa. Some patients have been mentally retarded but most are intellectually intact. The serum calcium levels in the aforementioned diseases are usually normal and there is no explanation of the calcification. The gene(s) have not been identified at the time of this writing but there may be a locus on chromosome 14q.

Hypoparathyroidism In hypoparathyroidism (idiopathic or acquired) and pseudohypoparathyroidism (a rare familial disease, caused by end-organ insensitivity

to parathyroid hormone with distinctive skeletal and developmental abnormalities), the diminution in ionized serum calcium induces not only tetany and seizures but also choreoathetosis. This last symptom is presumably a result of calcification of the basal ganglia, which occurs in about one-half of the patients but of unknown mechanism. Also, in some instances there are signs of a cerebellar lesion. Pseudopseudohypoparathyroidism is a disorder that imitates the bony abnormalities seen in pseudohypoparathyroidism but in which calcium metabolism is normal and there are no neurologic features.

Osteopetrosis

Sly and colleagues described the familial occurrence (21 cases in 12 families) of calcification in the caudate and lenticular nuclei, thalami, and frontal lobe white matter in association with osteopetrosis ("marble bones") and renal tubular acidosis. Clinically, there were multiple cranial nerve palsies—including optic atrophy as well as psychomotor delay and learning disabilities—but no extrapyramidal signs. The cranial nerve palsies, which are a result of bony encroachment in neural foramina, were much less severe than in the lethal form of osteopetrosis. The pattern of inheritance of this disease is autosomal recessive (rarely X-linked), and the basic abnormality was found to be a deficiency in carbonic anhydrase II in red blood corpuscles and probably in kidney and brain. Several types of disease have been associated with corresponding mutations, mostly in *CLCN7*.

Other Metabolic Disorders Associated With Choreoathetosis and Dystonia

We emphasize that acquired extrapyramidal disorders are much more common than metabolic ones. For example, athetosis may follow hypoxic encephalopathy of birth or follow kernicterus caused by Rh and ABO blood incompatibilities and erythroblastosis fetalis. The same is true of the Crigler-Najjar form of hereditary hyperbilirubinemia, in which kernicterus (with ataxia or athetosis) may rarely appear as late as childhood or adolescence, the defect being one of glucuronide-bilirubin conjugation. Later in life, the more common causes are medications, illicit drug use, focal cerebral lesions, hyperosmolar nonketotic state, antiphospholipid antibody syndrome, among many others discussed in Chap. 6. Furthermore, a number of other rare diseases, which can only be classified as hereditary degenerative, also figure in the differential diagnosis of choreoathetotic or dystonic syndromes and are discussed in Chap. 39. Torsion dystonia is the best-known example.

With regard to rarer metabolic causes, ceroid-lipofuscinosis of the Kufs type, G_{M1} gangliosidosis, late-onset metachromatic leukodystrophy, Niemann-Pick disease (type C), Hallervorden-Spatz disease, and Wilson disease may present with a syndrome of which dystonia or athetosis is an important component. Usually, there are other elements in the clinical picture as well, so that the correct diagnosis is seldom in doubt for long. dal Canto and colleagues have described a variant of neuronal ceroid-lipofuscinosis in which a boy and girl of unrelated

Figure 37-8. Idiopathic basal ganglionic and cerebellar calcification discovered 5 years after the onset of a slowly progressive rigid Parkinson syndrome in a 54-year-old woman.

non-Jewish parents developed severe choreoathetosis and dystonia at 6 to 7 years of age. Intellectual deterioration, gait abnormality, and seizures were added clinical features. Cerebral biopsy showed intraneuronal inclusions consisting of curvilinear bodies. These observations support the notion of nosologic heterogeneity among the nonglycolipid neuronal storage disorders.

Glutaric acidemia (type I) is another rare metabolic disorder, in which progressive choreoathetosis and dystonia are combined with intermittent acidemia. In some cases, ataxia of movement and a variable degree of mental retardation are also present. Glutaric acid is present in the urine, as are its metabolites 3-hydroxyglutarate and glutamate. The basic defect is in glutaryl CoA dehydrogenase, which has been found in leukocytes, hepatocytes, and fibroblasts. Neuropathologically, there is loss of neurons in the caudate, putamen, and pallidum, with gliosis. A spongy change is said to affect the white matter.

Infants with glutaric acidemia are often subject to sudden episodes of acidosis, coma, and flaccidity. There are signal changes on MRI, corresponding to the acute necrosis of nerve cells in the basal ganglia. These crises can be prevented and the infants can develop normally if the diagnosis is made before the development of neurologic signs, for example, in the sibling of an older affected child, and treatment is undertaken with a diet low in protein, particularly in tryptophan and lysine (Cho et al).

THE LEUKODYSTROPHIES: SYNDROMES OF BILATERAL HEMIPLEGIA, BLINDNESS, AND NEUROPATHY

Categorized here are late life manifestations of familial leukodystrophies. Of the several varieties of late-onset leukodystrophy, some are of unquestionable metabolic origin. The terms *metachromatic*, *sudanophilic*, *orthochromic*, etc., refer to the distinctive products of myelin degeneration and staining characteristics (or lack thereof) of the white matter in the individual leukodystrophies. As emphasized earlier, these are distinguished from the cerebral gray matter diseases (poliodystrophies), which have a different mode of presentation—seizures, myoclonus, chorea, choreoathetosis, and tremor being prominent. Instead, recognition of the entire group of leukodystrophies is based on symptoms and signs attributable to the interruption of tracts (corticospinal, corticobulbar, cerebellar peduncular, sensory) and visual pathways (optic nerve, optic tract, geniculocalcarine) and the infrequency or absence of seizures, myoclonus, and spike-and-wave abnormalities in the EEG. However, this distinction is not infallible, particularly in the later stages of the disease.

The syndrome of progressive spasticity and rigidity with spastic dysarthria and pseudobulbar palsy poses a difficult diagnostic problem. One's first impulse is to assume the presence of a corticospinal disorder, especially if tendon reflexes are brisk, but frequently the plantar reflexes are flexor and the facial reflexes are not enhanced ("pseudo-pseudobulbar palsy," a term we attribute to Marsden). In addition, unusual postures and a more

plastic type of rigidity may occur, consistent with an extrapyramidal condition. Adrenomyeloneuropathy is another syndrome that combines reduced or absent tendon reflexes and Babinski signs, signifies a combination of corticospinal and peripheral nerve lesions, and is highly characteristic of metachromatic leukoencephalopathy.

The leukodystrophies that become apparent only in later life pose yet another problem: the clinical and radiologic differentiation from cerebral forms of multiple sclerosis. In identifying the metabolic diseases of myelin, one is helped by the relative symmetry and steady progression of the clinical signs; the early onset of cognitive impairment (which is uncharacteristic of multiple sclerosis); and the symmetrical and massive degeneration of the cerebral white matter (in distinction to the asymmetrical and often multiple lesions of demyelinating disease). At various times in life, particularly in young individuals, CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) enters into the differential diagnosis (see Chap. 34); late in life, distinguishing a metabolic disorder of myelin from the subcortical multiple infarctions of Binswanger disease and from the ubiquitous rarefaction of the periventricular regions of the cerebrum may be a problem. Differentiation from cerebral gliomatosis, brain lymphoma, toxic forms of leukodystrophy, and progressive multifocal leukoencephalopathy, all affecting deep cerebral or white matter structures, offers less difficulty.

Adrenoleukodystrophy (Sudanophilic Leukodystrophy, ABCD1 Mutation)

This combination of leukodystrophy and Addison disease, originally included under the rubric of Schilder disease, is now set apart as an independent metabolic encephalopathy. It is transmitted as an X-linked recessive trait with an incidence of 1 in 20,000 male births. The fundamental defect is impairment in peroxisomal oxidation of very-long-chain fatty acids (VLCFAs), leading to their accumulation in the brain and adrenal glands (see the publications of H.W. Moser and of Igarashi and associates). The deficient membrane protein, encoded by a gene that maps to chromosome X28, is a peroxisomal membrane transporter (*ABCD1*). The gene is located close to the gene for color vision. In the typical X-linked adrenoleukodystrophy (ALD), there is an inability to metabolize VLCFAs, but it came as a surprise that the disease was not caused by an enzyme deficiency. The modern classification of the disease categorizes it as a disorder of peroxisomes, subcellular organelles containing numerous enzymes, each of which is unaffected. This peroxisomal assignment connects adrenoleukodystrophy with Zellweger and Refsum disease.

The onset is usually between 4 and 8 years, sometimes later; in the most common form of this disorder, only males are affected with the entire syndrome (women carriers may display a special myelopathy discussed further on). The signs of either the adrenal insufficiency or the cerebral lesion may be the first to appear. In the case described by Siemerling and Creutzfeldt, the first recorded example of this disorder, bronzing of the skin

of the hands appeared at 4 years of age; quadriparesis, with dysarthria and dysphagia (i.e., pseudobulbar palsy), became evident at 7 years; a single seizure occurred at 8 years; and by 9 years, shortly before death, the patient was *decerebrate* and unresponsive. In personally observed cases, the first abnormalities appeared at 9 to 10 years and took the form of episodic vomiting, decline in scholastic performance and change in personality with inappropriate giggling and crying. After a time, severe vomiting and an episode of circulatory collapse occurred, following which the gait became unsteady and arms ataxic with an intention tremor. Only then did the Addisonian increase of pigmentation of the oral mucosa and the skin around nipples and over elbows, knees, and scrotum become evident. *Cortical blindness* follows in some instances. The late stages are marked by bilateral hemiplegia (at first asymmetrical), pseudobulbar paralysis, blindness, deafness, and impairment of all higher cerebral functions.

The severity of the disease varies. We are caring for two adult men in whom the cerebral symptoms have been mild, allowing for high-level cognitive achievement, albeit with peculiarities of personality, and with mild spastic gait, urinary difficulty, testicular insufficiency, and baldness. In each family there was a male sibling who died in childhood, ostensibly of adrenal insufficiency.

Griffin and coworkers have described a spinal-neuropathic form of the disease (adrenomyeloneuropathy [AMN]). In their patients, evidence of adrenal insufficiency had been present since early childhood, but only in the third decade of life did a progressive spastic paraparesis and a relatively mild polyneuropathy develop. It should be noted that the spasticity is occasionally asymmetrical, and the gait may have an ataxic component. This neurologic picture, in mild form and without adrenal insufficiency, is also the manner in which the disease may present in *female carriers of the gene abnormality* (see below). Like adrenoleukodystrophy, adrenomyeloneuropathy is typically inherited as an X-linked, male-specific trait. However, we have encountered a large family with adrenomyeloneuropathy in which males and females are both affected in a pattern that suggests dominant inheritance. The VLCFAs are modestly elevated in affected individuals, and there is no evidence of cerebral involvement.

Moser and colleagues (1980), using clinical and biochemical criteria, have identified the following subtypes of ALD:

1. A progressive degeneration of cerebral white matter in young males, often with cortical blindness—the classic type, accounting for half of all cases (Fig. 37-9)
2. An intermediate form in juvenile or young adult males with cerebral and spinal involvement (5 percent of cases)
3. A progressive spinal cord tract degeneration in adult males (25 percent of cases)
4. A chronic mild, nonprogressive spastic paraparesis in *heterozygous female carriers* (10 percent of cases)
5. Familial instances of Addison disease without neurologic involvement in males (10 percent of cases)
6. Possibly, in male infants, a form originating at birth (e.g., Zellweger disease)

Illustrating the variability in presentation among kindreds, Marsden and colleagues (1982) and, subsequently, Kobayashi and coworkers described a familial spinocerebellar syndrome, and Ohno and associates reported a sporadic instance of adrenoleukodystrophy presenting as olivopontocerebellar atrophy. Moser found cerebral forms alone in 30 percent, adrenomyeloneuropathy alone in 20 percent, and combined childhood cerebral and myelopathic forms in the remaining half.

Female Heterozygotes Neurologic manifestations develop in up to 50 percent of female carriers but in our experience with siblings of affected patients, the figure has been lower. The onset of a *spastic paraparesis* tends to occur later in life, usually in the third or fourth decade, and progression tends to be slow, but an explosive onset has been reported (see Chap. 44). As already mentioned, multiple sclerosis is the main consideration in differential diagnosis, particularly as 20 percent of heterozygotes have white matter changes on cerebral MRI. Overt adrenal insufficiency is rare in female carriers, but scalp hair may be scant as a subtle manifestation of adrenal hypofunction.

Pathologically in classic instances, massive degeneration of the myelin occurs, often asymmetrically in various parts of the cerebrum, brainstem, optic nerves, and sometimes spinal cord (see Fig. 37-9). Degradation products of myelin are visible in macrophages in recent lesions,

Figure 37-9. Adrenoleukodystrophy. Axial T2-weighted MRI of an 8-year-old boy with headache. There is abnormal posterior periventricular white matter hyperintensity extending across the splenium of the corpus callosum. Laboratory testing confirmed adrenal insufficiency. (Image courtesy of Drs. Edward Yang and Sanjay Prabhu.)

namely, sudanophilic demyelination. There is extensive astrocytic gliosis. Axons are damaged, but to a lesser degree. The cortex of the adrenal glands is atrophic, and the cells and invading histiocytes contain an abnormal lipid material. The testes show marked interstitial fibrosis and atrophy of the seminiferous tubules. Electron microscopically, the macrophages of the brain and adrenals and the Leydig cells of the testes contain characteristic lamellar cytoplasmic inclusions.

Laboratory Diagnosis The specific laboratory marker of the disease is an excess of VLCFAs, in particular three measurements are of value: the absolute level of hexacosanoic acid (C26), the ratio of C26 to C22 (docosahexanoic acid; C26:C22), and of C24 (tetracosanoic acid) to docosahexanoic acid (C24:C22) in plasma, erythrocytes, leukocytes, or cultured fibroblasts as detailed by Moser and colleagues (1999). This reflects the basic biochemical fault in this disease, namely defective fatty acid oxidation within the peroxisomes. If skin fibroblasts and plasma testing are both performed, 93 percent of female carriers will show the abnormal VLCFA. MRI of the brain is abnormal in the majority of patients with cerebral symptoms and in a proportion of others.

Other laboratory findings are low serum sodium and chloride levels and elevated potassium levels reflecting the atrophy of the adrenal glands. The latter results in reduced excretion of corticosteroids, low serum cortisol levels, and lack of rise in 17-hydroxyketosteroids after adrenocorticotrophic hormone (ACTH) stimulation. The CSF protein may be elevated. As a research tool, Öz and colleagues have shown that magnetic resonance spectroscopy that measures the concentrations of several metabolites can be used as a guide to the progression of the disease and to gauge the effects of new therapies as they are introduced.

Treatment Adrenal replacement therapy prolongs life and occasionally effects a partial neurologic remission. A diet enriched with monounsaturated fatty acids and devoid of long-chain fatty acids has been said to slow the progress of the disease when administered before the age of 6 years. Bone marrow transplantation, to date performed in more than 50 children, has been the only treatment shown to stabilize the disease and reverse some of the MRI changes. The reviews by van Geel and colleagues, and the ones by Moser (1997 and 1999) the leading worker in the field, summarizing diagnosis and treatment, are recommended.

Juvenile and Adult Metachromatic Leukodystrophy

This form of leukodystrophy was described in relation to the inherited metabolic disorders of late infancy and early childhood in an earlier section. We mention it here to emphasize that the disease may have its onset at almost any age. Juvenile forms may begin between 4 and 12 years of age and adult forms between the midteens and the seventh decade of life. The mutations of the aryl sulfatase gene giving rise to these various forms are described in the earlier section on metachromatic leukodystrophy (MLD). Some of the sporadic cases reported in the adult probably were examples of cerebral multiple sclerosis, but we have seen, as have others, cases of MLD appearing as

late as middle adult life. In almost all cases, the clinical picture, like those described by Turpin and Baumann, was one of slowly evolving intellectual decline or behavioral abnormality, followed by spastic weakness, hyperreflexia, Babinski signs, and stiff, short-stepped gait, with or without a polyneuropathy. Without manifest neurologic signs, misdiagnosis of psychiatric disease is common. As the disease progresses over a period of 3 to 5 years there may be a loss of vision and speech, then of hearing, and finally a state of virtual decerebration.

In some of these cases it is impossible to distinguish the white matter disease from that of Pelizaeus-Merzbacher and of Cockayne, described in the preceding section.

Orthochromatic Leukodystrophies

This refers to a heterogeneous group of disorders, also called nonmetachromatic leukodystrophy, in which no enzyme defect or special staining characteristic of degenerated white matter has been identified. Furthermore, most of them have been sporadic, obscuring the nosology of the process. One type is associated with cerebellar ataxia and dementia; other adult cases have been described in which epilepsy was associated with a frontal lobe type of dementia. A surprising feature, such as in the cases of Letournel and colleagues, has been normal MRI, even with the more sensitive FLAIR sequences.

Cerebrotendinous Xanthomatosis (CYP27A Mutation)

This rare disease is probably transmitted by an autosomal recessive gene. It usually begins in late childhood, with cataracts and xanthomas of tendon sheaths and lungs. As it progresses, difficulty in learning, impairment of retentive memory, and deficits in attention and visuospatial perception (the earliest neurologic manifestations) give way to dementia, ataxic or ataxic-spastic gait, dysarthria and dysphagia, and polyneuropathy. In the late stages (after 5 to 15 years), the patient becomes bedfast and helpless; death occurs at 20 to 30 years of age. In other cases, the clinical course is much more benign. Neuropathologic examination shows masses of crystalline cholesterol in the brainstem and cerebellum and sometimes in the spinal cord, with symmetrical destruction of myelin in the involved areas. The white matter lesions are visible by CT and MRI.

The basic defect is in the synthesis of primary bile acids, leading to an increased hepatic production of cholesterol and cholestanol, which accumulate in brain and tendons. The serum cholesterol levels are normal in most cases but may be as high as 450 mg/dL in others. The tendon xanthomas contain cholesterol, of which 4 to 9 percent is cholestanol (dihydrocholesterol) according to the studies of Moser and colleagues (1984). Cholestanol levels in the serum and red cells are increased. The same elevated levels are found in heterozygotes. The causative mutation is in CYP27A.

Treatment In response to long-term treatment with chenodeoxycholic acid, 750 mg daily, the corticospinal and cerebellar signs and dementia receded in 10 of 17 patients treated and followed by Berginer and coworkers. This drug corrects the defective synthesis of bile

acids and restores the low level of chenodeoxycholic acid. Ideally, treatment should begin before the neurologic symptoms appear (Meiner et al).

STROKES IN ASSOCIATION WITH INHERITED METABOLIC DISEASES

In Chap. 34 it was remarked that strokes occur from time to time in children and young adults, often as a result of inherited disorders of the clotting system typified by protein C deficiency, but also of a number of other metabolic derangements, including the mitochondrial disorder MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes). Among the many causes, three metabolic diseases must always be considered in the diagnosis of such cases: *homocystinuria*, *Fabry disease*, and *sulfite oxidase deficiency*. Other less-common ones are *Tangier disease* and *familial hypercholesterolemia*. Stroke in young persons is also a central feature of the mitochondrial disorder MELAS, discussed further on in this chapter, and of the genetically determined microvasculopathy CADASIL ("Familial Subcortical Infarction" discussed in Chap. 34).

Homocystinuria

This aminoaciduria is inherited as an autosomal recessive trait and simulates Marfan disease. Tall, slender habitus; great length of limbs, sometimes scoliosis and arachnodactyly (long, spidery fingers and toes); thin and rather weak muscles; knock-knees; highly arched feet; and kyphosis are the typical skeletal features. Sparse, blond, brittle hair; malar flush; and livedo reticularis are common dermal manifestations, and a dislocation of one or both lenses (usually downward) may occur, imparting a tremulous appearance to the irides (iridodonesis). The only neurologic abnormality is mental retardation, usually of mild degree, which sets this syndrome apart from Marfan disease, in which intellect is unimpaired. Several mutations in different genes have been implicated, the most common being in CBS that codes for cystathionine beta-synthase.

Blood vessel changes of thickening and fibrosis of the coronary, cerebral, and renal arteries tend to appear later in the illness. An abnormality of platelets favoring clot formation and thrombosis of cerebral arteries has been observed. Some patients have died of coronary occlusions during adolescence, and a myocardial lesion may be the source of emboli to cerebral arteries.

Homocysteine is elevated in the blood and CSF, and homocystine in the urine. This is because of an inherited cystathionine synthase deficiency that results in an inadequacy of cystathionine formation, a substance essential to many tissues including the brain. This may be the explanation of the developmental delay. Plasma methionine levels are also elevated. The infarcts in the brain are clearly related to thrombotic and embolic arterial occlusions. The administration of large doses (50 to 500 mg) of pyridoxine (a cystathionine synthase coenzyme), folate 5 mg daily and cobalamin (vitamin B₁₂) 1,000 µg daily,

reduces the excretion of homocystine. If vascular lesions have occurred, anticoagulants probably prevent further occlusions.

Homocysteinemia and homocystinuria may also be expressions of 5,10-methylenetetrahydrofolate reductase deficiency. Again, the clinical manifestations consist of multiple cerebrovascular lesions, dementia, epilepsy, and polyneuropathy. The last is believed to be caused by a coincidental folic acid deficiency, but in some cases it may have been caused by chronic phenytoin administration (Nishimura et al).

Much milder elevations of serum homocystine have been recognized as contributing to the risk of coronary disease and stroke in otherwise normal individuals.

Fabry Disease (Anderson-Fabry Disease, GLA Mutation) (See also Chaps. 34 and 46)

This disease, also known as *angiokeratoma corporis diffusum*, is inherited as an X-linked recessive trait. It occurs in complete form in males and in incomplete form in female carriers. The primary deficit is in the enzyme alpha-galactosidase A, the result of which is the accumulation of ceramide trihexoside in endothelial, perithelial, and smooth muscle cells of blood vessels as well as in renal tubular and glomerular cells and other viscera and in nerve cells in many parts of the nervous system (hypothalamic and amygdaloid nuclei, substantia nigra, reticular and other nuclei of the brainstem, anterior and intermediolateral horns of the spinal cord, sympathetic and dorsal root ganglia).

The disease becomes manifest clinically in childhood or adolescence, with intermittent lancinating pains and dysesthesias of the extremities. A notable feature of these pains is their evocation by fever, hot weather, and vigorous exercise. Usually there is no sensory loss, but autonomic disturbances have been recorded in a series of our cases. Many years later there is a diffuse vascular involvement that leads to hypertension, renal damage, cardiomegaly, and myocardial ischemia. Thrombotic infarctions occur in the brain during early adult years. Occasional cases are discovered in adulthood with confluent cerebral white matter changes on MRI and progressive problems such as dysarthria.

The characteristic angiokeratomas tend to be most prominent periumbilically and resemble small angiomas that obliterate slightly with pressure. Desnick and colleagues have reviewed the neurologic, neuropathologic, and biochemical findings in this disease, and Cable and colleagues have written informatively on the autonomic aspects.

Treatment Enzyme replacement, given by infusion, is now available. The two main trials of this treatment, summarized in an editorial by Pastores and Thadhani, were each conducted quite differently. Both showed an improvement in kidney and other organ function but only one demonstrated a reduction in neuropathic pain, and neither studied the risk of stroke. Like enzyme replacement therapy for Gaucher disease, prolonged treatment is expensive; but some evidence from the trials cited above indicates that certain aspects of the disease are reversible.

The painful neuropathic features that have brought several cases to our attention are discussed with the polyneuropathies, in Chap. 46.

Sulfite Oxidase Deficiency

This disorder was discussed briefly with the neonatal metabolic disorders. The occurrence of stroke as a complication of this disorder was placed on record by our colleagues Shih et al (1977). A child 4.5 years of age, whose development had been retarded since birth (seizures and opisthotonos had been present), became hemiplegic. Another unrelated child, supposedly normal until 2 years of age, entered the hospital with fever, confusion, generalized seizures, right hemiplegia, and aphasia (infantile hemiplegia); subluxation of the lenses (upward) was discovered later. There was an increased level of sulfite and thiosulfate and an abnormal amino acid, S-sulfocysteine, in the blood. One child appeared to respond to a low-sulfur-amino-acid diet.

CHANGES IN BEHAVIOR AND INTELLECT AS MANIFESTATIONS OF INHERITED METABOLIC DISEASE

Certain metabolic diseases may be the cause of serious disturbances of cognitive function and behavior, even in the adolescent and early adult period. The diagnosis and management of these metabolic diseases are so unusual that some special remarks are appropriate. When they present later in adolescence and adult life they evolve more slowly than childhood forms. The most obvious and easily detectable of these derangements are in the cognitive sphere, i.e., memory, calculation, problem solving, and verbal skills. Impulsivity, loss of self-control, and antisocial behavior are the most troubling behavioral abnormalities. Each of these phenomena has its own cerebral anatomy, as pointed out in Chap. 22, and the state of dementia comprises various degrees and combinations of these abnormalities.

Intellectual functions are difficult to accurately assess in early childhood. Slowness in learning and in acquiring language functions become manifest in school and may then be interpreted loosely as mental retardation. Up until school age, these intellectual functions have not developed sufficiently to allow recognition of their regressive course. Only in late childhood do mental retardation and dementia become clearly distinguishable and measurable by standardized tests. Far less tangible are subtle changes in personality and behavior.

A useful principle in recognizing those adolescents with a metabolic brain disease is that sooner or later, such a condition will cause a *regression in cognitive and intellectual functions*. Bipolar disease, sociopathies, and character disorders do not result in the loss of neurologic function. The recognition of a metabolic cause of mental deterioration depends on the demonstration of failing memory, impaired thinking, inability to learn, and loss of verbal and arithmetic abilities, many of which are

measured quantitatively by intelligence tests. The appearance of pyramidal signs, aphasia, apraxia, ataxia, or areflexia further sets them apart.

If one reviews all the diseases described in this chapter and selects those that may demonstrate *regression of cognitive function in association with personality change and alteration of behavior in an adult*—diseases that may for a time be unaccompanied by other neurologic abnormalities—the following metabolic disorders merit special consideration in approximate relative order of importance:

1. Wilson disease
2. Adrenoleukodystrophy
3. Metachromatic leukodystrophy
4. Hallervorden-Spatz pigmentary degeneration
5. Late-onset neuronal ceroid-lipofuscinosis (Kufs form)
6. Juvenile and adult Gaucher disease (type III)
7. Some of the mucopolysaccharidoses
8. Adult G_{M2} gangliosidosis
9. Mucopolipidosis I (type I sialidosis)
10. Lafora-body myoclonic epilepsy
11. Nonwilsonian copper disorder (hereditary ceruloplasmin deficiency)

In each of these diseases, dementia and personality disorder may gradually develop and exist for many months, even a year or two, before other neurologic signs appear. One must look carefully for the earliest signs of movement disorders and other neurologic abnormalities, which greatly clarify the diagnostic problem. The common use of neuroleptic drugs, causing tardive dyskinesia and parkinsonian signs, is an obstacle to determining if there are neurologic features in these ostensibly psychiatric conditions.

ADULT FORMS OF INHERITED METABOLIC DISEASES

The increasing range and precision of biochemical and cytologic tests have brought to light a number of inherited metabolic diseases that sometimes have their onset in adult life. Such disorders, while uncommon, nevertheless are important because they must be considered in the differential diagnosis of degenerative diseases. Also to be considered in the differential diagnosis is an array of mitochondrial disorders, to be discussed further on in this chapter.

In the last three decades, the authors have personally observed or have otherwise come to know of examples of the following metabolic diseases, the onset of which was in adult life:

1. Metachromatic leukoencephalopathy
2. Adrenoleukodystrophy
3. Globoid body leukodystrophy (Krabbe disease)
4. Kufs form of neuronal ceroid lipofuscinosis
5. G_{M2} gangliosidosis
6. Wilson disease
7. Gaucher disease
8. Niemann-Pick disease
9. Carnitine palmitoyl transferase deficiency

10. Mucopolysaccharide encephalopathy
11. Mucopolidosis type I
12. Polyneuropathies (Andrade disease, Fabry disease, porphyria, Refsum disease)
13. Mitochondrial diseases, particularly progressive external ophthalmoplegia and Leigh disease

In the encephalopathic forms of the metabolic and mitochondrial diseases, the diagnosis is usually made only after symptoms have been present for months or years, the disease having been mistaken for some other condition, particularly depression or a degenerative dementia. Even a manifest psychosis may have occurred in relation to some of these disorders, but such occurrences are admittedly rare. For example, one of our patients with metachromatic leukodystrophy, a 30-year-old man, began failing in college years and was later unsuccessful in holding a job because of carelessness and mistakes in his work and indifference to criticism, irritability, and stubbornness (clearly traceable to a mild dementia). Only when Babinski signs and loss of tendon reflexes in the legs were detected was the correct diagnosis entertained for the first time. By then he had been ill for nearly 10 years. Bosch and Hart described a patient with the onset of dementia at 62 years of age and drew attention to 27 other similar cases of adult-onset metachromatic leukoencephalopathy (see also the 7 cases of Turpin and Baumann). Overt signs of neuropathy are usually lacking in these adult-onset cases, but EMG and sural nerve biopsy will disclose the characteristic abnormalities.

One of our adult patients with Wilson disease had been committed to a psychiatric hospital because of his paranoid tendencies and fighting with his family; the presence of a tremor and mild rigidity of the limbs had been attributed at first to phenothiazine drugs. In some of Griffin's cases of adrenomyeloneuropathy, a spastic weakness of the legs and sensory ataxia progressing over several years were the main clinical manifestations; a spinocerebellar degeneration was suspected. One of our patients with Kufs lipid storage disease began to deteriorate mentally in early adult life and only much later showed an increasing rigidity, with athetotic posturing of limbs and difficulty in walking; he succumbed to his disease after more than a decade of symptoms. Another recent patient with Kufs disease presented at age 51 with vague visual difficulty, which was followed by spasticity of the legs, behavioral disinhibition, and dementia spanning 6 years. Josephs and colleagues describe 2 of 5 patients with adult-onset type C Niemann-Pick disease who had a psychosis beginning at ages 61 and 27, respectively.

We have observed cerebellar ataxia, polymyoclonus, and progressive blindness in adolescents and adults with a variant of G_{M2} gangliosidosis; cherry-red macular spots provided the clue to diagnosis. Several such cases have been reported in the last decade, particularly among the Japanese (Miyatake et al). Nine cases of a spinocerebellar ataxia with dementia or psychosis of adult onset were described by Wilner and colleagues. Also in our service were 2 adult patients with progressive spinal muscular atrophy who proved to have this same G_{M2} hexosaminidase deficiency; the process was

clinically almost indistinguishable from a very slowly progressive lower motor neuron form of motor neuron disease but they had no macular changes and displayed the additional features of ataxia and an intermittent and atypical psychosis. An asymmetrical corticospinal syndrome with areflexia had advanced so slowly in one of our cases of Krabbe disease that she became disabled only in her sixties.

Another of our patients, an adolescent with severe diffuse myoclonus and seizures and slight intellectual deterioration, was found after several years to have one of the rare variants of Gaucher disease. Another with dementia, rigidity, choreoathetosis, slight cerebellar ataxia, and Babinski signs had a variant of Niemann-Pick disease. Rarely, Gaucher disease may be associated with an early and severe parkinsonian syndrome. Cases of familial adult-onset Leigh disease have been described by Kalimo and colleagues. Adrenoleukodystrophy presenting in adult life as a spinocerebellar or olivopontocerebellar syndrome has already been mentioned.

These rare forms of inherited metabolic disease are notable for their chronicity and for the early prominence of a particular neurologic symptom or syndrome. Once the disease is established, however, there is nearly always evidence of involvement of multiple neuronal systems, reflected in a subtle or overt dementia, character disorder, or signs referable to corticospinal, cerebellar, extrapyramidal, visual, and peripheral nerve structures. *This multiplicity of neuronal system involvement is much more a feature of heritable metabolic disease than of degenerative disease and the finding of such involvement should provoke a search for an inherited metabolic disorder.*

To reiterate the clinical aspects, the aforementioned dictum that tract involvement (corticospinal, cerebellar, peduncular, sensory, optic nerve) indicates a leukodystrophy and that "gray matter" signs (seizures, myoclonus, dementia, retinal lesions) indicate a poliodystrophy is useful mainly in the early stages of a disease. Some of the lysosomal storage diseases affect both galactolipids (galactocerebrosides and sulfatides) and gangliosides; hence both white and gray matters are involved. The paper by Turpin and Baumann is of interest when this group of diseases is viewed from the strictly psychiatric point of view.

Certain outstanding clinical symptoms that are more often attributable to common diseases of the adult nervous system, such as multiple sclerosis and atherosclerosis, are sometimes the result of an inborn error of metabolism. These infrequent instances are categorized by their main features in Table 37-8, which is adopted from Grey et al.

Viewed from another perspective, patients are sometimes referred for the evaluation of diffuse white matter disease of the cerebrum that has been found with imaging studies. Multiple sclerosis and its variants come to mind immediately but, as discussed in Chap. 36, diseases other than MS are more likely to cause *diffuse, symmetric, and bilateral changes in the deep hemispheres*. These include CADASIL, Susac syndrome, infiltrative tumors such as lymphoma and gliomatosis cerebri, and autoimmune systemic conditions that secondarily affect the white matter,

MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes.

perhaps by a mechanism of microvasculitis. However, the dysmyelinating leukodystrophies discussed in this chapter may manifest late in life and enter into the differential diagnosis of this imaging appearance. As a guide to evaluating such cases, Schiffmann and van der Knaap have provided an extensive listing of diseases and characterized them by the presence of the MRI characteristics, particularly the presence of *hypomyelination* in which the white matter is hyperintense or isointense to the cortex on T1-weighted images (and usually less T2 hyperintense than in other pathologic changes of white matter). They further divide the group that is not hypomyelinated by the feature of confluence of multifocal distribution. The algorithm they provide may guide the clinician in choosing an appropriate laboratory plan.

In concluding this discussion, which classifies the inherited monogenetic metabolic diseases in accordance with their clinical characteristics, the reader will appreciate its artificiality. Nearly every one of the diseases of each category may present some neurologic abnormality other than the ones we have emphasized, so that the potential number of variations is almost limitless. However, the plan presented here of thinking of these diseases in reference to age periods and syndromes, is of heuristic value and facilitates clinical study of this extremely difficult segment of neurologic medicine.

MITOCHONDRIAL DISORDERS

As with the metabolic disorders of the nervous system, the diseases included under this heading are so varied and may involve so many parts of the nervous system that the clinical entities by which they are identified cannot be easily addressed in any one part of this book. In their overlapping relationships, however, these diseases are unlike the more discrete clinical entities caused by nuclear genetic mutations. Their diversity is evident not only in the details of their clinical presentations but also in the age at which symptoms first become apparent and, what is most intriguing, sometimes in the abrupt onset of their neurologic manifestations. Most of this variability in presentation is understandable from the principles of mitochondrial genetics outlined in the introductory section of this chapter. Of particular importance is the mosaicism of the mitochondria within cells and from cell to cell and the crucial role the organelles play in the oxidative energy metabolism that supports the function of cells in all organs.

Fortunately for the clinician, the most important of these diseases are expressed in several recognizable core syndromes and in a few variants thereof. A number of acronyms derived from the initial letters of the main clinical features are used to designate the major mitochondrial syndromes: MERRF, MELAS, PEO, NARP, etc., as summarized in Table 37-9. The addition of certain subtle dysmorphic features including short stature; endocrinopathies, particularly diabetes; and a number of other systemic abnormalities such as lactic acidosis (discussed further on) aids in diagnosis of this class of disorder.

These diseases are the result of mutations in the mitochondrial genome, a ringed DNA of 16,569 base pairs and 37 genes contained within the organelle, or of mutations in a few nuclear genes that code for a component of the mitochondrion. To date, more than 100 point mutations and 200 deletions, insertions, and rearrangements have been identified. It is estimated that two-thirds of the point mutations affect the transfer RNA of the mitochondrion, one-third affect polypeptide units of the respiratory chain, and a small number affect mitochondrial ribosomal RNA. This corresponds approximately to the proportion of genes devoted to each of these functions. DiMauro and Schon wrote a thorough review of mitochondrial genomics and the most relevant diseases, which may be consulted by interested readers.

The first described and best-characterized member of this group of diseases is a symmetrical proximal myopathy that occurs as an isolated illness or in combination with any of the major mitochondrial syndromes. In 1966, Shy and coworkers described the histochemical and electron-microscopic abnormalities of the muscle mitochondria in a childhood myopathy, which they called *megaconial* (meaning marked enlargement of the mitochondria) or *pleoconial* (referring to an excessive number of mitochondria). Later this change came to be known as "ragged red fibers," so named because of the subsarcolemmal and intermyofibrillar collections of membranous

Table 37-9

THE MAJOR CATEGORIES OF MITOCHONDRIAL DISORDERS

SYNDROME	COMMON MITOCHONDRIAL GENE MUTATION	RAGGED RED FIBERS	LACTIC ACIDOSIS
Ragged red fiber polymyopathy	Point mutation at 3250	+	-
Progressive external ophthalmoplegia (PEO) and Kearns-Sayre variants	Heteroplasmic deletions or point mutation at 3243	-	-
Leigh syndrome, fatal lactic acidosis, and neuropathy with proximal weakness, ataxia, and retinitis pigmentosa (NARP)	Point mutation at 8993	-	+
Myoclonic-epilepsy and ragged red fibers in muscle (MERRF)	Point mutation at 8344	+ (usually)	±
Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)	Point mutation at 3243	+	+
Leber optic neuropathy	Point mutation at 3460, 4160, or 11778	-	-
Myoneural-gastrointestinal encephalopathy	Unknown (maternal inheritance)	+	-

+ = present; - = absent.

(mitochondrial) material in the type 1 (red) muscle fibers as visualized by the Gomori trichrome stain in sections of frozen muscle. This morphologic change may be an asymptomatic accompaniment of the mitochondrial disorders or, conversely, a mitochondrial disease of the CNS may exist without histologic or ultrastructural abnormalities in the muscle.

A second unifying feature of these diseases is an elevation of lactate concentration or of the lactate-to-pyruvate ratio in the blood and CSF; this is the result of the respiratory chain abnormalities. These elevations are most prominent after exercise, infection, fever, or alcohol ingestion and in some conditions are capable of inducing recurrent ketoacidotic coma, which may be the presenting manifestation of a mitochondrial disease. Leigh syndrome and MELAS particularly have a tendency to exhibit elevations of lactate; however, the diagnosis of either cannot be excluded in the presence of normal levels of this substance, even after provocation by exercise (see further on for a description of testing for elevated lactate). Using phosphorus MRI scans, one can compare levels of inorganic phosphate to phosphocreatine levels in muscle; in genetic muscle diseases of several types, this ratio increases, but it is highest in those of mitochondrial origin.

Although the mitochondrial diseases are considered here as a group, individual ones are of necessity mentioned in other chapters because of their outstanding characteristics. Thus the syndrome that combines epilepsy, deafness, and developmental delay with ragged red muscle fibers (myoclonic epilepsy with ragged red fibers, or MERRF) was discussed in Chap. 16, on epilepsy. The syndrome of progressive external ophthalmoplegia (PEO) has been included with other abnormalities of eye movements (see Chap. 50); lactic acidosis and stroke-like episodes (MELAS) were considered in Chap. 34, with the cerebrovascular diseases; and Leber hereditary optic neuropathy, with other causes of visual loss (see Chaps. 13 and 39). Leigh syndrome, a symmetrical subacute necrotizing encephalomyelopathy, usually with lactic acidosis, also has a number of complex presentations and is mentioned in the differential diagnosis of

several diseases. For each of the aforementioned processes, wide clinical experience will bring to light an individual or a family in whom some odd syndrome has been linked to a mitochondrial disorder. Furthermore, two major syndromes may coexist in one individual and fragmentary subsyndromes are known to occur, having an onset any time from childhood to early adult life. Consequently, it serves little purpose to catalogue all of these associations. Only the best-characterized entities, listed in Table 37-9, are described here. The most common combinations of mitochondrial syndromes have been of Kearns-Sayre syndrome with MELAS or with MERRF, progressive ophthalmoplegia with MERRF, and MERRF with MELAS.

We prefer to avoid the issue of what defines a "mitochondrial disorder"—its genetic defect, the biochemical disorder, or the clinical syndrome. The clinician assigns this term to the combination of a mutation of mitochondrial DNA and certain clinical features that constitute a recognizable syndrome; the biochemical changes are taken as markers of the disordered energy-producing mechanisms of the mitochondrial machinery. Mitochondrial failure has also become a focus of interest in various degenerative neurologic conditions, such as Alzheimer and Parkinson diseases but none of the currently understood mutations of the mitochondrial genome is clearly implicated in these conditions.

Mitochondrial Myopathies

The mildest form of muscle disorder caused by mitochondrial disease is a benign and relatively static proximal weakness that tends to be more severe in the arms. Exercise intolerance alone is reported by more than half of these patients. There are adult-onset cases, but careful questioning usually reveals lifelong symptoms (weakness, poor endurance, discomfort, exertional dyspnea, and tachycardia), which may be so slight and slowly progressive that the patient leads a relatively normal life for decades. Less-frequent patterns of muscle disease include a fascioscapulohumeral or limb-girdle pattern of weakness as well as occasional episodes of

exertional myoglobinuria. Some patients develop PEO several years after the limb weakness becomes evident. Several mutations are associated with a pure or predominant myopathic syndrome, the most common one being located at position 3250 of the mitochondrial genome. Rare variants, such as combined skeletal weakness and cardiomyopathy, are referable to other loci.

At the opposite end of the spectrum is an infantile myopathy in which weakness and lactic acidosis become evident in the first week of life and are fatal by 1 year. Many of these patients and some members of their families have a history of renal dysfunction combined with weakness of early onset. The muscle tissue shows numerous ragged red fibers, and cytochrome oxidase activity is virtually absent. DiMauro (1983) and others have described a remarkable partly reversible form, which, early on, requires ventilatory support and gastric feeding but improves clinically as the child ages; the lactic acidosis disappears by age 2 or 3 years. In these severe childhood cases, the deficiencies in cytochrome oxidase suggest a defect in mitochondrial genes, but the site has not been found.

As mentioned above, the histologic feature that unites mitochondrial myopathies is the presence of ragged red fibers. This finding points to the diagnosis of a mitochondrial disorder in any case where weakness is coupled with exercise intolerance and elevated serum lactate, particularly if there is a family history of similar problems. Also, the presence of ragged red fibers differentiates the mitochondrial myopathies from the glycogenoses but it bears emphasizing that ragged red fibers are rare in infants and young children, even in those with confirmed mitochondrial disease.

Progressive External Ophthalmoplegia and Kearns-Sayre Syndrome (See also Chap. 50)

The combination of progressive ptosis and symmetrical ophthalmoplegia is a common manifestation of mitochondrial disease. Usually there is no diplopia or strabismus or at most only transient diplopia, despite slightly dysconjugate gaze. Mitochondrial abnormalities are found in the extraocular muscles of these patients. We have been impressed at how long the illness can exist before it brings the patient to a physician. To be differentiated is myasthenia gravis, which is characterized by fatigable weakness and responsiveness to cholinergic medications, neither of which is a feature of mitochondrial disorders. In our experience, nearly all cases of PEO are because of mitochondrial disorders, but rarely the condition may be simulated by one of several genetically determined muscular dystrophies, including oculopharyngeal dystrophy and a type in which there are no other associated weaknesses but is, however, linked to facioscapulohumeral dystrophy (FSH; Chap. 50).

PEO bears a close relationship to the Kearns-Sayre syndrome of retinitis pigmentosa (onset before age 20 years), ataxia, heart block and other conduction defects, and elevated CSF protein; sensorineural deafness, seizures, or pyramidal signs may be added (see Chap. 50 for clinical description). The CNS syndromes of MELAS or MERRF (see further on) may also be combined with PEO.

Subacute Necrotizing Encephalomyelopathy (Leigh Disease)

This is a familial or sporadically occurring mitochondrial disorder with a wide range of clinical manifestations. Only some of the cases display a maternal pattern of inheritance. The onset of neurologic difficulty in more than half of these patients is in the first year of life, mostly before the sixth month; but late-onset forms, with great heterogeneity of presentation as late as early adulthood, are also known. Neurologic symptoms often appear subacutely or abruptly, sometimes precipitated by a febrile illness or a surgical operation. It has seemed to us that this rapid onset is more characteristic of Leigh disease than it is of the other mitochondrial disorders and the disease could reasonably be designated as “acute necrotizing encephalomyelopathy” (ANE), a term applied to a similar entity in Japan and China.

In infants, loss of head control and other recent motor acquisitions, hypotonia, poor sucking, anorexia and vomiting, irritability and continuous crying, generalized seizures, and myoclonic jerks constitute the usual clinical picture. If the onset is in the second year, there is delay in walking, ataxia, dysarthria, psychomotor regression, tonic spasms, characteristic respiratory disturbances (episodic hyperventilation, especially during infections, and periods of apnea, gasping, and quiet sobbing), external ophthalmoplegia, nystagmus, and disorders of gaze (like those of Wernicke disease), paralysis of deglutition, and abnormal movements of the limbs (particularly dystonia but also jerky and choreiform movements). Mild cases, showing mainly developmental delay, have been mistaken for cerebral palsy. Peripheral nerves are involved in some cases (areflexia, weakness, atrophy, and slowed conduction velocities of peripheral nerves); in a few, autonomic failure is the most prominent feature. In some children the disease is episodic; in others it is intermittently progressive and quite protracted, with exacerbation of neurologic symptoms in association with nonspecific infections. The CSF is usually normal but the protein content may be increased.

The pathologic changes take the form of bilaterally symmetrical foci of spongy necrosis with myelin degeneration, vascular proliferation, and gliosis in the thalami, midbrain, pons, medulla, and spinal cord. In cases of acute onset there may be minor hemorrhagic change. The basal ganglia are characteristically but not invariably affected. Also, there may be a demyelinating type of peripheral neuropathy. In their distribution and histologic appearance, the CNS lesions resemble those of Wernicke disease (caused by a deficiency of thiamine) except that the lesions of Leigh disease are more extensive—sometimes involving the striatum—and they spare the mammillary bodies. The lesions, particularly those of the lenticular nuclei and brainstem, may be seen in CT and are strikingly demonstrated by MRI. The histochemical appearance of muscle is normal, although electron microscopy may show an increased number of mitochondria.

The clinical boundaries of Leigh disease have not been defined precisely. A familial disorder of infancy and early childhood, referred to as *bilateral striatal necrosis* and associated with dystonia, visual failure, and other

neurologic defects, is probably a variant. The same may be true of an obscure adult-onset syndrome of progressive dementia, caused by thalamic lesions, in the form of necrosis, vascular proliferation, and gliosis. A resemblance to what has recently been termed acute necrotizing encephalomyelopathy, arising in children after an infectious illness, was alluded to earlier.

The mitochondrial 8993 mutation associated with Leigh disease that explains 20 percent of cases is also discussed below in relation to the NARP syndrome. The close relationship between the two processes reemphasizes the point that several mitochondrial mutations rise to the clinical and pathologic picture of a necrotizing encephalopathy. However, it has been recently pointed out that many cases of Leigh disease are associated with nuclear mutations, including in *RANBP2* that codes for a component of the nuclear pore.

Neuropathy, Ataxia, Retinitis Pigmentosa Syndrome (NARP)

As just indicated, Leigh syndrome exemplifies to a remarkable degree the heterogeneity of abnormalities that may be associated with cytochrome oxidase deficiency caused by a single mitochondrial gene mutation. A minor transversion error, the substitution of one nucleotide in the mitochondrial DNA at position 8993, the same site implicated in Leigh syndrome, also gives rise to a maternally inherited syndrome of sensory NARP. The mutation creates a defective ATPase-6 of complex V of the mitochondrial respiratory chain. Included in some cases of NARP are developmental delay, seizures, and proximal muscle weakness.

The severity of the NARP syndrome corresponds to the amount of aberrant DNA in the mitochondrial genome; mutations involving more than 90 percent of mitochondrial DNA produce the more severe phenotype of the necrotizing encephalopathy.

Santorelli and colleagues found that 12 of 50 patients with Leigh syndrome from 10 families displayed the 8993 point mutation. Within one kindred, the mitochondrial aberration may vary from a mild developmental delay, to NARP, to the full-blown Leigh syndrome, or early death with lactic acidosis. These differences in severity are thought to result from the mosaicism of mitochondrial genetics and specifically to the protective effect of even small amounts of the normal mitochondrial genome. The first manifestations of disease may not appear until adulthood, although it only rarely begins after age 20 years.

Further confounding the clinical classification of this disease complex is the observation that many patients with the Leigh syndrome have a pyruvate dehydrogenase (usually X-linked) or pyruvate decarboxylase deficiency or a cytochrome oxidase deficiency. These are common to many mitochondrial disorders and inherited usually as an autosomal recessive trait. However, patients with Leigh syndrome and the 8993 mutation tend not to have these enzymatic deficiencies. Bridging these complex cases to the typical ones are instances with cytochrome oxidase deficiency with psychomotor retardation, slowed growth, and lactic acidosis, many without the striatal or brainstem spinal necroses of Leigh syndrome.

Congenital Lactic Acidosis and Recurrent Ketoacidosis

Certain types of organic acidemia occurring in early infancy and of unproved genetic etiology have already been mentioned. Here reference is made to those few cases that are associated with deletions of mitochondrial DNA. The syndrome consists of *psychomotor regression* and *episodic hyperventilation, hypotonia, and convulsions* with intervening periods of normalcy. Choreoathetosis or progressive ophthalmoplegia have been added in a few cases. Probably most cases of this type are caused by disorders of the mitochondrial respiratory chain, particularly of the pyruvate-decarboxylase complex. Some children are dysmorphic, with a broad nasal bridge, micrognathia, posteriorly rotated ears, short arms and fingers, and other similar but mild dysmorphic features. De Vivo and colleagues have written a synopsis of this disease. Death usually occurs before the third year. The important laboratory findings are acidosis with high lactate levels and hyperalaninemia. The few cases that have been examined postmortem are found to have necrosis and cavitation of the globus pallidus and cerebral white matter, as in subacute necrotizing encephalomyelopathy (SNE). The diagnosis can be made by the finding of ragged red fibers in muscle or by measurement of enzyme activity. The process must be distinguished from the several diseases of infancy that are complicated by lactic acidosis.

Myoclonic Epilepsy With Ragged Red Fibers (MERRF)

This disease presents as progressive myoclonic epilepsy or myoclonic ataxia. As was noted in Chap. 6, these cases must be differentiated from several similar clinical entities, such as juvenile myoclonic epilepsy, Unverricht-Lundborg disease, Lafora-body disease, Baltic myoclonus, and neuronal ceroid-lipofuscinosis, discussed earlier in this chapter. Tsairis and colleagues were the first to describe the connection between familial myoclonic epilepsy and mitochondrial changes in muscle, and numerous variants have been identified since their report.

Myoclonus in a child or young adult is the most typical feature and is elicited by startle or by voluntary movement of the limbs. The nature of the seizures varies but includes drop attacks, focal epilepsy, or tonic-clonic types, some of which are photosensitive. The ataxia tends to worsen progressively, replacing the myoclonus and seizures in some instances and remaining a minor feature in others. The myopathy usually produces inapparent or mild weakness, but the presence of mitochondrial muscle abnormalities is necessary for clinical diagnosis. To this constellation may be added any of the other elements of the mitochondrial diseases that have already been denoted, including deafness (present in our cases), mental decline, optic atrophy, ophthalmoplegia, cervical lipomas, short stature, or neuropathy.

Most cases are familial and display maternal inheritance, but the age of onset may vary and affected individuals have been reported with symptoms beginning as late as the sixth decade. Almost always the patients with later onset have the mildest disease, with only myoclonic

epilepsy. Conversely, those with onset in the first decade tend to be more severely affected and die before the third decade. As with the other mitochondrial processes, the quantitative burden of mutant DNA bears some relationship to the time of onset and severity of the disease. Eighty percent of patients with MERRF have a point mutation of the mitochondrial genome at locus 8344, which codes for a transfer RNA and, conversely, most patients with this mutation will ultimately manifest some or all the clinical features of MERRF, including those with crossover features of the Leigh syndrome.

Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-Like Episodes (MELAS)

Patients with this syndrome have normal early development followed by poor growth, focal or generalized seizures, and recurrent acute episodes that resemble strokes or prolonged transient ischemic attacks. The stroke deficits often improve but in some cases lead to a progressive encephalopathy. Some have hemicranial headaches that cannot be distinguished from migraine, and others suffer repetitive vomiting or episodic lactic acidosis. If there is a characteristic feature it is the unusual clinical pattern of focal seizures, sometimes prolonged, which herald a stroke and produce an unusual radiographic pattern of infarction involving the cortex and immediate subcortical white matter. The CT may also show numerous low-density regions that have no clinical correlates. Most patients have ragged red fibers in muscle but only rarely is there weakness or exercise intolerance.

Approximately 80 percent of MELAS cases are related to a mitochondrial mutation occurring at the 3243 site of the mitochondrial gene or, in a few instances, at an alternative locus that also codes for a segment of transfer RNA. Maternal inheritance is common but sporadic cases are well known. In the survey conducted by Hammans and coworkers, only half of the cases of the 3243 mutation were associated with the MELAS syndrome. The finding of an abnormal mitochondrial genome in the endothelium and smooth muscle of cerebral vessels has been suggested as a basis for the strokes and migraine headaches.

The Diagnosis of Mitochondrial Disorders

The characteristic neurologic signs of a mitochondrial disorder fall into certain broad groups: (1) combinations of ataxia, seizures, and myoclonus, typified by the MERRF syndrome; (2) migraine-like headaches, recurrent small strokes, and preceding seizures, represented by the MELAS syndrome; (3) combinations of ophthalmoplegia (progressive external ophthalmoplegia), retinitis pigmentosa, polyneuropathy, or deafness (Kearns-Sayre syndrome); (4) optic atrophy (Leber type); and (5) a myopathy that is slowly progressive or fluctuating in severity. These may be combined with dementia, lactic acidosis, short stature, diabetes, ptosis, and cardiac conduction defects as well as with multiple symmetrical lipomas. Peripheral nerve involvement, although common in these disorders, is usually asymptomatic; autonomic failure may be a rare manifestation. A panoply of visceral dysfunctions are at times associated with the neurologic features including bone marrow changes of sideroblastic anemia, renal

tubular defects, endocrinopathies (mainly diabetes mellitus, but also hypothyroidism or deficiency of growth hormone), hepatopathy, cardiomyopathy, and recurrent vomiting with intestinal pseudoobstruction. Diabetes has been a marker in several of the early-onset MELAS and MERRF cases that we have seen, but less often when the first manifestations appeared in adulthood.

The investigation of a suspected case of mitochondrial disease begins with an exploration of the family history for unusual childhood diseases including neonatal death, unexplained seizure disorders, and progressive neurologic deficits of the types already described. Unexplained deafness or diabetes in family members might also raise the level of suspicion of a mitochondrial disorder. The diagnosis should be suspected when a disorder with these characteristics occurs in a pattern that indicates maternal inheritance. However, one encounters families with mendelian patterns of inheritance due to nuclear gene defects as described in the introductory section of this chapter. Commercial tests are available for the more frequent mitochondrial point mutation sites (3243, 8993, and 8344) in leukocytes. Detection of deletions requires analysis of muscle tissue. They are useful for diagnosis but reveal abnormalities in only a modest number, estimated to be approximately 15 percent of cases that have the index aspect of this group of diseases, ragged red muscle fibers; the frequency is higher in cases with identifiable phenotypes such as MERRF and MELAS. Resting and postexercise lactate and pyruvate determinations are helpful, but this test of aerobic capacity has limitations. The more recent work of Taivassalo and colleagues, although showing a wide range of values, suggests that measurement of the partial pressure of oxygen in venous blood from the forearm after ischemic exercise (ischemic forearm test) may still be useful in distinguishing patients with mitochondrial disease from normal subjects. In the former there is a paradoxical rise in P_{O_2} from an average of 27 to 38 mm Hg, whereas normals show a decline in this value.

A muscle biopsy will disclose several basic abnormalities; ragged red fibers can be recognized by use of the modified Gomori stain on frozen material, and the absence of succinate dehydrogenase and cytochrome oxidase by appropriate histochemical staining. In cases of suspected Leigh syndrome or MELAS, the CT or MRI may show some of the characteristic cerebral lesions; in the other mitochondrial disorders, there are often focal nondescript hyperintensities on T2-weighted MRI as well as atrophy, lucencies, or calcification. Sampling of chorionic villi for prenatal diagnosis may reveal mutant mitochondrial DNA, but this information is not entirely dependable.

It should be evident from the foregoing discussion that normal findings in any of these tests, including the muscle biopsy, do not exclude mitochondrial disease. In the final analysis, it is the clinical syndrome, family history, and corroborating evidence of a mitochondrial disorder or its genetic representation that is diagnostic. Jackson and coworkers suggest that isolated phenomena, such as dementia, muscle weakness, epilepsy, nerve deafness, migraine with strokes, small stature, myoclonic epilepsy, and cardiomyopathy, should prompt consideration of a mitochondrial disorder when no other explanation is evident.

Developmental Diseases of the Nervous System

This broad heading subsumes a large number of both genetically driven developmental malformations and diseases acquired during intrauterine or early neonatal periods of life. They number in the hundreds according to the tabulation of Dyken and Krawiecki although many, if not most, are rare. Taxonomically, they make up two broad categories. The first includes specific gene defects, either mutations, deletions, or duplications of parts of genes (copy number variation), or single nucleotide polymorphisms that give rise to developmental aberrations or delays. The second category comprises a variety of environmental and infectious agents acting at different times on the immature nervous system during embryonal, fetal, and perinatal periods of life.

GENERAL PRINCIPLES

Several points should be noted regarding the frequency of malformations. Jones, in the *Smith* monograph, has pointed out that a single minor malformation, usually of no clinical significance, occurs in 14 percent of newborns. Two malformations appear in 0.8 percent of newborns, and in this group, a major defect is five times more frequent than in the normal population. Three or more malformations are found in 0.5 percent of newborns, and in this latter group, more than 90 percent have one or more major abnormalities that seriously interfere with viability or physical well-being. The figures for major congenital malformations compiled by Kalter and Warkany are comparable but somewhat higher. What is most important for the neurologist is the fact that the nervous system is involved in most of infants with major malformations. Indeed, approximately 40 percent of deaths during the first postnatal year are in some manner related to prenatal malformations of the central nervous system.

Certain principles are applicable to the entire group of malformations. First, the abnormality of the nervous system is frequently accompanied by an abnormality of some other structure or organ (eye, nose, cranium, spine, ear, and heart), which relates them chronologically to a certain period of embryogenesis. Conversely, the presence of these malformations of nonnervous tissues suggests that an associated abnormality of the nervous system is developmental in nature. For example, the conjunction

of cardiac, limb, gut, and bladder abnormalities with a neurologic disorder indicates the time at which the insult takes place: cardiac abnormalities occur between the fifth and sixth week; extroversion of the bladder at less than 30 days; duodenal atresia, before 30 days; syndactyly, before 6 weeks; meningomyelocele, before 28 days; anencephaly, before 28 days; cleft lip, before 36 days; syndactyly, cyclopia, and holoprosencephaly, before 23 days. Each is discussed in this chapter. This principle is not inviolable; in certain maldevelopments of the brain that must have originated in the embryonal period, all other organs are normal. One can only assume that the brain was more vulnerable than any other organ to prenatal as well as natal influences. Perhaps this occurs because the nervous system, of all organ systems, requires the longest time for its development and maturation, during which it is susceptible to disease. Low birth weight and gestational age, indicative of premature birth, increase the risk of cognitive or sensory developmental delay, seizures, and cerebral palsy.

A maldevelopment of whatever cause should be present at birth and remain stable thereafter, that is, be nonprogressive, in contrast to the majority of metabolic diseases of infancy discussed in the preceding chapter. However, this principle requires qualification: The abnormality may have affected parts of the brain that have not matured at birth, so that an interval of time must elapse postnatally before the defect can express itself.

Many of the teratologic conditions that cause birth defects pass unrecognized because they end in spontaneous abortions. For example, defects caused by chromosomal abnormalities occur in approximately 0.6 percent of live births, but such defects are found in more than 5 percent of spontaneous abortuses at 5 to 12 weeks gestational age.

Regarding the genetic causes of malformations and developmental delay, much has been learned in the past decade but a picture of the genetic influences on these conditions is still incomplete. For half a century, whole chromosome karyotyping allowed the recognition of conditions such as Down syndrome and its association with triplication of the entire chromosome 21. As more refined techniques became available, such as high-resolution banding, subtle changes such as small deletions in chromosomal architecture became apparent, as occur in Angelman and Prader-Willi syndrome and fragile-X syndrome.

What followed, by the use of linkage analysis and other genetic techniques, was the elucidation of single gene mutations that were obligatorily associated with malformations or developmental delays; most of the inherited metabolic disorders of infancy and childhood discussed in Chap. 37 are of this type but also certain gross malformations of the brain such as lissencephaly, discussed further on.

These were the forerunners of a completely different category of technical innovations, anchored by the original method of sequencing short lengths of part of a gene by the Sanger method and its derivatives. With the development of the polymerase chain reaction and automated methods, longer and longer sequences of genes could be studied. This has allowed large population studies, merged with statistical techniques that expose genes in affected individuals that may be responsible for disease and are not present in high frequency in the general populations. From there, the rapid evolution of technology that is able to analyze thousands of portions of DNA in parallel and compare numerous sequences to a reference library of DNA has revealed variants at the resolution of single base pairs, *single nucleotide polymorphisms* (SNPs). Most exploration of human disease has been, until recently, based on the “common disease–common variant” model, in which a disease is attributable to limited number variants that exist in more than 1 to 5 percent of a population. For example, five polymorphisms are each responsible for doubling or tripling the risk of macular degeneration. However, most of these variants are probably not themselves responsible for the disease.

These types of genetic changes do not appear to explain the majority of the various developmental diseases. A newer concept of duplication or deletion of portions of genes, “*copy number variation*” is emerging as possibly explanatory of some proportion of diseases such as autism as discussed further on. What is interesting about copy number variation is that they give rise to several phenotypes of similar disorder, quite unlike conventional mendelian mutations. This indicates that copy number variants, like SNPs, probably are not directly causative of a condition but instead modulate other functions that express proteins. This is the situation for many of the forms of developmental abnormalities such as generic cognitive developmental delay, autism, and certain psychiatric diseases.

A textbook on the principles of neurology cannot catalog all the hereditary and congenital developmental abnormalities that affect the nervous system. For such details, the interested reader should refer to several excellent monographs. Three that the authors consult are Brett's *Pediatric Neurology*, Berg's *Principles of Child Neurology*, and Lyon and Evrard's *Neuropediatrie*. These are supplemented by special atlases of congenital malformations mentioned further on. In this chapter, we sketch only the major groups and discuss in detail a few of the more common entities. The classification in Table 38-1 adheres to a *grouping in accordance with the main presenting abnormality*. Represented here are the common problems that lead families to seek consultation with the pediatric neurologist: (1) structural defects of the cranium, spine, and limbs, and of eyes, nose, ears, jaws, and skin;

Table 38-1

CLASSIFICATION OF CONGENITAL NEUROLOGIC DISORDERS

- I. Neurologic disorders associated with craniospinal deformities
 - A. Enlarged head (see also Table 38-2)
 1. Hydrocephalus
 2. Hydranencephaly
 3. Macrocephaly
 - B. Craniostenoses
 1. Turricephaly
 2. Scaphocephaly
 3. Brachycephaly
 - C. Disturbances of neuronal formation and migration
 1. Anencephaly
 2. Lissencephaly, holoprosencephaly, and gyral malformations
 - D. Microcephaly
 1. Primary (vera)
 2. Secondary to cerebral disease
 - E. Combinations of cerebral, cranial, and other anomalies
 1. Syndactylic craniocerebral anomalies
 2. Other craniofacial anomalies
 3. Oculocephalic defects
 4. Oculoauriculocephalic anomalies
 5. Dwarfism
 6. Dermatocephalic anomalies
 - F. Rachischisis
 1. Cephalic and spinal meningocele, meningoencephalocele, Dandy-Walker syndrome, meningomyelocele
 2. Chiari malformation
 3. Platybasia and cervical-spinal anomalies (see Chap. 44)
 - G. Chromosomal abnormalities
- II. The phakomatoses (see Table 38-4)
 - A. Tuberous sclerosis
 - B. Neurofibromatosis
 - C. Cutaneous angiomatosis with central nervous system abnormalities
- III. Restricted developmental abnormalities of the nervous system
 - A. Focal cortical dysgenesis
 - B. Möbius syndrome
 - C. Congenital apraxia of gaze
 - D. Other restricted congenital abnormalities (Horner syndrome, unilateral ptosis, anisocoria, etc.)
- IV. Congenital abnormalities of motor function (cerebral palsy)
 - A. Subependymal (matrix) hemorrhage
 - B. Cerebral spastic diplegia
 - C. Infantile hemiplegia, double hemiplegia, and quadriplegia
 - D. Congenital extrapyramidal disorders (double athetosis; erythroblastosis fetalis and kernicterus)
 - E. Congenital ataxias
 - F. The flaccid paralyses
- V. Prenatal and paranatal infections
 - A. Rubella
 - B. Cytomegalic inclusion disease
 - C. Congenital neurosyphilis
 - D. HIV infection
 - E. Toxoplasmosis
 - F. Other viral and bacterial infections
- VI. Epilepsies of infancy and childhood
- VII. Developmentally delayed

(2) disturbed motor function, taking the form of retarded development or abnormal movements; (3) epilepsy; and (4) developmental delay—mental retardation. The following discussion focuses on each of these clinical states.

NEUROLOGIC DISORDERS ASSOCIATED WITH CRANIOSPINAL DEFORMITIES

A majority of the disorders in this group is the result of a genetic error, including those with a specific chromosomal abnormality. One has only to walk through an institution for the developmentally delayed to appreciate the remarkable number and diversity of dysmorphisms that attend abnormalities of the nervous system. Smith, in the third edition of his monograph on the patterns of human malformations, listed 345 distinctive syndromes; in the fourth edition (edited by K.L. Jones [1988]), many new ones were added. Indeed, a normal-appearing and severely cognitively impaired individual stands out in such a crowd and will frequently be found to have an inherited metabolic defect or birth injury.

The intimate relationship between the growth and development of the cranium and that of the brain is likely responsible for many of the associations in maldevelopment. In embryonic life the most rapidly growing parts of the neural tube induce unique changes in, and at the same time are influenced by, the overlying mesoderm (a process termed *induction*); hence abnormalities in the formation of skull, orbits, nose, and spine are regularly associated with anomalies of the brain and spinal cord. During early fetal life the cranial bones and vertebral arches enclose and protect the developing brain and spinal cord. Throughout the period of rapid brain growth, as pressure is exerted on the inner table of the skull, the latter accommodates to the increasing size of the brain. This adaptation is facilitated by the membranous fontanelles, which remain open until maximal brain growth has been attained; only then do they ossify (close). In addition, stature is apparently controlled by the nervous system, as shown by the fact that a majority of mentally retarded individuals are also stunted physically to a varying degree. Thus disorders of craniovertebral development assume importance not merely because of the physical disfigurement but also because they often reflect an abnormality of the underlying brain and spinal cord, whereby they become the main diagnostic signs of the maldevelopment.

Cranial Malformations at Birth and in Early Infancy

Certain alterations in size and shape of the head in the infant, child, or even the adult, always signify a pathologic process that affected the brain before birth or in early infancy. Because the size of the cranium reflects the size of the brain, the tape measure is one of the most useful tools in pediatric neurology—no examination in a neurologically affected child is complete without a measurement of the circumference of the head. Graphs of head circumference in males and females from birth to 18 years of age were compiled by Nellhaus and are commonly used by pediatricians. A newborn whose head circumference is below the third percentile for age and sex and whose fontanelles are closed may be judged to have a developmental abnormality of the brain. A head that is normal in size at term but

fails to keep pace with body length (microcephaly) reflects a later failure of growth and maturation of the cerebral hemispheres (microencephaly).

Enlargement of the Head (Macrocephaly)

This can be caused by factors extrinsic to the brain tissue, such as hydrocephalus and hydranencephaly (as defined below), or excessive brain growth (megalomacrophaly; Table 38-2). The *hydrocephalic head* is distinguished by several features: frontal protuberance, or bossing; a tendency for the eyes to turn down so that the sclerae are visible between the upper eyelids and iris (sunset sign); thinning of the scalp and prominence of scalp veins; separation of the cranial sutures; and a “cracked pot” sound on percussion of the skull. Infantile hydrocephalus usually comes to medical attention because of an expanding cranium that exceeds normal dimensions for age. The usual causes are type II Chiari malformation, hereditary aqueductal stenosis, and prenatal infections, for example, toxoplasmosis. These disorders are discussed further on.

Hydranencephaly, defined as hydrocephalus and destruction or failure of development of parts of the cerebrum, is often associated with enlargement of the skull. When the cranium is transilluminated with a strong flashlight in a darkened room, the fluid-filled region of the cranium glows like a jack-o'-lantern. It can be caused by cerebral infarction from intrauterine vascular occlusion or by diseases such as toxoplasmosis and cytomegalovirus (CMV) disease, which destroy parts of each cerebral hemisphere. The lack of brain tissue reduces resistance to intraventricular pressure, permitting great enlargement of both lateral ventricles; it is especially marked if there is an added hydrocephalic state because of interference with cerebrospinal fluid circulation. This type of destruction of the cerebral mantle in the embryonal period may lead to the formation of huge brain defects with apposition of ventricular and pial surfaces (*porencephaly*) and subsequent failure of development of that part of the brain. Yakovlev and Wadsworth referred to the localized failure of evagination as *schizencephaly* and postulated that it was the result of a focal developmental defect in the wall of the cerebral mantle. They based their interpretation on the finding of malformed cortex in the margins of the defect but this might indicate only that the lesion preceded neuronal migration. Levine and coworkers

Table 38-2

CAUSES OF MACROCEPHALY

1. Hydrocephalus
2. Hydranencephaly
3. Macrocephaly (enlarged brain)
 - a. Alexander disease
 - b. Canavan disease
 - c. Tay-Sachs disease
4. Agenesis of corpus callosum
5. Subdural hematoma
6. Constitutional (familial) macrocephaly
7. Hemimegalencephaly

attributed it to a destructive, possibly ischemic, lesion occurring in the first few weeks of gestation, at a time when neuronal migration was incomplete. However, at least some forms have been traced to genetic defects as detailed further on.

The *macrocephalic head* (a large head with normal or only slightly enlarged ventricles) may be indicative of an advancing metabolic disease that enlarges the brain, as in *Alexander disease*, *Canavan spongy degeneration of infancy*, and *later phases of Tay-Sachs disease*, all of which are described in Chap. 37. *Agenesis of the corpus callosum*, a common congenital defect, may be associated with macrocephaly and varying degrees of mental impairment, optic defects, and seizures. In a series of 56 patients with agenesis of the corpus callosum, Taylor and David reported the presence of epilepsy in 32 and varying degrees of developmental delay in 28; only 9 had no recognizable neurologic defects. Also noted was a high incidence of psychiatric disturbances in these patients. In such cases, CT and MRI reveal the characteristic "bat-wing" deformity of the ventricles. There is also asynchrony of electrical activity of the two cerebral hemispheres on the electroencephalogram (EEG). In a few of these patients, an autosomal dominant inheritance was found (Lynn et al). Agenesis of the corpus callosum is also part of the Aicardi syndrome (see further on) and the Andermann syndrome, and it has been noted, without explanation, in some cases of nonketotic hyperglycinemia.

Subdural hematomas also enlarge the child's head and cause bulging of the fontanel and separation of the sutures. The infant is usually irritable and listless, taking nourishment poorly. Infants and children with neurofibromatosis, osteogenesis imperfecta, and achondroplasia also have enlarged heads; in the last of these, some degree of hydrocephalus appears to be responsible. Ultrasonography, which can be performed in the prenatal and neonatal periods, is usually diagnostic in all these cranial enlargements. Also MRI and CT scanning will disclose the size of the ventricles and the presence of subdural blood or fluid (*hygroma*).

Apart from patients with these pathologic states, there are individuals whose heads and brains are enlarged but who are normal in all other respects. Many of them come from families with large heads. Schreier and colleagues, who traced this condition through three generations of several families, declared it to be an autosomal dominant trait. This group represented 20 percent of 557 children referred to a clinic because of cranial enlargement, according to Lorber and Priestley.

Hemimegalencephaly This term refers to a marked enlargement of one cerebral hemisphere as a result of a developmental abnormality. The cortical gray matter and sometimes the basal ganglia are greatly increased in volume and weight. The cerebellum, brainstem, and spinal cord retain their normal dimensions. The cranium may be misshapen or enlarged but is normal in size in some cases. Rarely, the face and body are enlarged on the side of the enlarged hemisphere. The cortex of the giant hemisphere is thick and disorganized. Neurons are in disarray and some are enlarged; in some places the natural lamination of the cortex is effaced. Nothing is known about causation,

but clearly embryogenesis has been deranged at the stage of neuroblast formation.

Clinically, these individuals are cognitively delayed and some have epilepsy. A degree of hemiparesis may be present but severe hemispherical neurologic deficits are generally not reported. However, hemimegalencephaly has been discovered at autopsy in a few individuals who had no mental or neurologic deficits.

Craniostenoses

Some of the most startling cranial deformities are caused by premature closure of the cranial sutures (membranous junctions between bones of the skull). Such conditions are estimated to occur in 1 of every 1,000 births, with predominance in males (Lyon and Evrard). The growth of the cranium is inhibited in a direction perpendicular to the involved suture(s), creating a compensatory enlargement in other dimensions as allowed by the patent sutures. For example, when the lambdoid and coronal sutures are both affected, the thrust of the growing brain enlarges the head in a vertical direction (*tower skull*, or *oxycephaly*, also referred to as *turricephaly* and *acrocephaly*). The orbits are shallow, the eyes bulge, and skull films show islands of bone thinning (*lückenschädel*). When only the sagittal suture is involved, the head is long and narrow (*scaphocephalic*) and the closed suture projects, keel-like, in the midline. With premature closure of the coronal suture, the head is excessively wide and short (*brachycephalic*). The nervous system is usually normal in these restricted craniostenoses. If this condition is recognized before 3 months of age, the surgeon can make artificial sutures that may permit the shape of the head to become more normal (Shillito and Matson). Once brain growth has been completed, little can be done aside from complex reconstructive surgery. When several sutures (usually coronal and sagittal) are closed, so as to diminish the cranial capacity, intracranial pressure may increase, causing headache, vomiting, and papilledema. An operation is then needed to increase the capacity of the skull.

In acrocephalosyndactyly, or Apert syndrome, craniostenoses are combined with syndactyly (fused, or webbed, fingers or toes). There are often added complications: mental retardation, deafness, convulsions, and loss of sight secondary to papilledema. The so-called clover-shaped skull is the most severe and lethal of the craniostenoses because of the associated developmental anomalies of the brain (see further on).

Approximately one-quarter of affected children with craniostenoses will be found to have a single gene or chromosomal abnormality, most commonly in the *FGFR3* gene.

When, for any reason, an infant lies with the head turned constantly to one side (because of a shortened sternomastoid muscle or hemianopia, for example), the occiput on that side, over time, becomes flattened, as does the opposite frontal bone. The other occipital and frontal bones bulge, so that the maximum length of the skull is not in the sagittal but in the diagonal plane. This condition is called *plagiocephaly*, or *wry head*. Craniostenosis of one-half of a coronal suture may also distort the skull in this way.

Disturbances of Neuronal Migration and Cortical Development

Neuroembryologic studies have identified several milestones of neuroblast formation, migration, cortical organization, neuron differentiation, and connectivity. Certain developmental anomalies can be traced to one of these stages of cytogenesis and histogenesis in the first trimester of gestation and to the growth and differentiation that take place in the second and third trimesters. During the first trimester, postmitotic neurons that will ultimately reside in the cortex arise in the ventricular zone adjacent to the ventricles. They migrate along the scaffold of radial glia to form the multilayered cortex. It is interesting that neurons moving up the scaffold must pass through neurons that are already in position in the cortex, leading to an “inside-out” lamination in which the most recently born and arrived neurons reside on the outermost surface of the forming cortex.

Originally there is an excess of neurons, many of which degenerate during development—a process properly called *apoptosis*. There are recorded instances in which the full complement of neuroblasts and neurons fails to be generated. In the extreme, the emergence of two separate cerebral hemispheres may not occur (*holoprosencephaly*), or the bihemispheric brain may remain small (*microcephaly*). In other described instances, a diminished number of neurons are less obvious than their failure to migrate to the cortical surface; they remain scattered through the mantle zone in sheets and heterotopic aggregates. One type of focal band-shaped subcortical heterotopia is termed “double cortex.” *Polymicrogyria* refers to an excessive number of abnormally small gyri. It is expressed by a syndrome of mental retardation, seizures, delayed speech, and motor abnormalities. The cortex may fail to become sulcated—that is, it is *lissencephalic* or may be defectively convoluted, forming microgyric and *pachygyric* (broad gyral) patterns. In yet other brains, neuronal migration is normal for the most part, but small groups of neurons in particular regions may lag or present in regional *heterotopias* (focal dysgeneses; Fig. 38-1). These migrational disorders, particularly heterotopias, are now being recognized more often by MRI and are found to have a functional significance in epilepsy but also possibly in such states as nonspecific developmental delay, and dyslexia. Finally, the cortex may be normally formed and structured but there is a failure of differentiation of intra- and intercortical and interhemispheric connections, the most obvious one being agenesis of the corpus callosum.

The timing of embryogenesis of the main visceral organs and of the coincident stages of neural tube closure were given in the introduction. With these elementary facts of neuroembryology in mind, the bases of the following clinical states are readily conceptualized: anencephaly, lissencephaly, holoprosencephaly, polymicrogyria and pachygyria, microcephaly, and special combinations of cranial and somatic abnormalities. Each is described below.

In regard to disorders of brain development, there are also special types of tumors that are the consequence of abnormal neuronal or glial development. These are

Figure 38-1. Focal cortical dysplasia. MRI in the coronal plane in a patient with seizures. Deep in the white matter, adjacent to the lateral ventricles, are multifocal heterotopic aggregates of gray matter, more apparent on the left.

variously termed gangliomas, or gangliocytomas, dysembryoplastic neuroepitheliomas (DNETs), and low-grade astrocytomas. Sometimes they become manifest in the first year of life or even before birth. Their relatively slow growth and benign character suggest that some of them represent hamartomas rather than true neoplasms (see Chap. 31). Among the ones we have encountered in adults is the Lhermitte-Duclos type of cerebellar gangliocytoma that is characterized by a “tigroid” appearance on MRI (see Fig. 31-15).

Genetics of Cerebral Disorders of Neuronal Migration (Table 38-3) Because each phase of cerebral development is under genetic control, it comes as no surprise that aberrant development might have a genetic basis. A singular advance in this field has been the identification in recent years of large numbers of genetic defects that underlie disorders of neuronal migration. These mutations, and what are known of their effects on the developing nervous system, were reviewed extensively by Mochida and Walsh, by Kato and Dobyn, and by Barkovich and colleagues; a summary is given in Table 38-3. The reader will notice that several quite different mutations may give rise to the same type of maldevelopment and that any given gene can cause malformations of varying severity but in most cases, the affected gene is active at a stage in brain development that makes the nature of the malformation understandable.

It should at the same time be noted that metabolic disturbances may also give rise to malformations of cerebral development. For example, in their review of the inborn errors of metabolism those are linked to cerebral dysgeneses. Nissenkorn and colleagues point out that disorders such as Zellweger syndrome and disorders

Table 38-3

MUTATIONS ASSOCIATED WITH DISORDERS OF NEURONAL MIGRATION AND CORTICAL MALDEVELOPMENT

DISEASE	GENE	GENE FUNCTION
Lissencephaly		
Lissencephaly with cerebellar hypoplasia	<i>RELN</i> (reelin)	Extracellular matrix protein
Lissencephaly (Miller-Dieker) or isolated lissencephaly	<i>LIS1</i>	Microtubule regulator
X-linked lissencephaly with hypogonadism (Partington syndrome)	<i>ARX</i> (aristaless)	Transcription factor
Muscle-eye-brain disease	<i>POMGNT1</i>	Glycosyltransferase
Walker-Warburg	<i>POMT1</i>	Glycosyltransferase
Holoprosencephaly	<i>SHH</i> (sonic hedgehog)	Transcription factor
Double cortex		
Double-cortex or X-linked lissencephaly	<i>DCX</i> (doublecortin)	Microtubule-associated protein
Heterotopias		
Periventricular nodular heterotopia	<i>FLNA</i> (filamin A)	Actin-binding protein
Tuberous sclerosis	<i>TSC1</i> (hamartin)	Tumor suppressor
Tuberous sclerosis	<i>TSC2</i> (tuberin)	Tumor suppressor
Fukuyama muscular dystrophy	<i>FCMD</i> (fukutin)	Possible glycosyltransferase
Schizencephaly		
Schizencephaly	<i>EMX2</i>	Transcription factor
Microcephaly		
Microcephaly	<i>MCPH1</i> (microcephalin)	? DNA repair
Microcephaly	<i>MCPH5 ASPM</i>	Mitotic/meiotic spindle

of fatty oxidation, phenylketonuria (PKU), hyperglycinemia, and pyruvate dehydrogenase deficiency cause aberrant neuronal migration and dysgenesis of the corpus callosum.

Anencephaly

This is one of the most frequent and also most appalling congenital malformations of the brain. Its incidence is 0.1 to 0.7 per all 1,000 births and females predominate in ratios ranging between 3:1 and 7:1 in different series. The concordance rate is low, both in identical and fraternal twins, but the incidence of the malformation is, nonetheless, several times the expected rate if one child in the sibship has been affected. Anencephaly has also been more frequent in certain geographic areas, for example, Ireland, for which various explanations of population genetics or environmental exposure have been postulated.

Missing in cases of anencephaly are large portions of scalp, cranial bones, and brain, including both cerebral cortex and white matter. All that remains is a hemorrhagic nubbin of nerve, glial, and connective tissue. Brainstem, cerebellum, and spinal cord are present but often, they too are malformed, as are the heart and other organs (15 to 40 percent of cases). In anencephalics who survive for a few days (65 percent die in utero and almost 100 percent before the end of the first postnatal week), startle reactions may be observed, as well as movements of limbs, spontaneous respirations, pupillary light reactions, ocular movements, and corneal reflexes. In a few, avoidance reactions, crying, and feeding reflexes can be elicited, indicating that only the rudimentary brain structures are required for these functions.

This condition, or a related one, can be anticipated if the mother's serum levels of alpha-fetoprotein and acetylcholinesterase are elevated—even more reliably anticipated if they are elevated in the amniotic fluid.

Positive tests should lead to ultrasonograph imaging of the fetus. Hydramnios is common.

The causes of anencephaly are multiple and include chromosomal abnormalities, maternal hyperthermia, and, apparently, deficiencies of folate, zinc, and copper (see Medical Task Force on Anencephaly). Of these, there is fairly secure evidence that supplemental intake of folic acid during the first trimester of pregnancy (i.e., from the time of conception) reduces the incidence of anencephaly and of myelomeningocele. Additional comments on anencephaly are given further on in this chapter in the section on "Dysraphism, or Rachischisis" (lack of fusion of the neural tube).

Lissencephaly (Agyria), Holoprosencephaly, and Gyral Malformations

Included under this heading are several forms of defects of cerebral sulcation. In the lissencephalies, cortical convolutions may be absent altogether and there is morphologic evidence of several types of neuroblast deficiency. Such cases are of particular interest to neonatologists because of their associated physical abnormalities. The degree of impairment of neurologic function seldom allows longevity, so that relatively few affected individuals are found in institutions for the developmentally delayed. Seizures, poor temperature regulation, failure to accept nourishment, and apneic attacks combine to shorten life.

The failures of sulcation vary in severity. Neurons may fail to form or to migrate along glial projections to reach the more superficial layers of the cortex (a condition called in the past, Bielschowsky type); or the cortex, meninges, and eyes may fail to differentiate normally except for the dentate gyrus and hippocampus (Walker-Warburg type); or there may be other more minor focal derangements of cortical migrations and laminations with heterotopias of neurons in the white matter.

In the complete lissencephalies, the lateral and third ventricles enlarge because of a lack of the normal quantities of surrounding cerebral tissue (i.e., the aforementioned hydranencephaly). The cerebellar cortex is also abnormal. In some lissencephalic brains, there is slight sulcation presenting as abnormally broad or narrow convolutions, with thick, poorly laminated cortex; these are called *pachygyrias* or *microgyrias*, respectively, but the fundamental migratory abnormality is basically the same. The cerebellum is also abnormal, usually showing hypoplasia or aplasia involving the vermis or neocerebellum.

In the severe defects, the cranium is small at birth. In one type, which is inherited as an autosomal recessive trait, there are subtle craniofacial features (short nose, small mandible, ear abnormalities) as well as congenital heart disease. In another group, there is an associated familial congenital muscular dystrophy, placing the case between the Fukuyama and Walker-Warburg syndromes (see “Congenital Muscular Dystrophy” in Chap. 48).

Alobar and lobar *holoprosencephalies* are other examples of sulcation defects with craniofacial abnormalities in which development has gone awry in the fifth and sixth weeks of gestation (see Volpe, 1995). In these subtypes, the two cerebral hemispheres, either totally or only in part, form as a single telencephalic mass. In nearly all cases the cerebral defect is reflected by a single eye (cyclopia) and the absence of the nose, imparting an astonishing and diagnostic appearance.

Most of the severe disorders are sporadic, and the infants seldom survive for long. In a few of the malformations, a congenital infection with CMV or rubella has been implicated (Hayward et al).

The *Dandy-Walker syndrome* represents a more restricted form of migration and neural tube defect. There is cerebellar vermian hypoplasia with or without hydrocephalus and, in some cases, an added agenesis of the corpus callosum with cerebral cortical dysgeneses (Landrieu). This defect, which is identified by the cystic enlargement of the fourth ventricle, is discussed further on, with the dysraphic neural tube defects.

That some instances of lissencephaly have a genetic basis has already been mentioned (see Table 38-3). Two genes that modify microtubular function have been identified: *LIS1* and “doublecortin” or *DCX*. Large chromosomal deletions that span *LIS1* cause Miller-Dieker syndrome, in which lissencephaly is associated with distinctive facial abnormalities; small defects in the same gene cause only lissencephaly. Lissencephaly with cerebellar hypoplasia is caused by mutations in the human “reelin” gene (*RELN*), the analogue of the defective gene in reelin mice (which have a reeling gait and abnormal cortical neuronal lamination). Defects in the transcription factor *ARX* are associated with X-linked lissencephaly, agenesis of the corpus callosum, and hypogonadism. Periventricular nodular heterotopia is caused by another gene defect, filamin A gene on the X chromosome. Some cases of holoprosencephaly have been traced to mutations in the sonic hedgehog gene.

Microcephaly

In most of the above-described cerebral dysplasias, the cranium and brain are small, but there is also a primary form of hereditary microcephaly, called *microcephaly vera*, in which the head is astonishingly reduced in size (circumference less than 45 cm in adult life—i.e., 5 standard deviations below the mean). In contrast, the face is of normal size, the forehead is narrow and recedes sharply, and the occiput is flat. The brain often weighs less than 300 g (normal adult range: 1,100 to 1,500 g) and shows only a few primary and secondary sulci. The cerebral cortex is thick and unlaminated and grossly deficient in neurons. A few cases have an associated cerebellar hypoplasia or an infantile muscular atrophy. Stature is usually moderately reduced. Such individuals can be recognized at birth by their anthropoid appearance and later by their lumbering gait, extremely low intelligence, and lack of communicative speech. Vision, hearing, and cutaneous sensation are spared. In one of the cases studied by our colleagues, laborious effort using operant conditioning made it possible to teach the patient the shapes of simple figures. (His sister’s brain, examined by R.D. Adams, was malformed and weighed only 280 g.) Skull films show that the cranial sutures are present, as are convolutional markings on the inner table.

Lesser degrees of microencephaly have been associated with progressive motor neuron disease and degeneration of the substantia nigra (Halperin et al). Evrad and associates have described another rare type of microcephaly, which they call “radial microbrain.” The sulcal pattern is normal, and neuronal arrangements in the cerebral cortex are normal as well. The defect appears to be in the small number of neurons that are generated, not in their migration.

Disorders of the Pial Surface

This category of maldevelopment is characterized by inappropriate migration of neurons to the pial surface, leading to a nodularity of the surface described as a *cobblestone* appearance. In the three disorders with this pathologic finding, the clinical picture is one of developmental delay conjoined with congenital muscular dystrophy. Three identified gene defects are thought to alter the glycosylation of critical proteins in the brain and in skeletal muscle. These genes include the gene *fukutin* in Fukuyama muscular dystrophy (see “Congenital Muscular Dystrophy” in Chap. 48), the *POMGNT1* gene in muscle-eye-brain disease, and the *POMT1* gene in Walker-Warburg syndrome, as summarized in Table 38-3.

Combined Cerebral, Cranial, and Somatic Abnormalities

There are so many cerebrosomatic anomalies that one can hardly retain visual images of them, much less recall all the physicians’ names by which they are known. There is great advantage in grouping these anomalies according to whether the extremities, face, eyes, ears, and skin are associated with a cerebral defect. The sheer number and variety of these anomalies permit only an enumeration of

the more common ones and their most obvious physical characteristics. Unfortunately, apart from certain genetic linkages, no useful leads as to their origin have been forthcoming. Of necessity, one turns to atlases, one of the most thorough of which was compiled by Holmes and colleagues and is based on clinical material drawn in large part from the Fernald School and Eunice K. Shriver Center in Massachusetts. The reader may also turn to the texts by Gorlin and colleagues and by Jones for specific information. The older Ford's *Diseases of the Nervous System in Infancy, Childhood, and Adolescence* is still a valuable reference, as is Jablonski's *Dictionary of Syndromes and Eponymic Diseases*.

The Syndactyllic–Cranio cerebral Anomalies (Acrocephalosyndactyly)

Fusion of two fingers or two toes or the presence of a tab of skin representing an extra digit may be seen at birth in an otherwise normal individual. However, when syndactyly is more severe and is accompanied by premature closure of cranial sutures, the nervous system usually proves to be abnormal as well. The general term *acrocephalosyndactyly* is used to describe the several combinations of craniosynostotic and facial deformities and fusion of digits. Several of these disorders are a consequence of mutations in genes encoding one of two fibroblast growth factors or proteins related to them. The following descriptions include only the major features; most have, in addition, distinctive malformations of the orbits, ears, and palate.

1. *Acrocephalosyndactyly types I and II (typical and atypical Apert syndrome)*. Turribrachycephalic skull, syndactyly of hands and feet ("mitten hands," "sock feet"), moderate to severe mental retardation.
2. *Acrocephalosyndactyly III (Saethre–Chotzen syndrome)*. Various types of craniosynostoses, proximally fused and shortened digits, moderate degree of mental retardation. Transmission as an autosomal dominant trait.
3. *Acrocephalosyndactyly IV (Pfeiffer syndrome)*. Turribrachycephaly; broad, enlarged thumbs and great toes; partially flexed elbows (radiohumeral or radioulnar synostoses); mild and variable mental retardation; autosomal dominant inheritance.
4. *Acrocephalopolysyndactyly V (Carpenter syndrome)*. Premature fusion of all cranial sutures with acrocephaly, flat bridge of nose, medial canthi displaced laterally, excess digits and syndactyly, subnormal intelligence.
5. *Acrocephalosyndactyly with absent digits*. High, bitemporally flattened head; absent toes and syndactyllic fingers; moderate mental retardation.
6. *Acrocephaly with cleft lip and palate, radial aplasia, and absent digits*. Microbrachycephaly because of craniosynostosis, cleft lip and palate, absent radial bones, severe mental retardation.
7. *Dyschondroplasia, facial anomalies, and polysyndactyly*. Keel-shaped skull and ridge through center of forehead (metopic suture), short arms and legs, postaxial polydactyly and short digits, moderate mental retardation.

In all the foregoing types of syndactyly and cranial abnormalities, which may be regarded as variants of a common syndrome, the diagnosis can be made at

a glance because of the deformed head, protuberant eyes, and abnormal hands and feet. The degree of cognitive delay proves to be variable, usually moderate to severe, but occasionally intelligence is normal or nearly so. The brain has been examined in only a few instances and not in a fashion to display fully the type and extent of this developmental abnormality.

Other Craniocephalic–Skeletal Anomalies

Members of this group have distinctive anomalies of the cranium, face, and other parts, but craniosynostosis is not a consistent feature.

1. *Craniofacial dysostosis (Crouzon syndrome)*. Variable degrees of craniosynostosis; broad forehead with prominence in the region of the anterior fontanel region; shallow orbits with proptosis; midline facial hypoplasia and short upper lip; malformed auditory canals and ears; high, narrow palate; moderate mental retardation. As noted above, a genetic defect in one of the fibroblast growth factor receptors is responsible for about one-third of cases that are not associated with other deformities (Moloney et al). Autosomal dominant inheritance is seen in most cases.
2. *Median cleft facial syndrome (frontonasal dysplasia; hypertelorism of Greig)*. Widely spaced eyes, broad nasal root, cleft nose and premaxilla, V-shaped frontal hairline, heterotypic anterior frontal fontanel (midline cranial defect); mild to severe mental retardation.
3. *Chondrodystrophia calcificans congenita (chondrodysplasia punctata, Conradi–Hünemann syndrome)*. Prominent forehead; flat nose; widely separated eyes; short neck and trunk with kyphoscoliosis; dry, scaly, atrophic skin; cicatricial alopecia; irregularly deformed vertebral bodies; mental retardation infrequent. Severe shortening of limbs is seen in some cases.
4. *Orofaciodigital syndrome*. All the patients are female; they have pseudoclefts involving the mandible, tongue, maxilla, and palate; hypertrophied buccal frenula; hamartomas of tongue; sparse scalp hair; subnormal intelligence in one-half of cases.
5. *Pyknodysostosis*. Large head and frontal-occipital bossing, underdeveloped facial bones, micrognathia, unerupted and deformed teeth, dense and defective long bones with shortened limbs, short and broad terminal digits of fingers and toes, mental retardation in one-quarter of the cases.
6. *Craniotubular bone dysplasias and hyperostoses*. Included under this title are several different genetic disorders of bone, characterized by modeling errors of tubular and cranial bones. Frontal and occipital hyperostosis, overgrowth of facial bones, and widening of long bones occur in various combinations. Hypertelorism, broad nasal root, nasal obstruction, seizures, visual failure, deafness, prognathism, and retardation of growth are the major features.

Oculoencephalic (Cranio–Ocular) Defects

In this category of anomalies, there is simultaneous failure or imperfect development of eye and brain.

One member of this group, the oculocerebrorenal syndrome of Lowe, has already been mentioned and, of course, many of the mucopolysaccharidoses are characterized by corneal opacities, skeletal changes, and psychomotor regression as considered separately in Chap. 37. Also, congenital syphilis, rubella, toxoplasmosis, and CMV inclusion disease may affect retina and brain; hypoxia at birth requiring treatment with oxygen may injure the brain and lead to *retrolental fibrodysplasia*. The true developmental defects in this group are as follows:

1. *Anophthalmia with mental retardation*. Sex-linked recessive. Absent eyes; orbits and maxillae remain underdeveloped, but adnexal tissues of eyes (lids) are intact; subnormal intelligence. Some cases of anophthalmia have been ascribed to genes encoding transcription factors that play a role in the development of the neuraxis (SOX2, RAX, RAX6).
2. *Norrie disease*. Also sex-linked recessive; some sight may be present at birth; later, eyes become shrunken and recessed (phthisis bulbi); some have short digits, outbursts of anger, hallucinations, and possibly regression of psychomotor function. A novel gene, *norrin*, on the X chromosome has been implicated.
3. *Oculocerebral syndrome with hypopigmentation*. Autosomal recessive with absence of pigment of hair and skin; small, cloudy, vascularized corneas and small globes (microphthalmia); marked mental retardation; athetotic movements of limbs.
4. *Microphthalmia with corneal opacities, eccentric pupils, spasticity, and severe mental retardation*.
5. *Aicardi syndrome with ocular abnormality*. Chorioretinopathy, retinal lacunae, staphyloma, coloboma of optic nerve, microphthalmos, mental retardation, infantile spasms and other forms of epilepsy, agenesis of corpus callosum, and cortical heterotopias. The "batwing" deformity of the third and lateral ventricles on MR images and asynchronous burst-suppression discharges and sleep spindles are diagnostic. The condition is found only in females.
6. *Lissencephaly of the Walker-Warburg type*. This anomaly has already been mentioned, as has its association with congenital muscular dystrophy. Inheritance is autosomal recessive. Ocular lesions are a regular feature but of variable type (retinal dysplasia, microphthalmia, coloboma, cataracts, corneal opacities). There may be hydrocephalus, and CT scans and MRI disclose the lack of cerebral sulci (lissencephaly). The abnormal eyes and orbits and absence of cerebellar vermis are diagnostic (see Table 38-3).
7. *Congenital tapetoretinal degeneration (Leber amaurosis)*. Visual loss from birth, moderate to severe mental retardation, and microcephaly. Early onset of blindness and absent electrical potentials on the electroretinogram (ERG) distinguish it from later-onset Leber optic atrophy, which is a mitochondrial disorder (see Chaps. 13 and 37).
8. *Septooptic dysplasia (de Morsier syndrome)*. Diminished visual acuity, small optic discs, absence of septum pellucidum, and precocious puberty. Varying degrees of pituitary insufficiency may be present, requiring endocrine replacement.

Oculoauriculocephalic Anomalies

These are less important from the neurologic standpoint, and mental retardation is present only in some cases.

1. *Mandibulofacial dysostosis (Treacher-Collins syndrome, Franceschetti-Zwahlen-Klein syndrome)*
2. *Oculoauriculovertebral dysplasia (Goldenhar syndrome)*
3. *Oculomandibulodyscephaly with hypotrichosis (Hallermann-Streiff syndrome)*

Dwarfism

Midgets are abnormally small but perfectly formed people of normal intelligence; they differ from dwarfs, who are not only very small but whose bodily proportions are markedly abnormal and who may or may not be cognitively normal. It should be commented that a majority of severely cognitively delayed patients fall below average for height and weight, but there is a small group whose fully attained height is well below 135 cm (4.5 ft) and who stand apart by this quality alone (see Jones for Smith's classification of dwarfs). The main types of dwarfism are as follows:

1. *Nanocephalic dwarfism (Seckel bird-headed dwarfism)*. The uncomplimentary term *bird head* has been applied to individuals with a small head, large-appearing eyeballs, beaked nose, and underdeveloped chin. Such a physiognomy is not unique to any disease, but when combined with dwarfism it includes a few more or less specific syndromes. Up to 1976, approximately 25 cases had been reported, some with other skeletal and urogenital abnormalities, such as medial curvature of middle digits; occasional syndactyly of toes; dislocations of elbow, hip, and knee; premature closure of cranial sutures; and clubfoot deformity. These individuals are short at birth and remain so, living until adolescence or adulthood. Retardation is severe. The cause is a homozygous or compound heterozygous mutation in RAD3-related protein, which is also implicated in ataxia-telangelectasia. At autopsy the brain is found to have a simplified convoluted pattern; one of our patients had a type of myelin degeneration similar to that of Pelizaeus-Merzbacher disease.
2. *Russell-Silver syndrome*. Possibly an autosomal dominant pattern of inheritance, with short stature of prenatal onset, craniofacial dysostosis, short arms, congenital hemihypertrophy (arm and leg on one side larger and longer), pseudohydrocephalic head (normal-sized cranium with small facial bones), abnormalities of genital development in one-third of cases, delay in closure of fontanels and in epiphyseal maturation, elevation of urinary gonadotropins. Some cases appear to be caused by a nonmutational modification of genes, which are nonetheless inherited (imprinting).
3. *Smith-Lemli-Opitz syndrome*. Autosomal recessive inheritance with microcephaly, broad nasal tip and anteverted nares, wide-set eyes, epicanthal folds, ptosis, small chin, low-set ears, enlarged alveolar maxillary ridge, cutaneous syndactyly, hypospadias in boys, short stature, subnormal neonatal activity, and normal amino acids and serum immunoglobulins.

Older survivors are bereft of language and are paraparetic, with increased reflexes and Babinski signs. The hips are usually dislocated. The responsible mutation is in *DHCR7*. The brain is small but has not been fully examined. Two of our patients are sibling girls.

4. *Rubinstein-Taybi syndrome*. Microcephaly but no cranio-stenosis, downward palpebral slant, heavy eyebrows, beaked nose with nasal septum extending below alae nasi, mild retrognathia, "grimacing smile," strabismus, cataracts, obstruction of nasolacrimal canals, broad thumbs and toes, clinodactyly, overlapping digits, excessive hair growth, hypotonia, lax ligaments, stiff gait, seizures, hyperactive tendon reflexes, absence of corpus callosum, mental retardation, and short stature. This dominantly inherited disease is a result of disruption of so-called CREB-binding protein, a nuclear protein necessary for gene expression that is modulated by cyclic adenosine monophosphate (cAMP).
5. *Pierre Robin syndrome*. Possible autosomal recessive pattern of inheritance with microcephaly but no cranio-stenosis, small and symmetrically receded chin, glossoptosis (tongue falls back into pharynx), cleft palate, flat bridge of nose, low-set ears, mental deficiency, and congenital heart disease in half the cases. Camptomelia (bent bones) and diastrophic dwarfism (short limbs) are common.
6. *DeLange syndrome (Cornelia DeLange syndrome)*. This phenotype shows some degree of variability but the essential diagnostic features are intrauterine growth retardation and stature falling below the third percentile at all ages, microbrachycephaly, generalized hirsutism and synophrys (eyebrows that meet across the midline), anteverted nostrils, long upper lip, and skeletal abnormalities (flexion of elbows, webbing of second and third toes, clinodactyly of fifth fingers, transverse palmar crease). All are moderately or, more often, severely retarded mentally, which, with the above craniofacial abnormalities, is diagnostic. It has been said, and it has been our experience, that many of these patients are prone to have a bad disposition, manifested by biting and spitting. Over half of cases are due to mutations in the *NAPBL* gene; the others involve *SMC1A* or *SMC3*.
7. *Smith-Magenis syndrome*. This is caused by deletions on chromosome 17, in which there is learning disability, severe behavioral problems (violence and self-injury), hyperactivity, deafness, and ocular abnormalities.

Neurocutaneous Anomalies With Mental Retardation

It is not surprising that skin and nervous system should share in pathologic states that impair development, as both have a common ectodermal derivation. Nevertheless, it is difficult to find a common theme in the diseases that affect both organs. In some instances, it is clear that ectoderm has been malformed from early intrauterine life; in others, a number of nondevelopmental acquired diseases of skin may have been superimposed. For reasons to be discussed later in this chapter, neurofibromatosis, tuberous sclerosis, and Sturge-Weber encephalofacial

angiomatosis must be set apart in a special category of disease termed *phakomatoses*.

Hemangiomas of the skin are without doubt the most frequent cutaneous abnormalities present at birth, and usually they are entirely innocent. Many recede in the first months of life. However, an extensive vascular nevus located in the territory of the trigeminal nerve—and sometimes in other parts of the body as well—causes permanent disfigurement and usually portends an associated and topographically underlying cerebral lesion (Sturge-Weber syndrome).

Other neurocutaneous diseases are summarized below. A more complete review of these diseases will be found in the article by Short and Adams in Fitzpatrick's *Dermatology* and the 1987 monograph by Gomez. The importance of recognizing the cutaneous abnormalities relates to the fact that the nervous system is usually abnormal, and often the skin lesion appears before the neurologic symptoms are detectable. Thus the skin lesion becomes a predictor of potential neurologic involvement.

Basal-cell nevus syndrome. This condition is transmitted as an autosomal dominant trait and is characterized by superficial pits in the palms and soles; multiple solid or cystic tumors over the head, face, and neck appearing in infancy or early childhood; mental retardation in some cases; frontoparietal bossing; hypertelorism; and kyphoscoliosis.

Congenital ichthyosis, hypogonadism, and mental retardation. This disorder is inherited as a sex-linked recessive trait. Aside from the characteristic triad of anomalies, there are no special features.

Xeroderma pigmentosum. The genetic pattern of inheritance is autosomal recessive. Skin lesions appear in infancy, taking the form of erythema, blistering, scaling, scarring, and pigmentation on exposure to sunlight; old lesions are telangiectatic and parchment-like, covered with fine scales; skin cancer may develop later; loss of eyelashes, dry bulbar conjunctivae; microcephaly, hypogonadism, and mental retardation (50 percent of cases). Kanda and associates classify this disease with what in the past had been called DeSanctis-Cacchione syndrome of "xerodermic idiocy" and believe the basic mechanism to be a faulty repair of DNA. They described two young adults with low intelligence, evidence of spinal cord degeneration, and peripheral neuropathy. The peripheral nerve lesions resembled those of amyloidosis, Riley-Day syndrome, and Fabry disease in that there was a predominant loss of small fibers. Other variants are described.

Sjögren-Larsson syndrome. Autosomal recessive with congenital ichthyosiform erythroderma, normal or thin scalp hair, sometimes defective dental enamel, pigmentary degeneration of retinae, spastic legs, and mental retardation.

Poikiloderma congenitale (Rothmund-Thompson syndrome). Autosomal recessive heredity; appearance of skin changes from the third to sixth months of life; diffuse pink coloration of cheeks spreading to ears and buttocks, later replaced by macular and reticular pattern of skin atrophy mixed with striae, telangiectasia, and pigmentation; sparse hair in half of the cases; cataracts; small genitalia; abnormal hands and feet; short stature; and mental retardation.

Linear sebaceous nevus syndrome. Here there is a linear nevus of one side of face and trunk, lipodermoids on bulbar conjunctivae, vascularization of corneas, mental retardation, focal seizures, and spike and slow waves in the EEG. Genetics remain uncertain.

Incontinentia pigmenti (Bloch-Sulzberger syndrome). Only females are affected; appearance of dermal lesions in first weeks of life; vesicles and bullae followed by hyperkeratoses and streaks of pigmentation, scarring of scalp, and alopecia; abnormalities of dentition; hemiparesis; quadripareisis; seizures; mental retardation; and up to 50 percent eosinophils in blood. The status of this disease is uncertain.

Focal dermal hypoplasia. Also a disease limited to females. Areas of dermal hypoplasia with protrusions of subcutaneous fat, hypo- and hyperpigmentation, scoliosis, syndactyly in a few, short stature, thin body habitus. Intelligence is occasionally subnormal.

Other rare entities are neurocutaneous melanosis, neuroectodermal melanolyosomal disease with mental retardation, progeria, Cockayne syndrome, and ataxia-telangiectasia (see Chap. 37; also Gomez, 1987).

Dysraphism, or Rachischisis: Meningocele, Encephaloceles, and Spina Bifida

Included under this heading is the large number of disorders of fusion of dorsal midline structures of the primitive neural tube, a process that takes place during

the first 3 weeks of postconceptual life. Exogenous factors are presumed to be operative in most cases but there are genetic forms. The most extreme form is anencephaly, as described earlier; it is characterized by the absence of the entire cranium at birth, and the undeveloped brain lies in the base of the skull, a small vascular mass without recognizable nervous structures.

An eventration of brain tissue and its coverings through an unfused midline defect in the skull is called an *encephalocele*. Frontal encephaloceles may deform the forehead or remain occult. Associated defects of the frontal cortex, anterior corpus callosum, and optic-hypothalamic structures, as well as cerebrospinal fluid (CSF) leakage into frontal or ethmoid sinuses, pose a risk of meningitis. Some of these children are relatively normal mentally. Far more severe are the posterior encephaloceles, some of which are enormous and are attended by grave neurologic deficits such as blindness, ataxia, and mental retardation. However, lesser degrees of the defect are well known and may be small or hidden, such as a *meningoencephalocele* connected with the rest of the brain through a small opening in the skull. Small nasal encephaloceles may cause no neurologic signs, but if they are mistaken for nasal polyps and snipped off, CSF fistulae result.

A failure of development of the midline portion of the cerebellum referred to earlier, forms the basis of the *Dandy-Walker syndrome* (Fig. 38-2). A cyst-like structure, representing the greatly dilated fourth ventricle, expands in the midline, causing the occipital bone to

Figure 38-2. Dandy-Walker syndrome. MRI showing agenesis of the midline cerebellum and large midline cyst, representing the greatly dilated fourth ventricle, which occupies almost the entire posterior fossa. A. Axial view. B. Sagittal view.

bulge posteriorly and displace the tentorium and torcula upward. In addition, the cerebellar vermis is aplastic, the corpus callosum may be deficient or absent, and there is dilatation of the aqueduct as well as the third and lateral ventricles.

Even more frequent are abnormalities of closure of the vertebral arches. These take the form of a *spina bifida occulta*, *meningocele*, and *meningomyelocele* of the lumbosacral or other regions. In *spina bifida occulta*, the cord remains inside the canal and there is no external sac, although a subcutaneous lipoma or a dimple or wisp of hair on the overlying skin may mark the site of the lesion. In *meningocele*, there is a protrusion of only the dura and arachnoid through the defect in the vertebral laminae, forming a cystic swelling usually in the lumbosacral region; the cord remains in the canal, however. In *meningomyelocele*, which is 10 times as frequent as meningocele, the cord (more often the cauda equina) is extruded also and is closely applied to the fundus of the cystic swelling.

The incidence of spinal dysraphism (myeloschisis), like that of anencephaly, varies widely from one locale to another, and the disorder is more likely to occur in a second child if one child has already been affected (the incidence then rises from 1 per 1,000 to 40 to 50 per 1,000).

Etiology Exogenous factors (e.g., potato blight in Ireland) were many times implicated in an increased rate of both myeloschisis and anencephaly, but the effects of starvation and vitamin deficiency could never be separated from the potential effect of a toxic factor. It has now been established by numerous case-control and randomized treatment trials that inadequate intake of folate in early pregnancy is associated with an increased risk of these malformations. Folic acid, given before the 28th day of pregnancy is protective; vitamin A may also have slight protective benefit. Similar associations have been found with less certainty with exposure during pregnancy to certain antiepileptic drugs, particularly valproic acid and carbamazepine. Maternal diabetes and possibly obesity have been risk factors in some epidemiologic studies, as summarized by Mitchell and colleagues. The greatest risk, however, almost 30-fold higher, attaches to a previous pregnancy affected with spina bifida in particular.

Diagnosis As with anencephaly, the diagnosis can often be inferred from the presence of alpha-fetoprotein in the amniotic fluid (sampled at 15 to 16 weeks of pregnancy) and the deformity confirmed by ultrasonography in utero. Blood contamination is a source of error in the fetoprotein test (Milunsky). Acetylcholinesterase immunoassay, done on amniotic fluid, is another reliable means of confirming the presence of neural tube defects.

In the case of meningocele, the child is born with a large externalized lumbosacral sac covered by delicate, weeping skin. The defect may have ruptured in utero or during birth, but more often the covering is intact. There is severe dysfunction of the cauda equina roots or conus medullaris contained in the sac. Stroking of the sac may elicit involuntary movements of the legs. As a rule the legs are motionless, urine dribbles, keeping the patient constantly wet, there is no response to pinprick over the lumbosacral dermatomal zones, and the tendon reflexes are absent. In contrast, craniocervical

structures are normal unless a Chiari malformation is associated, as it often is (see further on). Differences are noted in the neurologic picture depending on the level of the lesion. If the lesion is entirely sacral, bladder and bowel sphincters are affected but legs escape; if lower lumbar and sacral, the buttocks, legs, and feet are more impaired than hip flexors and quadriceps; if upper lumbar, the feet and legs are sometimes spared and ankle reflexes retained, and there may be Babinski signs. The two common complications of these severe spinal defects are meningitis and progressive hydrocephalus from a Chiari malformation (see below). The subject of spina bifida and neural tube defects was reviewed by Botto and colleagues and by Mitchell and coworkers.

Treatment Prevention by the administration of folate during pregnancy is obviously paramount. Opinions as to proper management of the established lesion vary considerably. Excision and closure of the coverings of the meningomyelocele in the first few days of life are advised if the objective is to prevent fatal meningitis. After a few weeks or months, as hydrocephalus reveals its presence by a rapid increase in head size and enlargement of the ventricles, a ventriculoperitoneal shunt is required. Less than 30 percent of such patients survive beyond 1 year and the long-term results of treating these patients have not been encouraging. Lorber and colleagues report that 80 to 90 percent of their surviving patients are developmentally delayed to some degree and are paraplegic. The decision to undertake rather formidable surgical procedures is being questioned more frequently. Exceptionally, patients with meningocele, and most of those with lumbar meningocele, are mentally normal.

Other Developmental Spinal Defects Including Tethered Cord

The problems of meningocele and its complications are so largely pediatric and surgical that the neurologist seldom becomes involved—except perhaps in the initial evaluation of the patient—in the treatment of meningeal infection, or in the case of shunt failure with decompensation of hydrocephalus. Of greater interest to the neurologist are a series of closely related abnormalities that produce symptoms for the first time in late childhood, adolescence, or even adult life. These include sinus tracts with recurrent meningeal infections, lumbosacral lipomas with low tethering of the spinal cord (“tethered cord”) causing an early childhood or delayed radicular or spinal cord syndrome; diastematomyelia, cysts, or tumors with spina bifida and a progressive myeloradiculopathy; and the Chiari malformation and syringomyelia that first present in adolescence or adult life. These abnormalities are described below.

Another class of disorders involves an occult lumbosacral dysraphism that is not inherited but is a result of faulty development of the cell mass that lies caudal to the posterior neuropore (normally this undergoes closure by the 28th day of embryonic life). Occult spinal dysraphism of this type is also associated with meningoceles, lipomas, and sacrococcygeal teratomas. Another well-recognized anomaly is agenesis of the sacrum and sometimes the lower lumbar vertebrae (*caudal regression syndrome*).

Interestingly, in 15 percent of such cases, the mother is diabetic (Lyon and Evrard). Here there is flaccid paralysis of legs, often with arthrogryptic contractures and urinary incontinence. Sensory loss is less prominent, mental function develops normally, and there is no hydrocephalus.

Sinus tracts in the lumbosacral or occipital regions are of importance, for they may be a source of bacterial meningitis at any age. They are often betrayed by a small dimple in the skin or by a tuft of hair along the posterior surface of the body in the midline. (The pilonidal sinus should not be included in this group.) The sinus tract may lead to a terminal myelocystocele and be associated with dermoid cysts or fibrolipomas in the central part of the tract. Cloacal defects (no abdominal wall and no partition between bladder and rectum) may be combined with anterior meningoceles. Evidence of sinus tracts should be sought in instances of unexplained meningitis, especially when there has been recurrent infection or the cultured organism is of nosocomial dermal origin.

Of great interest are *congenital cysts* and *tumors*, particularly lipoma and dermoid, that arise in the filum terminale and attach (tether) the cord to the sacrum. Progressive symptoms and signs are produced as the spine elongates during development, thereby stretching the caudally fixed cord (Fig. 38-3). Some of these children have bladder and leg weakness soon after birth. Others deteriorate neurologically at a later age (generally

Figure 38-3. MRI of an adult with tethered cord and the typical lipoma at its caudal extent. No dysraphism is present. The main features were a flaccid bladder, asymmetrical weakness and atrophy of the forelegs, and a degree of spasticity in the legs.

between 2 and 16 years, sometimes later—see below). Complex disturbances of bladder function that produce urgency and incontinence beginning in the second or third decade may be the only manifestation, or the bladder symptoms may be combined with impotence (in the male) and numbness of the feet and legs or foot-drop (Pang and Wilberger). Several of our adult patients have had unusual visceral reflex reactions, such as involuntary defecation or priapism with stimulation of the abdomen or perineum. According to most surgeons, it is not the myelolipoma but the tethering of the cord that gives rise to symptoms; removal of the tumor is of little benefit unless the cord is detached from the sacrum at the same time. This may be difficult, for the lipoma may be fused with the dorsal surface of the spinal cord.

Diastematomyelia is another unusual abnormality of the spinal cord often associated with spina bifida. Here a bony spicule or fibrous band protrudes into the spinal canal from the body of one of the thoracic or upper lumbar vertebrae and divides the spinal cord into halves for a variable vertical extent. In extreme examples, the division of the cord may be complete, each half with its own dural sac and complete set of nerve roots. This longitudinal fissuring and doubling of the cord are spoken of as *diplomyelia*. With body growth, the restriction created by the bone spicule leads to a *traction myelopathy*, presenting with pain and progressive sensory, motor, and bladder symptoms, sometimes as late as adult life. Removal of the fibrous-bony spicule and untethering of the spinal cord have been beneficial in some cases.

Syringomyelia (see also Chap. 44) is a developmental cavity within the cervical cord, extending a variable distance caudally or rostrally, and usually associated with an Arnold-Chiari malformation that is described below. There are a variety of other neurodevelopmental spinal abnormalities in the high cervical region, such as fusion of atlas and occiput or of cervical vertebrae (Klippel-Feil syndrome), congenital dislocation of the odontoid process and atlas, platybasia, and basilar impression. These abnormalities are discussed in Chap. 44, with other diseases of the spinal cord.

Chiari Malformation

Encompassed by this term are a constellation of related congenital anomalies at the base of the brain, the most consistent of which are (1) extension of a tongue of cerebellar tissue posterior to the medulla and cord that extends into the cervical spinal canal; (2) caudal displacement of the medulla and the inferior part of the fourth ventricle into the cervical canal; and (3) a frequent but not invariable association with syringomyelia or a spinal developmental abnormality. These and associated anomalies were first clearly described by Chiari (1891). Several translations of his original material have been made, but they have been criticized as inaccurate. Arnold's name is attached to the syndrome, but his contribution to our understanding of these malformations was relatively insignificant. Use of the double eponym *Arnold-Chiari malformation* is so entrenched that a dispute over its propriety serves little purpose. Chiari recognized

four types of abnormalities. In recent years, the term has come to be restricted to Chiari's types I and II—that is, to cerebellomedullary descent without and with a meningo-myelocele, respectively. Type III Chiari malformation is no more than a high cervical or occipitocervical meningo-myelocele with cerebellar herniation, and type IV consists only of cerebellar hypoplasia.

The incidence among adults, acquired from autopsy series and more recently, from incidentally discovered descent of the cerebellar tonsils on imaging procedures, is about 0.6 percent of the population. It should be emphasized that a proportion of normal individuals have a small tongue of the posterior cerebellum protruding by a few millimeters below the lower lip of the foramen magnum; this is usually of no significance and does not justify inclusion as a Chiari malformation. A historical account of the clinical, pathologic, and imaging aspects of this malformation and the evolution of ideas concerning it has been given by Bejjani.

Several other morphologic features are characteristic of the true Chiari anomaly. The medulla and pons are elongated and the aqueduct is narrowed. The displaced tissue (medulla and cerebellum) occludes the foramen magnum; the remainder of the cerebellum, which is small, is also displaced so as to obliterate the cisterna magna. The foramina of Luschka and Magendie often open into the cervical canal, and the arachnoid tissue around the herniated brainstem and cerebellum is fibrotic. All these factors are probably operative in the production of hydrocephalus, which is always associated. Just below the herniated tail of cerebellar tissue there is a kink or spur in the spinal cord, which is pushed posteriorly by the lower end of the fourth ventricle. In this fully expressed form of the malformation, a meningo-myelocele is nearly always found. It should again be emphasized that *hydromyelia* or *syringomyelia of the cervical cord* are commonly associated findings and the main theories of causation of the latter are based on the change in CSF dynamics produced by the Chiari malformation.

Developmental abnormalities of the cerebrum, particularly polymicrogyria may infrequently coexist, and the lower end of the spinal cord may extend as low as the sacrum (i.e., a tethered cord). There are usually cranial bony abnormalities as well. The posterior fossa is small; the foramen magnum is enlarged and grooved posteriorly. Nishikawa and colleagues suggested that smallness of the posterior fossa with overcrowding is the primary abnormality leading to the brain malformation. Often the base of the skull is flattened or infolded by the cervical spine (basilar impression).

Clinical Manifestations

In type II Chiari malformation (with meningo-myelocele), the problem becomes one of progressive hydrocephalus. Cerebellar signs cannot be discerned in the first few months of life. However, lower cranial-nerve abnormalities—laryngeal stridor, fasciculations of the tongue, sternomastoid paralysis (causing head lag when the child is pulled from lying to sitting), facial weakness, deafness, bilateral abducent palsies—may be present in varying combinations.

If the patient survives to later childhood or adolescence, one of the syndromes that are more typical of the type I malformation may become manifest.

In the more common type I Chiari malformation (without meningocele or other signs of spinal dysraphism), neurologic symptoms may not develop until adolescence or adult life. The symptoms are those of (1) increased intracranial pressure, mainly headache, (2) progressive cerebellar ataxia, (3) progressive spastic quadriparesis, (4) downbeating nystagmus, or (5) the syndrome of cervical syringomyelia (segmental amyotrophy and sensory loss in the hands and arms, with or without pain). Or the patient may show a combination of disorders of the lower cranial nerves, cerebellum, medulla, and spinal cord (sensory and motor tract disorders), usually in conjunction with headache that is mainly occipital. This combination of symptoms is easily mistaken for multiple sclerosis or a tumor at the foramen magnum. The symptoms are usually chronic but may have an acute onset after sustained or forceful extension of the neck, as, for example, after a long session of dental work, hairdressing in women, or chiropractic manipulation. The physical habitus of such patients may be normal, but approximately 25 percent have signs of an arrested hydrocephalus, or a short "bull neck." When basilar impression (a congenital abnormality of the occipital bone that invaginates the posterior atlas into the cranial cavity) and a Chiari malformation coexist, it may be impossible to decide which of the two is responsible for the clinical findings.

The nature and severity of headache that are reasonably attributable to a Chiari malformation is somewhat unclear. Occipitocervical pain with coughing, position change, or the Valsalva maneuver is the most dependable association, but even then, decompression may not relieve the symptoms. Exertional headache alone is a questionable association. Only large and genuine malformations, not minor descent of the tonsils should be considered causative. More generalized headaches may or may not be explained by the finding of a Chiari malformation and the advisability of a surgical treatment then depends on the degree of disability created by other aspects of the malformation. Further discussion of this subject is found in Chap. 10.

The tongue of cerebellar tissue and the kinked cervical cord obstruct the upward flow of CSF and give a highly characteristic imaging profile, particularly on sagittal MRI (Fig. 38-4). Inspection of the axial sections of scans at the level of the foramen magnum demonstrates crowding of the upper cervical canal by inferiorly displaced cerebellar tissue, but one must be aware of the variations in the normal position of the cerebellar tonsils at this level. A slight descent of the cerebellar tonsils that is reversible is also seen with low cerebrospinal fluid pressure and not indicative of a Chiari malformation. Recent inceptions in phase contrast MRI technology allow the imaging of CSF flow in the region of the foramen magnum but the relevance to choosing patients for surgical decompression has not been clarified (see summary by Menick). The CSF in Chiari malformation is usually normal but may show an elevated pressure and protein level in some cases for unexplained reasons.

Figure 38-4. Chiari-type malformation and developmental syringomyelia. T2-weighted MRI of the low-lying cerebellar tonsils below the foramen magnum and behind the upper cervical cord and the syrinx cavity in the upper cord.

Treatment

The treatment of Chiari malformation and any associated basilar impression is far from satisfactory. If clinical progression is slight or uncertain, it is probably best to do nothing. If disability by way of spasticity, ataxia, pain in the shoulders or arms, or lower cranial-nerve disease is increasing, upper cervical laminectomy and enlargement of the foramen magnum are indicated. The proper course for patients that have headaches alone is uncertain but many such patients are operated upon if their cranial pain has been progressive, or if it is consistently and markedly worsened by cough or similar Valsalva actions, or if there is fainting or another associated symptom that can be reasonably related to the Chiari abnormality. The outcome of surgery, in our experience, has been less satisfactory when decompression was performed mainly for intractable headache, but there have been exceptions, especially when exertion or Valsalva maneuver elicits the symptoms.

The basic operation is suboccipital and C-1 decompression; various forms of shunting may be added if there is syringomyelia (the shunt is to the adjacent subarachnoid space) or hydrocephalus. The surgical procedure must be done cautiously. Opening of the dura and extensive manipulation of the malformation or excision of herniated cerebellum may aggravate the symptoms

but is performed by some neurosurgeons to decompress the lower brainstem. Often, surgery halts the progress of the neurologic illness, arrests the hydrocephalus, or results in some other clinical improvement. The surgical series reported by Alzate and colleagues is representative. Emphasis was placed on proper patient selection, but the analysis of 66 cases, as in most other reports, was retrospective. (This reference is part of a very informative monograph). Most series report that a CSF leak follows surgery in about 5 percent of patients. The fate of an associated syringomyelia has been uncertain but most series report optimistic results.

As alluded to earlier, the role of phase-contrast MRI of CSF flow around the foramen magnum in selecting patients for decompression is unknown. The treatment of an associated syringomyelia and other developmental abnormalities in this region is discussed further in Chap. 44 under "Intramedullary Syringomyelic Syndrome." We are unable to comment on the use by a limited number of neurosurgeons of posterior fossa decompression for the treatment of chronic fatigue syndrome and all manner of other symptoms except to say that it is entirely illogical, even when a Chiari malformation is detected.

CHROMOSOMAL ABNORMALITIES (KARYOTYPIC CHROMOSOMAL DYSGENESES)

As mentioned in the introduction, mid-twentieth-century discovery of outstanding significance was the recognition of a group of developmental anomalies of the brain and other organs associated with a demonstrable abnormality of the karyotype of autosomal and sex chromosomes. Jacobs and Lejeune in 1959 almost simultaneously were the first to note a triplication of the 21st chromosome in Down syndrome, and there followed the discovery of a number of other trisomies as well as deletions or translocations of other autosomal chromosomes and a lack or excess of one of the sex chromosomes. Such an event must take place sometime after the formation of the oocyte, during the long period when it lies fallow in the ovary or during the process of conception or germination and first cell divisions. Thus, all the cells in the embryo may carry the changed chromosome, or only some of them may carry it, the latter condition being called *mosaicism*.

The precise manner in which triplication or some other imperfection of a chromosome is able to derail the pathways of ontogenesis is a mystery. In some instances, a chromosomal imperfection may result from the lack of a gene or a distortion or fragmentation of an unstable gene, as in the fragile X syndrome. These germ line alterations are to be distinguished from acquired partial duplications and deletions of parts of genes that occur as acquired somatic mutations in many tremors and from variations in copy number of segments of genes that are emerging as possible explanations for a number of diseases such as autism.

Certain chromosomal abnormalities are incompatible with life, and it has been found that the cells of many

abortuses and stillborns show abnormal karyotypes. Conversely, the organism may survive and exhibit any one of many syndromes, of which the following are the most frequent: (1) Down syndrome (mongolism, trisomy 21); (2) one type of arrhinencephaly (trisomy 13, Patau syndrome); (3) trisomy 18 (Edwards syndrome); (4) cri-du-chat syndrome (deletion of short arm of chromosome 5); (5) monosomy 21 (so-called antimongolism); (6) ring chromosomes; (7) Klinefelter syndrome (XXY); (8) Turner syndrome (XO); (9) others (XXXX, XXX, XYY, YY, XXYY); (10) fragile X syndrome, the most common form of inherited mental retardation; (11) Williams syndrome; and (12) Prader-Willi and Angelman syndromes. There are numerous less-frequent types, some of which are also discussed below because they have special neurologic interest. The overall frequency of chromosomal abnormalities in live births is 0.6 percent (see the review by Kalter and Warkany). For a comprehensive account of the chromosome-linked disorders the reader is referred to the article by Lemieux and for speculations on the nature of genetic retardations, can be found in the article by Nokelainen and Flint.

Down Syndrome (Trisomy 21)

Described first in 1866 by Langdon Down, this is easily the best known of the chromosomal dysgeneses. Its frequency is 1 in 600 to 700 births, and it accounts for approximately 10 percent of all cases in every large series of cases of severe mental retardation. One cannot distinguish the Down syndrome with the common triplication of chromosome 21 from that caused by a translocation, and therefore duplication, of one arm, specifically the distal portion of the long arm that seems to contain the region responsible for the syndrome. Two genes have been of greatest interest in that region: *DYRK1A* and *DSCR1*.

Familiarity with the condition permits its recognition at birth, but the somatic appearance becomes more obvious with advancing age. The round head, open mouth, stubby hands, slanting palpebral fissures, and short stature impart an unmistakable appearance. The ears are low-set and oval, with small lobules. The palpebral fissures slant slightly upward and outward owing to the presence of medial epicanthal folds that partly cover the inner canthi (hence the old term *mongolism*). The bridge of the nose is poorly developed and the face is flattened (hypoplasia of the maxillae). The tongue is usually enlarged, heavily fissured, and protruded. Gray-white specks of depigmentation are seen in the irides (Brushfield spots). The little fingers are often short (hypoplastic middle phalanx) and incurved (clinodactyly). The fontanels are patent and slow to close. The hands are broad, with a single transverse (simian) palmar crease and other characteristic dermal markings. Lenticular opacities and congenital heart lesions (septal and other defects), as well as gastrointestinal abnormalities (stenosis of duodenum), are frequent. The patient with Down syndrome is slightly below average size at birth and is characteristically of short stature at later periods of life. The height attained in adult life seldom exceeds that of a 10-year-old child.

Hypotonia of the limbs is a prominent finding. At first, the Moro response is reduced or absent, and feeding is difficult. Most affected children do not walk until 3 to

4 years of age; their acquisition of speech is delayed, but over 90 percent talk by 5 years. The IQ is variable, and that of a large group follows a Gaussian curve with the median IQ being 40 to 50 and the range, 20 to 70. A placid, docile, and affectionate personality characterizes most Down patients. A high incidence of atlantoaxial instability puts these individuals at risk of traumatic spinal cord compression in athletic ventures.

An increased incidence of myelocytic and lymphocytic leukemia takes its toll. A number of patients have had embolic strokes and brain abscesses secondary to cardiac abnormalities and there is disproportionate occurrence of the rare cerebrovascular disorder known as moyamoya (see Chap. 34). Life expectancy is later shortened by the almost universal development of Alzheimer disease by the 40th year of life. This is explained by the presence on the duplicate copy of chromosome 21 of the gene for the precursor of the protein amyloid, a central factor in the development of Alzheimer disease. As Alzheimer disease develops, the usual clinical picture is marked by inattentiveness, reduced speech, impairment of visuospatial orientation, loss of memory and judgment, and seizures.

The triplication is found mostly in the offspring of older mothers, whereas the less-frequent translocation is found equally in the offspring of young and older women. In other subtypes of the Down syndrome, referred to as *mosaics*, some cells share in the chromosomal abnormality and others are normal. Affected individuals have atypical forms of the syndrome, and some such individuals are of normal intelligence.

The genetic changes that lead to cerebral maldevelopment and dysmorphic physical features are just beginning to be understood. A connection to genes that code for enzymes of folate has been suggested (among other mechanisms). The genetic aspects, as well as features pertaining to the medical care of these patients, are well summarized by Roizen and Patterson. They emphasize the high frequency of enteric sprue (celiac disease) and hypothyroidism and the need for screening for these conditions.

Laboratory and Pathologic Findings Brain weight is approximately 10 percent less than average. The convolutional pattern is rather simple. The frontal lobes are smaller than normal, and the superior temporal gyri are thin. There are claims of delayed myelination of cerebral white matter and also of immature and poorly differentiated cortical neurons. Alzheimer neurofibrillary changes and neuritic plaques are practically always found in Down patients who are older than 40 years of age, as mentioned.

It is possible to make the diagnosis of Down syndrome by demonstrating the chromosomal abnormalities in cells of the amniotic fluid. About one-third of pregnant mothers also have an abnormal elevation of serum alpha-fetoprotein in the second trimester of pregnancy. Other independent predictors of fetal Down syndrome are elevated serum chorionic gonadotropin and decreased estriol (Haddow et al). One can uncover a considerable proportion of the Down population by prenatal screening for these serum markers and by performing amniocentesis on women with positive tests to search for the chromosomal abnormality. Early detection is aided by the absence on imaging of a nasal bone between 11 and 14 weeks, at which time it is normally detected (Cicero et al).

Other Chromosomal Dysgeneses

These are listed here with brief descriptions of their main features.

1. *Trisomy 13 (Patau syndrome)*. Frequency 1 in 2,000 live births, more female than male, average maternal age 31 years, microcephaly and sloping forehead, microphthalmos, coloboma of iris, corneal opacities, anosmia, low-set ears, cleft lip and palate, capillary hemangiomas, polydactyly, flexed fingers, posterior prominence of heels, dextrocardia, umbilical hernia, impaired hearing, hypertonia, severe mental retardation, death in early childhood.
2. *Trisomy 18*. Frequency 1 in 4,000 live births, more in females, average maternal age 34 years, slow growth, occasional seizures, severe mental retardation, hypertonia, ptosis and lid abnormalities, low-set ears, small mouth, mottled skin, clenched fists with index fingers overlapping the third finger, syndactyly, rocker-bottom feet, shortened big toe, ventricular septal defect, umbilical and inguinal hernias, short sternum, small pelvis, small mandible, death in early infancy.
3. *Cri-du-chat syndrome* (deletion in short arm of chromosome 5). Abnormal cry, like a kitten, severe mental retardation, hypertelorism, epicanthal folds, brachycephaly, moon face, antimongoloid slant of palpebral fissures, micrognathia, hypotonia, strabismus.
4. *Ring chromosomes*. Mental retardation with variable physical abnormalities.
5. *Klinefelter syndrome (XXY)*. Only males affected. Eunuchoid appearance, wide arm span, sparse facial and body hair, high-pitched voice, gynecomastia, small testicles, usually developmentally delayed but not severely so; high incidence of psychosis, asthma, and diabetes.
6. *Turner syndrome (XO)*. Only females affected. Triangular face, small chin, occasionally hypertelorism and epicanthal folds, widely spaced nipples, clinodactyly, cubitus valgus, hypoplastic nails, short stature, webbed neck, delayed sexual development, mild developmental delay. The manner of inheritance of the X chromosome may have bearing on the patient's personality and level of functioning, as noted in Chap. 21.
7. *Colpocephaly*. A rare type of malformation of the brain consisting of marked dilatation of the occipital horns of the lateral ventricles, thickening of the overlying rim of cortical gray matter, and thinning of the white matter. The associated clinical picture comprises developmental delay, spasticity, seizures, and visual abnormalities (because of optic nerve hypoplasia). This disorder is probably of diverse causation, but it is listed here with the chromosomal abnormalities because some cases have been associated with the mosaicism for trisomy 8 (Herskowitz et al). The term *colpocephaly* is often used incorrectly to apply to all forms of ventricular enlargement (including hydrocephalus) associated with abnormal development of the brain.
8. *Fragile X syndrome* (see further on for additional clinical details in the section on developmental delay). This abnormality is among the most common inherited forms of developmental delay, estimated to occur in 1 of every 1,500 male live births and accounting for 10 percent of severe developmental delay in males. Females, with two X chromosomes, are affected about half as frequently, and then only to a slight degree. With the advent of new markers for the detailed structure of chromosomes, Lubs observed an unusual site of frequent breakage ("fragility") on the X chromosome and related it to a syndrome that included developmental delay, flaring ears, elongated facies, slightly reduced cranial perimeter, normal stature, and enlarged testes. More recently, rare *progressive ataxia* has been reported in adults who harbor the chromosomal abnormality and had displayed little or no cognitive deficiency.
9. The chromosomal fragility appears to be due to a heritable, unstable CGG repeating sequence in the X chromosome. Affected individuals have over 230 repeats and carriers have 60 to 230 repeats. The prolonged sequence inactivates a gene (*FMR1*) that codes for an RNA-binding protein of as yet an unknown connection to brain function. The genetics of this and other retardations was reviewed by Nokelainen and Flint. Rousseau and colleagues described a simple and sensitive test using DNA analysis for the diagnosis of the syndrome both prenatally and after birth. Because of mosaicism, the length of the triplet repeat does not directly relate to the degree of expression of retardation, and the fragile X alteration occasionally turns up in mentally normal males; in some instances, the male children of their daughters have the disease. In some of the cases we have observed, the intellectual deficit has been mild in degree and the main abnormalities have taken the form of troublesome behavior, logorrhea, an autistic type of gaze aversion, and asociality. These and other neurobehavioral features of the syndrome and its unique pattern of inheritance (it is neither recessive nor dominant) have been discussed by Shapiro.
10. *Williams syndrome*. Described by J.C.P. Williams and colleagues of Australia from the perspective of a supravalvular aortic stenosis and a year later by Beuren and colleagues, this unique combination of cerebral maldevelopment and cardiovascular abnormalities has been traced in most patients to a microdeletion on chromosome 7 in the region of the gene that codes for the protein elastin. Its frequency is 1 in 20,000 newborns. Further discussion of clinical features of this syndrome is found later in the chapter.
11. *Prader-Willi and Angelman syndromes*. The Prader-Willi syndrome was already mentioned in relation to the hyperphagia of hypothalamic disorders (adiposogenital dystrophy, Froehlich syndrome). It is not uncommon (1 in 20,000 births) and affects both sexes equally. Hypotonia (floppy infant), areflexia, small stature, dysmorphic facies, and hypoplastic genitalia are evident, and arthrogryposis may be present at birth. After the first year, developmental delay becomes obvious and obesity, due to hyperphagia, becomes prominent. Patients are identified by the "H3O" mnemonic, referring to hypomentia, hypotonia, hypogonadism, and obesity. The disorder is associated with a deletion at 15q11-q13 (a so-called microdeletion, as in Williams syndrome), which can

be identified by a combination of cytogenetic and DNA analyses. In 70 percent of cases the disease is caused by a noninherited deletion from the paternal X chromosome.

12. The Angelman syndrome, another cause of severe developmental delay, is associated with the identical chromosomal abnormality to that found in the Prader-Willi syndrome, but there is usually a maternally inherited single-gene defect. The difference in phenotype derives from a complex genetic phenomenon termed *spatially restricted imprinting*. The phenotype comprises severe developmental delay, microcephaly, refractory seizures, absence of speech, ataxia, inappropriate laughter, prominent jaw, thin upper lip, and prolonged tongue. Outstanding are an unusual marionette-like stance coupled with a persistent tendency to laugh and smile (hence the old name “happy puppet syndrome”; see also Chap. 37).
13. *Rett syndrome*, discussed more fully further on, is mentioned here because it is the result of a dominant defect on the X chromosome. It affects 1 of every 10,000 to 15,000 girls. After 6 to 18 months of normal development, motor skills and mental abilities seem slowly to regress. Certain handwringing and other stereotyped hand movements appear as the disease progresses and are characteristic.

Several generalizations can be made about these chromosomal dysgeneses. First, the autosomal ones are often lethal (Rett syndrome is an exception), and they almost always have a devastating effect on cerebral growth and development, whether the infant survives or not. Anomalies of nonneural and a degree of externally visible dysmorphism structures are regularly present—an association so constant that one may safely predict that an otherwise normally formed infant will not have a detectable chromosomal defect. However, only in the Down syndrome and trisomy 13 (and possibly trisomy 18) are the physiognomy and bodily configuration highly characteristic. Surprisingly, some of the most grotesque disfigurements, such as anencephaly and multiple severe congenital anomalies, are not related to a morphologic abnormality of chromosomes. By contrast, an insufficiency of sex chromosomes induces only subtle effects on the brain, affecting intellect and personality; to some extent this is true of supernumerary sex chromosomes (XYY, for example).

The basic abnormality of the brain underlying the developmental delay in many of these chromosomal dysgeneses has not been ascertained. The cerebrum is slightly small, but only minor changes are seen in the convolutional pattern and cortical architecture in conventional microscopic preparations. Neurocellular methodologies to date are not sufficiently advanced to reveal the fundamental cerebral abnormality.

Teratologic Deformations of the Nervous System

A number of observations have repudiated the former belief that the human embryo is naturally shielded against exogenous causes of maldevelopment. Irradiation during

the first trimester, rubella and CMV infections, severe hypothyroidism of the mother during this same period, and the action of alcohol, vitamin A, and thalidomide have all been observed, among a multitude of other agents, to give rise to serious disorders of development. Quite relevant to the neurologist, the offspring of mothers receiving anticonvulsant drugs during the early months of pregnancy have a slightly increased risk of developing birth defects (approximately 5 percent, compared to 3 percent for the general population—see “Teratogenic Effects of Antiepileptic Medications” in Chap. 16). Cleft lip and palate are the most common anomalies attributable to anticonvulsant drugs; other craniofacial defects, spina bifida, minor cardiac defects, and dysraphisms have also been reported at a slightly increased rate. Claims and counterclaims have been made concerning the pathogenicity of numerous other substances. Mainly, the data are from animals given amounts far in excess of any possible therapeutic doses in humans. The data from humans are so meager from a multitude of such substances that they are not discussed here. The reader may refer to the article by Kalter and Warkany for further information.

THE PHAKOMATOSES (CONGENITAL NEUROECTODERMOSSES)

As stated earlier, there are two broad categories of neurocutaneous diseases. In one, the infant is born with a special type of skin disease or develops it in the first weeks of life; in the other forms, the cutaneous abnormality, although often present in minor degree at birth, later evolves as quasineoplastic disorders. The quasineoplastic disorders to which van der Hoeve in 1920 applied the term *phakomatoses* (from the Greek *phakos*, meaning “mother spot,” “mole,” or “freckle”) are tuberous sclerosis, neurofibromatosis, and cutaneous angiomas with central nervous system (CNS) abnormalities, which have many features in common: hereditary transmission, involvement of organs of ectodermal origin (nervous system, eyeball, retina, and skin), slow evolution of lesions in childhood and adolescence, a tendency to form hamartomas (benign tumor-like formations because of maldevelopment), and a disposition to fatal malignant transformation. These disorders are discussed below and listed in Table 38-4.

Table 38-4

THE CONGENITAL NEUROECTODERMOSSES

True phakomatoses
1. Tuberous sclerosis
2. Neurofibromatosis
Cutaneous angiomas with abnormalities of the central nervous system
1. Sturge-Weber syndrome
2. Dermatomeal hemangiomas and spinal vascular malformations
3. Epidermal nevus (linear sebaceous nevus) syndrome
4. Osler-Weber-Rendu disease
5. von Hippel-Lindau disease
6. Ataxia-telangiectasia (Louis-Bar disease)
7. Fabry disease

Tuberous Sclerosis (Bourneville Disease)

Tuberous sclerosis is a congenital disease of hereditary type in which a variety of lesions, because of a limited hyperplasia of ectodermal and mesodermal cells, appear in the skin, nervous system, heart, kidney, and other organs. It is characterized by the triad of *adenoma sebaceum*, *epilepsy*, and *developmental delay*. Hypomelanotic skin macules (“ash-leaf” lesions) and the subepidermal fibrotic “shagreen patch” are diagnostic features.

It is stated that Virchow recognized scleromas of the cerebrum in the 1860s and that von Recklinghausen reported a similar lesion combined with multiple myomata of the heart in 1862, but Bourneville’s articles, appearing between 1880 and 1900, presented the first systematic accounts of the disease and it was he who related the cerebral lesions to those of the skin of the face. Vogt (1890) fully appreciated the significance of the neurocutaneous relationship and formally delineated the triad of facial adenoma sebaceum, epilepsy, and developmental delay. “Epiloia,” a term for the disease introduced by Sherlock in 1911, never gained general acceptance. These and other historical aspects are reviewed in Gomez’s monograph.

Epidemiology

The disease has been described in all parts of the world and is equally frequent in all races and in both sexes. Heredity is self-evident in only a minority of cases—50 percent in some series and as little as 14 percent in the series of Bundag and Evans (cited by Brett). The disease is determined by two autosomal dominant genes (see below), but it has been estimated as 1 in 20,000 to 300,000. The disease is inherited in an autosomal dominant fashion but with variable penetrance. The abnormal gene may be in one of two sites—the long arm of chromosome 9, designated as *TSC 1* (hamartin), or in the short arm of chromosome 16, *TSC 2* (tuberin), which is common. A wide variety of mutations have been described and both alleles must be affected for expression of the disease (“loss of heterozygosity”). Approximately 15 percent of sporadic cases show no identifiable mutation and tend to have milder manifestations, perhaps on the basis of mosaicism. Hamartin and tuberin function as tumor suppressor proteins and interact to suppress cell growth. This may, in part, explain the proclivity to develop various growths and hamartomas. The cerebral lesions and two of the three associated skin lesions of tuberous sclerosis are of this type. Several hypotheses relating to neuronal migration or to excessive secretion of growth factors have been proposed to link the inactivation of these genes with the pathogenesis of the characteristic lesions. Much of the work in understanding the function of these two proteins and their role in tumor formation has been performed in *Drosophila* and are summarized in the extensive review by Crino and colleagues.

The disease involves many organs in addition to the skin and brain and it may assume a diversity of forms, the least severe of which (i.e., the *forme fruste*) is difficult to diagnose; hence, one cannot be precise about its incidence. Tuberous sclerosis accounts for about 0.66 percent

of the developmentally delayed in institutions and 0.32 percent of epileptics. The medical literature contains a number of reports of patients whose mentality is preserved and who have never had convulsions.

Etiology and Pathogenesis

The cellular elements within the nodular cerebral lesions (called tubers; see below) are abnormal in number, size, and orientation. The tumor-like growths in different organs may include cells of more than one type (e.g., fibroblasts, cardiac myoblasts, angioblasts, glioblasts, and neuroblasts), and their number is locally excessive. Something appears to have gone awry with the proliferative process during embryologic development, yet it is kept under control, in the sense that only rarely do the growths undergo malignant transformation. Highly specialized cells within the lesions may attain giant size; neurons 3 to 4 times normal size may be observed in the cerebral scleroses. These facts emphasize the potentially blastomatous character of the process.

Surgically resected tubers show activation of a cell-size control pathway (mammalian target of rapamycin [mTOR]); this is in keeping with the effects of *TSC* mutations on this cascade and probably explains the giant neurons as mentioned further below.

Clinical Manifestations (Table 38-5)

The disease may be evident at the time of birth (the diagnosis has been made by CT scan in neonates), but more often the infant is judged at first to be normal. In approximately 75 percent of cases, attention is drawn to the disease initially by the occurrence of focal or generalized seizures or by slowed psychomotor development. As with any condition that leads to developmental delay, the first suspicion is raised by delay in reaching normal maturational milestones. Whatever the initial symptom, the convulsive disorder and developmental delay

Table 38-5

MANIFESTATIONS OF TUBEROUS SCLEROSIS

Cutaneous and ectodermal

- Shagreen patch
- Facial angiofibromas (adenoma sebaceum)
- Ungular and subungual fibromas
- Hypomelanotic skin macules (more than 3)
- Multiple dental enamel pits
- Bone cysts
- Hamartomatous rectal polyps
- Gingival fibromas
- Retinal achromatic patch
- Multiple renal cysts
- Cardiac rhabdomyoma
- Renal angiomyolipoma
- Lymphangiomatosis

Neural

- Seizures
- Developmental delay
- Cortical tubers
- Subependymal nodules
- Subependymal giant cell “astrocytoma”
- Retinal hamartoma

become more prominent within 2 to 3 years. The facial cutaneous abnormality, adenoma sebaceum, appears later in childhood, usually between the fourth and tenth years, and is progressive thereafter.

As the years pass, the seizures change pattern. In the first year or two they take the form of massive flexion spasms with hypsarrhythmia (irregular dysrhythmic bursts of high-voltage spikes and slow waves in the EEG). As many as 25 percent of patients with these types of seizures have been found to have tuberous sclerosis. Later, the seizures change to more typical generalized motor and psychomotor attacks or atypical petit mal. Any one of the seizure types may be brief, especially if the patient is receiving anti-epileptic medication. Focal neurologic abnormalities, which one might expect to occur from the size and location of some of the lesions, are distinctly uncommon.

Mental function continues to deteriorate slowly. Exceptionally there is a spastic weakness or mild choreoathetosis of the limbs and in a few cases an obstructive hydrocephalus develops. As in any state of severe developmental delay, a variety of nonspecific motor peculiarities—such as constant crying, muttering, stereotypical rocking and swaying movements, and digital mannerisms—may be observed. In nearly half of the cases, affective and behavioral derangements, often of hyperkinetic and aggressive type, are added to the intellectual deficiency.

The lack of parallelism in the severity of the epilepsy, the mental deficit, and cutaneous abnormalities has been noted by all clinicians who have wide experience with this disease. Some patients are subject to recurrent seizures while retaining relatively normal mental function; in others, trivial skin lesions or a retinal phakoma (see below) may suggest the diagnosis in a mentally normal person with few seizures. In such cases, recognition may elude competent neurologists and dermatologists. As a general rule, early onset of seizures is predictive of developmental delay. Gomez and colleagues suggested that the seizures damage the brain, a point with which we tend to agree in part. However, it seems likely that both the epilepsy and developmental delay are the product of severe involvement of the brain by the lesions of tuberous sclerosis.

Limitation of space allows no more than a catalogue of the other visceral abnormalities in tuberous sclerosis. In about half the cases, gray or yellow plaques (in reality gliomatous tumors) may be found in the retina in or near the optic disc or at a distance from it. It is from this lesion, called a *phakoma*, that van der Hoeve derived the term that is applied to all neurocutaneous diseases of this class. About half of all benign rhabdomyomas of the heart are associated with tuberous sclerosis; if located in the wall of the atrium, they may cause conduction defects. Other benign tumors of mixed cell type (angiomyolipomas) have been found in the kidneys, liver, lungs, thyroid, testes, and gastrointestinal tract. Cysts of the pleura or lungs, bone cysts in digits, and zones of marbling or densification in bones are some of the less common abnormalities.

In approximately 90 percent of patients with tuberous sclerosis, congenital hypomelanotic macules—"ash-leaf"

lesions—formerly mistaken for partial albinism or vitiligo, appear before any of the other skin lesions (Fitzpatrick et al). Gold and Freeman, as well as Fitzpatrick and colleagues, emphasized the frequency of these leukodermic lesions and their value in the diagnosis of tuberous sclerosis during infancy, before the appearance of the other characteristic cutaneous lesions. The hypomelanotic areas are arranged in linear fashion over the trunk or limbs and range in size from a few millimeters to several centimeters; their configuration is oval, with one end round and the other pointed, in the shape of an ash leaf. A Wood lamp, which transmits only ultraviolet rays, facilitates the demonstration of the ash-leaf lesions because of the absence of melanoblasts, which normally absorb light in the ultraviolet range (360-nm wavelength). These lesions become pink when rubbed and contain sweat glands; they are not usually present on the face or head. There is occasionally a white tuft of hair (poliosis). Electron microscopic examination of the hypomelanotic lesions shows a normal or reduced number of melanocytes, but their dopa reaction is reduced and melanosomes are small.

The well-developed facial lesions (adenomas of Pringle), pathognomonic of tuberous sclerosis, are present in 90 percent of patients older than 4 years of age. Although called "adenoma sebaceum," these nodules are actually angiofibromas; the sebaceous glands are only passively involved (Fig. 38-5). Typically they are red to pink nodules with a smooth, glistening surface, and they tend to be limited to the nasolabial folds, cheeks, and chin; sometimes they also involve the forehead and scalp. The earliest manifestation of facial angiofibromatosis may be a mild erythema over the cheeks and forehead that is intensified by crying. The occurrence of large plaques of connective tissue on the forehead is usually expressive of a severe form of the disease.

On the trunk, the diagnostic lesion is the "shagreen patch" (in reality a plaque of subepidermal fibrosis) found most often in the lumbosacral region. It appears as a flat, slightly elevated, flesh-colored area of skin 1 to 10 cm in

Figure 38-5. Adenoma sebaceum of tuberous sclerosis.

Figure 38-6. Shagreen patch on the skin of the lower back in a young patient with tuberous sclerosis.

diameter, with a “pigskin,” “elephant hide,” or “orange peel” appearance (Fig. 38-6). Another common site of fibromatous involvement is the nail bed; subungual fibromas usually appear at puberty and continue to develop with age. Other common skin changes, not in themselves diagnostic, include fibroepithelial tags (soft fibromas), café-au-lait spots, and port-wine hemangiomas.

Pathology

The brain exhibits a number of diagnostic anomalies. Broadening, unnatural whiteness, and firmness of parts of some of the cerebral convolutions are simulated by no

other disease. These are the *tubers* after which the disease is named. On the surface of the brain, they range in width from 5 mm to 2 or 3 cm. Their cut surface reveals a lack of demarcation from cortex and white matter and the presence of white flecks of calcium; these, which are readily seen on CT and MRI, are called *brain stones* (see below and Fig. 38-7). The walls of the lateral ventricles may be encrusted with white or pink-white masses resembling candle gutterings. When calcified, they appear in radiographs as curvilinear opacities that follow the outline of the ventricle. Rarely, nodules of abnormal tissue are observed in the basal ganglia, thalamus, cerebellum, brainstem, and spinal cord.

Under the microscope the tubers are seen to be composed of interlacing rows of plump, fibrous astrocytes (much like an astrocytoma, though lacking in glial fibrillar protein). In the cerebral cortex and ganglionic structures, derangements of architecture result from the presence of abnormal-appearing cells: greatly enlarged “monstrous,” or “balloon” neurons and glia cells—often difficult to distinguish from one another. Also, displaced normal-sized neurons contribute to the chaotic histologic appearance. Gliomatous deposits may obstruct the foramina of Monro or the aqueduct or floor of the fourth ventricle, causing hydrocephalus. Neoplastic transformation of abnormal glia cells, a not infrequent occurrence, usually takes the form of a large-cell astrocytoma, less often of a glioblastoma or meningioma. Recently, certain relationships have been drawn between the balloon cells of this disease and similar cells in focal cortical dysplasias (see Crino and colleagues for details).

Figure 38-7. Tuberous sclerosis. *A.* MRI showing multiple hamartomas. *B.* Subependymal nodules are demonstrated on CT, where their calcific nature has led them to be termed “brain stones.”

The phakomas of the retina are also composed mainly of neuronal and glial components, but occasionally there is an admixture of fibrous tissue.

Diagnosis

When the full combination of seizures and mental and dermal abnormalities is conjoined, the diagnosis is self-evident. It is the early stage of the disease and the *formes frustes* that give trouble, and here the experienced dermatologist can be of great help. Epilepsy—that is, flexion spasms in infancy—and delay in psychomotor development are by no means diagnostic of tuberous sclerosis, as they occur in many diseases. It is in these cases, and also in every sizable population of the epileptic or developmentally delayed, especially when the family history is unrevealing, that a search for the dermal equivalents of the disease—the hypomelanotic ash-leaf spots, adenoma sebaceum, collagenous skin patch, phakoma of the retina, or subungual or gingival fibromas—is so rewarding. The finding of any one of these lesions provides confirmation of the partial and atypical case. Adenoma sebaceum may occasionally occur alone and is easily confused with acne vulgaris in the adolescent. The history of epilepsy or demonstration of developmental delay is helpful but neither is a requisite for the diagnosis of tuberous sclerosis (see the monograph by Gomez).

The most useful laboratory measures for corroborating the disease are the CT scan and MRI (see Fig. 38-7). The calcific tuber lesions tend to be periventricular and are particularly well shown on the CT scan, whereas MRI is more sensitive in detecting the hamartomatous giant cell subependymal and subcortical lesions. There is an absence of edema in the surrounding tissue. Roach and colleagues have indicated that an increasing number of cortical lesions demonstrated with MRI appear to correlate with an increased impairment of neurologic function. Clinics that treat large numbers of these patients recommend imaging of the kidneys and lungs and, in children, echocardiography. Serial examinations to detect enlargement of the subependymal tumors is advised annually for those younger than age 21 years and every 2 to 3 years thereafter, but the best course of action if a glioma emerges has not been clearly established.

Treatment

Nothing can be offered in the way of prevention other than genetic counseling. Antiepileptic therapy of the standard type suppresses the convulsive tendency more or less effectively and should be applied assiduously. Adrenocorticotropic hormone (ACTH) suppresses the flexor spasms in infancy and tends to normalize the EEG for a time.

It is usually pointless to attempt the excision of tumors, especially in severely affected individuals (with the exception of renal hamartomas that impair kidney function). However, sirolimus, which suppresses the mTOR signaling pathway, causes slight regression of the bodily angioliomas (Bissler et al) and, of greater interest to the neurologist and neurosurgeon, the similar drug rapamycin has tentatively been shown in a report by Franz and colleagues to shrink subependymal giant cell astrocytomas in some patients. Everolimus, another

mTOR inhibitor has been found to be useful in suppressing the status epilepticus associated with some cases of tuberous sclerosis (Krueger et al).

Some patients undergo dermabrasion of the facial lesions for cosmetic reasons, with the knowledge that these slowly regrow. To an increasing degree, neurosurgeons are excising single epileptogenic cortical tubers in otherwise relatively normal children. There are about 15 specialized centers in the United States, and several abroad, that are expert at caring for these patients and establishing a regimen of radiologic surveillance. (See <http://www.tsalliance.org> for further information including guidelines for testing and surveillance.)

Course and Prognosis

In general, the disease advances so slowly that years must elapse before one can be sure of progression. Of the severe cases, approximately 30 percent die before the fifth year, and 50 to 75 percent before attaining adult age. Worsening is mainly in the mental sphere. Status epilepticus accounted for many deaths in the past, but improved medication therapy has reduced this hazard. Neoplasias take their toll; the authors have had several such patients who died of malignant gliomas arising in striatthalamic regions.

Neurofibromatosis of von Recklinghausen (NF1 and NF2)

Neurofibromatosis (NF) is a comparatively common hereditary disease in which the skin, nervous system, bones, endocrine glands, and sometimes other organs are the sites of a variety of congenital abnormalities, often taking the form of benign tumors. The typical clinical picture, usually identifiable at a glance, consists of multiple circumscribed areas of increased skin pigmentation accompanied by dermal and neural tumors of various types.

The condition known as multiple idiopathic neurofibromatosis was the subject of a monograph by R.W. Smith in 1849; even at that time, he referred to examples recorded by other writers. It was von Recklinghausen, however, who, in 1882, gave the definitive account of its clinical and pathologic features. The subsequent studies of the disease by Yakovlev and Guthrie; Lichtenstein; Riccardi; and Martuza and Eldridge; and more recently by Créange and colleagues; and the comprehensive monographs of Crowe and colleagues and of Riccardi and Mulvihill are informative references that provide a complete analysis of the clinical, pathologic, and genetic data pertaining to the disease.

Epidemiology Crowe and associates calculated the prevalence of the disease to be 30 to 40 per 100,000, with the expectancy of 1 case in every 2,500 to 3,300 births over 50 years ago and these rates pertain in the all series from the current era. Approximately half of their cases had affected relatives, and in all instances the distribution of cases within a family was consistent with an autosomal dominant mode of inheritance. The disease has been observed in all races in different parts of the world, and males and females are about equally affected.

Cause and Pathogenesis The hereditary nature of NF has been appreciated for a century. More recently,

it has been established that NF comprises two distinct disorders, the genes for which are located on different chromosomes. Both are inherited in an autosomal dominant pattern with a high degree of penetrance, but half the cases are a result of spontaneous mutations. The classic form of the disease with multiple neurofibromas, described below, is caused by a mutation located near the centromere on chromosome 17 in a gene called neurofibromin (Barker et al). The second type, in which the main feature is bilateral acoustic nerve neuromas, described further on, is caused by a mutation in the *merlin* gene (also called *schwannomin*). These two forms of NF have been loosely referred to as peripheral and central, respectively, but the terms *neurofibromatosis type 1 (NF1)* and *neurofibromatosis type 2 (NF2)* are less confusing (Martuza and Eldridge) and are used in the following discussion.

The large size of the *NF1* gene (60 exons) and the widely scattered mutations has made genetic testing complex but such testing is available. Virtually all families manifest different mutations and there have been no clear associations between specific mutations and phenotypic characteristics except that the rare complete deletion leads to early onset multiple neurofibromas, developmental delay, and facial dysmorphism.

The pathogenesis is less obscure now that the genes implicated in both diseases have been identified. Both involve tumor suppression. As with tuberous sclerosis, there is a suggestion of a disorder that allows low-grade ectodermal cell proliferation without tumor transformation. Cellular elements derived from the neural crest (i.e., Schwann cells, melanocytes, and endoneurial fibroblasts, the natural components of skin and nerves) proliferate excessively in multiple foci, and the melanocytes function abnormally. The hormones and growth factors involved in this proliferative process and the mechanism by which it occurs are as obscure as they are in tuberous sclerosis. It is known, however, that most of the numerous mutations in the *NF1* gene lead to premature termination of protein synthesis and a consequent "loss of function." This is in keeping with the tumor suppressor characteristics of the gene and the emergence of neoplasms in the presence of homozygous mutations.

Neurofibromatosis Type 1 (Classic, or Peripheral, NF) (Table 38-6)

In the majority of patients, spots of hyperpigmentation (café-au-lait lesions) and cutaneous and subcutaneous neurofibromatous tumors are the basis of clinical diagnosis. Pigmentary changes in the skin are nearly always present at birth, but neurofibromas are infrequent at that age. Both lesions increase in number and size during late childhood and adolescence. There may be a spurt of new lesions at puberty or during pregnancy. Exceptionally, a neurofibroma of a cranial nerve or a spinal root (sometimes with compression of the cord), disclosed during imaging of the spine or a neurosurgical intervention, may be the initial manifestation of the disease. In a large series of patients with neurofibromatosis (Crowe et al), approximately one-third were found to have only the cutaneous manifestations that were noted while being

Table 38-6

MANIFESTATIONS OF NEUROFIBROMATOSIS TYPE 1

Cutaneous and ectodermal

- Café-au-lait spots (generally 6 or more of >5 mm diameter prepubertal and >15 mm postpubertal)^a
- Axillary and integumentary freckling (Crowe sign)^a
- Lisch nodules (hamartomas of the iris)^a
- Bony lesions including sphenoid dysplasia or thinning of long bone cortex, pseudoarthroses^a
- Increased incidence of chronic myeloid leukemia, neurofibrosarcoma (malignant transformation of neurofibroma), rhabdomyosarcoma, pheochromocytoma
- Short stature

Neural

- Neurofibromas^a
 - Cutaneous (most common)
 - Subcutaneous
 - Nodular plexiform
 - Diffuse plexiform
- Seizures
- Optic pathway glioma^a
- Risk of cerebral astrocytoma, brainstem glioma
- Hypertension

^aDenotes main diagnostic criteria, in addition to having an affected first-degree relative.

examined for symptoms of some other disease; that is to say, the NF was asymptomatic. Usually these are the patients with the slightest degree of cutaneous abnormality. Of the remaining two-thirds, most consulted a physician because of the disfigurement produced by the skin tumors or because some of the neurofibromas were producing neurologic symptoms.

The patches of cutaneous pigmentation, appearing shortly after birth and occurring anywhere on the body, constitute the most obvious clinical expression of the disease. They are approximately oval in shape and vary in size from a 1 to 2 mm to many centimeters, and in color from a light to dark brown (the term *café-au-lait* is applied) and are rarely associated with any other pathologic state (Fig. 38-8).

Figure 38-8. Typical large café-au-lait spot. The presence of 6 or more hyperpigmented lesions, each larger than 1.5 cm after puberty (>5 mm prepubertal), is diagnostic of neurofibromatosis type 1.

They do not appear to change in number as the patient ages, but they do enlarge during puberty and become more pigmented. In a survey of pigmented spots in the skin, Crowe and associates found that 10 percent of the normal population had one or more spots of this type; however, *anyone with more than 6 such spots, some exceeding 1.5 cm in diameter in postpubertal individuals (bigger than 0.5 mm in prepubertal ones), nearly always proved to have neurofibromatosis.* Of their 223 patients with NF, 95 percent had at least 1 spot and 78 percent had more than 6 large spots. Freckle-like or diffuse pigmentation of the axillae and other intertriginous areas (groin, under breast) and small, round, whitish spots are characteristic; when coupled with café-au-lait patches, they are together virtually pathognomonic of the disease.

The appearance of multiple cutaneous and subcutaneous tumors in late childhood or early adolescence is the other principal feature of the disease. The cutaneous tumors are situated in the dermis and form discrete soft or firm papules varying in size from a few millimeters to a centimeter or more (molluscum fibrosum; Fig. 38-9). They assume many shapes—flattened, sessile, pedunculated, conical, lobulated, and so on. They are flesh-colored or violaceous and often topped with a comedo. When pressed, the soft tumors tend to invaginate through a small opening in the skin, giving the feeling of a seedless raisin or a scrotum without a testicle. This phenomenon, spoken of as “buttonholing,” is useful in distinguishing the lesions of this disease from other skin tumors, for example, multiple lipomas. A patient may have anywhere from a few of these dermal tumors to hundreds.

The subcutaneous neural tumors, which are also multiple, take two forms: (1) firm, discrete nodules attached to a nerve or (2) an overgrowth of subcutaneous tissue, sometimes reaching enormous size. The latter, which are called *plexiform neuromas* (also *pachydermatocele*, *elephantiasis neuromatosis*, *la tumeur royale*), occur most often in the face, scalp, neck, and chest, and may cause hideous disfigurement. When palpated, they feel like a

bag of worms or strings; the bone underlying the tumor may thicken. Neurofibromas are easily distinguished from lipomas, which are soft, unattached to the skin or nerve, and not accompanied by any neurologic disorder. An exception to this last statement is the rare disease of multiple symmetrical lipomatosis with axonal polyneuropathy (Launois-Bensaude disease). As a rule, congenital neurofibromas tend to be highly vascular and invasive and are especially prominent in the orbital, periorbital, and cervical regions. They may be accompanied by hypertrophy of a segment of the body (a sign also seen in the arteriovenous malformation of Klippel-Trenaunay-Weber syndrome). When the hyperpigmentation lesion overlies a plexiform neurofibroma and extends to the midline, one should suspect an intraspinal neurofibroma tumor at that level.

Another unique finding is the Lisch nodule. This is a small whitish spot (actually a hamartoma) in the iris that was present in 94 percent of Riccardi's type 1 cases, but was not found in patients with NF2 or in normal individuals (Fig. 38-10 and below).

Headache, hydrocephalus, and tumors involving the optic pathways, meningiomas, gliomas, and malignant peripheral nerve tumors are common, even among adults, according to the survey of 158 patients by Créange and colleagues; also, pain was a common symptom in adults and often related to a malignant peripheral nerve sheath tumor.

Other abnormalities associated less consistently with type 1 (peripheral) NF include bone cysts, pathologic fractures (pseudoarthrosis), cranial bone defects with pulsating exophthalmos (sphenoid bone dysgenesis), bone hypertrophy, precocious puberty, pheochromocytoma, scoliosis, syringomyelia, nodules of abnormal glia cells in brain and spinal cord, and macrocephaly, rarely with obstructive hydrocephalus as a result of overgrowth of glial tissue around the sylvian aqueduct and fourth ventricle. Some degree of intellectual impairment is common; it was found in 40 percent of Riccardi's series of 133 patients. But in our experience, the figure is much lower and the impairment is usually not profound.

Figure 38-9. Molluscum fibrosum nonneural skin tumors of von Recklinghausen disease.

Figure 38-10. Hamartomas of the iris (Lisch nodules), typical of neurofibromatosis type 1. (Reproduced by permission from Damato BE, Spalton DJ: The uveal tract, in Spalton DJ, Hitchings RA, Hunter PA (eds): *Atlas of Clinical Ophthalmology*, 3rd ed. Oxford, Mosby Elsevier Ltd, 2005.)

Learning difficulty, developmental disorder, and hyperactivity have been more frequent abnormalities, occurring in almost 40 percent of patients. Rosman and Pearce have ascribed developmental delay in NF to congenital malformation of the cerebral cortex (cortical dysgenesis). The incidence of seizures is about 20 times higher than that in the general population, but these tend not to be a very frequent or intractable problem.

Exceptionally, NF is associated with peroneal muscular atrophy, congenital deafness, and partial albinism (Bradley et al).

In childhood, progressive blindness is a particularly dire complication from a tumor mass composed mainly of astrocytes (optic glioma). The tumor may involve one or both optic nerves. The diagnosis comes to mind at once in a child with any of the cutaneous manifestations of NF and this tumor. Uncertainty as to its nature arises from the fact that the neuropathologist may be unable to decide between a benign hamartoma and a grade 1 astrocytoma. Progressive enlargement in a succession of MRI scans may be needed to affirm its nature.

It needs to be stated that neurofibromas of the spinal roots occur regularly in patients without NF (see Chap. 44). Whether multiple such lesions implicate NF is not clear.

Neurofibromatosis Type 2 (Acoustic, or Central, NF)

This condition is considerably less frequent than NF1. Here there is an absence or paucity of cutaneous lesions. Progressive deafness and the demonstration by enhanced CT or MRI of *bilateral acoustic neuromas* afford accurate diagnosis (see Fig. 31-18). Also, an acoustic neuroma developing before age 30 years is suspect as being caused by NF2. Other cranial or spinal neurofibromas, meningioma (sometimes multiple), and glioma may be added to the syndrome of deafness or may occur prior to its emergence. Juvenile cataracts of the subcortical or capsular variety are seen in some affected patients.

Analysis for the *NF2* gene has become available from several laboratories. The genetics and affected protein (merlin or schwannomin) are discussed in "Cause and Pathogenesis" above.

Familial Schwannomatosis

As commented in Chap. 31 in the discussion of acoustic neuroma, it is now apparent that the propensity to develop multiple schwannomas can also be inherited as a dominant trait, without the vestibular tumors characteristic of NF2. This trait maps to a genetic locus on chromosome 22 that is distinct from the one for NF2. It has been estimated that 2 to 5 percent of schwannomas requiring resection are from this disease. The diagnostic criteria are based on the presence of two of more schwannomas without vestibular nerve tumors in an individual older than age 18 years, as summarized in a thorough review by MacCollin and colleagues, and more recently by Plotkin and colleagues. Pain is the dominant problem.

Pathology of NF1 and NF2

The cutaneous tumors are characterized by a rather thin epidermis whose basal layer may or may not be pigmented.

The collagen and elastin of the dermis is replaced by a loose arrangement of elongated connective tissue cells. The lack of compactness of the normal dermal collagen allows the palpable opening in the skin. The pigmented (café-au-lait) lesions contain only the normal numbers of melanocytes; the dark color of the skin is instead the result of an excess of melanosomes in the melanocytes. Some of the abnormally large melanosomes measure up to several microns in diameter.

The nerve tumors are composed of a mixture of fibroblasts and Schwann cells (except the optic nerve tumors, which contain a combination of astrocytes and fibroblasts). Predominance of one or the other of these cells in the nerve is the basis of the diagnosis of neurofibroma or schwannoma. Palisading of nuclei and sometimes encircling arrangements of cells (Verocay bodies) are features of both (see Chap. 31). Occasionally, along spinal roots or sympathetic chains, one may find a tumor made up of partially or completely differentiated nerve cells, a typical ganglioneuroma. Clusters of abnormal glia cells may be found in the brain and spinal cord, and, according to Bielschowsky, they imply a link with tuberous sclerosis that has never been proved. Clinically and genetically, the two diseases are quite independent.

Malignant degeneration of the tumors is found in 2 to 5 percent of cases; peripherally they become sarcomas and centrally, astrocytomas or glioblastomas (Fig. 38-11).

Diagnosis

If skin tumors and café-au-lait spots are numerous and Lisch nodules are present in the iris, the identification of the disease as type 1 neurofibromatosis offers no difficulty. A history of the illness in antecedent and collateral family members makes diagnosis even more certain. Doubt arises most frequently in patients with bilateral acoustic neuromas or other cranial or spinal neurofibromas or schwannomas with no skin lesions or only a few random ones. The tendency for these forms of NF to have few skin lesions is well known, but differentiation of type 1 from type 2 may be uncertain unless genetic studies are undertaken. Plexiform neuromas with muscle weakness because of nerve involvement and abnormalities of underlying bone may be confused with other tumors, especially in young children, who tend to have few café-au-lait spots and few cutaneous tumors. Hypertrophy of a limb requires differentiation from other developmental anomalies including Klippel-Trenaunay-Weber syndrome.

As already mentioned, Crowe and coworkers expressed the view that 80 percent of patients with von Recklinghausen disease can be diagnosed by the presence of more than 6 café-au-lait spots. Of the remaining 20 percent, those older than 21 years of age will be found to have multiple cutaneous tumors, axillary freckling, and a few pigmented spots; in those younger than 21 years of age with no dermal tumors and only a few café-au-lait patches, a positive family history and radiographic demonstration of bone cysts will be helpful in some instances. Café-au-lait spots and cutaneous tumors should always be sought, for they may help the neurologist diagnose an otherwise obscure progressive spinal syndrome, a cerebellopontine angle syndrome, bilateral deafness, progressive

blindness, and an occasional case of precocious puberty, hydrocephalus, or developmental delay.

Because of the many potentially dangerous conditions that accompany classic NF, the initial clinical evaluation should be supplemented by a number of ancillary examinations that may include measurement of IQ, EEG, slit-lamp examination of irides, visual and auditory evoked responses, and CT scans or MRI of cranium and, sometimes, of the spine and mediastinum. In the series reported by Duffner and colleagues, 74 percent of cases had abnormal signals in T2-weighted images of the basal

ganglia, thalamus, hypothalamus, brainstem, and cerebellum. The EEG was abnormal in 25 percent. If there is suspicion of a pheochromocytoma, 24-h urine should be tested for metabolites of epinephrine. Each of these tests not only is an aid to diagnosis but also is essential to the effective management of the illness.

Treatment

The skin tumors should not be excised unless they are cosmetically objectionable or show an increase in size, suggesting malignant change. The effects of radiotherapy

on these lesions are so insignificant that they do not justify the risk of exposure. Plexiform neuromas about the face pose especially difficult problems. Here one must resort to plastic surgery, but the results are not always satisfactory because the growths may encompass distal branches of cranial nerves (with risk of greater paralysis after surgical excision) or alter the underlying bone, the latter being either eroded from pressure or hypertrophied from increased blood supply. Cranial and spinal neurofibromas are amenable to excision, and the gliomas and meningiomas usually demand surgical measures as well. Here the differentiation of hamartomas from gliomas of structures such as the optic nerves, hypothalamus, or pons may be difficult. Bilateral optic nerve gliomas are usually treated with radiation; unilateral ones are excised. Peripheral nerve tumors that have undergone malignant (sarcomatous) degeneration pose special surgical problems.

Affected individuals should be advised not to have children, a precaution that may not be necessary because fertility, especially in males, seems to be reduced by the disease. Prognosis varies with the grade of severity, being most favorable in those with only a few lesions. But the disease is always progressive, and the patient should remain under surveillance.

Other Cutaneous Angiomatoses With Abnormalities of the Central Nervous System

There are at least 7 additional diseases in which a cutaneous or ocular vascular anomaly is associated with an abnormality of the nervous system: (1) meningo- or encephalofacial (encephalotrigeminal) angiomatosis with cerebral calcification (Sturge-Weber syndrome); (2) dermatomal hemangiomas and spinal vascular malformations (sometimes with limb hypertrophy, as also occurs in Klippel-Trenaunay-Weber syndrome and in neurofibromatosis); (3) the epidermal nevus (linear sebaceous nevus) syndrome; (4) familial telangiectasia (Osler-Rendu-Weber disease); (5) hemangioblastoma of cerebellum and retina (von Hippel-Lindau disease); (6) ataxia-telangiectasia (Louis-Bar disease); and (7) angiokeratosis corporis diffusum (Fabry disease). The last three disorders are considered elsewhere: ataxia-telangiectasia and Fabry disease with the inherited metabolic disorders in Chap. 37, and von Hippel-Lindau disease below and with hemangioblastoma in Chap. 31.

Sturge-Weber Syndrome (Meningo- or Encephalofacial Angiomatosis with Cerebral Calcification)

This condition has been referred to as the Sturge-Weber syndrome, as it was W. Allen Sturge who, in 1879, described a child with sensorimotor seizures contralateral to a facial "port-wine mark," and Parkes Weber (1922, 1929), who gave the first radiographic demonstration of the atrophy and calcification of the cerebral hemisphere ipsilateral to the skin lesion. This eponym overlooks the important intervening contributions of Kalischer (1897, 1901), who first described the meningeal angioma in conjunction with the facial one; of Volland (1913), who demonstrated the intracortical calcific deposits; and of Dimitri (1923), who

described the characteristic double-contoured radiographic shadows. Krabbe (1932, 1934) showed conclusively that the calcification lay not in the blood vessels (as Dimitri and many others had concluded), but in the second and third layers of the cortex (see Wohlwill and Yakovlev for historical review and bibliography).

A vascular nevus is observed at birth to cover a large part of the face and cranium on one side (in the territory of the ophthalmic division of the trigeminal nerve). In one-quarter of the cases the nevus is bilateral. The lesions vary in extent, the most limited being an involvement of only the upper eyelid and forehead, and the most extensive being the entire head and even other parts of the body. The skin lesion is deep red (port-wine nevus) and its margins may be flat or raised; soft or firm papules, evidently composed of vessels, cause surface elevations and irregularities. Orbital tissue, especially the upper eyelid, is almost invariably involved; congenital buphthalmos may enlarge the eye before birth and glaucoma may develop later in that eye, causing blindness. The choroid is implicated in some cases. The increased cutaneous vascularity may result in an overgrowth of connective tissue and underlying bone, giving rise to a deformity like that of the Klippel-Trenaunay-Weber syndrome. Indications of cerebral disease appear as early as the first year of life or later in childhood; the most frequent clinical manifestations are unilateral seizures followed by increasing degrees of spastic hemiparesis with smallness of the arm and leg, hemisensory defect, and homonymous hemianopia, all on the side contralateral to the trigeminal nevus. Skull films (usually normal just after birth) taken after the second year reveal a characteristic "tramline" calcification, which outlines the involved convolutions of the parietooccipital cortex. CT scanning and MRI show the abnormalities of the involved cortex at an earlier age (Fig. 38-12).

It is not the case that all cranial hemangiomas affect the cerebrum; the common facial nevi, especially the flat midline ones and the elevated strawberry nevi, are of no neurologic significance. And a cerebral-meningeal angiomatosis may be present without skin lesions. The involvement of the upper eyelid is of greatest importance since nearly all such cases are associated with cerebral lesions (Barlow). There seems to be a close correlation between the persistence or maldevelopment of the embryonic vascular plexus of the eyelid and forehead and that of the occipitoparietal parts of the brain. When the nevus lies entirely below the upper eyelid or high on the scalp, a cerebral lesion is usually absent, although in a few instances such an angioma has been associated with a vascular malformation of the meninges overlying the brainstem and cerebellum. In angiograms, the abnormal meningeal vessels, which are largely veins, are not well seen; thus they can be distinguished from true arteriovenous malformations. These purely meningeal venous nevi are rarely the source of subarachnoid or cerebral hemorrhage and they do not enlarge to form a mass. The cortical lesion is, however, destructive of cortical tissue, which is replaced by glial tissue that calcifies. One explanation holds that diversion of blood to the meninges during seizures causes progressive ischemia of the cerebral cortex. Barlow has stated that the seizures themselves

Figure 38-12. Sturge-Weber. *Left:* CT showing calcification of the vascular malformation and underlying cortical atrophy. *Right:* MRI, T2-FLAIR sequence, showing the pronounced atrophy in the same patient.

are responsible for the progressive neurologic deficits and that a special effort should be made to prevent them by carefully regulated medical therapy. Occasionally surgical excision of intractable discharging foci may be necessary, but often this may not be feasible in view of the magnitude of the cerebral lesion. Radiotherapy is unsuccessful in reducing the skin blemish; sensitive individuals usually try to hide it with cosmetics. There is little literature on treating the brain vascular malformation with endovascular techniques.

Although a hereditary trait has long been known, it was only recently that Shirley and colleagues found a polymorphism in the responsible gene, *GNAQ*, in almost 90 percent of individuals with the trait and in a similar number of patients with non-syndromic port-wine stains on the cranium. The variant may be of a mosaic type, being present only in affected tissues. This substitution in the gene activates extracellular signal-regulated kinase. Similar SNPs have been known to participate in other conditions that feature abnormal skin pigmentation.

Dermatomal Hemangiomas With Spinal Vascular Malformations

A hemangioma of the spinal cord may rarely be accompanied by a vascular nevus in the corresponding dermatome, as was first pointed out by Cobb. Such nevi are most frequent on the arm and trunk. When the cutaneous lesion involves an arm or leg, there may be enlargement of the entire limb or fingers in combination with underdevelopment of certain other parts (Klippel-Trenaunay-Weber syndrome). Some of these angiomatous syndromes combine a spinal or retinal-diencephalic arteriovenous

malformation (AVM) with a nevus of the trunk or face, respectively. Such cases provide a link to the common AVMs described in Chap. 34.

Epidermal Nevus Syndrome

This is a closely related congenital neurocutaneous disorder in which a specific skin lesion (epidermal nevus or linear sebaceous nevus) is associated with a variety of hemicranial and neurologic abnormalities. The skull and brain abnormalities are ipsilateral to the nevus. One-sided thickening of the bones of the skull is characteristic. Developmental delay, seizures, and hemiparesis are the usual neurologic manifestations and have their basis in a wide variety of cerebral lesions—unilateral cerebral atrophy, porencephalic cyst, leptomenigeal hemangioma, arteriovenous malformation, and atresia of cerebral arteries and veins. The somatic and neurologic abnormalities of this syndrome have been comprehensively reviewed by Solomon and Esterley and by Baker and associates.

Hereditary Hemorrhagic Telangiectasia (Osler-Rendu-Weber Disease)

This vascular anomaly is transmitted as an autosomal dominant trait. To date, two mutant genes have been identified as causes of this disease: endoglin and novel kinase. The small arteriovenous malformations affect the skin, mucous membranes, gastrointestinal and genitourinary tracts, lungs, and occasionally the nervous system. The basic lesion is probably a defect in the vessel wall, and the main complication, bleeding, is thought to be a result of the mechanical fragility of the vessel. Located sparsely in the skin of any part of the body, these vascular lesions first

appear during childhood, enlarge during adolescence, and may assume spiderly forms, resembling the cutaneous telangiectases of cirrhosis in late adult life. The lesions range from the size of a pinhead to 3 mm or more, are bright red or violaceous, and blanch under pressure.

The significance of the lesions lies in their hemorrhagic tendency. During adult years they may give rise to severe and repeated epistaxis or gastric, intestinal, or urinary tract bleeding and result in an iron-deficiency anemia. Pulmonary fistulas constitute another important feature of the generalized vascular dysplasia; patients with such lesions are particularly subject to brain abscesses and less so to bland embolic strokes.

The angiomas of this disease may infrequently form in either the spinal cord or brain, where they can produce acute hemorrhage, or as in one of our patients, there may be an intermittently progressive focal thalamic syndrome resulting from enlargement of the vascular lesions or possibly from a succession of small hemorrhages. Repeated unexplained gastrointestinal, genitourinary, intracranial, or intraspinal hemorrhages warrant a search for small cutaneous lesions, which are easily overlooked. Satellite lesions tend to form after obliteration of an angioma.

von Hippel-Lindau Disease

This is a genetic disease of multiple neoplasms, specifically by the presence of a hemangioblastoma, sometimes multiple (these are discussed with other cerebral tumors in Chap. 31). The tumor is situated in the cerebellum in most cases, but may also arise in the brainstem or spinal cord. In addition to the characteristic cerebellar tumor with its nodule within a cyst, half of these patients have retinal hemangioblastomas and somewhat fewer develop renal cell cancer; an even smaller number have a pheochromocytoma, pancreatic tumors or cysts, or cystadenomas. Polycythemia vera is an interesting feature in a few cases. We have encountered rare cases that presented as subarachnoid hemorrhage.

The cerebellar hemangioblastoma typically develops in the fourth decade and causes symptoms of ataxia and headache. On imaging studies, the lesions have a striking appearance of a cyst with a nodule contained in its wall, and angiography demonstrates the highly vascular nature of the nodule, which represents the actual neoplasm (see Fig. 31-13). The other identifying features of the disease, retinal hemangiomas, are smaller but indistinguishable histologically from the craniospinal ones. They are multiple and bilateral, usually appearing earlier than the cerebellar lesions but remaining asymptomatic until they become extensive (retinal detachment is one feature). Their diagnosis is made by funduscopy, by which a large feeding vessel leading to an irregularly shaped ovoid tumor in the retina can usually be appreciated. Imaging studies of the cranium that use dye enhancement will reveal them as well.

Inheritance is autosomal dominant with variable but high penetrance by older age. The causative mutation is in the *VHL* gene located on chromosome 3. This is a tumor suppressor gene that is inactivated by the mutation and may induce oncogenesis by increasing the expression of vascular mitogenic factors such as vascular endothelial

growth factor (VEGF) but the precise mechanisms are not known. Renal cell cancer is a serious component of the disease, occurring in up to 60 percent of cases, but the tumors, although multiple, tend initially to be small and of low grade. Nonetheless, renal cancer accounts for one-third of deaths from the disease, the remainder being largely the result of complications of the cerebellar neoplasm. An extensive review of the subject was written by Losner and colleagues.

Mentioned here is the cerebellar gangliocytoma of Lhermitte-Duclos disease. There are no cutaneous malformations but small vascular anomalies in the brain and elsewhere may accompany the cerebellar tumor as discussed in Chap. 31 (see Fig. 31-15).

Ataxia-Telangiectasia

This disease, also referred to as the *Louis-Bar syndrome*, was first described by Sylaba and Henner in 1926, long before Louis-Bar's report in 1941. It combines a progressive ataxia with humoral immune deficiency and telangiectasias. Like xeroderma pigmentosum and the Cockayne syndrome, ataxia-telangiectasia has been attributed to defective repair of DNA. The inheritance pattern is autosomal recessive and the clinical presentation is somewhat heterogeneous, with certain features predominating in a particular child and his siblings, as summarized by Boder and Sedgwick. An adult form may show few of the characteristic telangiectasias.

The disorder first presents as an ataxic-dyskinetic syndrome in children who appear to have been normal in the first few years of life. The onset of the disease coincides more or less with the acquisition of walking, which is awkward and unsteady. Later, by the age of 4 to 5 years, the limbs become ataxic, and choreoathetosis, grimacing, and dysarthric speech are added. The eye movements become jerky, with slow and long-latency saccades, and there is also apraxia for voluntary gaze (the patient turns the head but not the eyes on attempting to look to the side). This movement of the head and eyes in tandem is the most specific feature of the process. Optokinetic nystagmus is lost and reading becomes all but impossible. Severe cognitive developmental delay is infrequent, affecting perhaps 10 percent of children but in those affected, it is apparent by the age of 9 to 10 years; slight intellectual limitation is more common. Signs of mild polyneuropathy are evident at this age as well, appearing similarly the Charcot-Marie-Tooth phenotype. Seizures are not part of the syndrome.

Muscle power is reduced little if at all until late in the illness, but tendon reflexes may disappear. The characteristic telangiectatic lesions, which are mainly transversely oriented subpapillary venous plexuses, appear at 3 to 5 years of age or later (they are not apparent in some patients until approximately age 7) and are most apparent in the outer parts of the bulbar conjunctivae (Fig. 38-13), over the ears, on exposed parts of the neck, on the bridge of the nose and cheeks in a butterfly pattern, and in the flexor creases of the forearms. Vitiligo, café-au lait spots, loss of subcutaneous fat, and premature graying of hair are observed in some older patients. Many of the patients have endocrine alterations (absence

Figure 38-13. Ocular appearance of ataxia-telangiectasia. (Reproduced by permission from Lyon G, Kolodny EH, Pastores GM: *Neurology of Hereditary Metabolic Diseases of Children*, 3rd ed. New York, McGraw-Hill, 2006.)

of secondary sexual development, glucose intolerance). The disease is progressive, and death may occur in the second decade from intercurrent bronchopulmonary infection or neoplasia—usually lymphoma, less often glioma, that develop in fewer one-third of patients.

As mentioned, the *adult form of ataxia-telangiectasia*, in which some of the deficient enzyme activity is retained (see below), manifests few telangiectasias but may be identified by an extrapyramidal syndrome in childhood and only later, with mild ataxia as summarized by Verhagen and colleagues; there may be a family history of cancers.

The significant abnormalities in the CNS are severe degeneration in the cerebellar cortex (visible on MRI scans); loss of myelinated fibers in the posterior columns, spinocerebellar tracts, and peripheral nerves; degenerative changes in the posterior roots and cells of the sympathetic ganglia; and loss of anterior horn cells at all levels of the spinal cord. In a few cases, vascular abnormalities, like the mucocutaneous ones, have been found scattered diffusely in the white matter of the brain and spinal cord, but they are of questionable significance. Also, there may be a loss of pigmented cells in the substantia nigra and locus ceruleus (a feature shared with PKU), and cytoplasmic inclusions (Lewy bodies) in the cells that remain (Agamanolis and Greenstein). During early development there are abnormalities of Purkinje cell migration and variations in nuclear size. Intranuclear inclusions and bizarre nuclear formations have also been found in the satellite cells (amphicytes) of dorsal root ganglion neurons (Strich).

There is an absence or decrease in several immunoglobulins—IgA, IgE and isotypes, IgG₂, IgG₄—in practically every patient. These deficiencies, shown by McFarlin and associates to be a result of decreased synthesis, are associated with hypoplasia of the thymus, loss of follicles in lymph nodes, failure of delayed hypersensitivity reactions, and lymphopenia. This immunodeficient state accounts for the striking susceptibility of these patients to recurrent pulmonary infections and bronchiectasis. Transplantation of normal thymus tissue into the patient and administration of thymus extracts have been of no therapeutic value.

The defective gene (designated *ATM*) is a kinase that is a transducer in the pathway for DNA repair that halts the cell cycle after DNA damage. For this reason, there is faulty repair of DNA after radiation and a greatly increased risk of lymphomas, leukemias, and other tumors as well as certain specific susceptibilities to the effects of cancer treatment. The protein is normally expressed ubiquitously and 90 percent of patients have no ATM protein, usually because of a stop codon in the mutated gene.

The only therapy centers on the control of infections. Free radical scavengers such as vitamin E have been recommended without proof of their effectiveness. Because of radiation sensitivity, even conventional diagnostic tests (dental, chest radiography) should be avoided unless there is a compelling reason for them.

RESTRICTED DEVELOPMENTAL ABNORMALITIES OF THE NERVOUS SYSTEM

In the course of clinical practice, one encounters a remarkable number of restricted disorders of the nervous system, many of which are transmitted from generation to generation as a mendelian, usually dominant, trait. Of the more severe ones, only a few of the more striking examples are described here. Milder and more restricted conditions, such as stuttering and dyslexia, that are pervasive in the population are described in Chap. 28. The reader may turn to books on genetics or teratology for an account of such oddities as hereditary unilateral ptosis, hereditary Horner syndrome, pupillary inequalities, jaw winking, and absence of a particular skeletal muscle.

Bifacial and Abducens Palsies (Möbius Syndrome)

The syndrome of congenital facial diplegia with convergent strabismus is referred to as *Möbius syndrome*, although Von Graefe had described it earlier. Its presence at birth is disclosed by the lack of facial movements and of full eye closure. A review of the subject in the English literature was written by Henderson, and a more recent analysis of 37 affected individuals was written by Harriette and colleagues. In Henderson's study of 61 cases of the congenital facial diplegia syndrome, there were 45 instances of associated abducens palsy,

15 of complete external ophthalmoplegia, 18 of lingual palsy, 17 of clubfeet, 13 of a brachial disorder, 6 of mental defect, and 8 of an absent pectoral muscle. Thus the overlap with other neuromuscular and CNS abnormalities is evident. Moreover, at least two configurations of brainstem dysfunction have been proposed, one because of a lack of the facial nerve nucleus and the other in the nerve, perhaps acquired in type, based on electrophysiologic studies, but we have no basis to judge the validity of this. Harriette and coworkers emphasize the frequency of hypoplastic or dysplastic tongue, palatal involvement, and general motor clumsiness. They suggest that the disorder represents a widespread form of brainstem maldevelopment.

Early in life the mouth hangs open, the lower lip is everted, and there is difficulty in sucking. Usually this syndrome can be distinguished from the facial palsy of forceps or birth injury by its bilaterality and the other associated weaknesses. Occasionally, more than one family member is affected (usually in a pattern suggesting autosomal dominant inheritance). The cause of this peculiar condition is not known. The few adequate pathologic studies have shown a paucity of nerve cells in the motor nuclei of the brainstem, changes that also characterize the Fazio-Londe type of muscular dystrophy discussed in Chap. 50. Rarely, there may be an aplasia of facial muscles. The Möbius syndrome is also referred to in Chap. 47 in relation to restricted palsies of myopathic and nuclear origin.

Partial paralysis of facial muscles that dates from birth and cannot be attributed to obstetric trauma is not infrequent. In a common type, the lower lip on one side remains immobile when the child smiles or cries; the lip on the unaffected side is drawn downward and outward, resulting in a prominent asymmetry of the lower face. Often it is not appreciated that the side that droops during crying is the normal side (Hoefnagel and Penry).

Congenital Lack of Lateral Gaze (Cogan Oculomotor Apraxia)

Children with this congenital defect are unable to turn their eyes to either side volitionally or on command. Attempting to look to the right, the child turns the head to the right (there is no associated apraxia of head turning), but the eyes lag and turn to the left. As a result, the patient has to overshoot the mark with the head in order to attain ocular fixation. Once the eyes fixate, the head returns to the primary position. To compensate for the deficiency of eye movements, the patient develops jerky thrusting movements of the head, which characterize all attempts at voluntary gaze. Caloric stimulation of the labyrinth causes tonic movement of the eyes but not nystagmus, as in the normal person. Also, optokinetic nystagmus cannot be induced. Vertical eye movements are normal. A similar ocular condition may occur in conjunction with ataxiatelangiectasia and in Gaucher disease. Children with oculomotor apraxia are slow to walk; Ford observed one such child whose sibling had an absence of the vermis of the cerebellum. Aside from this observation, the anatomic basis of the condition has not been studied.

CONGENITAL ABNORMALITIES OF MOTOR FUNCTION (CEREBRAL PALSY)

In this group of congenital disorders, a major disturbance of motor function, usually nonprogressive, has been present since infancy or early childhood. The popular terms for these conditions have been *infantile cerebral paralysis* (Freud) and *cerebral palsy*. The latter name is neither appropriate nor useful from the physician's viewpoint, collocating as it does diseases of widely differing etiologic and anatomic types, wherein the hereditary and acquired and the intrauterine, natal, and postnatal diseases lose their identity. But the name has been adopted as a slogan by fund-raising societies and for rehabilitation clinics throughout the United States, hence it will not soon disappear from medical terminology. The term, often abbreviated CP, is still being used indiscriminately to designate every conceivable cognitive and motor disorder of corticospinal, extrapyramidal, cerebellar, and even neuromuscular type in infants and children.

Etiology of the Congenital Cerebral Motor Disorders

Motor abnormalities that have had their onset early in life are numerous and diverse in their clinical manifestations. Marked prematurity is an associated factor in a large proportion of cases. Each year, approximately 50,000 infants weighing less than 1,500 g are born in the United States; approximately 85 percent survive. Of these, 5 to 15 percent have a motor disorder of cerebral origin and 25 to 30 percent are found to be mentally impaired at school age (Volpe, 1995; also Hack et al). It is helpful to categorize a given case according to the extent and nature of the motor abnormality. A careful history of prenatal, perinatal, or postnatal insults to the developing nervous system must be sought; certain correlations of these factors with the resulting pattern of neurologic deficit are outlined below. Most patients with these motor abnormalities reach adult years. Many but not all have epilepsy in addition to the motor abnormalities and there is an unavoidable overlap in considering the causes and mechanisms of these three clinical states.

The following discussion is given from the perspective of the three major etiologic syndromes: matrix hemorrhages in the immature infant, hypoxic-ischemic encephalopathy, and certain other developmental motor abnormalities including those due to intrauterine stroke.

Germinal Matrix (Subependymal) Hemorrhage in Premature Infants

In low-weight and premature immature infants (20 to 35 weeks' gestational age), there sometimes occurs, within a few days after birth, a catastrophic decline in cerebral function, usually preceded by respiratory distress (hyaline membrane disease) with spells of cyanosis and apnea. Also evident are deficiencies of brainstem automatisms (sucking and swallowing), bulging of the fontanelles, and sanguineous CSF. If the infant becomes completely

unresponsive, death usually ensues within a few days. Autopsy discloses a small lake of blood in each cerebral hemisphere (often asymmetrically distributed), occupying the highly cellular (subependymal) germinal matrix zone, near the caudate nucleus at the level of the foramen of Monro. This region is supplied by the lenticulostriate, choroidal, and Heubner recurrent arteries and is drained by deep veins, which enter the vein of Galen. In approximately 25 percent of cases, the blood remains loculated in the matrix zone, while in the majority it ruptures into the lateral ventricle or adjacent brain tissue. In a series of 914 consecutive autopsies in newborns, subependymal hemorrhage was found in 284 (31 percent); practically all of these neonates were of low birth weight, according to Banker and Bruce-Gregorios.

Lesser degrees of this cerebral hemorrhage are now being identified by ultrasonography (Fig. 38-14) and CT scans, and it is apparent that many infants with smaller hemorrhages survive. Some rapidly develop an obstructive hydrocephalus and require a ventricular shunt. In others, the hydrocephalus stabilizes and there is clinical improvement. Several series of surviving cases have now been followed for many years. Those in whom the hemorrhage was more extensive are often left with motor and intellectual handicaps.

Viewed from the perspective of cerebral palsy, just over half of the patients in the Swedish series of Hagberg and Hagberg with spastic diplegia had matrix hemorrhages, leukomalacia (see further on), or both. Congenital hemiplegia or quadriplegia was observed at a lower frequency. In another series of 20 cases of posthemorrhagic hydrocephalus (Chaplin et al), 40 percent had significant motor deficits and more than 60 percent had IQ scores of less than 85. In an experience with 12 less severely affected surviving cases (mean birth weight 1.8 kg and gestational age of 32.3 weeks), R.D. Adams noted that only 1 had a residual spastic diplegia and 9 had IQs in the low-normal or normal range (personal communication).

The cause of matrix hemorrhage is not entirely clear. In all probability it is related to greatly increased pressure in the thin-walled veins of the germinal matrix coupled with a lack of adequate supporting tissue in these zones. During periods of unstable arterial or venous blood pressure that occur with the pulmonary disorders of immature infants, these thin-walled vessels rupture. These infants

Figure 38-14. Ultrasonograph demonstration of subependymal matrix hemorrhage in a premature infant (arrow).

are also prone to the development of another characteristic lesion of the cerebral white matter (periventricular leukomalacia; see below), and the neurologic deficits resulting from these two lesions may be additive.

Treatment Control of the respiratory distress of prematurity may reduce the incidence of matrix hemorrhages and periventricular leukomalacia. Claims have been made that the administration of indomethacin ethamsylate, a drug that reduces capillary bleeding, and the intramuscular injection of vitamin E for the first 3 days after birth and possibly the use of betamethasone or other corticosteroids appears to be of value in reducing the incidence of periventricular hemorrhage (Benson et al; Sinha et al; see also Volpe [1989] for discussion of control of cerebral hemodynamics and effects of medications in the neonatal period). Acetazolamide and furosemide, which reduce the formation of spinal fluid, have been widely used in the treatment of posthemorrhagic hydrocephalus. However, in a large-scale controlled study, the effects were negligible and shunt placement was required to control worsening hydrocephalus (see International PHVD Drug Trial Group in the references).

Periventricular Leukomalacia

These are zones of necrosis of white matter in the deep territories of cortical and central arteries. They lie lateral and posterolateral to the lateral ventricles, in a position to involve the occipital radiations and the sensorimotor fibers in the corona radiata (first described by Banker and Larroche; see also Shuman and Selednik). The white matter lesions occur in about one-third of cases of subependymal hemorrhage as mentioned, but they may develop independently in both premature and full-term infants who have suffered hypotension and apnea. In a study of 753 preterm infants, those born at 28 weeks' gestation or less were at highest risk of this complication; the combination of intrauterine infection and premature rupture of membranes carried a 22 percent risk (Zupan et al). Survivors often manifest cerebral hemiplegia or diplegia and variable degrees of mental impairment. The motor disorder is usually more severe than the cognitive and language impairment. Increasingly, small lesions of this nature are being identified in term infants by cerebral imaging including ultrasound.

The mechanism of this type of periventricular infarction has been debated, and the terminology and clinical features, insofar as they overlap with germinal matrix hemorrhage, have been confusing. In recent years, most theories and experimental evidence converge on the notion that these represent regions of venous ischemia and infarction.

Hypoxic-Ischemic Damage and Neonatal Encephalopathy

It has been estimated that in the range of 1 to 6 of every 1,000 live births manifests a neonatal encephalopathy (as quoted in the review by Ferriero). The seriousness of the condition is further emphasized by the associated mortality rate of 20 percent in the newborn period and the 25 percent rate of neurodevelopmental disability in survivors. Little's conception of the hypoxic-ischemic

form of "birth injury," enunciated in 1862, has been reconsidered over the years. Although it is evident that many newborns suffer some degree of perinatal asphyxia, relatively few seem to manifest brain damage. Moreover, many, if not most, infants with a variety of cerebral motor syndromes appear to have passed the parturitional (perinatal) period without mishap, indicating the greater importance of other prenatal and postnatal causative factors. Nonetheless, *severe neonatal asphyxia* of term or preterm babies can be an important cause of spastic, dystonic and ataxic syndromes, often accompanied by seizures and mental delay in development.

This field has been sullied by an unprecedented rise in malpractice litigation, spawned in part by the belief that early detection of asphyxia and rapid delivery would have prevented the motor, epileptic, and cognitive problems of birth injury. The fallacy of this assumption is highlighted both by the below comments and by the observation that the incidence of cerebral palsy has not changed in term infants over the past 30 years, despite the institution of fetal monitoring and more frequent cesarean sections.

One has the impression that the brain tolerates hypoxia and reduced blood flow in the immediate postnatal period better than at any other time in life. Indeed, animal experimentation supports this view. Not until the arterial oxygen tension is reduced dramatically to 10 to 15 percent of normal does brain damage occur, and even then the impaired function of other organs contributes to the damage. It is probably correct to think of the encephalopathy in terms of both hypoxia and ischemia, both of which usually occur in utero and are expressed postnatally by recognizable clinical syndromes.

Fenichel (1990), following the original work of Sarnat and Sarnat and of Levene and colleagues, has found it helpful to divide the encephalopathies that follow a complicated birth into three purely descriptive groups according to their severity, each having a prognostic value beyond that of the Apgar score: (1) In newborns with mild hypoxic-ischemic encephalopathy, the symptoms are maximal in the first 24 h and take the form of hyperalertness and tremulousness of the limbs and jaw (the "jittery baby") and a low threshold of the Moro reaction. The tone of the limbs is normal except for a mild increase in head lag during traction. The reflexes are brisk and there may be ankle clonus. The anterior fontanel is soft. The EEG is normal. Recovery is usually complete and the risk of handicap is low. (2) Newborns with moderate hypoxic-ischemic encephalopathy are lethargic, obtunded, and hypotonic, with normal movements. After 48 to 72 h, the neonate may improve (having passed through a jittery hyperactive phase) or worsen, becoming less responsive in association with convulsions, cerebral edema, hyponatremia, and hyperammonemia from liver damage. The EEG is abnormal. Fenichel associates epileptiform activity and voltage suppression with an unfavorable outcome. Abnormal visual and auditory evoked potentials are other poor prognostic signs. (3) In neonates with severe hypoxic-ischemic encephalopathy, stupor or coma is present from birth; respirations are irregular, requiring mechanical ventilation. There are usually

convulsions within the first 12 h. The limbs are hypotonic and motionless even during attempts to elicit the Moro response. Sucking and swallowing are depressed or absent, but pupillary reactions and eye movements may at first be retained, only to be lost as the coma deepens.

It is in the second and third categories, that is, the states of moderate to severe encephalopathy, where correction of the respiratory insufficiency and the metabolic abnormalities permits survival, that a number of motor abnormalities (corticospinal, extrapyramidal, and cerebellar) and developmental delay eventually emerge. Included in the category of severe hypoxic-ischemic encephalopathy are also newborns with a variety of developmental anomalies of the brain and other organs. However, clouding the issue of causality is the absence of perinatal complications in a large number of children with cerebral palsy and the large number of normal babies who are born after complicated deliveries. Notably, only a few cases result from often blamed intrapartum factors such as forceps delivery, breech presentation, cord prolapse, abruptio placentae, and maternal fever.

In addition, such infants may have been exposed to certain prenatal risk factors (toxemia of pregnancy, antepartum uterine hemorrhage, maternal hypotension, and certain epidemiologic associations such as hypothyroidism or fertility treatment), or their growth may have been abnormal (small-for-date babies). Some of these babies are born at term; others are premature, and the birth process may or may not have been abnormal. One must then consider the possibility, originally pointed out by Sigmund Freud, that the abnormality of the birth process, instead of being causal, was actually the consequence of prenatal pathology. The latter might include preterm intrauterine hypoxia-ischemia.

Other evidence of multifactorial etiology in the "causation" of cerebral palsy has been provided by Nelson and Ellenberg, who found that maternal developmental delay, birth weight below 2,000 g, and fetal malformation were among the leading predictors. Breech presentation was another factor, and one-third of these cases also had some noncerebral malformation. Twenty-one percent of the 189 children in their series had also suffered some degree of asphyxia. Additional determinants were maternal seizures, a motor deficit in an older sibling, two or more prior fetal deaths, hyperthyroidism in the mother, preeclampsia, and eclampsia. In children with cerebral diplegia born at term, likely contributory factors that were operative in nearly half included toxemia of pregnancy, low birth weight for age, placental infarction, and intrauterine asphyxia.

The factors enumerated above are involved to different degrees in the outcome of pregnancies but are informative because they bring to light the significant proportion of cases of cerebral birth injury in which hypoxia-ischemia, matrix hemorrhages, and leukomalacia were not operative. In this group, can be included the symmetrical porencephalies and hydranencephalies.

Thus the complexity of assigning a cause for cerebral palsy is evident. In respect to the motor disorders discussed below, hypoxic-ischemic perinatal injury is still the most commonly specified cause of neonatal

encephalopathy but is often unrelated to a permanent defect of cerebral palsy. This statement has been amply confirmed by a large and often cited study from Western Australia that detected neonatal encephalopathy in 3.8 of 1,000 live term births but was able to identify causative intrapartum factors alone in only 5 percent (Badawi et al). Furthermore, only 10 percent of all the infants with neonatal encephalopathy developed spastic quadriplegia, according to Evans and colleagues.

Imaging studies of cerebral palsy have increasingly appeared and it has even been suggested, perhaps with excessive enthusiasm, that all such children undergo scanning. Cowan and colleagues (2003) used MRI to determine the proportion of infants with a neonatal encephalopathy who had antenatal brain injury. Excluding those with major congenital malformations or obvious chromosomal abnormalities, 80 percent of cases had no established lesion or brain atrophy. In contrast, those with only seizures and no neonatal encephalopathy in 69 percent of cases had evidence of antenatal damage on MRI; infarctions because of thrombophilic disorders were most common. An MRI-clinical correlative study of children with cerebral palsy by Bax and colleagues in The European Cerebral Palsy Study came to similar conclusions but found that periventricular leukomalacia of prematurity was the most common MRI change, present in 42 percent of infants, followed in frequency by basal ganglionic damage (13 percent), cortical-subcortical lesions (9 percent), malformations (9 percent), and focal infarcts (7 percent). These authors found a correspondence between the clinical and MRI findings. These studies demonstrate the utility of MRI in identifying neonatal forms of encephalopathy and indicate that few are the result of obstetric accidents. Added difficulty is caused by the fact that the clinical signs of perinatal injury may emerge only when the maturational process of the nervous system exposes them at a later period of life. Woodward and coworkers suggested that the MRI pattern is predictive of developmental outcome in preterm infants, but this requires corroboration.

Treatment Much of the resources of neonatal intensive care is devoted to sustaining oxygenation and blood pressure, and reducing hyperbilirubinemia in premature and full-term but ill infants. Techniques such as the predelivery administration of corticosteroids in premature births to promote lung maturity, attempting to bring early births to 34 to 36 weeks' gestation, and the treatment of maternal infection have all contributed to improved outcomes in children.

The avoidance of the ostensible causes of cerebral palsy has been discussed in previous sections and endlessly in the medical literature. None of the usually assigned causes of birth injury, particularly perinatal hypoxia-ischemia, explains most cases. In addition, several trials have investigated the effects of induced hypothermia for severe neonatal encephalopathy from hypoxia but have given mixed results. Attempts to ameliorate brain injury by the use of hypothermia, a technique that has met with success in adult cardiac arrest, have given conflicting results. A randomized trial by

Shankaran and colleagues using systemic hypothermia administered to infants with neonatal encephalopathy or a need for resuscitation showed a reduction in death or moderate to severe disability from 62 to 44 percent and a small benefit in IQ at age 7 that was not statistically significant. Hypothermia was applied soon after birth, at a mean of about 4 hours. The effects were seen mostly among infants with only moderate and not severe encephalopathy and none of the measures of mental and psychomotor disability was improved by cooling. Previous trials, such as the one reported by Azzopardi and colleagues, had shown no difference in outcomes but used different techniques, mainly selective cerebral cooling. Cooling appears promising but requires further study, and at the time of this writing, has not been widely adopted. It is also unclear if the short-term followup will be reflected at school age and beyond.

Clinical Syndromes of Congenital Spastic Motor Disorders

The most frequent motor disorder evolving from the four major categories of neonatal cerebral disease—matrix hemorrhage, periventricular leukomalacia, hypoxic-ischemic encephalopathy, kernicterus (discussed further on)—is spastic diplegia; that is, a motor disturbance that is severe in the lower limbs and mild in the upper, as discussed below. In addition, hypoxic-ischemic injury occurring in the term or preterm infant may take the form of a hemiplegia, double hemiplegia (quadriplegia), or a mixed pyramidal-extrapyramidal or spastic-ataxic syndrome.

A second form of motor disorder is characterized by the development of severe spastic quadriplegia and developmental delay. The major insult is usually intrapartum asphyxia and attendant fetal distress. Usually such infants will have required resuscitation and will have had low 5-min Apgar scores and seizures, which have important predictive value in this circumstance. The pathologic lesions of the brain in this second group consist of hypoxic-ischemic infarction in distal fields of arterial flow, primarily in the cortex and white matter of parietal and posterior frontal lobes, leaving a ulegyric sclerotic cortex.

A third group, discussed below, is characterized mainly by extrapyramidal abnormalities, combining athetosis, dystonia, and ataxia in various proportions. After reviewing the results of several large series of congenital and neonatal motor disorders, we have concluded that spastic diplegia occurs in 10 to 33 percent of cases, spastic quadriplegia in 19 to 43 percent, extrapyramidal forms in 10 to 22 percent, and mixed forms in 9 to 20 percent.

Spastic Diplegia ("Little Disease") The pattern of paralysis is more variable than the term *spastic diplegia* implies; actually, several subtypes may be distinguished: paraplegic, diplegic, quadriplegic, pseudobulbar, and generalized. Pure paraplegic and pseudobulbar types are relatively rare. The eponymic "Little disease" has been applied mainly to the spastic diplegic type, but it also has been attached to all forms of motor cerebral palsy in some older writings.

Usually all four extremities are affected, but the legs much more than the arms, which is the real meaning of *diplegia*. Hypotonia—with retained tendon reflexes and hypoactivity—is usually present initially. Only after the first few months will evident weakness and spasticity appear, first in the adductors of the legs. The plantar reflexes, which often take on ambiguous direction in the normal infant, here are clearly extensor, a finding that is pathologic at any later age. Also, stiff, awkward movements of the legs, which are maintained in an extended, adducted posture when the infant is lifted by the axillae, often do not attract attention until several weeks or months have passed. Seizures occur in approximately one-third of the cases, and it is not uncommon to observe a delay in all developmental sequences, especially those that depend on the motor system.

Once walking is attempted, usually at a much later date than usual, the characteristic stance and gait become manifest. The slightly flexed legs are advanced stiffly in short steps, each describing part of an arc of a circle; adduction of the thighs is often so strong that the legs may actually cross (scissors gait); the feet are flexed and turned in with the heels not touching the floor. In the adolescent and adult, the legs tend to be short and small, but the muscles are not markedly atrophic, as they are in spinal muscular atrophy. Passive manipulation of the limbs reveals spasticity in the extensors and adductors and slight shortening of the calf muscles. The arms may be affected only slightly or not at all, but there may be awkwardness and stiffness of the fingers and, in a few, pronounced weakness and spasticity. In reaching for an object, the hand may overpronate and a grasp may be difficult to release. Speech may be well articulated or noticeably slurred, and in some instances the face is set in a spastic smile. Scoliosis is frequent and may secondarily give rise to root compression and impaired respiratory function. As a rule, there is no disturbance of sphincteric function, although delay in acquiring voluntary bowel and bladder control is usual. Athetotic postures and movements of the face, tongue, and hands are present in some patients and may actually conceal the spastic weakness.

One subtype of spastic diplegia is associated with a relatively slight diminution in head size and of intelligence. As indicated above, there is no unifying neuropathology; the condition occurs independently of matrix hemorrhages and periventricular leukomalacia as well as with them. The frequency of cerebral spastic diplegia, which is closely related to the degree of prematurity, has declined significantly since the introduction of neonatal intensive care facilities, and there is reason to believe that genetic factors are of more importance.

Infantile Hemiplegia and Quadriplegia Hemiplegia is a common condition of infancy and early childhood. The functional difference between the two sides may be noticed soon after birth, but more often it is not perceived by the mother until after the first 4 to 6 months of life. In a second group, the child is in excellent health for a year or longer before the abrupt onset of hemiplegia (see below). In hemiplegia that dates from earliest infancy—that

is, congenital hemiplegia—the parents first notice that movements of prehension and exploration are carried out with only one arm. A manifest hand preference at an early age should always raise the suspicion of a unilateral motor defect. The affection of the leg is usually recognized later, that is, during the first attempts to stand and walk. Sitting and walking are usually delayed by a few months. In the older child, there is evident hyperactivity of tendon reflexes and usually a Babinski sign. The arm is held flexed, adducted, and pronated, and the foot assumes an equinovarus posture. Sensory and visual field defects can be detected in some patients. A mental slowness may be associated with infantile hemiplegia but is less common and lesser in degree than with cerebral diplegia. There may also be speech delay, regardless of the side of the lesion; when this is present, there is usually developmental delay and bilaterality of motor abnormality. Convulsions occur in 35 to 50 percent of children with congenital hemiplegia, and these may persist throughout life. They may be generalized but are frequently unilateral and limited to the hemiplegic side (or the contralateral side if the hemiplegia is severe). After a series of seizures, the weakness on the affected side will be increased for several hours or longer (Todd paralysis). Gastaut and associates have described a hemiconvulsive-hemiplegic syndrome in which progressive paralysis and cerebral atrophy are attributed to the convulsions. As months and years pass, the osseous and muscular growth of the hemiplegic limbs is impeded, leading to an obvious hemiatrophy of the body.

With respect to the causation of congenital hemiplegia, it is generally agreed that perinatal asphyxia is only one of the possibilities. In the series of 681 children with “cerebral palsy” collected by Hagberg and Hagberg, there were 244 with hemiplegia of whom 189 were full-term babies and 55 were preterm. Prenatal risk factors were identified in only 45 percent, and mostly in the infants born prematurely. In nearly half of the cases, there was no clue as to the time in the intrauterine period when the cerebral lesion occurred.

In another group—*acquired infantile hemiplegia*—a normal infant or young child, usually between the ages of 3 and 18 months, develops a massive hemiplegia, with or without aphasia, within hours. The disorder often begins with seizures, and the hemiplegia may not be recognized until the seizures have subsided. In Banker’s series of autopsy cases, there was arterial or venous thrombosis in some cases, but instances without vascular occlusions were found. Some of the latter cases, in which arteriography had been normal, may have been embolic, possibly of cardiac origin. In the recent era, imaging has shown a large area of cerebral infarction, consistent with a stroke in the territory of the middle cerebral artery (Fig. 38-15). If the stroke occurs at an early age, the recovery of speech may be complete, though reduced scholastic capacity remains. The degree of recovery of motor function varies. Often, as the deficit recedes, the arm becomes involved by athetotic, tremulous, or ataxic movements; there may be an interval of months or years between the hemiplegia and the athetosis.

Figure 38-15. MRI of an adult with congenital hemiplegia. There is severe encephalomalacia mainly in the territory of the right middle cerebral artery.

Destructive lesions underlie most of the cases of infantile hemiplegia and some cases of bilateral hemiplegia (as well as many cases of seizures in the first few days of life). The pathologic change is essentially that of ischemic necrosis. In many cases, the lesions must have been acquired in utero. Precipitant delivery, fetal distress, and parturition uterine hemorrhage may have been indications, more so than causes, of the process. What is most notable is that the ischemia tends to affect the tissues lying in arterial cortical border zones; there may also be venous stasis with congestion and hemorrhage occurring particularly in the deep central structures such as the basal ganglia and periventricular matrix zones. If they are purely hypoxic, the lesions should be bilateral. Myers has reproduced such lesions in the neonatal monkey by reducing the maternal circulation for several hours. As the lesions heal, the monkeys develop the same gliotic changes in the cortex and white matter of the cerebrum (lobar sclerosis) and the “marbling” (*état marbré*) that characterizes the brains of patients with spastic diplegia and double athetosis (see below).

The quadriplegic state differs from bilateral hemiplegias in that the bulbar musculature is often involved in the latter and developmental delay is more severe. The condition is relatively rare and is usually a result of a bilateral cerebral lesion. However, one should also be alert to the possibility of a high cervical cord lesion. In the infant, this is usually the result of a fracture dislocation of the cervical spine incurred during a difficult breech delivery. Similarly, in paraplegia, with weakness or paralysis limited to the

legs, the lesion may be either a cerebral or a spinal one. Sphincteric disturbances and a loss of somatic sensation below a certain level on the trunk always point to a spinal localization. Congenital cysts, tumors, and diastematomyelia are more frequently causes of paraplegia than of quadriplegia. Another recognized cause of infantile paraplegia is spinal cord infarction from thrombotic complications of umbilical artery catheterization.

Extrapyramidal Syndromes

The spastic cerebral diplegias discussed above shade almost imperceptibly into the congenital extrapyramidal syndromes. These children are found in every cerebral palsy clinic, and, ultimately, they reach adult neurology clinics. Corticospinal tract signs may be absent and the student, familiar only with the syndrome of pure spastic diplegia, is always puzzled as to their classification. Some cases of extrapyramidal type are undoubtedly attributable to severe perinatal hypoxia and others to diseases such as erythroblastosis fetalis with kernicterus. To state the probable pathologic basis and future course of these illnesses, it is useful to separate the extrapyramidal syndromes of prenatal-natal origin (which usually become manifest during the first year of life) from the acquired or hereditary postnatal syndromes, such as familial athetosis, Wilson disease, dystonia musculorum deformans, and the hereditary cerebellar ataxias, which become manifest later.

Double Athetosis This is probably the most frequent of the congenital extrapyramidal disorders. Two types stand out—one that is caused by hyperbilirubinemia or Rh incompatibility (kernicterus; see below) and hypoxic-ischemic encephalopathy. With control of neonatal hyperbilirubinemia (by use of anti-Rh immune globulin, exchange transfusions, and phototherapy), kernicterus has almost disappeared, whereas the severe hypoxic-ischemic form regularly continues to be seen. Rarely, a congenital, nonhemolytic icterus or a glucose-6-phosphate dehydrogenase deficiency produces the same syndrome.

Like the spastic states, double athetosis may not be recognized at birth but only after several months or a year has elapsed. In some cases, the appearance of choreoathetosis is for unexplained reasons delayed for several years; it may seem to progress during adolescence and even early adult life. It must then be differentiated from some of the inherited metabolic and degenerative extrapyramidal diseases. Chorea and athetosis dominate the clinical picture, but bewildering combinations of involuntary movements—including dystonia, ataxic tremor, myoclonus, and even hemiballismus—may be found in a single case. At times, we have been unable to classify the movement disorder because of its complexity. It should be noted that practically all instances of double athetosis are also associated with a defect in voluntary movement.

Choreoathetosis in infants and children varies greatly in severity. In some, the abnormal movements are so mild as to be misinterpreted as restlessness or “the fidgets”; in others, every attempted voluntary act provokes violent involuntary spasms, leaving the patient nearly helpless. The clinical features of choreoathetosis and other involuntary movements are discussed in Chap. 4.

Early hypotonia, followed by delayed motor development, is the rule in these cases. Erect posture and walking may not occur until the age of 3 to 5 years and may never be attained in some patients. Tonic neck reflexes or fragments thereof tend to persist well beyond their usual time of disappearance. The plantar reflexes are usually flexor, although they may be difficult to interpret because of the continuous flexion and extension of the toes. Sensory abnormalities are not found. Because of the motor and speech impairment, patients are often erroneously thought to be mentally slow. In some, this conclusion is doubtless correct, but intellectual function is adequate in many others.

A variety of rehabilitative measures have been tried: physiotherapy, surgery, sensory integrative therapy, progressive patterned movement, and various undocumented forms of neuromuscular facilitation. We agree with Hur, who has critically reviewed this subject, that properly controlled studies provide no proof of the success of any of them. Surely, with growth and development, new postures and motor capacities are acquired. The less-severely affected patients make successful occupational adjustments. The more-severely affected children rarely achieve a degree of motor control that permits them to live independently. One sees some of these unfortunate persons bobbing and twisting laboriously as they make their way in public places.

Imaging studies are seldom of diagnostic value. Mild cerebral atrophy and loss of volume of the basal ganglia are seen in some cases, and cavitary lesions are present in some of the severe anoxic encephalopathies. The EEG is rarely helpful unless there are seizures.

The most frequent pathologic finding in the brain has been a whitish, marble-like appearance of the putamen, thalamus, and border zones of the cerebral cortex. These whitish strands represent foci of nerve cell loss and gliosis with condensation of bands of transverse myelinated fibers—so-called *status marmoratus* (*état marbré*). This lesion does not develop if the insult occurs after infancy, that is, after myelination has completed its early developmental cycle.

Kernicterus This is now a rare cause of extrapyramidal motor disorder in children and adults. Such cases are the neurologic sequelae of erythroblastosis fetalis secondary to Rh and ABO blood incompatibilities or to a deficiency of the hepatic enzyme glucuronosyltransferase. The symptoms of kernicterus appear in the jaundiced neonate on the second or third postnatal day. The infant becomes listless, sucks poorly, develops respiratory difficulties as well as opisthotonos (head retraction), and becomes stuporous as jaundice intensifies. The serum bilirubin is usually greater than 25 mg/dL. In acidotic and hypoxic infants (e.g., those with low birth weight and hyaline membrane disease), the kernicteric lesions develop with much lower levels of serum bilirubin.

A proportion of infants with this disease die within the first week or two of life. Many of those who survive are developmentally delayed, deaf, hypotonic, and totally unable to sit, stand, or walk. There are exceptional patients, however, who are mentally normal or at most only slightly limited. They develop a variety of persistent neurologic

sequelae—choreoathetosis, dystonia, and rigidity of the limbs—a picture not too different from that of cerebral spastic diplegia with involuntary movements. Kernicterus should always be suspected if an extrapyramidal syndrome is accompanied by bilateral deafness and paralysis of upward gaze. Later, in childhood there may be a greenish pigmentation of the dental enamel.

Neonates who die in the acute postnatal stage of kernicterus show a unique yellow staining (icterus) of nuclear masses at one time was called the “Kern nuclei” and gave the disease its name in the basal ganglia, brainstem, and cerebellum. In those surviving this postnatal insult, the pathologic changes consist of a symmetrically distributed nerve cell loss and gliosis in the subthalamic nucleus, the globus pallidus, the thalamus, and the oculomotor and cochlear nuclei; these lesions are the result of the hyperbilirubinemia. In more than 30 cases examined by R.D. Adams, the immature cerebral cortex including the hippocampus was spared. In the newborn, unconjugated bilirubin can pass through the poorly developed blood–brain barrier into these nuclei, where it is assumed to be directly toxic. Acidosis and hypoxia exacerbate the effect. Also in the newborn, the development of hyperbilirubinemia is enhanced by a transient deficiency of the enzyme glucuronosyltransferase, essential for the conjugation of bilirubin. *Hereditary hyperbilirubinemia*, caused by lack of this enzyme (*Crigler-Najjar syndrome*), may exhibit the same effects on the nervous system at a later period of infancy or childhood as hyperbilirubinemia because of Rh incompatibility.

Immunization, phototherapy, and exchange transfusions designed to prevent high levels of unconjugated serum bilirubin have been shown to protect the nervous system from the toxic effects of erythroblastosis fetalis. If the blood bilirubin level can be held to less than 20 mg/dL (10 mg/dL in premature infants), the nervous system may escape perinatal damage. The effective use of these measures has practically eradicated this disease.

Both kernicterus and ischemic *état marbré* must be differentiated clinically from hereditary choreoathetosis, the Lesch-Nyhan syndrome, and—later in life, from ataxia-telangiectasia and Friedreich ataxia.

Congenital and Neonatal Ataxias

In these patients, difficulty in standing and walking cannot be attributed to spasticity or paralysis. Hypotonia and poverty of movement are the initial motor abnormalities—as they are in athetoid cerebral palsy. The cerebellar deficit becomes manifest only later when the patient begins to sit, stand, and walk. There may or may not be a delay in reaching the normal motor milestones. Attempts to attain sitting balance early on reveal an unsteadiness that is not soon overcome, even with practice. Reaching for a proffered toy is accomplished by jerky, incoordinated movements. The first steps are unsteady, as would be expected, with many tumbles, but the gait remains clumsy. Instability of the trunk may be accompanied by similar, more or less rhythmic bobbing movements of the head—titubation. Despite the severity of the ataxia, the muscles are of normal size, and voluntary movements,

although weak in some patients, are possible in all the limbs. The tendon reflexes are present, and the plantar reflexes are either flexor or extensor. In some cases, the ataxia is later associated with spasticity rather than hypotonia (spastic-ataxic diplegia). Relative improvement may occur in later years. In the older child, a cerebellar gait, ataxia of limb movements, nystagmus, and uneven articulation of words are readily distinguished from myoclonus, chorea, athetosis, dystonia, and tremor.

In only a few cases have the pathologic changes been studied. Aplasia or hypoplasia of the cerebellum has been observed, but sclerotic lesions of the cerebellum are more common. The CT scan or MRI verifies the cerebellar atrophy. However, in a few cases of a cerebellar-like tremor in adults under our care that had been attributed to neonatal injury the MRI did not show cerebellar atrophy. A cerebral and cerebellar lesion may coexist in patients with congenital ataxia, which is the reason for the term *cerebrocerebellar diplegia*.

Several risk factors have been identified in the congenital ataxias. Most importantly, cerebellar ataxia may be the most prominent or sole effect of neonatal ischemia-hypoxia. A genetic factor is operative in some cases (Hagberg and Hagberg). Mercury poisoning in utero is another cause of congenital ataxia. The many cases that are not the result of a degenerative condition, some of which are described just below, remain unexplained in our experience.

Pontocerebellar Hypoplasias and Joubert Syndrome

Aside from the congenital ataxia described above, there are several rare familial forms in which a failure of cerebellar development is associated with developmental delay. What has now come to be called Joubert syndrome was reported in a family in which the central feature is dysgenesis of the vermis; developmental delay; episodic hyperpnea; irregular, jerky eye movements; and unsteady gait in 4 of 6 siblings. In other reports, choroidal-retinal colobomas, polydactyly, cryptorchidism, and prognathism have been mentioned. Detailed examination of the cerebra of such individuals has been lacking but the MRI has a characteristic configuration of a "molar tooth sign" that reflects a deep invagination caused by vermian hypoplasia with a narrow cleft separating the cerebellar hemispheres and thickening of the superior cerebellar peduncles. Several genetic loci have been implicated, most acting as recessive traits.

In the *Gillespie syndrome*, a combination of aniridia, cerebellar ataxia, and developmental delay is the denominating feature. In the *Paine syndrome*, a familial disorder with developmental delay and developmental delay, there is microcephaly, spasticity, optic hypoplasia, and myoclonic ataxia, the last presumably related to the cerebellar hypoplasia. These dysgeneses and the disequilibrium syndrome reported from Sweden are unified by the cerebellar ataxia; in the past, they were categorized as ataxic cerebral palsies. Imaging studies demonstrate the cerebellocerebral abnormality. Genetic factors are operative in some, but matters pertaining to etiology remain obscure (see the older monograph by Harding for details). One form of a pure nonprogressive congenital cerebellar

hypoplasia has been mapped to a gene locus on chromosome Xq; it does not appear to be related to the fragile X syndrome, which may cause ataxia and tremor in adults as noted further on.

Differential Diagnosis of the Congenital Ataxias

The congenital ataxias must be distinguished from the progressive hereditary ataxias. The latter are likely to begin at a later age than the congenital ones. Some hereditary ataxias are intermittent or episodic, one of which is responsive to acetazolamide and is the result of an abnormality of the calcium channel as discussed in Chaps. 5 and 37.

Also to be distinguished from the ataxias of congenital and neonatal origin is an *acute cerebellar ataxia of childhood*, which can usually be traced to a viral infection or postinfectious encephalitis, particularly after chickenpox. The *opsoclonus-myoclonus ("dancing eyes") syndrome* of Kinsbourne is another postinfectious disease peculiar to childhood (see Chaps. 14 and 39). The cerebellar ataxia in this disease may be overshadowed by polymyoclonus, which mars every attempted movement. With improvement, under the influence of corticosteroids, a cerebellar disorder of speech and movement becomes evident. A majority of the patients in which the disease became chronic (16 of the 26 cases followed by Marshall et al) were found later to be mentally slowed. The cause of the disease has never been established. An occult neuroblastoma or other tumor is uncovered occasionally. In the differential diagnosis of these acute forms of cerebellar ataxia, one must not overlook intoxication with phenytoin, barbiturates, or similar drugs.

The Flaccid Paralyzes and the "Floppy Infant"

(Table 38-7; See also Chaps. 39 and 48)

The rare cerebral form of generalized flaccidity, first described by Foerster and called *cerebral atonic diplegia*, has already been alluded to in the discussion of cerebral palsy. It can usually be distinguished from the paralysis of spinal and peripheral nerve origin and congenital muscular dystrophy by the retention of postural reflexes (flexion of

Table 38-7

CAUSES OF CONGENITAL HYPOTONIA—THE FLOPPY INFANT SYNDROME

- I. Cerebral
 - A. Cerebral atonic diplegia (Foerster)
 - B. Prader-Willi syndrome
 - C. Idiopathic slackness
- II. Spinal
 - A. Werdnig-Hoffman spinal muscular atrophy
 - B. Spinal cord natal injury
- III. Myopathic

 - B. Infantile muscular dystrophy
 - C. Myotonic dystrophy
 - D. Polymyositis
- IV. Neuropathic
 - A. Inflammatory demyelinating neuropathy

(See also Chap. 48.)

the legs at the knees and hips when the infant is lifted by the axillae), preservation of tendon reflexes, and coincident failure of mental development. The Prader-Willi syndrome, discussed earlier in the chapter, also presents at first as a generalized hypotonia.

The syndrome of *infantile spinal muscular atrophy* (*Werdnig-Hoffmann disease*) is the leading example of flaccid paralysis of lower motor neuron type. Perceptive mothers may be aware of a paucity of fetal movements in utero; in most cases the motor defect becomes evident soon after birth or the infant is born with arthrogryptic deformities. Several other types of familial progressive muscular atrophies have been described in which the onset is in early or late childhood, adolescence, or early adult life. Weakness, atrophy, and reflex loss without sensory change are the main features and are discussed in detail in Chap. 39. A few patients suspected of having infantile or childhood muscular atrophy prove, with the passage of time, to be merely inactive “slack” children, whose motor development has proceeded at a slower rate than normal. Others may remain weak throughout life, with thin musculature. These and several other congenital myopathies—*central core, rod-body, nemaline, mitochondrial, myotubular, and fiber-type disproportion and predominance*—are described in Chap. 52. Unlike Werdnig-Hoffmann disease, the effects of many of them tend to diminish as the natural growth of muscle proceeds. Rarely, polymyositis and acute idiopathic polyneuritis manifest themselves as a syndrome of congenital hypotonia.

Infantile muscular dystrophy and lipid and glycogen storage diseases may also produce a clinical picture of progressive atrophy and weakness of muscles. The diagnosis of *glycogen storage disease* (usually the Pompe form) should be suspected when progressive muscular atrophy is associated with enlargement of the tongue, heart, liver, or spleen. The motor disturbance in this condition may be related in some way to the abnormal deposits of glycogen in skeletal muscles, although it is more likely the result of degeneration of anterior horn cells that are also distended with glycogen and other substances. Certain forms of *muscular dystrophy* (myotonic dystrophy and several types of congenital dystrophy) may also be evident at birth or soon thereafter. The latter may have led to arthrogryposis and clubfoot (see Chap. 52 for an extensive discussion of the congenital neuromuscular disorders).

Brachial plexus palsies, well-known complications of dystocia, usually result from forcible extraction of the fetus by traction on the shoulder in a breech presentation or from traction and tipping of the head in a shoulder presentation. The effects of such injuries are sometimes lifelong. Their neonatal onset is betrayed later by the small size and inadequate osseous development of the affected limb. Either the upper brachial plexus (fifth and sixth cervical roots) or the lower brachial plexus (seventh and eighth cervical and first thoracic roots) suffer the brunt of the injury. Upper plexus injuries (Erb palsy) are about 20 times more frequent than lower ones (Klumpke palsy). Sometimes the entire plexus is involved. Further details are found in Chap. 46.

Facial paralysis, because of forceps injury to the facial nerve immediately distal to its exit from the stylomastoid foramen, is another common (usually unilateral) peripheral nerve affection in the newborn. Failure of one eye to close and difficulty in sucking make this condition easy to recognize. It must be distinguished from the congenital facial diplegia that is often associated with abducens palsy, that is, the Möbius syndrome discussed earlier in the chapter. In most cases of facial paralysis caused by physical injury, function is recovered after a few weeks; in some, the paralysis is permanent and may account for lifelong facial asymmetry.

Treatment

Once the motor features of cerebral palsy have been established, assistive devices, stretching therapy, and conventional orthopedic measures for joint stabilization and relief of spasticity are all useful. Injection of botulinum toxin for the relief of spasticity has gained wide favor and is now used early in the child's life to preempt deformities. Most published trials have been too small, however, to allow firm conclusions to be drawn about the durability of this treatment. Finally, hyperbaric oxygen treatment of children with cerebral palsy was ineffective in a randomized trial conducted by Collet and colleagues, despite periodic claims to the contrary.

In summary, it can be said that all these forms of disabling motor abnormalities rank high as important issues in neuropaediatrics. In attempts at prevention, steps have been taken in most hospitals to identify and eliminate risk factors. Indeed, better prenatal care, reduction in premature births, and control of respiratory problems in critical care wards have reduced their incidence and prevalence. Physical and mental therapeutic measures appear to be helpful, but many of the methods have been difficult to evaluate in a nervous system undergoing maturation and development. The neurologist can contribute most by segregating groups of cases of identical pattern and etiology and in differentiating the congenital groups of delayed expressivity from the treatable acquired diseases of this age period. Woefully lacking are critical neuropathologic studies.

INTRAUTERINE AND NEONATAL INFECTIONS

Throughout the intrauterine period the embryo and fetus are subject to particular infections. Because the infective agent must reach the fetus through the placenta, it is evident that the permeability of the latter at different stages of gestation and the immune status of the maternal organism are determinative. We include a discussion of these intrauterine infections here because some of them may lead to malformations or destructive lesions of the brain and, later in life, must be distinguished from developmental abnormalities.

Until the third to fourth month of gestation, the large microbial organisms—such as bacteria, spirochetes, protozoa, and fungi—cannot invade the embryo, even if the

mother harbors the infection. Viruses, however, may do so, specifically rubella, CMV, HIV, and possibly others. The rubella virus enters embryonal tissues during the first trimester, *Treponema pallidum* in the fourth to fifth post-conceptual months, and *Toxoplasma* after that period. Bacterial meningitis (except for that caused by *Listeria monocytogenes*, described below) is essentially a perinatal infection contracted during or immediately after parturition. Neonatal herpes simplex encephalitis, as a result of the type 2 (genital) virus, is also usually acquired by passage through an infected birth canal. Some cases of HIV infection may be acquired during delivery, but most are a result of transplacental transmission.

The main neonatal infections—toxoplasmosis, rubella, CMV, and herpes—have been commonly designated by the acronym TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex). With the persistence of *Listeria*, the rise of AIDS infections, and a marked reduction in rubella infections, the mnemonic LATCH, which includes *Listeria* and AIDS, might be more appropriate. Infants with any of these infections share certain common features, such as low birth weight, prematurity, congenital heart disease, purpura, jaundice, anemia, microcephaly or hydrocephaly, cerebral calcifications, chorioretinitis, cataracts, microphthalmia, and pneumonitis; as a corollary, if any combination of these features is manifest, one should suspect one of these infectious agents and take measures to identify it. However, all these clinical manifestations are unlikely to be present in any one infant, and in the cases of rubella and CMV, only a small percentage of infected infants will show major systemic signs or symptoms. Nevertheless, on clinical grounds alone, certain infections can be identified and others excluded. For example, cerebral calcifications are present mainly in toxoplasmosis and CMV encephalopathy, being rare in rubella and absent in herpes simplex virus (HSV) encephalitis; the calcifications are widely disseminated in toxoplasmosis (Fig. 38-16) and have a periventricular distribution in CMV infection. Cardiac lesions are present only with rubella, and deafness occurs only with CMV and rubella. Thus, there are clinical signposts to guide the clinician in selecting the appropriate diagnostic tests. And importantly, in considering neonatal infections, one must also search for other, less-common infectious types (see Chaps. 32 and 33).

Added difficulty in the diagnosis of embryonal and fetal infections arises when the mother has been entirely asymptomatic. Isolation of the organism from fetal and neonatal tissues is possible, but usually they are inaccessible, and it may be impossible to demonstrate antibodies or other immune responses because of the early stage of the infection or limitations of the infant's immune response.

Congenital Rubella

Gregg, in 1941, first reported the association of maternal rubella and congenital cataracts in the neonate. His observations were quickly verified, and soon it became widely known that cataracts, deafness, congenital heart disease, and developmental delay constituted a kind of

Figure 38-16. CT scan from a developmentally delayed adult with healed congenital toxoplasmosis. There is hydrocephalus and multiple calcifications in the white matter. Contrast this image with Fig. 38-7, which shows the periventricular calcifications of tuberous sclerosis.

tetrad diagnostic of this disease. That a virus could affect so many tissues, causing in essence a noninflammatory developmental disorder of multiple organs, was a novel concept, and it raised the interesting prospect that other viruses might have similar effects. Surprisingly, however, only CMV and possibly HSV have been incriminated in embryonal-developmental neuropathology. A large number of other viruses (e.g., influenza, Epstein-Barr, hepatitis) have been implicated in human teratogenesis, but in none is the relationship beyond doubt.

It is now well established that most instances of congenital rubella infection occur in the first 10 weeks of gestation and that the earlier the infection occurs, the greater the risk to the fetus. However, there may be some risk beyond the first trimester, up to the twenty-fourth week, according to Hardy.

Following the experience of the massive rubella epidemics of 1964 and 1965, the congenital rubella syndrome has been expanded to include low birth weight; sensorineural deafness, sometimes unilateral (the most common complication); microphthalmia; pigmentary degeneration of the retina (salt-and-pepper chorioretinitis); glaucoma, cloudy corneas, and cataracts of special type (the latter two abnormalities usually cause visual impairment); hepatosplenomegaly, jaundice, and thrombocytopenic purpura; and patent ductus arteriosus or interventricular septal defect. There may be one, a few, or many of these abnormalities, in various combinations. The developmental delay is severe and may be accompanied by seizures and motor defects such as hemiplegia or spastic diplegia and rarely by seizures. Psychiatric symptoms, some resembling autism, are said to occur.

Infection of the fetus after the first trimester results in a less impressive neonatal syndrome. The infant may seem lethargic and fail to thrive. The cranium is abnormally small. Only a cardiac abnormality, deafness, or chorioretinitis may provide clues to the diagnosis. The CSF later may show an increase of mononuclear cells and an elevated protein. The infection may persist for a year or longer. Foci of calcification are rare, and CT scanning and MRI are of little help in diagnosis. The maternal infection may be so mild that it is passed off as minor; but even when it is evident, the fetus is spared in approximately 50 percent of cases. Diagnosis can be verified in the neonate by demonstrating immunoglobulin (Ig) M antibodies to the virus or by the isolation of the virus from the throat, urine, stool, or CSF. Also, the virus has been obtained from cells in the amniotic fluid. In subsequent pregnancies, the fetus has been normal in our experience.

The neuropathology is of considerable interest. In the nervous system of fetuses exposed to maternal rubella in the first trimester, R.D. Adams found no visible lesions by light microscopy, even though the virus had been isolated from the brain by Enders (personal communications). At this period of development there is no inflammatory reaction because of the absence of polymorphonuclear leukocytes, lymphocytes, and other mononuclear cells in the fetus. At birth the brain is usually of normal size, and there may be no discernible lesions. There may be a mild meningeal infiltration of lymphocytes, and a few zones of necrosis and vasculitis with later calcification of vessels are seen, as are small hemorrhages, presumably related to the thrombocytopenia. Smallness of the brain and delay in myelination have been observed in children who died at 1 to 2 years of age. None of the brains in Adam's series was malformed. Rubella virus continues to be recoverable from the CSF for at least 18 months after birth. A form of delayed progressive rubella encephalitis in childhood is also known and is described in Chap. 33 under "Progressive Rubella Panencephalitis." Because there is no treatment for the active infection, the obvious approach to the problem of congenital rubella infection is to make sure that every woman of childbearing age has been vaccinated against rubella or has antibodies as a result of infection prior to pregnancy. The widespread use of rubella vaccine has reduced the chance of major outbreaks, but sporadic infections continue to be seen, and outbreaks of epidemic proportions continue to occur in developing countries.

Congenital Cytomegalovirus Infection

For many years it was known that there were swollen cells containing intranuclear and cytoplasmic inclusions in the tissues of some infants who died in the first weeks and months of life. This cytologic change seemed related to the fatalities. In 1956 and 1957, three different laboratories isolated what has come to be called the *human cytomegalovirus* (see Weller). This has proved to be the most frequent intrauterine viral infection, rivaled in the current era only by HIV.

CMV disease is widespread in the general population. Although cervicitis is common, the virus is probably

transmitted to the fetus transplacentally. Infection of the fetus usually occurs in the first trimester of pregnancy, sometimes later, by way of an inapparent maternal viremia and infection of the placenta. The newborn can also be infected in the course of delivery or afterward by the mother's milk or by transfusions. However, only a small proportion of women known to harbor the virus give birth to infants with active infection. The likelihood of the fetus being infected is much greater if the seronegative mother becomes infected for the first time during pregnancy. In one study, 18 percent of infants born to such mothers were symptomatic at birth, and 25 percent became blind, deaf, or cognitively impaired within a few years (Fowler et al). In mothers with recurrent CMV infection, the infants were asymptomatic at birth, and only a few developed serious sequelae. Evidently, the presence of maternal antibodies before conception protects against congenital CMV infection.

Early infection of the fetus may result in a malformation of the brain; later, there is only inflammatory necrosis from encephalitis in parts of the normally formed brain. Disseminated inflammatory foci have been observed in the cerebrum, brainstem, and retinae. Here there were aggregates of lymphocytes, mononuclear cells, and plasma cells. The mononuclear histiocytes (microglia cells) contain inclusion bodies; some astrocytes are similarly affected. Granulomas form and later calcify, particularly in the periventricular regions. Often there is hydrocephalus. In the low-birth-weight or full-term infant, the clinical picture is one of jaundice, petechiae, hematemesis, melena, direct hyperbilirubinemia, thrombocytopenia, hepatosplenomegaly, microcephaly, mental defect, and convulsions. Cells in the urine may show cytomegalic changes. There is a pleocytosis and an increased protein in the CSF.

Congenital CMV infections pose a much greater problem than does rubella. There is no way of identifying the infected fetus prior to birth or to prevent inapparent infections in the pregnant woman. As indicated above, if the pregnant woman has measurable titers of antibodies to CMV at the time of conception, her infant is relatively protected. Moreover, some infected infants (with viruria) may appear normal at birth but develop neural deafness and developmental delay several years later. Viral replication in infected organs continues after the first year and health workers are at risk. A second child may be infected.

There is no known treatment. The difficulties in prenatal diagnosis of maternal infection preclude planned abortion. Routine serologic testing should be done on every young woman of childbearing age. Until an effective vaccine becomes available, pregnancy should be avoided if a sexual partner is infected.

Congenital HIV Infection and AIDS

In the United States, approximately 10 percent of cases of AIDS have occurred in women, almost all of them of childbearing age, and the rate of new cases is increasing at a faster rate among them than among men. The numbers are higher in many developing countries and

particularly in parts of Africa. In children, practically all instances of AIDS come from an HIV-infected mother ("vertical transmission"). The infection may be acquired in utero, during delivery, or from breast-feeding. The relative importance of each of these modes of transmission has not been settled.

It is estimated that HIV infection and AIDS occur in 15 to 30 percent of infants born to HIV-seropositive mothers (see Prober and Gerson). Infected infants present special difficulties in diagnosis, and the infection runs a more accelerated course in them than in adults. In the perinatal period, infected and noninfected infants can only rarely be distinguished clinically, and laboratory diagnosis is hampered by the presence of maternally derived antibody to HIV. The initial clinical signs usually appear within a few months after birth; practically all infected infants become ill before their first birthday, and very few are asymptomatic beyond 3 years of age. Early signs consist of lymphadenopathy, splenomegaly, hepatomegaly, failure to thrive, oral candidiasis, and parotitis. In the European Collaborative Study, comprising 600 children born to HIV-infected mothers, 83 percent of infected children showed laboratory or clinical features of HIV infection by 6 months of age. By 12 months, 26 percent had clinical symptoms of AIDS and 17 percent had died of HIV-related diseases. Once AIDS is established in children, it does not differ materially from the syndrome in adults as described in Chap. 33.

There is often a delay in the attainment of psychomotor milestones. Or after a period of normal development, a psychomotor decline begins, with corticospinal or peripheral nerve signs, often with pleocytosis in the CSF. The typical giant cell AIDS encephalitis, neuritis, and myelitis are easily distinguished from CMV encephalitis and toxoplasmosis.

Infected children are also subject to a variety of opportunistic infections, including bacterial meningitis, toxoplasmosis, CMV encephalitis, fungal infections (cryptococcosis, aspergillosis, candidiasis), herpes simplex, syphilis, zoster, and mycobacterial meningitis. There may also be vascular lesions, with infarction or hemorrhage and lymphoid neoplasia. These are discussed in Chaps. 32 and 33. To date, there is little that one can do for these children, but this may be changing with the current use of 3-drug antiretroviral therapy.

Congenital Toxoplasmosis

This tiny protozoan *Toxoplasma gondii*, occurring freely or in pseudocyst form, is a frequent cause of meningo-encephalitis in utero or in the perinatal period of life. The disease exists in all parts of the world but is more frequent in Western European countries, particularly in those with hot, humid climates, than it is in the United States. The mother is most often infected by exposure to cat feces, handling uncooked infected mutton or other meat, or eating partially cooked meat, but she is nearly always asymptomatic or has only a mild fever and cervical lymphadenopathy.

The precise times of placental and fetal invasion are unknown, but presumably they occur late in the

gestational period. The clinical syndrome usually becomes manifest in the first days and weeks of postnatal life, when seizures, impaired alertness, hypotonia, weakness of the extremities, progressive hydrocephalus, and chorioretinitis appear. The retinal lesions consist of large pale areas of destroyed retina surrounded by deposits of pigment. If the infection is severe, the maculae are destroyed; optic atrophy and microphthalmos follow. We have several times observed hemiplegias in older infants, first on one side and then on the other, followed by tension hydrocephalus. The latter is present in about one-third of the cases.

The CSF contains a moderate number of white blood cells, mostly lymphocytes and mononuclear cells, and the protein content is in the range of 100 to 400 mg/dL (i.e., a higher protein content than all other neonatal infections except bacterial meningitis). The glucose values are normal. Fewer than 10 percent of infected children recover; the others are developmentally delayed to varying degrees, with seizures and paralysis. In those without symptoms of infection at birth, the outcome is better.

Granulomatous masses and zones of inflammatory necrosis about the ependyma and meninges. The organisms, 6 to 7 mm in length and 2 to 4 mm in width, are visible in and near the lesions. Microcysts may also be found, lying free in the tissues without surrounding inflammatory reaction. The necrotic lesions calcify rapidly and, after several weeks or months, are readily visible in plain films of the skull. These appear in periventricular and other regions of the brain as multiple nodular densities (see Fig. 38-16).

In adults, often in association with AIDS, the disease takes the form of a rapidly evolving meningitis and multifocal encephalitis in conjunction with myocarditis, hepatitis, and polymyositis.

This syndrome is described in Chap. 32, as are the diagnostic tests and current treatment. In the infant, infections such as rubella, syphilis, CMV disease, and herpes simplex must be considered in the differential diagnosis. The most reliable means of diagnosis is the IgM indirect fluorescent antibody test, performed on umbilical cord blood. Passive transfer of IgG antibody from mother to fetus takes place, but its presence in the fetus is not proof of active infection.

In women who develop antibodies in the first 2 or 3 months of pregnancy, treatment with spiramycin (Rovamycine) prevents fetal infection. Once the fetus is infected, pyrimethamine and sulfadiazine must be used. A later second pregnancy is not affected.

Congenital Neurosyphilis

The clinical syndromes and pathologic reactions of congenital neurosyphilis of the newborn are similar to those of the adult, as described in Chap. 32. Such differences that exist are determined principally by the immaturity of the nervous system at the time of spirochetal invasion. The syphilitic infection may be transmitted to the fetus at any time from the fourth to the seventh months. The fetus may die, with resulting miscarriage or stillbirth, or may survive only to be born with florid manifestations of secondary syphilis. The dissemination of the spirochetes throughout

the body, the time of appearance of the secondary manifestations, and the time of formation of antisyphilitic antibodies (reagin) in the blood are all governed by the same biologic principles that apply to adult syphilis.

At birth, the spirochetemia may not have had time to cause syphilitic antibodies to appear; hence a negative Venereal Disease Research Laboratory (VDRL) reaction in umbilical cord blood does not exclude congenital syphilis. In unselected groups of syphilitic mothers, 25 to 80 percent of fetuses have been infected, and in 20 to 40 percent of those infected, the CNS is invaded as judged by the finding of abnormal CSF. The types of congenital neurosyphilis (asymptomatic and symptomatic meningitis, meningovascular disease, hydrocephalus, general paresis, and tabes dorsalis) are the same as those in the adult except for the great rarity of tabes dorsalis. The classic Hutchinson triad (dental deformities, interstitial keratitis, and bilateral deafness) is infrequently observed in complete form.

The sequence of neurologic syndromes is also the same as in the adult, all stemming basically from chronic spirochetal meningitis. The infection may become symptomatic in the first weeks and months of postnatal life, meningovascular lesions and hydrocephalus reaching maximal frequency during the period from 9 months to 6 years. An early form of syphilitic meningoencephalitis may occur at 1 to 2 years and result in severe developmental delay. More often, a congenital paresis and tabes usually appear between the ninth and fifteenth years. The pathologic basis of the neurosyphilitic syndromes is discussed in Chap. 32.

Fewer cases of congenital neurosyphilis are being observed as the years pass, but there may be a recrudescence of the disease in HIV-infected patients. If the syphilitic mother is treated before the fourth month of pregnancy, the fetus will not be infected. The affected infant may be normal at birth or exhibit only mucocutaneous lesions, hepatosplenomegaly, lymphadenopathy, and anemia. In the neonatal period, there are no signs of meningeal invasion, or there may be only asymptomatic meningitis. If the latter is actively treated until the CSF is normal, vascular lesions of brain and spinal cord, hydrocephalus, general paresis, and tabes dorsalis will not develop.

Congenital syphilis must be considered a potential, albeit rare, cause of epilepsy and developmental delay. Once the syphilitic infection has been treated in early life and rendered inactive (acellular CSF, normal protein), the occurrence of a congenital infection can only be substantiated by an accurate history; the finding of the syphilitic stigmata in the eyes, teeth, and ears; or a positive serologic reaction in the CSF.

Treatment of syphilis in the child follows along the same lines as treatment of the syphilitic adult (see Chap. 32), with appropriate adjustment of dosage in accordance with the child's weight.

Other Viral and Bacterial Infections

Several other infections of late fetal life or the neonatal period are only mentioned here, for to describe them

all would be excessive and would elucidate no new neurologic principles. Meningitis as a result of the small gram-positive rod *L. monocytogenes* may be acquired in the usual way, at the time of passage through an infected birth canal or in utero, as a complication of maternal and fetal septicemia because of this organism. In the latter case, it causes abortion or premature delivery. Neonatal bacterial meningitis with this organism is a particularly devastating and often fatal type of bacterial infection, not easily diagnosed unless the pediatrician is alert to the possibility of a silent meningitis in every case of neonatal infection. Coxsackievirus B, polioviruses, other enteroviruses, and arboviruses (western equine) seem to be able to cross the placental barrier late in pregnancy and cause encephalitis or encephalomyelitis in the near-term fetus, which is indistinguishable from the disease in the very young infant. Herpes zoster may occur in utero, leaving cutaneous scars and retarding development. Or zoster may appear soon after birth, the infection having been contracted from the mother. Only later in childhood can varicella induce an autoimmune perivenous demyelination and possibly a direct infection, affecting predominantly the cerebellum (see Chap. 33), or it may precede the now rare Reye syndrome.

Epstein-Barr virus is another frequent cause of meningoencephalitis. In some instances, it may present as aseptic meningitis or a Guillain-Barré type of acute polyneuritis. This infection tends to affect the nervous system of children rather than that of adults, but there are exceptions to this comment. It is estimated that approximately 2 percent of children and adolescents with this infection have some type of neurologic dysfunction; rarely will this be the only manifestation of the disease. Stupor, chorea, and aseptic meningitis were the main neurologic findings in the case reported by Friedland and Yahr, and acute cerebellar ataxia and deafness were observed in the case of Erzurum and associates (see also Chaps. 32 and 33).

EPILEPSIES OF INFANCY AND CHILDHOOD

The major types of seizure disorder have already been discussed in some detail in Chap. 16. In bringing them up here, attention is drawn to the fact that epilepsy is mainly a disease of infancy and childhood. Approximately 75 percent of epileptics fall into these age periods, and some of the most interesting and unique types of seizures are peculiar to these epochs of life. Epilepsies that are observed exclusively in infants and children are benign neonatal convulsions; benign myoclonic epilepsy of infancy; febrile seizures (both genetic and acquired); infantile spasms of West; absence seizures; the Lennox-Gastaut syndrome; rolandic and occipital paroxysms and other benign focal epilepsies; and the juvenile myoclonic epilepsies.

One principle that emerges is that the form taken by seizures in early life is in part age-linked. Neonatal seizures are predominantly partial or focal; infantile seizures take the form of myoclonic flexor (sometimes

extensor) spasms; and the various forms of petit mal are essentially diseases of childhood (4 to 13 years). The motor phenomena of epilepsy in young children are often termed *myoclonic*, but this should not be confused with other, later-occurring epilepsies that are endowed with the same name. Furthermore, certain epileptic states tend to occur only during certain epochs of life—one type of febrile seizure from 6 months to 6 years, generalized or temporal spike-wave activity with benign motor and complex partial seizures from 6 to 16 years, and juvenile myoclonic epilepsy in the mid- and late-adolescent years. In general, idiopathic epilepsy, so called because the cause cannot be determined, is predominantly a pediatric neurologic problem. This is not to say that seizures of unknown cause do not occur for the first time in adult life but rather that the onset of such seizures is far more frequent in childhood and tends to diminish once adulthood is reached.

The clinical characteristics of infantile and childhood seizures, including those of genetic origin, are fully described in Chap. 16.

Developmental Delay Without Physical Morphologic Changes (Nondysmorphic Developmental delay)

Clinical Features

Two clinical types can be recognized based on the adequacy of motor skills that are acquired in parallel with cognitive skills. *In the first*, the essential characteristic is that, almost from birth, the infant is delayed in all aspects of development. There is a tendency to sleep more, to be less demanding of nourishment, to move less than normal, and to suck poorly and regurgitate. Parents comment on how good their baby is, how little he troubles them by crying. As the months pass, every expected achievement is late. The baby is usually more hypotonic and turns over, sits unsupported, and walks later than the normal infant. Yet despite these obvious motor delays, there is later no sign of paralysis, ataxia, chorea, or athetosis. These babies do not smile at the usual time and take little notice of the mother or other persons or objects in their environment. They are less attentive to visual, and often to auditory, stimuli, to the point where questions may be raised about blindness or deafness. Certain phases of normal development, such as hand regard, may persist beyond the sixth month, when they are normally replaced by other activities. Mouthing (putting everything in the mouth) and slobbering, which should end by 1 year of age, also persist. There are only fleeting signs of interest in toys, and the impersistence of attention becomes increasingly prominent. Vocalizations are scant, often guttural, piercing, or high-pitched and feeble. Babbling is not replaced by attempts at word formation at the usual time.

In the second type, early motor milestones (supporting the head, rolling over, sitting, standing, and walking) are attained approximately at their normal times, yet

the infant is inattentive and slow in learning the usual nursery tricks. It seems as though motor development had somehow escaped the retardation process. There may, however, be aimless overactivity and persistence of rhythmic movements, grinding of the teeth (bruxism), and hypotonia.

Because the developmental sequence of motor function and speech may be normal, even to the point where the baby acquires a few words by the end of the first year, the examiner may be misled into thinking that the delayed infant was at first normal and had then deteriorated. In such infants it can even be shown that various test procedures yield lower scores with progressing age (from 3 years onward); this is not the result of a decline in ability but of the fact that the tests are not comparable at different times. In the early years, the tests are weighted toward sensorimotor functions and after that toward perception, memory, and concept formation. Interestingly, the development of language depends upon both groups of functions, needing a certain maturation of the auditory and motor apparatus at the start and highly specialized cognitive skills for continued development. These and other aspects of development of speech and language were considered earlier in this chapter and are commented on further in Chaps. 23 and 38.

Members of both groups of these mildly delayed individuals exhibit a number of noteworthy features that have medical and social implications. Although not overtly dysmorphic and having a normal or low-normal head circumference, they have a high incidence of minor congenital anomalies of the eyes, face, mouth, ears, and hands; they tend to be sickly, and the more severely affected among them have poor physiques and are often under-sized. Difficult behavior occurs frequently, most often taking the form of poor self-control and aggressiveness, especially pronounced in children with temporal lobe epilepsy. Other behavioral disturbances are restlessness, repetitive activity, explosive rage reactions and tantrums, stereotyped play, and the seeking of sensory experiences in unusual ways (Chess and Hassibi). Pica (the compulsive ingestion of nonnutritive substances) is a problem between ages 2 and 4 years of age, but is also seen in normal, neglected children.

An endless debate is centered on matters of causation—whether this category of mild delay is the product of genetic influence or of societal discrimination and lack of training and education coupled with the effects of malnutrition, infections, or other exogenous factors. Surely both factors are at work, with the genetic being dominant for the reasons discussed above, although the relative importance of each has proved difficult to determine (Moser et al).

A pathologic basis for most cases of mild developmental delay has not been established and new methodologies, perhaps relating to neuronal connectivity, will be needed if the brains of these individuals are to be differentiated from normal children. Differences might be expected in terms of the number of neurons in thalamic nuclei and cortex, in dendritic-axonal connectivity, or in synaptic surfaces, elements that are not being assayed by

the conventional techniques of tissue neuropathology. The observations of Huttenlocher, who found a sparsity of dendritic arborization in Golgi-Cox preparations, and of Purpura, who found an absence of short, thick spines on dendrites of cortical neurons and other abnormalities of dendritic spines, are first steps in this direction but require confirmation.

Genetic Aspects of Nonsyndromic Developmental Delay

Sex linkage is a notable feature of some types of mild developmental delay. The fragile X syndrome, discussed later, is the most important of this group, predominating in males and accounting for approximately 10 percent of all cases of male developmental delay. These individuals may be physically normal except for large testicles. Renpenning and colleagues reported a series of 21 developmentally delayed males in three generations of a Canadian family, all free of any congenital malformations and with normal head size, and Turner and coworkers have described a similar Australian series. Other X-linked forms of developmental delay that have few or no dysmorphic features include the Partington, Lowe, Lesch-Nyhan, and Menkes syndromes and adrenoleukodystrophy, each with special characteristics in addition to developmental delay, as discussed in Chap. 37. Numerous other X-linked retardation syndromes with profound accompanying neurologic anomalies have been delineated; for example, the one caused by a mutation in the oligophrenin gene, in which there is epilepsy, and another involving cerebellar hypoplasia. The relationship of intelligence in general to the X chromosome is discussed in Chap. 21.

However, there is emerging information relating autosomal mutations, rather than X-linked ones, in genes that control synaptic function such as SYNGAP1, and non-dysmorphic developmental delay as detailed in the publication by Hamdan and coworkers. There are approximately 30 X-linked and 6 autosomal recessive genes associated with nonsyndromic developmental delay and more are sure to be found. Investigated from another perspective, de Ligt and colleagues sequenced the coding regions of over 21,000 genes in a series of 100 individuals with IQ below 50 and found that there were numerous *de novo* mutations that involved cerebral development of function. Together, all of the aforementioned genetic alterations, mutations, lesser polymorphisms and copy number variants, account for approximately 15 to 20 percent of cases of mild, moderate, and severe developmental delay and autism. Most are *de novo* mutations, making their discovery difficult. The challenge will be to elucidate the manner in which they disrupt cerebral development on a synaptic or subcellular level.

Diagnosis

Infants should be considered at risk for developmental delay when there is a family history of mental slowness, low birth weight in relation to the length of gestation (small-for-date babies), marked prematurity, maternal

infection early in pregnancy (especially rubella), and toxemia of pregnancy. In the first few months of life, certain of the behavioral characteristics described above are of value in predicting developmental delay. Prechtel and associates have found that a low Apgar score (especially at 5 min after delivery, Table 28-3), flaccidity, underactivity, and asymmetrical neurologic signs are the earliest indices of subnormality in the infant. Slow habituation of orienting reactions to novel auditory and visual stimuli and the presence of "fine motor deficits" (as previously discussed under "Delays in Motor Development") are other early warnings of developmental delay.

In the first year or two of life, suspicion of developmental delay is based largely on clinical impression, but it should always be validated by psychometric procedures. Most pediatric neurologists use some of the criteria laid down by Gesell and Amatruda or the Denver Developmental Screening Scale, from which a DQ is calculated.

For testing of preschool children, the Wechsler Preschool and Primary Scale of Intelligence is used, and for school-age children, the Wechsler Intelligence Scale for Children is preferred. IQ tests for preschoolers must be interpreted with caution, as they have had less predictive validity for school success than the tests that are used after 6 years of age. In general, however, normal scores for age on any of these tests essentially eliminate developmental delay as a cause of poor school achievement and learning disabilities; special cognitive defects may, however, be revealed by low scores on particular subtests. Developmentally delayed children not only have low scores but exhibit more scatter of subtest scores. Also, like demented adults, they generally achieve greater success with performance than with verbal items. It is essential that the physician know the conditions of testing, for poor scores may be due to fright, inadequate motivation, lapses in attention, dyslexia, or a subtle auditory or visual defect rather than a developmental lag.

The EEG, in addition to exposing asymptomatic seizure activity, shows a high incidence of other abnormalities in the developmentally delayed child. Presumably this is because of a greater degree of immaturity of the cerebrum at any given age. However, a normal EEG is not infrequent and of relatively little help. Moreover, CT scanning and MRI have been singularly unhelpful in revealing abnormalities in this group of children.

In the diagnosis of milder grades of retardation, the possible effects of severe malnutrition, neglect and deprivation, chronic systemic disease, iodine deficiency, impaired hearing and vision, and possibly childhood psychosis should be considered. *Of particular importance is the differentiation of a group of patients who are normal for a variable period after birth and then manifest a progressive decline from disease of the nervous system.* This type of disorder is representative of the group of hereditary metabolic and degenerative diseases discussed in Chap. 37. Seizure disorders (and antiepileptic medications) can impair cerebral function, and several special childhood seizure disorders are associated with a progressive decline in mental function in this group of patients (see Chap. 16).

Management of Mild Developmental Delay

Because there is little or no possibility of restoring function to a nervous system that is developmentally or structurally damaged, the medical objective is to assist in planning for the patient's training, education, and social and occupational adjustments. As Voltaire remarked long ago, guidance is needed more than education. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he can acquire, to the fullest extent possible, self-help skills, self-control, good work habits, and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life. Special schooling enables such patients to realize their full potential. Social factors that contribute to underachievement must be eliminated if possible. Later, there is need for advice about possible occupational attainments. Great care must be exercised in deciding about institutionalization. Whereas severe degrees of retardation are all too apparent by the first or second year, less-severe degrees are difficult to recognize early. As stated above, psychologic tests alone are not trustworthy. The method of assessment suggested many years ago by Fernald still has a ring of soundness. It includes (1) physical examination, (2) family background, (3) developmental history, (4) school progress (grade achieved), (5) performance in schoolwork (tests of reading, arithmetic, etc.), (6) practical knowledge, (7) social behavior, (8) industrial efficiency, (9) moral reactions, and (10) intelligence as measured by psychologic tests. All these data except (5) and (10) can be obtained by a skillful physician during the initial medical and neurologic examination and are used to guide the family in its difficult decisions.

SEVERE FORMS OF DEVELOPMENTAL DELAY

The subject of developmental delay was introduced in Chap. 28, where it was pointed out that two major categories of this disorder have been delineated. In one, and by far the more common group, the mental limitation is relatively mild, allowing the individual to succeed with training and education; it is often familial and is featured by a lack of definite neurologic abnormalities (except possibly a slightly higher incidence of seizures) and the absence of neuropathologic changes. A large part of this group, falling between 2 and 3 standard deviations below the normal mean IQ, probably are the lower end of the Gaussian curve of intelligence, the converse of which is genius. This group is, however, contaminated with a small number of defined diseases of the nervous system occurring in a less-severe form. In a second group, the degree of developmental delay is usually more severe (IQ of 50 to 70), and yet more so in the third group (IQ less than 50 or not measurable because of limitations of cooperation or physical impediments). Most of the cases in the second and third groups are nonfamilial, and a wide variety of

neuropathologic changes are in evidence. The subdivisions are not absolute, for there are a few metabolic and developmental diseases in which developmental delay is profound yet with no somatic or neurologic abnormalities and, most importantly, well-defined neuropathologic changes are lacking. Here we refer to conditions such as Rett syndrome, autism, and the X-linked developmental delay syndromes (Renpenning and fragile X types). In this chapter, these major types of *severe developmental delay* are described.

The overall frequency of severe developmental delay cannot be stated precisely. Rough estimates place the figure at 0.2 to 0.4 percent of the general population and at approximately 10 percent of the general developmentally delayed segment of society. It is important to emphasize that in a large proportion of individuals with severe developmental delay, a particular congenital abnormality or anomaly of development cannot at present be traced to any of the disorders reviewed in the preceding pages. More precisely stated, when groups of such severely impaired patients are studied clinically, a reasonably accurate etiologic determination of the underlying brain disease can be made in only slightly more than half. According to Penrose, chromosomal abnormalities account for 15 percent, single-gene disorders for 7 percent, and environmental agents for 20 percent. More recent studies of the subtelomeric parts of chromosomes reportedly find abnormalities in another 7 percent of severely retarded children (Knight et al). No cause is found for the remaining cases. Males outnumber females 3 to 1.

However, from the neuropathologic standpoint, *the examination of the brains of the severely developmentally delayed by conventional histopathologic methods discloses lesions in approximately 90 percent, and in fully three-quarters of the entire group, an etiologic diagnosis can be determined or tentatively assigned.* Many of the remaining 10 percent lack definite pathologic changes, but their brains are lighter in weight by 10 to 15 percent than age-matched normal brains. Interestingly, the proportion of vascular, hypoxic-ischemic, metabolic, and genetic lesions in this group of severely impaired individuals is much the same as is found in a group selected on the basis of "cerebral palsy."

Here it is important to repeat a point made earlier and in Chap. 28: A few of the severely disabled and a large majority of the mildly affected do not have a recognizable cerebral pathology or exhibit any of the familiar and conventional signs of cerebral disease. Although the milder forms of developmental delay tend to be familial, this does not by itself separate them from the severe forms of developmental delay. There are several types of hereditary developmental delay, in which the retardation may be severe and in some of which there may be maldevelopment of the cerebral cortex. These are discussed further on.

Clinical Characteristics of the Severely Developmentally Delayed

These cases can be broadly divided into four groups. In one large group, designated *dysmorphic retardation*, a variety of physical deformities, including microcephaly, is

commonly present. In a second group, with *multiple-system retardation*, the developmental delay is linked to nonskeletal abnormalities (e.g., hepatosplenomegaly, hematologic and skin disorders), which provide reliable clues to the underlying somatic disease. In a third group, *neurologic retardation*, somatic abnormalities are lacking but a configuration of neurologic signs leads to the diagnosis. In the fourth group, and the most difficult one to clarify, that comprising *uncomplicated retardation*, there are no or minimal somatic, visceral, or neurologic abnormalities. One is then forced to turn to special features of the developmental delay itself for identification of the underlying disease. Table 38-8 elaborates a reasonable classification of the types of developmental delay.

The profoundly developmentally delayed infant with a virtually untestable IQ is identified early in life because he does not sit, stand, or walk. If any one of these motor activities is acquired, it appears late and is imperfectly performed. Language never develops; at most a few spoken words or phrases are understood and fewer are uttered, or the patient only vocalizes in a meaningless way. Such a person may not even indicate bodily needs for food, drink, excretion, and so on. Usually the patient is continuously idle and interacts little with people and objects. Only the most primitive emotional reactions are exhibited, often without connection to an appropriate stimulus. Physical growth is usually retarded, nutrition may be poor, and susceptibility to infections is increased. Sphincteric control may never be attained and, if attained, is precarious.

When the mental defect is less severe than described above, falling into the IQ ranges of 20 to 45, or 45 to 70, there may be somatic neurologic abnormalities. If specific motor defects do not coexist, then sitting, standing, and walking are achieved but not at the expected times. The existence of a mental defect is most clearly evidenced by a delay in psychomotor development and a failure to speak by the second or third postnatal year. The patient does not acquire the usual household and play activities as well as other children. However, delay in speech development must not, by itself, be taken as a mark of developmental delay, for in some children a unique delay in speech can be an isolated abnormality as described in Chap. 28, with subsequent normal development of speech and mental ability. Toilet training may be difficult to accomplish in the developmentally delayed child, but, again, bedwetting may be a problem in an otherwise normal child. Also, the deaf child may have to be considered separately; here the problem becomes apparent by an indifference to noise and reduced vocalization (stereotypy of babbling).

More thorough analyses of cognitive functions in the moderately cognitively impaired child have been undertaken by O'Connor and Hermelin, Pulsifer, and others. These authors measured the efficiency of visual and auditory perception, adequacy of communication, relations between language development and thought, crossmodal sensory encoding, alertness, attention, and memory. It was concluded that none of these functions was specifically impaired. Instead, the child could not properly encode new information because the memory systems and the stock of past assimilated knowledge were insufficient to provide a framework

Table 38-8

TYPES OF SEVERE DEVELOPMENTAL DELAY

- I. Dysmorphic defect with somatic developmental abnormalities in nonnervous structures
 - A. Those affecting cranioskeletal structures
 1. Microcephaly
 2. Macrocephaly
 3. Hydrocephalus (including myelomeningocele with Chiari malformation and associated cerebral anomalies)
 4. Down syndrome
 5. Cretinism (congenital hypothyroidism)
 6. Mucopolysaccharidoses (Hurler, Hunter, and Sanfilippo types)
 7. Acrocephalosyndactyly (craniosostenosis) and other craniosomatic abnormalities
 8. Arthrogryposis multiplex congenita (in certain cases)
 9. Rare specific syndromes: De Lange
 10. Dwarfism, short stature: Russel-Silver dwarf, Seckel bird-headed dwarf, Rubinstein-Taybi dwarf, Cockayne-Neel dwarf, etc.
 11. Hypertelorism, median cleft face syndromes, agenesis of corpus callosum
 - B. Those affecting nonskeletal structures
 1. Neurocutaneous syndromes: tuberous sclerosis, Sturge-Weber, neurofibromatosis
 2. Congenital rubella syndrome (deafness, blindness, congenital heart disease, small stature)
 3. Chromosomal disorders: Down syndrome, some cases of Klinefelter syndrome (XXY), XYY, Turner (XO) syndrome (occasionally), and others
 4. Laurence-Moon-Biedl syndrome (retinitis pigmentosa, obesity, polydactyly)
 5. Eye disorders: toxoplasmosis (chorioretinitis), galactosemia (cataract), congenital rubella
 6. Prader-Willi syndrome (obesity, hypogonadism)
- II. Nondysmorphic mental defect without somatic anomalies but with cerebral and other neurologic abnormalities
 - A. Cerebral spastic diplegia
 - B. Cerebral hemiplegia, unilateral or bilateral
 - C. Congenital choreoathetosis or ataxia
 1. Kernicterus
 2. Status marmoratus
 - D. Congenital ataxia
 - E. Congenital atonic diplegia
 - F. Syndromes resulting from hypoglycemia, trauma, meningitis, and encephalitis
 - G. Associated with other neuromuscular abnormalities (muscular dystrophy, cerebellar ataxia, etc.)
 - H. Cerebral degenerative diseases (lipidoses)
 - I. Associated with inborn errors of metabolism (phenylketonuria, other aminoacidurias, organic acidurias, Lesch-Nyhan syndrome)
 - J. Congenital infections (some cases of congenital syphilis, cytomegalic inclusion disease)
- III. Genetic mental defect with minor or no signs of somatic abnormality or neurologic disorder
 - A. Infantile autism, Rappaport, Williams, fragile X, Partington, and Rett syndromes

of items and categories with which new information could be integrated. Some patients also seemed unable, perhaps on the basis of this encoding problem, to extract from perceived material selective features that could be interpreted. Furthermore, they were unable to deal with an array of sensory experiences like normal children. The complexity of these mental operations, which we

would reduce to a global failure of the normal processes of apperception and integration, was called by Piaget a "failure of assimilation and accommodation." However, within the spectrum of developmental delay, apart from cognitive impairments, there are curious differences in behavior and personality, even in those with more or less the same IQ. Some individuals with moderately severe retardation are pleasant and amiable and achieve a satisfactory social adjustment. This is particularly notable in patients with Down and Williams syndromes. At the opposite end of the behavioral scale are the syndromes of autism and that of Smith-Magenis and of DeLange, in which the individual fails to manifest normal interpersonal social contact, including communicative language. The phenylketonuric child is usually irritable, unaffectionate, and implacable, and the same is said of certain other forms of retardation, discussed earlier in the section on retardation with dwarfism.

Regarding differences in motor activity levels, many developmentally delayed individuals are slow, clumsy, and relatively akinetic. Others, as many as half, display an incessant hyperactivity characterized by a restless, seemingly inquisitive searching of the environment. When thwarted, they may exhibit a low frustration tolerance. They may be destructive and recklessly fearless and impervious to the risk of injury. Some exhibit a peculiar anhedonia that renders them indifferent to both punishment and reward. Other aberrant types of behaviors, such as violent aggressiveness and self-mutilation, are common.

Rhythmic rocking, head-banging, incessant arm movements—so-called *rhythmi* or *movement stereotypies*—are observed in the majority of those who are severely and moderately severely impaired. These movements are maintained hour after hour without fatigue and may be accompanied by breathing sounds, squeals, and other exclamations. A number of them tend to be particularly common in certain forms of retardation: hand-flapping in autism, handwringing in Rett syndrome, and hand-waving in Down syndrome and other disorders. Self-stimulation, even hurtful—such as striking the forehead or ears or biting the fingers and forearms—seems to be compulsive or perhaps to provide some sort of satisfaction. It is not that these rhythmi are by themselves abnormal, for some of them occur for brief periods in normal babies, but that they persist. Nevertheless, many moderately delayed persons, when assigned to a simple task such as putting envelopes in a box, can continue this activity under supervision for several hours.

In the least-severe types of retardation, all the mental activities are intact but subnormal. The point to be made is that all aspects of intellectual life, personality, and deportment are affected in slightly differing degrees and that these effects have a neurologic basis. There is more than a hint that in particular diseases, because of their anatomy, the cognitive experience, affective life, and behavior are affected in special ways.

The group of moderately delayed, like the severely affected ones, is divisible into groups with somatic systemic and neurologic abnormalities, although the proportions are not the same. There are fewer of the dysmorphic type and more of the nondysmorphic, nonneurologic group.

Etiology of Severe Developmental Delay

From Table 38-1 it is obvious that many diseases can blight the development and maturation of the brain. Some of these are acquired and some are congenital and hereditary. Some affect all parts of the organism, giving rise to associated dermal, skeletal, and visceral abnormalities, while others affect only the nervous system in particular patterns. With respect especially to the *milder degrees of developmental delay*, in all populations thus far studied, infants of extremely low birth weight are more likely to have disabilities, brain abnormalities, and poorer language development and scholastic achievement (see Chap. 28). Mild developmental delay also tends to correlate with lower social status, which must relate in some manner to biological factors, as pointed out in the Scottish Low-Birth-Weight Study. Viral and spirochetal infections and parturitional accidents are other common causes. They act acutely and are theoretically preventable.

The factor of malnutrition during the fetal or infantile period of life as a cause of severe developmental delay has received considerable attention because it is a worldwide problem. Animal experiments by Winick and others demonstrated that severe undernutrition in early life leads to behavioral abnormalities and biochemical and morphologic changes in the brain, which may be permanent (see Chap. 41). Galler studied a group of infants in Barbados who were severely malnourished during the first year of life and then given an adequate diet. These children were followed to adulthood and compared with normally nourished siblings. No effect was observed on physical growth, but there were persistent attention deficits in 60 percent of the undernourished group and in only 15 percent of controls. The IQ scores of the former were also lower. Unfortunately, genetic factors could not be completely controlled for. In general, it may be said that the data showing developmental delay to be caused by malnutrition, while suggestive, are far from convincing.

Severe protein-calorie malnutrition in the first 8 months of life, which induces kwashiorkor, has been reported to retard mental development. However, such patients are said to regain mental function when fed. The authors have been impressed with the ability of the nervous system to withstand the effects of nutritional deficiency, perhaps better than any other organ.

The action of exogenous toxins during pregnancy is another factor to be considered. Severe maternal alcoholism has been linked to a dysmorphic syndrome and developmental delay, but the findings of several studies have not been consistent (see Chap. 42); a similar problem attaches maternal exposure to anticonvulsant medications (see Chap. 16). Surprisingly, maternal addiction to opiates, while causing an opiate withdrawal in infants for weeks or even months (Wilson et al), seems not to result in permanent injury to the nervous system. The importance of exposure to extremely small amounts of environmental lead is also controversial.

The effect of psychological deprivation on cognitive development has been of interest. Following the observations that complete isolation of young female monkeys

had a devastating effect on their later sexual and nurturing behavior, the idea became popular that such deprivation might cause faulty mental development in humans. Orphaned and neglected babies were found to be inactive, apathetic, and backward in comparison with those who were constantly stimulated by caring mothers. But surprisingly, when nurtured properly at a later time, these babies soon caught up with their peers. This general idea of psychologic deprivation has been the basis of many interesting educational programs for poor and neglected children. To this day, however, it has not been proven that sensory, emotional, and psychologic deprivations of a degree observed in humans are the causes of severe developmental delay or repeated scholastic failure. The controversies regarding the effects of prematurity, maternal hypertension, and eclampsia, which are often associated with neonatal cerebral pathology and slowed psychomotor development, have been mentioned earlier in this chapter. The problem is complex and the argument's pro and con have been elaborated by Haywood and Wachs.

A Clinical Approach to Developmental Delay

As a particular guide to the pediatrician and neurologist who must assume responsibility for the diagnosis and management of backward children harboring a wide array of diseases and maldevelopments of the nervous system, the following clinical approach is suggested. First, as already described, there is an advantage in setting aside as one large group those who are only mildly developmentally delayed from those who have been severely delayed in psychomotor development since early life. With regard to the former group, having no obvious neurologic signs or physical stigmata, one should nevertheless initiate a search for the common metabolic, chromosomal, and infective diseases. In this large group, one must be sure that their deficit is a general one and not one of hearing, poor sight, or the special isolated language and attention deficits.

For patients with moderately severe and very severe cognitive deficits, one begins with a careful physical examination, searching specifically for somatic stigmata and neurologic signs. Abnormalities of eyes, nose, lips, ears, fingers, and toes are particularly important, as are head circumference and a variety of neurologic abnormalities, as outlined in Table 38-8. Data so obtained allow classification into one of three categories, as follows:

In those with somatic abnormalities (with or without obvious neurologic signs), one assumes the presence of a maldevelopment of the brain, possibly caused by a chromosomal abnormality. The psychomotor retardation is usually severe and often nongenetic and, as a rule, has a well-defined neuropathology. Diagnosis is determined by the gestalt of physical signs. The possible maldevelopments are numerous and diverse and are summarized in Tables 38-1 and 38-9; some of the main ones are described earlier in the chapter. Inevitably, one turns to the several atlases to denominate the syndromes (Holmes et al; Jones).

In the group in which the *abnormalities are confined to the nervous system*, attention is focused on a larger number

of diseases, many caused by exogenous factors such as perinatal hypoxia-ischemia, pre- or postnatal infections, trauma, and so on. There are usually conspicuous neurologic signs. The degree of developmental delay is variable, depending on the location and extent of a demonstrable neuropathology. Usually the family history is negative, but careful questioning of parents regarding the pregnancy, delivery, and early postnatal period and examination of hospital records from birth may disclose the nature of the neurologic insult.

The third category is one in which *neither somatic anomalies nor focal neurologic signs* are present, or if present, they are minimal. The more severely delayed in cognitive development of this special group are represented by the following disease states: autism (Asperger-Kanner syndrome), the Rett and Williams syndromes, and the fragile X and Renspenning syndromes. All of these but autism are now known to have a genetic basis as noted earlier in the chapter and are described together below.

The practical importance of this clinical approach is that it directs the intelligent use of laboratory procedures for confirmation of the diagnosis. CT scanning and MRI are useful in clarifying maldevelopment and neurologic diseases but are seldom helpful in the third group of cases. EEG confirms seizure discharges when there is uncertainty as to the nature of episodic neural dysfunction. Karyotyping and genetic studies are useful in group 1 and rarely in group 2.

A major pitfall in this clinical approach is in mistaking a hereditary metabolic disease for a developmental one. Here one is helped by the fact that manifestations of the metabolic diseases are not usually present in the first days of life; they appear later and are progressive and often associated with specific visceral abnormalities. However, some metabolic diseases are of such slow progression that they appear almost stable, especially the late-onset ones, such as one type of metachromatic leukodystrophy, late-onset Krabbe leukodystrophy, adult adrenoleukodystrophy, and adult hexosaminidase deficiency (see Chap. 37).

Hereditary Developmental Delays

Fragile X Syndrome (See earlier discussion under "Other Chromosomal Dysgeneses")

There has been great interest in this syndrome, which some geneticists hold accountable at least in part for the preponderance of developmentally delayed males in whom an etiology could not be previously established. A large kindred in whom developmental delay was inherited in an X-linked pattern was first reported by Martin and Bell in 1943. It was in such a family, with X-linked developmental delay, that Lubs, in 1969, discovered a fragile site at the distal end of the long arm of the X chromosome; subsequently, it was established that there is an unstable inherited CGG repeating sequence at this site, which leads to breakage, as discussed previously. At first, it was assumed that the fragile X syndrome was only an example of the Renspenning syndrome (an X-linked hereditary developmental delay in males; see below)

until it was pointed out that in this latter condition, stature was reduced, as was the cranial circumference, and further that the X chromosomes of the Renpenning patients were normal. The nature of chromosomal breakage that can be attributed to an expanded trinucleotide repeat sequence of the *FMR1* gene and a resultant loss of protein function were discussed earlier in "Other Chromosomal Dysgeneses."

In some series, fully 10 percent of developmentally delayed males have this fragile X chromosomal abnormality, although 2 to 4 percent is more accurate according to other series. Females are sometimes affected, but their mental function is only slightly reduced. Affected males have only mild dysmorphic features (large ears, broad forehead, elongated face, and enlarged testes) that may not become obvious until puberty. Others are somatically normal. Behavioral problems of one sort or another are almost universal. Pulsifer, whose review of the neuropsychologic aspects of developmental delay is recommended, lists self-injurious, hyperactive, and impulsive behaviors as the most common. The hand-flapping that is more characteristic of autism may be seen.

Fragile X Premutation Syndrome of Adults As discussed in Chap. 5, a curious form of progressive adult onset ataxia and tremor, previously thought to be of a degenerative type, has been discovered to be caused by a "premutation" of the fragile X gene (50 to 200 trinucleotide repeats). Some of these patients have characteristic symmetrical signal MRI changes in the middle cerebellar peduncles in the T2 sequence. Other unusual late presentations have been described, including a spastic paraparesis without ataxia or tremor (Cellini et al). A report by Grigsby and coworkers suggests that cognitive function may be diminished in these men, but only when adjusted for their level of education and not compared to normative data; the observation requires confirmation and any suggestions that a fragile X premutation is responsible for dementia in adults should be accepted cautiously. The permutation expansion may be manifest in women as premature ovarian failure. In contrast to the mutation that causes developmental delay, this disorder is thought to be related in some way to an excess of messenger RNA. Several papers suggest that the premutation may also be the cause of some cases of mild retardation and autistic-like behavior.

Rett Syndrome

This is yet another hereditary form of developmental delay, but one that affects girls. None of the cases in the extensive studies of Hagberg and coworkers (1983) was male. The responsible spontaneous mutation was shown to relate to a defect at chromosomal site Xq28, making it one of the X-linked developmental delays. A fatal outcome in boys because of a severe neonatal encephalopathy explains the expression of the disease only in girls, who are mosaics for the mutation. The involved gene, *MECP2*, is responsible for suppressing various other genes at critical stages of development (see Dunn and MacLeod). It has this effect by binding to methylated DNA. Defective function of the gene leads to

an alteration in synaptogenesis and neural connectivity (Neul and Zoghbi). Severe inactivation of gene expression causes classic Rett syndrome, but it has become apparent that incomplete expression and mosaicism lead to a number of partial syndromes, including nonspecific developmental delay, tremor, psychiatric disturbances, and autism-like presentations.

Prevalence studies from Sweden indicate an occurrence of 1 per 10,000 girls; thus Rett syndrome is more common than phenylketonuria. Although most cases appear to be sporadic, there is a high familial incidence and some degree of concordance in twins (this is still uncertain).

The syndrome is usually marked by withdrawn behavior that simulates autism, dementia, ataxia, loss of purposeful hand movements, and respiratory irregularities. Highly characteristic is a period of 6 to 18 months of normal development followed by the rapid appearance and progression of all these signs, and then by relative stability for decades. Spasticity, muscle wasting, scoliosis, and lower limb deformities may become evident in the late stages of the illness. Handwringing and similar stereotypes are very typical features (and are different in subtle ways from the hand-flapping of autistic children).

Armstrong and Naidu, who have reviewed the neuropathology of Rett syndrome, have drawn attention to a number of subtle cortical abnormalities, most of which are consistent with disruption of the postnatal integrative phase of cerebral development; however, not all cases showed these abnormalities. There is generally a decrease in brain size, most marked frontally. Dendritic branching is reduced in several areas. The MRI scan is normal, but some patients show frontal or cerebellar atrophy in their teenage years.

Partington Syndrome

This is yet another X-linked type of developmental delay, which in its fully expressed form is associated with prominent dystonia of the hands and sometimes of the feet, or ataxia. Like Rett syndrome, discussed above, variations in gene expression appear to cause other syndromes including myoclonic epilepsy, West syndrome, autism, and nonspecific retardation, as well as lissencephaly. The mutated gene, termed Aristaless-related homeobox (*ARX*), is involved with regulation of protein-DNA interactions. The subject is reviewed by Sherr.

Renpenning Syndrome

A similar type of hereditary, male-sex-linked developmental delay was described by Renpenning and associates (and subsequently associated with Renpenning's name). The originally described family comprised 21 males in 2 generations of Mennonites in western Canada whose IQs ranged from 30 to 40. It has now been described in 15 families. As with the fragile X syndrome, female siblings may show slight degrees of retardation. Affected members were small in stature and slightly microcephalic but otherwise free of somatic and neurologic abnormalities. The mutated gene responsible is *PQBPL*, the polyglutamine binding protein of which produces the syndrome through unknown means.

Williams (Williams-Beuren) Syndrome

This inherited form of developmental delay is manifest in both males and females and was mentioned earlier. It is characterized by mild and variable developmental delay but with sometimes striking retention and even precocity or superiority of musical aptitude and social amiability. In some instances, a retained facility for writing permits the production of long, written descriptions; yet at the same time, these subjects are barely able to draw simple objects. The child is physically slow and has minor but distinctive somatic changes (wide mouth, almond-shaped eyes, short upturned nose, flat nasal bridge, long philtrum, delicate chin, and small pointed ears), together imparting an “elfin appearance” that is nonetheless variable and not as apparent in adulthood as the facial features coarsen. There is often an unusual sensitivity to auditory stimuli. The delay in acquisition of communicative speech and defects in visual, spatial, and motor skills make these children seem more deficient than they actually are. Striking sociability and empathy set them apart; they represent virtually the converse of autism in this respect. Memory for musical scores—such as memorizing parts of a complete symphony after one hearing—may be prodigious.

By the use of high-resolution cytogenetics, the disease was traced in over 90 percent of cases to a deletion on chromosome 7 in the *ELN* gene that controls the production of elastin (Nickerson et al). This is of interest because one index feature of these cases is supravalvular aortic stenosis and variations (but not necessarily deletions) in the same gene account for cases of familial supravalvular stenosis without developmental delay. This cardiovascular disease is the main cause of death in these individuals.

It is not known whether there is a characteristic brain pathology, but one 35-year-old patient examined by Golden and associates showed no cerebral abnormalities except for Alzheimer changes, mainly plaque formation in the entorhinal cortex and amygdala. The laboratory diagnosis can be established by the use of *ELN*-specific probes or other techniques that show only one allele of the gene. A most interesting related finding by Somerville and colleagues is that duplication at the same site on chromosome 7 implicated in Williams syndrome can cause a delay in the acquisition of expressive speech. The reader is referred to an extremely thorough clinical and genetic review of the syndrome by Pober.

Doublecortin Mutations

Among the disorders of cerebral sulcation, lissencephaly and the related disorder of subcortical band heterotopia are usually associated with severe defects in mental development. However, in female carriers, other mutations in the doublecortin gene (*DCX*) on the X chromosome have given rise to mild nondysmorphic developmental delay and cryptogenic epilepsy (see Guerrini and colleagues). Thus this disorder joins the group of X-linked developmental delays with minimal dysmorphic features and has implications for the understanding of X-chromosome inactivation in female carriers.

Autism (Kanner-Asperger Syndrome; Autistic Spectrum Disorders)

This condition was described almost simultaneously by Kanner in Baltimore (in 1943) and Asperger in Vienna (in 1944). Among a large group of developmentally delayed children, Kanner observed exceptional ones who appeared to be *asocial, lacking in communicative skills both verbal and nonverbal, and committed to repetitive ritualistic behaviors*. At the same time certain intellectual capacities—such as focused attention, retentive memory, skilled sensory and motor aptitudes, and capacity for visuospatial perception—were often retained or overly developed. In other words, the disorder pervaded only certain aspects of mental development.

It is the gestalt of negative and positive aptitudes that sets this syndrome apart from other types of delay. Kanner incorrectly ascribed the condition to psychosocial factors—such as a cold, aloof parent—and regarded it as a psychopathy. The implication that these children are literally “autistic”—that is, that they have a rich inner psychic life or dream world out of relation to reality—is an assumption wholly without foundation. Asperger, whose observations included somewhat older children who were less completely disabled, later ascribed the retardation (also incorrectly) to a metabolic disease, possibly related to hyperammonemia. Opinion varied as to the relationship between the severe Kanner syndrome and the less-severe Asperger syndrome. The authors have taken the more modern view that these forms of autism represent a single syndrome of varying severity, with similar pathologic underpinnings but possibly of multiple etiologies, including genetic. Some 1 percent of autistic children are of normal or superior intelligence.

In our opinion, the overarching issues in classification have become (1) the existence or embedding of autistic traits in a vast number of syndromes that are characterized by developmental delay; examples of this confluence include processes as divergent as fragile X syndrome, phenylketonuria, and tuberous sclerosis; and (2) the extent and margins of the diagnosis of “autistic spectrum disorder.” If most socially awkward children are included, the disease begins to encroach on the spectrum personality structure and presents serious problems in diagnosis and the allocation of resources. With regard to the first issue of autistic elements that are part of another well-defined disease, it has become all too easy to ascribe genetic findings to that feature of the syndrome, confusing the problem of sorting out the true etiologies of a clearly identifiable clinical syndrome of autism alone. Baker takes another perspective in an article on the history of the definitions of the disorder that also comments on the DSM classification.

Despite many claims to the contrary, there is no evidence of a psychogenesis. However, as Rapin points out, behavioral modification and special education are beneficial for less-severely affected children.

The overall prevalence of the autistic state has been calculated at 4.5 to 20 per 10,000. Although there was said in the past to be no familial tendency, this is almost certainly incorrect; we have seen the disease in both identical twins and in brothers, and small familial subgroups are

known to exist. Autistic traits, without the full syndrome, are being found with increasing frequency in sibs and other family members, suggesting a polygenic inheritance. DeMyer found that 4 of 11 monozygotic twins were concordant for autism and that siblings have a 50 times greater risk of developing the disorder than normal children. Bailey and associates and also LeCouteur and associates have reported a concordance rate in monozygotic twins of 71 percent for the autistic spectrum disorder (as defined below) and 92 percent for an even broader phenotype of disordered social communication and stereotypic or obsessive behaviors. DeLong has found an increased incidence of bipolar disease in the families of one group of autistic children and superior mathematical aptitudes in other family members.

The recent elucidation of microdeletions and microduplications within chromosome 16p by Weiss and the Autism Consortium is the first hint of a genetic locus for susceptibility to autism. Despite a high degree of penetrance in individuals with these changes, the importance of these findings is as a biologic direction for research as it explains no more than 1 percent of cases. Furthermore, certain polymorphisms, particularly in the SHANK3 may explain a small number of cases and this gene has variants that appear disproportionately often in schizophrenia, leading to speculation on common biologic processes. The reader is also referred to the discussion of genetic changes in mental retardation in the earlier sections of the chapter.

Clinical Features

The autistic child is ostensibly normal at birth and may continue to be normal in achieving early behavioral sequences until 18 to 24 months of age. Then an alarming regression occurs, sometimes fairly abruptly. In some instances, the abnormality appears even before the first birthday and the child is identified as different in some way by the mother; or, if there had been a previously autistic child, she recognizes the early behavioral characteristics of the disorder. The level of activity is reduced or increased. There may be less crying and an apparent indifference to surroundings. Toys are ignored or held tenaciously. Spinning toys or running water may hold a strange fascination for the child. Cuddling may be resisted. Motor developments, on the other hand, proceed normally and may even be precocious. Later there may be an unusual sensitivity to all modes of sensory stimulation. Occasionally the onset appears to have a relationship to an injury or an upsetting experience.

Regardless of the time and rapidity of onset, the autistic child exhibits a disregard for other persons; this is typically quite striking but can be subtle in milder cases. Little or no eye contact is made, and the child is no more interested in another person than in an article of furniture. Proffered toys may be manipulated cleverly, placed in lines, or rejected. Insistence on constancy of environment may reach a point where the patient becomes distraught if even a single one of his possessions has been moved from its original place and remains distressed until it is replaced. If speech develops at all, it

is automatic (echolalic) and not used effectively to communicate. A repertoire of elaborate stereotyped movements—such as whirling of the body, manipulating an object, toe-walking, and particularly hand-flapping—are characteristic. It is important to point out, that in any sizable group of autistic children *there is a wide range of deficits in sociability, drive, affect, and communicative (verbal and gestural behavior) ability*, ranging from an a verbal, completely isolated state to considerable language skill and some capacity for attachment to certain people as well as for scholastic achievement. However, the IQ of the majority is below 70 and in 20 percent it is below 35; 1 percent, however, have normal or superior intelligence. In this higher-functioning group, taken to typify the Asperger syndrome, the child may be unusually adept or even supernormal in reading, calculating, drawing, or memorizing (“idiot savant”) while still having difficulty in adjusting socially and emotionally to others and in interpreting the actions of others. Many are clumsy and inept in athletic activities. The least degree of deficit allows success in a professional field but with handicap in the social sphere.

We take the current emphasis on the term *autistic spectrum disorders* to reflect a concept that each of the core elements of autism (in social, language, cognitive, and behavioral domains) may occur in widely varying degrees of severity. This view expands the diagnosis to many children who are highly functional except for a tendency to gaze aversion and other “soft signs,” together called “pervasive developmental disorder” (Filipek). There is also crossover with a number of namable developmental delays as noted below.

Rapin, drawing on a large clinical experience, has carefully documented the linguistic, cognitive, and behavioral features of the syndrome. She uses the term *semantic-pragmatic disorder* to designate the characteristic problem with language and behavior and to distinguish it from other forms of developmental disorders and developmental delay. There is a striking ability to understand isolated facts but not to comprehend concepts or conceptual groupings; consequently, these children and adults seem to have difficulty generalizing from an idea. Temple Grandin, a patient with a high-functioning Asperger type of autism who has written of her experiences and has been described by Sacks, indicates that she thinks in pictures rather than in semantic language. She reports a curious comfort from being tightly swaddled and has a highly developed emotional sensibility to the experiences of cattle, which has allowed her success in reforming and designing abattoirs. According to Eisenberg, who reviewed many of Kanner’s original cases and followed many other cases into adult life, one-third never spoke and remained social isolates, one-third acquired a rudimentary language devoid of communicative value, and the remainder were functional to various degrees, possessing an affected, stilted, colorless speech. It is in the latter group, representing the mildest degrees of autism, that one finds eccentrics, the mirthless, flat personalities, unable to adapt socially and habitually avoiding eye contact but sometimes possessing certain unusual aptitudes

in memory, mathematics, factual knowledge, history, and science. Rutter, who has written extensively on the subject, says that the degree of language impairment and lowered intelligence predicts outcome; those who do not speak by 5 years of age will never learn to speak well.

As mentioned, elements of autism, but not the whole syndrome with its positive and negative attributes, may appear in other diseases that interfere with brain development, specifically fragile X and Rett syndromes, and fragmentary similarities are found in a few children with phenylketonuria, tuberous sclerosis, Angelman syndrome, and, rarely, Down syndrome—but these patients are easily distinguished from those with the far more common type of autism. Bolton and Griffiths have made the intriguing observation that autistic traits in patients with tuberous sclerosis correspond to the finding of tubers in the temporal lobe, and DeLong and Heinz point out that patients with seizures from bilateral (but not unilateral) hippocampal sclerosis may fail to develop (or may lose) language ability as well as failing to acquire social skills after a period of normal development, in a manner similar to autism.

Etiology and Pathology of Autism

The basis of childhood autism is as much a mystery today as it was when Kanner and Asperger described it. Most of these children are physically normal except for a slightly larger head size, on average, but with no other somatic anomalies. Despite instances in which the onset of mental and behavioral regression seems to be quite sudden, no environmental factors, including the often-mentioned measles-mumps-rubella (MMR) vaccination, mercury exposure, and food allergies, have been credibly connected to autism. The genetic microdeletions and microduplications described earlier have given few hints as to the biologic cause.

The EEG is normal, as is CT or MRI. The significance of cerebellar vermal changes, reported originally by Courchesne and colleagues, remains uncertain (Filipek). In the few brains examined postmortem, no lesions of any of the conventional types have been found. In 5 brains studied in serial sections by Bauman and Kemper, smallness of neurons and increased packing density were observed in the medial temporal areas (hippocampus, subiculum, entorhinal cortex), amygdala and septal nuclei, and mammillary bodies. In a subsequent review of the neuropathology, Kemper and Bauman concluded that three changes stood out: a curtailment of the normal development of neurons in the limbic system; a decrease in the number of Purkinje cells that appears to be congenital; and age-related changes in the size and number of the neurons in the diagonal band of Broca (located in the basal frontal and septal region), as well as in the cerebellar nuclei and inferior olive. The latter changes were inferred from studying the brains of autistic children who died at different ages, and they gave the appearance of a progressive or ongoing pathology that continues into adult life. These findings are in keeping with the concept of autism as a neurodevelopmental disorder, but they allow only speculation regarding the derivation of the

clinical features of the disease. An increased concentration of platelet serotonin and low serum serotonin is detected in many but not all patients; also, serum oxytocin is reduced. The biologic significance of these findings is unclear.

Course, Treatment, and Prognosis

The disease is essentially nonprogressive although some patients, as they grow older, begin to manifest additional visuoperceptive or auditory defects. In the typical case, the outcome is bleak, although many less affected children show improvement in social relationships and schoolwork when given a serotonin reuptake inhibitor, sometimes in very small doses (DeLong; Filipek, personal communication). Administration of the peptide secretin had produced a number of anecdotal successes, but this could not be reproduced in controlled studies. Selective serotonin reuptake inhibitors (e.g., fluoxetine, citalopram) have also shown some benefit in managing repetitive behaviors and mood swings such that medications in this class are being widely prescribed to autistic children. In addition, serious behavioral changes such as self-injurious activities, aggression, and severe tantrums have been treated with drugs such as risperidone. These represent a therapeutic advance but, as pointed out by Hollander and colleagues in their review of the drug treatment of autism, the patients studied were selected for the severity and type of their symptoms for which reason these medications cannot be expected to be of help to all autistic individuals.

Management of Developmental Delay

Because there is little or no possibility of treating most of the diseases underlying developmental delay and there is no way of restoring function to a nervous system that is developmentally subnormal, the objective is to assist in planning for the patient's care, training, education, and social adjustment. The parents must be guided in forming realistic attitudes and expectations. Psychiatric and social counseling may help the family to maintain gentle but firm support of the patient so that he can acquire, to the fullest extent possible, good work habits and a congenial personality.

Most individuals with an IQ above 60 and no other handicaps can be trained to live an independent life; special schooling may enable them to learn skills useful in a vocation. Social factors that contribute to underachievement must be sought and eliminated if possible.

If the IQ is below 20, institutionalization is almost inevitable, for few families can provide the long-term custodial care that is needed. Well-run institutions are usually better than community homes because they offer many more facilities (medical, educational, recreational). Often institutional care is necessary for individuals with IQs of 20 to 50. Patients in this group, if stable in temperament and relatively well adjusted to society, can work under supervision, but they rarely become vocationally independent. For the more severely cognitively impaired, special training in hygiene and self-care is the most that can be expected.

Great care must be exercised in recommending institutionalization. Whereas the need will be all too apparent in the gravely impaired by the first or second year of life, the less-severely affected are difficult to evaluate at an early age. As stated earlier, psychologic tests alone are not altogether trustworthy. It is best to observe the patient over a period of time. As noted in Chap. 28, the method of evaluation suggested long ago by Fernald has a ring of

soundness, albeit in quite dated terms. It should include observations of (1) the physical, medical, and neurologic findings; (2) family background; (3) developmental history; (4) school progress or lack thereof; (5) performance tests; (6) social behavior; (7) industrial efficiency; (8) behavioral disinhibition, which was called in Fernald's time "moral behavior"; and (9) intelligence as measured by psychologic tests.

Degenerative Diseases of the Nervous System

The adjective *degenerative* has no great appeal to the modern neurologist. It is also not an entirely satisfactory term medically, as it implies an inexplicable decline from a previous level of normalcy to a lower level of function—an ambiguous conceptualization of disease that satisfies neither a clinician nor a scientist. Moreover, it gives no hint as to the fundamental causation of a process and in all likelihood combines a number of mechanisms under 1 nondescript term. It would be tempting to attribute all progressive disease of the nervous system that are of unknown cause to degeneration. The problem is that many degenerative diseases of mundane type are caused in a proportion of cases by germ line genetic changes. All are currently called *degenerative*, but this nosology may be a transitional method of holding a place while awaiting more refined understanding. What is lacking at the moment is a precise subcellular mechanism for cellular loss; that is knowledge that a protein aggregates within or between cells is not equivalent to understanding the cause of an illness.

Gowers in 1902 suggested the term *abiotrophy* to encompass the degenerative diseases, by which he meant a lack of “vital endurance” of the affected neurons, resulting in their premature death. This concept embodies an unproven hypothesis—that aging and degenerative changes of cells are based on the same process. Understandably, contemporary neuropathologists are reluctant to attribute to simple aging the diverse processes of cellular diseases that are constantly being revealed by ultrastructural and molecular genetic techniques. It is increasingly evident that many of the diseases included in this category depend on genetic factors. Some appear in more than one member of the same family, in which case they may be properly designated as *heredodegenerative*. Even more diseases, not differing in any fundamental way from the heredodegenerative ones, occur sporadically, that is as isolated instances but still, genetic factors such as single nucleotide polymorphisms and copy number variations are often involved in pathogenesis.

Degeneration is nonetheless used as a clinical and pathologic term that refers to a process of neuronal, myelin, or tissue breakdown, the degradative products of which evoke a reaction of phagocytosis and cellular astrogliosis. What characterizes the degenerative disease as much as the loss of cells is the concentration of damage in functionally related cells, or systems; for example the

cerebral cortex, motor system, extrapyramidal apparatus, or cerebellum, which are representative of the structures that are the targets of damage in this class of disease.

The basis of aging changes is also explainable at the neuronal level, but the nature of these alterations is not understood. A fundamental problem is the distinction of these aging deteriorations from degenerative disease. When a degenerative neurological disease appears in adult life, one must assume that the clinical presentation is modified to some extent by life-cycle phenomena—the patient’s function being a sum of both processes. However, their separation is of fundamental importance in diagnosis and therapeutics. One has to reconcile the fact that most degenerative diseases manifest themselves in later life, leading to the tentative conclusion that some aspect of the aging process is entwined with the cellular degenerations of disease. This creates a problem for the clinician, who may be inclined to attribute changes in a person’s function to aging alone rather than searching for a disease that may allow for treatment or for specific prognostication and counseling. Moreover, a long-standing uncertainty pertains to certain degenerative conditions such as Alzheimer disease, which becomes so prevalent in later age as to offer the possibility that the disease is an invariable aspect of aging rather than an acquired perturbation in cellular function. For most degenerative diseases of the nervous system, however, this inevitability of occurrence with aging is clearly not the case. For example, the proportional incidence of Alzheimer pathologic change decreases continuously from age 70 to age 100 according to Savva and colleagues. This polemic regarding aging and degenerative disease is irresolvable and exposes difficulties with meaning of the term “disease.” If the human being lived another 50 years beyond the current expectation, would all nervous structures show the changes of degenerative disease? The answer is probably “no,” as there are distinctive cellular and subcellular features of degenerative diseases that are different from the uncomplicated, programmed loss of cells that is due to aging.

Much new and essential information has been gained regarding the biologic derangements that lead to neuronal death and dysfunction as a result of investigating the inherited forms of degenerative diseases. The application of the techniques of molecular genetics to these diseases has given stunning results. Even when the hereditary

form of a degenerative condition is rare in comparison to the sporadic type, general principles have been exposed that are common to the mechanisms of both forms of the disorder. This approach holds promise for effective treatment of what heretofore have been considered progressive and incurable diseases.

It has been proposed that all degenerative diseases be classified according to their genetic and molecular abnormalities. However, when one notes the diversity of pathologic change that may accompany a single, seemingly unitary gene abnormality or, reciprocally, the diversity of genetic defects that may underlie a single phenotype, this type of classification does not prove immediately helpful to the clinician. In other words, the practice of creating new disease categories to encompass all the molecular and pathologic changes associated with a particular type of neuronal degeneration offers no great advantage in practice. For example, certain diseases are unified by the deposition of proteins such as tau and have been termed "tauopathies," "synucleinopathies," "amyloidopathies," and so forth. We endorse a more useful clinical approach that is based on an awareness of constellations of clinical features that relate to degeneration of neural systems. Until such time as the causation of the degenerative neurologic diseases is known, there must be a name and a place for a group of diseases that are united only by the common attribute of gradually progressive disintegration of a part or parts of the nervous system.

General Clinical Characteristics of Degenerative Diseases

The diseases included in the degenerative category have 2 outstanding characteristics: (1) *They affect specific parts or functional systems of the nervous system* and (2) *They begin insidiously, after a long period of normal nervous system function, and pursue a gradually progressive course*. Frequently, it is impossible to assign a date of onset. The patient or the patient's family may give a history of the abrupt appearance of disability, particularly if some injury, infection, surgical procedure, stroke, or other memorable event coincided with the initial symptoms. A skillfully taken history will reveal that there had been subtle symptoms for some time but had attracted little attention. Whether trauma or other stress can actually evoke or aggravate a degenerative disease is a question that cannot be answered with certainty; at present, evidence to this effect is largely anecdotal. Instead, these degenerative disease processes, by their very nature, appear to develop *de novo*, without relation to known antecedent events, and their symptomatic expressions are late events in the pathologic process, occurring only when the degree of neuronal loss exceeds the ability of a system to function at a clinically acceptable level. Irreversibility and steady progression of clinical manifestations when measured over periods of months or years is another feature common to the neurodegenerative conditions. However, several of these diseases sometimes display periods of relative stability.

Although most degenerative disease do not manifest expression in other members of the family, the *familial occurrence* of degenerative disease is of great importance

both clinically and for scientific reasons as mentioned earlier, but such information is often difficult to obtain. The family may be small or widely scattered, so that the patient is unaware of the health of other members. The patient or the patient's relatives may be reluctant to acknowledge that a neurologic disease has affected another family member. Furthermore, it may not be realized that an illness is hereditary if other members of the family have a much more or much less severe, or a different form of the disorder than the patient. Or paternity may be in question. Even without clear familial occurrence, the patient's ethnicity may give clues to a propensity for certain diseases. Sometimes only the careful examination of other family members will disclose the presence of a hereditary disease. Also, it should be remembered that familial occurrence of a disease does not necessarily mean that it is inherited, but may indicate instead that more than one member of a family had been exposed to the same infectious or toxic agent.

Many symptoms of degenerative disease, while not currently curable, can be alleviated by skillful management. The physician's interest and advice are invaluable to the patient and his family by way of providing support, perspective, and information. This accords with the highest calling of the physician's abilities to relieve suffering.

General Pathologic and Pathogenic Features

Most of the degenerative diseases, as emphasized in the earlier general comments, are characterized by the *selective involvement of anatomically and physiologically related systems of neurons*. This feature is exemplified by amyotrophic lateral sclerosis (ALS), in which the pathologic process is virtually limited to motor neurons of the cerebral cortex, brainstem, and spinal cord, and by the progressive ataxias, in which only the Purkinje cells of the cerebellum are affected. Many other examples could be cited (e.g., Friedreich ataxia, Parkinson disease) in which discrete neuronal systems disintegrate, leaving others unscathed. Thus, these degenerative diseases had in the past been called *system atrophies*. The selective vulnerability of certain systems of neurons is not an exclusive property of the degenerative diseases; several different processes of known cause have similarly circumscribed effects on the nervous system. Contrariwise, in many degenerative diseases, the pathologic changes are somewhat less selective and eventually quite diffuse. Even then, there is an early tendency to involve special categories of neurons.

As one would expect of any pathologic process that is based on the slow wasting and loss of neurons, not only the cell bodies but also their dendrites, axons, and myelin sheaths disappear, unaccompanied by an intense tissue reaction or cellular response. The cerebrospinal fluid (CSF) shows little, if any, change, or at most a slight increase in protein content. Moreover, because these diseases invariably result in tissue loss, imaging examination shows either no change or only a volumetric reduction (atrophy) with a corresponding passive enlargement of the CSF compartments. These findings distinguish the neuronal atrophies from other large classes of progressive disease of the nervous system, namely, tumors, infections, and processes of inflammatory type.

At the cellular level, several processes characterize the death of individual cells. Among these mechanisms is *apoptosis*, a term borrowed from embryology to specify the mechanisms that lead to neuronal degeneration. The original meaning of the term refers to a naturally occurring cell death during development that is driven by the expression of genes over a short period of time (i.e., “programmed” cell death), leaving no trace of a pathologic reaction. The process of neuronal degeneration is quite different in that it refers to a series of changes in mature neurons that occur over a protracted period of time, leading to cell death and often leaving a discrete glial scar, but not to regional tissue necrosis. In some models of degenerative disease, cell loss involves activation of specialized genes, although the time course and cellular morphology are not apoptotic in the original sense of the term. It is increasingly apparent that mechanisms other than programmed cell death will prove central to understanding the degenerative diseases, and that the clinical features of these conditions are manifest even before cellular destruction occurs. For example, interference with synaptic signaling and dysfunction of supporting glia cells are equally important to morphologic neuronal death.

It will become clear in the following discussion that the current theme in the study of degenerative diseases is that of aggregation within specific neurons of normal cellular proteins such as amyloid, tau, synuclein, ubiquitin, and huntingtin. In some cases, the protein is overproduced as a result of the simple fact of a triplication or overactivity of its corresponding gene. In other instances, enzymatic cleavage of a normal precursor protein yields a product with physical properties that lead to its aggregation (as happens with amyloid in Alzheimer disease) or, there may be failure of the normal mechanisms of protein removal, resulting in its excess accumulation. As mentioned above, this has resulted in the denomination of groups of diseases by the type of protein aggregate: tauopathy, synucleinopathy, etc. Even this is an uncertain or intermediate classification as it is not known in most cases if the protein is the cause or the result of cellular damage, and in any case, the fundamental mechanisms of cellular destruction are still being determined.

Another characteristic that has guided understanding of degenerative disease is the possible contiguous “spread” of protein aggregation from one to another region by synaptic connections. In some cases, this results in adjacent regions being affected sequentially and in others, circuits that are functionally integrated but not necessarily contiguous areas are affected. This geographic mechanism, proposed by Braak and Braak, conforms to certain pathologic observations such as the sequential appearance of synuclein in the olfactory system, thence in the Meissner-Auerbach plexus of the gut, followed by the vagus, to involvement of the vagal nuclei in the medulla, ascending trans-synaptically to the pons and midbrain nuclei. Whether this accounts for the selectivity of disease in areas such as the substantia nigra that is most affected in Parkinson disease, is not entirely known. In any case, the biologic and the physicochemical properties of these aggregated proteins have assumed great importance and

the mechanisms by which they interfere with cellular function and potentially cause cell death are major areas of research in the degenerative diseases.

CLINICAL CLASSIFICATION

Because grouping of the degenerative diseases in terms of etiology is not entirely possible (except that a hereditary or genetic factor can be recognized in some), we resort for practical purposes to a division based on the presenting clinical syndromes and their pathologic anatomy. Although this is the most elementary mode of classification of naturally occurring phenomena, it is a necessary prelude to diagnosis and scientific study and preferable to a purely genetic or molecular classification. It is certainly an improvement on a haphazard listing of diseases by the names of the neurologists or neuropathologists who first described them. For reasons given in the introduction to this chapter, this approach remains the most effective in analyzing the problem presented by an individual patient. The main clinical categories are as follows:

- I. Syndrome of progressive dementia, other neurologic signs absent or inconspicuous
 - A. Alzheimer disease
 - B. Some cases of Lewy-body disease
 - C. Frontotemporal dementias—Pick disease, including behavioral variant, primary progressive aphasia (several types)
 - D. Posterior cortical atrophy (visuospatial dementia)
- II. Syndrome of progressive dementia in combination with other neurologic abnormalities
 - A. Huntington disease (chorea)
 - B. Lewy-body disease (parkinsonian features)
 - C. Some cases of Parkinson disease
 - D. Corticobasal ganglionic degeneration (rigidity, dystonia)
 - E. Cortical-striatal-spinal degeneration (Jakob disease)
 - F. Dementia-Parkinson-amyotrophic lateral sclerosis complex
 - G. Cerebrocerebellar degeneration
 - H. Familial dementia with spastic paraparesis, amyotrophy, or myoclonus
 - I. Polyglucosan body disease (neuropathy)
 - J. Frontotemporal dementia with parkinsonism or ALS
- III. Syndrome of disordered posture and movement
 - A. Parkinson disease
 - B. Multiple system atrophy, MSA-P (striatonigral degeneration, Shy-Drager syndrome)
 - C. Progressive supranuclear palsy
 - D. Dystonia musculorum deformans
 - E. Huntington disease (chorea)
 - F. Acanthocytosis with chorea
 - G. Corticobasal ganglionic degeneration
 - H. Lewy-body disease
 - I. Restricted dystonias, including spasmodic torticollis and Meige syndrome
 - J. Essential tremor

- IV. Syndrome of progressive ataxia
 - A. Spinocerebellar ataxias
 - 1. Friedreich ataxia
 - 2. Non-Friedreich, early-onset ataxia (with retained reflexes, tremor, hypogonadism, myoclonus, and other disorders)
 - B. Cerebellar cortical ataxias
 - 1. Holmes type of familial pure cerebellar-olivary atrophy
 - 2. Late-onset cerebellar atrophy
 - C. Complicated hereditary and sporadic cerebellar ataxias (later-onset ataxia with brainstem and other neurologic disorders)
 - 1. Multiple system atrophies (MSA-C) including olivopontocerebellar degenerations (OPCA)
 - 2. Dentatorubral degeneration (Ramsay Hunt type)
 - 3. Dentatorubropallidoluysian atrophy (DRPLA)
 - 4. Machado-Joseph (Azorean) disease; SCA-3
 - 5. Other complicated late-onset, autosomal dominant ataxias with pigmentary retinopathy, ophthalmoplegia, slow eye movements, polyneuropathy, optic atrophy, deafness, extrapyramidal features, and dementia
- V. Syndrome of slowly developing muscular weakness and atrophy
 - A. Motor disorders with amyotrophy
 - 1. Amyotrophic lateral sclerosis

DISEASES CHARACTERIZED MAINLY BY PROGRESSIVE DEMENTIA

Alzheimer Disease

This is the most common and important degenerative disease of the brain, having an immense societal impact. Some aspects of the intellectual deterioration that characterize this disease were described in Chap. 21, under “The Neurology of Dementia,” and the still ambiguous relationship of this disease to the aging process is mentioned above and in Chap. 29. There it was pointed out that some degree of shrinkage in size and weight of the brain, that is “atrophy,” is an inevitable accompaniment of advancing age, but that these changes alone are of relatively slight clinical significance and uncertain structural basis (e.g., whether the loss of brain weight aging is the result of a simple depletion of neurons). By contrast, severe degrees of diffuse cerebral atrophy that evolve over a few years are associated with dementia, and the underlying pathologic changes in these cases most often prove to be those of Alzheimer disease. As also commented on in Chap. 29, the rate of cerebral atrophy, specifically of the hippocampus and medial parts of the temporal lobes, is accelerated in the early stages of Alzheimer disease, and longitudinal studies by magnetic resonance imaging can identify individuals who will subsequently develop the disease (Rusinick). Nevertheless, there is not a continuous increase in the deposition of plaques and tangles, the pathologic markers of Alzheimer disease, with increasing age. Therefore, Alzheimer changes are not an inevitable result of aging.

The now outdated practice of giving Alzheimer disease and senile dementia the status of separate diseases is attributable to the relatively young age (51 years) of the patient originally studied by Alois Alzheimer in 1907. Such a division is no longer tenable, as the 2 conditions, except for their age of onset, are clinically and pathologically indistinguishable. It is probably useful to consider as related but separable, the several hereditary forms of Alzheimer disease discussed below.

Epidemiology

Although Alzheimer disease has been described at every period of adult life, the majority of patients are in their sixties or older; a relatively small number have been in their late fifties or younger. It is one of the most frequent mental illnesses, making up a large proportion of persons in assisted living and skilled nursing facilities. The incidence of clinically diagnosed Alzheimer disease is similar throughout the world, and it increases with age, approximating 3 new cases yearly per 100,000 persons younger than age 60 years and a staggering 125 new cases per 100,000 of those older than age 60 years. The prevalence of the disease per 100,000 population is near 300 in the group aged 60 to 69 years; it is 3,200 in the 70- to 79-year-old group and 10,800 in those older than age 80. In the year 2008, there were estimated to be more than 2 million persons with Alzheimer disease in the

United States. (It should be borne in mind that these are not pathologically proven cases and, while probably correct as an approximation, are likely combined with other diseases.) Prevalence rates, which depend also on overall mortality, are 3 times higher in women, although the incidence of new cases is only slightly disproportionate in women. The survival of patients with Alzheimer disease is reduced to half the expected rate, mainly because of respiratory and cardiovascular causes and inanition, but also for other reasons that are not entirely clear.

Several putative epidemiologic risk factors for Alzheimer disease, such as birth order, mother's age at birth, and a family history of Down syndrome seem marginal at best and in some instances may be a result of selection bias. Depression and possibly head injuries do seem to confer a somewhat increased risk later in life. Whether low educational attainment is a risk factor for the development of Alzheimer disease or, conversely, whether cognitively demanding occupations or higher intelligence protects against dementia is still under discussion. Provocative data indicating that inherent intellectual endowment is important were presented in Chap. 21 (Katzman; Cobb et al). Finally, associations between diabetes or hyperglycemia and dementia, in general, have emerged from epidemiologic studies, for example, one reported by Crane and coworkers, but the ostensible mechanism by which this confers risk has not been established. In their report, a higher than average glucose level over the preceding 5 years conferred a slightly increased risk of dementia but not necessarily of Alzheimer disease.

The *familial occurrence* of Alzheimer disease has been well established. In less than 1 percent of such cases there is a dominant inheritance pattern with a high degree of penetrance and appearance of disease at a younger age (Nee et al; Goudsmit et al; see further). Reports of substantial familial aggregations of dementia without a specific pattern of inheritance also suggest the operation of more than one genetic factor. Many studies have documented an increase in the risk of ostensibly sporadic Alzheimer disease among first-degree relatives of patients with this disorder. Again, this risk is disproportionately greater in females, adding to the evidence that women in general are at slightly higher risk for Alzheimer disease (Silverman et al). Li and coworkers have provided evidence that patients with an earlier age of onset of Alzheimer disease (before age 70 years) are more likely to have relatives with the disease than are patients with later onset. Genetic studies are difficult to carry out because the disease does not appear at the same age in a given proband. Even in identical twins, the disease may develop at the age of 60 years in one of the pair and at 80 years in the other. Death from other causes may prevent its detection. The other genetic contributions to the occurrence of Alzheimer disease are discussed extensively further on.

Clinical Features (See also Chap. 21)

The onset of mental changes is usually so insidious that neither the family nor the patient can date the time of its beginning and most patients come to attention months or years after the decline began. Occasionally, however, the process becomes manifest by an unusual degree of

confusion in relation to a febrile illness, an operation, mild head injury, or the institution of a new medication. Other patients have as their initial complaints dizziness, mental fogginess, nondescript headaches, or other vaguely expressed and changeable somatic symptoms.

The gradual development of forgetfulness is the major symptom. Small day-to-day happenings are not remembered. Seldom-used names become particularly elusive. Little-used words from an earlier period of life also tend to be lost. Appointments are forgotten and possessions misplaced. Questions are repeated again and again, the patient having forgotten what was just discussed. It is said that remote memories are preserved and recent ones lost (the Ribot law of memory), but this is only relatively true and it is difficult to check the accuracy of distant personal memories. For example, Albert and associates, who tested Alzheimer patients' recognition of dated political events and pictures of prominent people past and present, found that some degree of memory loss extends to all previous decades of the person's life (neuropsychologic testing is discussed further on).

Once the memory disorder has become pronounced in the prototypic disorder, other failures in cerebral function become increasingly apparent. The patient's speech is halting because of failure to access the needed word. The same difficulty interrupts writing. Vocabulary becomes restricted, and expressive language becomes stereotyped and inflexible. Comprehension of spoken words seems at first to be preserved, until it is observed that the patient does not carry out a complicated request; even then it is uncertain whether the request was not understood because of inattention or because it was forgotten. Almost imperceptible at first, these disturbances of language become increasingly apparent as the disease progresses. The range of vocabulary and the accuracy of spelling are reduced. Finally, after many years of illness, there is a failure to speak in full sentences; the finding of words requires a continuous search; and little that is said or written is fully comprehended. There is a tendency to repeat a question before answering it, and later there may be a rather dramatic repetition of every spoken phrase (*echolalia*). The deterioration of verbal skills has by then progressed beyond a groping for names and common nouns to an obvious anomic aphasia. Other elements of receptive and executive aphasia are later added, but discrete aphasias of the Broca or Wernicke type are characteristically lacking. In general, there is a paucity of speech and a quantitative reduction in mentation.

Skill in arithmetic suffers a similar deterioration. Faults in balancing the checkbook, mistakes in figuring the price of items and in making the correct change; all these and others progress to a point where the patient can no longer carry out the simplest calculations (*acalculia* or *dyscalculia*).

In some patients, visuospatial orientation becomes defective. The car cannot be parked; the arms do not find the correct sleeves of the jacket or shirt; the corners of the tablecloth cannot be oriented with the corners of the table; the patient turns in the wrong direction on the way home or becomes lost. The route from one place to another cannot be described, nor can given directions

be understood. As this state worsens, the simplest of geometric forms and patterns cannot be copied.

Late in the course of the illness, the patient forgets how to use common objects and tools while retaining the necessary motor power and coordination for these activities. The razor is no longer correctly applied to the face; the latch of the door cannot be unfastened; and eating utensils are used awkwardly. Finally, only the most habitual and virtually automatic actions are preserved. Tests of commanded and demonstrated actions cannot be executed or imitated. *Ideational* and *ideomotor apraxia* are the terms applied to the advanced forms of this motor incapacity as described in Chaps. 3 and 22.

As these many amnesic, aphasic, agnostic, and apraxic deficits declare themselves, the patient at first seems unchanged in overall motility, behavior, temperament, and conduct. Social graces, whatever they were, are retained in the initial phase of the illness, but troublesome alterations may gradually appear in this sphere as well. Imprudent business deals may be made. Restlessness and agitation or their opposites—*inertia* and *placidity*—become evident. Dressing, shaving, and bathing are neglected. Anxieties and phobias, particularly fear of being left alone, may emerge. A disturbance of the normal day and night sleep patterns is prominent in some patients. A poorly organized paranoid delusional state, sometimes with hallucinations, may become manifest. The patient may suspect his elderly wife of having an illicit relationship or his children of stealing his possessions. A stable marriage may be disrupted by the patient's infatuation with a younger person or by sexual indiscretions, which may astonish the community. The patient's affect coarsens; he is more egocentric and indifferent to the feelings and reactions of others. A gluttonous appetite sometimes develops, but more often eating is neglected, resulting in gradual weight loss. Later, grasping and sucking reflexes and other signs of frontal lobe disorder are readily elicited (Neary et al), sphincteric continence fails, and the patient sinks into a state of relative akinesia and mutism, as described in Chap. 21.

Difficulty in locomotion, a kind of unsteadiness with shortened steps but with only slight motor weakness and rigidity, frequently supervenes. Elements of parkinsonian akinesia and rigidity and a fine tremor can be perceived in patients with advanced stages of the disease. Ultimately, the patient loses the ability to stand and walk, being forced to lie inert in bed and having to be fed and bathed, the legs curled into a fixed posture of paraplegia in flexion (in essence, a persistent vegetative state).

The symptomatic course of this illness is quite variable but usually extends over a period of 5 or more years, but judging from pathology studies, the pathologic course has a much longer asymptomatic duration. This concept of a preclinical stage is supported by the detailed studies of Linn and colleagues, who found that a lengthy period (7 years or more) of stepwise decline in memory and attention span preceded the clinical diagnosis. In the dominantly inherited forms of disease, careful studies of biomarkers in the spinal fluid and by imaging show that changes occur 15 years or longer before the clinical manifestations are apparent (Bateman et al). Throughout this

period, corticospinal and corticosensory functions, visual acuity, ocular movements, and visual fields remain intact. If there is hemiplegia, homonymous hemianopia, and the like, either the diagnosis of Alzheimer disease is incorrect or the disease has been complicated by a stroke, tumor, or subdural hematoma. Exceptions to this statement are rare. The tendon reflexes are little altered and the plantar reflexes almost always remain flexor. There is no sensory or cerebellar ataxia. Convulsions are rare until late in the illness, when up to 5 percent of patients reportedly have infrequent seizures. Occasionally, widespread myoclonic jerks or mild choreoathetotic movements are observed late in the illness. Eventually, with the patient in a bedfast state, an intercurrent infection such as aspiration pneumonia or some other disease mercifully terminates life.

The sequence of neurologic disabilities may not follow this described order and one or another deficit may take precedence, presumably because the disease process, after becoming manifest in the memory cortex of the temporal lobes, affects a particular part of the associative cortex earlier or more severely in one patient than in another. This allows a relatively restricted deficit to become the source of early medical complaint, long before the full syndrome of dementia has declared itself.

There are at least 4 limited deficits that may represent the opening features of Alzheimer disease but each of which alone may be mild enough to qualify as *mild cognitive impairment* (MCI). According to Petersen, who developed this concept, the MCI syndrome is defined by the presence of cognitive difficulties in one or all spheres that are not severe enough to interfere with daily life.

The early presentation of Alzheimer disease may manifest mainly as one of the following syndromes of the first, memory dysfunction being the most common and, even as other aspects of the disease advance, it tends to remain the most prominent.

1. *Amnesia* The early stages of Alzheimer disease are usually dominated by a disproportionate failure of episodic (autobiographical) memory, with integrity of other cognitive abilities. This may be the sole difficulty for many years. In such patients, immediate memory (essentially a measure of attention), tested by the capacity to repeat a series of numbers or words, is intact; it is the short- and long-term (retentive) memory that fails. Memory may become impaired but as a business executive, for example, the individual may continue to make acceptable decisions if the work uses long-established habit patterns and practices.
2. *Dysnomia* The forgetting of words, especially proper names, may first bring the patient to a neurologist. Later the difficulty involves common nouns and progresses to the point where fluency of speech is seriously impaired. Every sentence is broken by a pause and search for the wanted word; if the desired word is not found, a circumlocution is substituted or the sentence is left unfinished. When the patient is given a choice of words, including the one that was missed, there may be a failure of recognition. Repetition of the spoken words of others, at first flawless, later brings out a lesser degree of the same difficulty. The defect in

naming is evident with even simple tests, for example, asking the patient to generate a list of farm animals or car brands—a test that may elicit only 3 or 4 responses. A more extensive examination entails asking the patient to name as many items as possible in each of 3 categories in 1 min—vegetables, tools, and clothing. Alzheimer patients fall well below a score of 50 items.

3. *Visuospatial disorientation* Parietooccipital functions are sometimes deranged in the course of Alzheimer disease and in a few cases may fail while other functions are relatively preserved. When it occurs in a pure form it is termed *posterior cortical atrophy*, as discussed in a later section (see Renner et al). As remarked above and in Chap. 22, prosopagnosia (impaired facial recognition), losing one's way in familiar surroundings or inability to interpret a road map, to distinguish right from left, or to park or garage a car, and difficulty in setting the table or dressing are all manifestations of a special failure to orient the schema of one's body with that of surrounding space. Exceptionally, there is a neglect of stimuli in one visual field. In the late states, some of these patients develop the Balint syndrome or Gerstmann syndrome (Tang-Wai et al; McMonagle et al).
4. *Paranoia and personality changes* Occasionally, at some point in the development of Alzheimer dementia, paranoia or bizarre behavior occasionally assumes prominence. This may appear before the more obvious memory or language defects announce themselves. The patient becomes convinced that relatives are stealing his possessions or that an elderly and even infirm spouse is guilty of infidelity. He may hide his belongings, even relatively worthless ones, and go about spying on family members. Hostilities arise, and wills may be altered irrationally. Many of these patients are constantly worried, tense, and agitated. Of course, paranoid delusions may be part of a depressive psychosis and of other dementias, but most of the elderly patients in whom paranoia is the presenting problem, seem not to be depressed, and their cognitive functions are for a time relatively well preserved. Social indiscretions, rejection of old friends, embarking on imprudent financial ventures, or an amorous pursuit that is out of character are examples of these types of behavioral change.
5. *Executive dysfunction* This may be the most disabling of the main aspects of the disease and when it appears early on, is not specific to Alzheimer dementia as it is a component of several other processes that affect the frontal lobes. These patients display early difficulties in coordinating and planning tasks and following complex conversations or instructions. They may become disinclined to participate in social activities and become withdrawn or quieter than usual. As the problem advances, simpler and formerly automatic actions such as driving become problematic for the patient; the degree of insight varies. Some are able to express that they feel "confused" but more often, it is the family that brings these changes to attention.

If one of the foregoing restricted deficits remains uncomplicated over a long period, one is justified in

suspecting a cause other than Alzheimer disease, such as one of the lobar atrophies such as frontotemporal dementia (see further on), Binswanger disease, hydrocephalus, or embolic infarctions of the temporal or parietal lobes. Each of the restricted clinical disorders described above is only relatively pure. Careful testing of mental function—and this is of diagnostic importance—frequently discloses subtle abnormalities in several cognitive spheres. Initially, most patients have a disproportionate disorder of the temporoparietal cortices, reflected by an earlier impairment on the performance parts of the Wechsler Adult Intelligence Scale. Within a year or two, the more generalized aspects of mental deterioration become apparent, and the aphasic–agnosic–apraxic aspects of the syndrome become increasingly prominent. Although it is true that most patients with Alzheimer disease walk normally until relatively late in their illness, infrequently a short-stepped gait and imbalance draw attention to the disease and worsen slowly for several years before cognitive manifestations become evident. The general decrepitude in appearance that accompanies the middle and late stages of the disease in many patients is commented on in Chap. 21.

For research purposes and to establish certain inclusive and exclusive criteria for the diagnosis of Alzheimer disease, a working group of the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Diseases Association (ADRDA) had proposed the following criteria: (1) dementia defined by clinical examination, the Mini-Mental Scale (see Table 21-6), the Blessed Dementia Scale, or similar mental status examination; (2) patient older than age 40 years; (3) deficits in 2 or more areas of cognition and progressive worsening of memory and other cognitive functions, such as language, perception, and motor skills (praxis); (4) absence of disturbed consciousness; and (5) exclusion of other brain diseases (McKhann et al, 1984; Tierney et al, 1988). These criteria have essentially been reaffirmed by more recent consensus panels (see McKhann et al, 2011). Using these measures, the correct diagnosis is achieved in more than 85 percent of patients, but this is not surprising given that Alzheimer disease is overwhelmingly the most common cause of adult dementia. Most cases are identifiable without resorting to restrictive lists such as these, especially if the patient is observed serially over a period of months or years. There is strong interest in the addition of biomarkers to the diagnostic criteria for the disease but these have not reached the point of general clinical utility and the diagnosis remains predominantly a clinical one, aided by imaging and other tests.

Pathology

In the advanced stages of the disease, the brain presents a diffusely atrophied appearance and its weight is usually reduced by 20 percent or more. Cerebral convolutions are narrowed and sulci are widened. The third and lateral ventricles are symmetrically enlarged to varying degrees. Usually, the atrophic process involves the frontal, temporal, and parietal lobes, but cases vary considerably. The extreme

atrophy of the hippocampus, the most prominent finding visible on MRI (mainly coronal images), is diagnostic in the proper clinical circumstances.

Microscopically, there is widespread loss of nerve cells. Early in the disease this is most pronounced in layer II of the entorhinal cortex. In addition to marked neuronal loss in the hippocampus, adjacent parts of the medial temporal cortex—namely, the parahippocampal gyri and subiculum—are affected. The anterior nuclei of the thalamus, septal nuclei, and diagonal band of Broca, amygdala, and particular brainstem parts of the monoaminergic systems are also depleted. The cholinergic neurons of the nucleus basalis of Meynert (the substantia innominata) and locus ceruleus are also reduced in number, a finding that has aroused great interest because of its putative role of the former in memory function (see below). In the cerebral cortex, the cell loss predominantly affects the large pyramidal neurons. Residual neurons are observed to have lost volume and ribonucleoprotein; their dendrites are diminished and crowd one another owing to the loss of synapses and neuropil. Astrocytic hypertrophy (more than proliferation) is in evidence as a compensatory or reparative process, most prominent in layers III and V.

Moreover, 3 microscopic changes give this disease its distinctive character: (1) The presence within the nerve cell cytoplasm of thick, fiber-like strands of silver-staining material, also in the form of loops, coils, or tangled masses (Alzheimer neurofibrillary changes or “tangles”) (Fig. 39-1). These strands are composed of a hyperphosphorylated form of the microtubular protein, tau, and appear as pairs of helical filaments when studied ultrastructurally. (2) Spherical deposits of amorphous material scattered throughout the cerebral cortex and easily seen with periodic acid-Schiff (PAS); the core of the aggregates is the protein amyloid, surrounded by degenerating nerve terminals (*neuritic plaques*) that stains with silver. Amyloid is also scattered throughout the cerebral cortex in a nascent “diffuse” form, without organization

Figure 39-1. Photomicrograph of Alzheimer amyloid plaques and neurofibrillary tangles. Bielschowsky silver stain.

or core formation and then is appreciated mainly by immunohistochemical methods, as well as deposition in the walls of small blood vessels near the plaques, so-called congophilic angiopathy. (3) *Granulovacuolar degeneration* of neurons, most evident in the pyramidal layer of the hippocampus. This last change is least important in diagnosis but there is uncertainty regarding its nature; it had been thought to be simply a reactive process but recent studies suggest it reflects a defect in phagocytosis of degraded proteins.

Neuritic plaques and neurofibrillary changes are found in all the association areas of the cerebral cortex, but it is the neurofibrillary tangles and quantitative neuronal loss, not the amyloid plaques, that correlate best with the severity of the dementia (Arriagada et al). If any part of the brain is disproportionately affected, it is the hippocampus, particularly the CA1 and CA2 zones (of Lorente de Nó) and the entorhinal cortex, subiculum, and amygdala. These parts have abundant connections with other parts of the temporal lobe cortex and dentate gyrus of the hippocampus and undoubtedly account for the amnesic component of the dementia. The associative regions of the parietal lobes are another favored site. Only a few tangles and plaques are found in the hypothalamus, thalamus, periaqueductal region, pontine tegmentum, and granule-cell layer of the cerebellum.

Experienced neuropathologists recognize a form of Alzheimer disease, particularly in older patients (75 years), in which there are senile plaques but few or no neuronal tangles (about 20 percent of 150 cases reported by Joachim et al). Increasingly, other pathologic changes are being appreciated in Alzheimer cases with fewer plaques and tangles than anticipated for the degree of dementia; Lewy bodies in particular are found by sophisticated techniques. Another problem for the neuropathologist is to distinguish between the normal-aged brain and that of Alzheimer disease. It is not unusual to find a scattering of senile plaques in individuals who were ostensibly mentally normal during life. Anderson and Hubbard studied 27 demented individuals aged 64 to 92 years and 20 age-matched nondemented controls. In the former, 3 to 38 percent of the hippocampal neurons contained neurofibrillary tangles; in all but 2 of the controls, the number of hippocampal neurons with tangles fell below 2.5 percent. Moreover, an increased number of tangles in the aged are associated with mild cognitive impairment and a higher likelihood of progression to Alzheimer disease.

Many demented individuals with clinical features of Alzheimer disease have sufficient neuronal loss and Lewy bodies in cortex and the substantia nigra to justify a diagnosis on histopathologic grounds of Parkinson disease (see further on). Leverenz and Sumi found that 25 percent of their Alzheimer patients showed the pathologic (and clinical) changes of Parkinson disease, a much higher incidence than can be attributed to chance. Similarly, of 11 patients with progressive supranuclear palsy (also discussed further on) reported by Gearing and coworkers, 10 were demented and 5 had the neuropathologic features of Alzheimer disease. These mixed cases present problems not only of classification but also in understanding the neurobiology

of these degenerative diseases. This subject is discussed further in the section on Parkinson disease.

It is of historical interest that Alzheimer was not the first to describe plaques, one of the hallmarks of the pathologic state. Miliary lesions (*Herdchen*) had been observed in senile brains by Blocq and Marinesco in 1892 and were named *senile plaques* by Simchowicz in 1910. In 1907, Alzheimer described the case of a 51-year-old woman who died after a 5-year illness characterized by progressive dementia. Throughout the cerebral cortex he found the characteristic plaques, but he also noted, thanks to the use of Bielschowsky's newly devised silver impregnation method, a clumping and distortion of fibrils in the neuronal cytoplasm, the neurofibrillary change that now, appropriately, carries Alzheimer's name.

Pathogenesis

Analyses of the plaques and neuronal fibrillary changes have been undertaken in an attempt to elucidate the mechanism of Alzheimer disease, but so far, to little avail. Several histologic techniques assist in this endeavor, including refined methods for silver impregnation that stain both amyloid and its main constituent (beta-amyloid protein [$A\beta$]); immunostaining using antibodies specific to such proteins as ubiquitin, neuronal tau protein, and beta-amyloid protein; and visualization of β -pleated protein sheets using thioflavine S and Congo red with ultraviolet and polarized light. Tau (composed chemically of beta₂-transferrin) is a discrete cytoskeletal protein that promotes the assembly of microtubules, stabilizes their structure, and participates in synaptic plasticity in a yet to be defined manner. In the pathologic circumstances of Alzheimer disease, progressive supranuclear palsy, and frontotemporal dementia (see further on), tau is hyperphosphorylated and aggregates, resulting in paired helical filaments that make up the neurofibrillary tangles. Electrophoretically, tau moves with the β_2 -globulins and is thought to function as a transferrin, that is it binds iron and delivers it to the cell. Its concentration can be measured in the CSF and serum, but this has not yet proven clearly to be useful as a diagnostic test.

The $A\beta$ protein is a small portion of a larger entity, the *amyloid precursor protein* (APP), which is normally bound to neuronal membranes. As shown in Fig. 39-2, the $A\beta$ protein is cleaved from APP by the action of proteases termed α , β , and γ secretase. One current hypothesis, developed by Selkoe and others, focuses on the manner in which APP is cleaved by these enzymes to give rise to different-length residues of $A\beta$. During normal cellular metabolism, APP is cleaved by either α or β secretase. The products of this reaction are then cleaved by the γ -secretase isoform of the enzyme. The sequential cleavage by α and then γ produces tiny fragments that are not toxic to neurons. However, cleavage by β and then γ results in a 40-amino-acid product, $A\beta_{40}$, and a longer 42-amino-acid form. The latter $A\beta_{42}$ form is toxic in several models of Alzheimer disease, and it has been proposed that the ratio of $A\beta_{42}$ to $A\beta_{40}$ is critical to the neuronal toxicity of amyloid.

Several pieces of evidence favor the view that elevation of the levels of $A\beta_{42}$ leads to aggregation of amyloid

Figure 39-2. Diagram of proteolysis of amyloid precursor protein (APP). When APP is cleaved sequentially by β secretase and then secretase, the resulting amyloid protein can be 40 ($A\beta_{40}$) or 42 ($A\beta_{42}$) amino acids in length. The latter favors the formation of aggregated fibrillary amyloid protein (fibrillogenesis) rather than normal APP degradation. The fibrillary form of amyloid is neurotoxic, a mechanism favored as the cause of cell damage in Alzheimer disease. Formation of $A\beta_{42}$ is promoted by mutations, either in the APP gene itself or in the presenilins. In Down syndrome, excess production of APP and its product $A\beta_{42}$ is caused by triplication of the long arm of chromosome 21, the location of the APP gene. The Apo E4 allele is associated with inadequate clearance of $A\beta_{42}$ and is another mechanism that promotes fibrillogenesis. (Modified by permission from Sisodia SS, St. George-Hyslop PH: γ -Secretase, notch, $A\beta$ and Alzheimer's disease: Where do the presenilins fit in? *Nat Rev Neurosci* 3:281–290, 2002.)

and then to neuronal toxicity. It appears that the diffuse deposition of $A\beta_{42}$ precedes the formation of better-defined neurofibrils and plaques. The fact that the gene coding for APP is located on chromosome 21, one of the regions linked to one type of familial Alzheimer disease and the duplicated chromosome in Down syndrome, in which Alzheimer changes almost inevitably occur with aging (see further on), suggests that the overproduction of amyloid and all its $A\beta$ residues are causative factors in the disease. Furthermore, the ratio of $A\beta_{42}$ to $A\beta_{40}$ is increased in Down syndrome. Another suggestive connection has been the finding that there are genetic defects in the genes encoding APP and in a pair of endosomal proteins termed *presenilin 1* and *2* in some familial forms of Alzheimer disease. The presenilins interact with, or may be a component of, γ secretase, the enzyme that produces the $A\beta_{42}$ fragment. Mutations of presenilin 1 and 2 also increase the relative levels of $A\beta_{42}$. It should be noted that mutations of the APP and presenilin genes explain a very small proportion of Alzheimer cases (Terry). Transgenic mice that express human Alzheimer disease-associated mutations in APP or presenilin genes

develop plaques with A β 42 but not neurofibrillary tangles. Many of the relationships and mechanisms depicted in Fig. 39-2 are derived from the understanding of genetic forms of Alzheimer disease; the extent to which they will be implicated in the idiopathic disease is unknown. However, some form of disruption in these mechanisms is likely to be involved in the sporadic disease.

It must be emphasized, however, that there is still uncertainty regarding the relationship of amyloid deposition to the loss of neurons and brain atrophy. Alternatively, soluble oligomers of A β amyloid may be the toxic agents, whereas the emphasis until now has been on the effects of visible assemblies of insoluble amyloid fibrils. Similarly, TDP-43, the product of inadequate functioning of the progranulin gene, is also deposited in neurons and may play a substantial role in the severity of expression of Alzheimer disease; this protein has been implicated in the pathogenesis of frontotemporal dementia and motor neuron disease, both discussed later in the chapter. Others have questioned the amyloid hypothesis and pointed to the imprecise relationship between amyloid deposition and neuronal loss, even suggesting that aggregated amyloid is in some way a protective mechanism of cells.

The importance of neurofibrillary tangles has also been questioned, and the manner in which amyloid deposition relates to tangle formation is unclear. Unexplained also is prominent senile plaque formation in some cases and neurofibrillary tangles in others. One prevalent view is that the tangles are a secondary phenomenon. In their review, Hardy and Selkoe, authoritative investigators in this field, pointed out that "Although the amyloid hypothesis offers a broad framework to explain AD pathogenesis, it is currently lacking in detail, and certain observations do not fit easily with the simplest version of the hypothesis." Nonetheless, the amyloid hypothesis is currently the strongest.

In recent years, some of the subcellular mechanisms that are deranged by the presence of intracellular or extracellular amyloid have been elucidated. The finding of a reduced number and enlargement of synapses in affected cortex early in the disease by DeKosky and Scheff and others could be interpreted as either the first sign of neuronal death or the result of the neuronal loss. Amyloid deposition would then be a later, secondary phenomenon. These are complex and uncertain connections but they are among the most promising findings in this field of research.

It was long ago established that Alzheimer disease is not caused by any of the usual types of arteriosclerosis. On the other hand, several studies have indicated that the presence of cerebral infarctions, small or large, and nondescript ischemic white matter disease accelerates the deposition of amyloid and the development of neurofibrillary tangles in the brains of Alzheimer patients (see further on); the mechanism of these interactions is not understood. Not surprisingly, cerebrovascular disease also exaggerates the rate of progression and degree of dementia. How this relates to the entity of *arteriosclerotic, multiinfarct, or vascular dementia* is entirely clear. Without doubt, as discussed in Chap. 34, multiple cerebral strokes cause increasing deficits that cumulatively qualify as a dementia. At least some of the focal lesions that contribute

to the cognitive syndrome can be identified clinically and there is a stepwise decline in function that corresponds to strokes. Admittedly, this type of vascular dementia may be more difficult to recognize when a number of the infarcts are of the relatively silent lacunar type; the mental capacities of such patients may then appear to fail in a gradual and continuous fashion. Memory is relatively spared in the early stages and usually a pseudobulbar state or deterioration in gait accompanies the dementia. The subcortical white matter change of Binswanger disease causes similar diagnostic problems. We are inclined toward the view expressed in Chap. 21 and summarized in the commentary by Jagust that there is an undefined, and perhaps synergistic, interaction between strokes and progressive mental decline in patients with Alzheimer disease. Most often, in our experience, it is the degenerative condition of Alzheimer that explains the dementia. A similar relationship between Alzheimer disease and previous head injuries is tentative but has led to speculation that several types of brain injuries are conducive to the development of neurofibrillary tangles and amyloid deposition, perhaps as if they were part of a reparative response.

No relationship to premorbid personality traits earlier in life has been established, but an intriguing finding from what has become known as the "nun study" and several similar studies suggests that poorer linguistic capability early in life corresponded to the development of Alzheimer disease with aging (D.A. Snowden et al). In this study, the autobiographies of 93 nuns, written in their twenties, were rated for linguistic and ideational complexity. Of 14 sisters who died in late life, deterioration of cognitive function and neuropathologically proven Alzheimer disease occurred in 7 who had a low "idea density" in their writings and in none of 7 whose writings were cognitively more complex. Obviously this type of correlation is subject to several interpretations, but the general notion of "cognitive reserve" having either a protective property or simply hiding mental decline, has emerged from numerous other studies. Also, there has been a general perception confirmed by a few studies such as the one by Verghese and colleagues, that an active mental life may reduce the severity of mental decline with aging, but firm conclusions cannot be made from the available information.

Neurotransmitter Abnormalities Considerable interest was created in the late 1970s by the finding of a marked reduction in choline acetyltransferase (ChAT) and acetylcholine in the hippocampus and neocortex of patients with Alzheimer disease. This loss of cholinergic synthetic capacity was attributed to a reduction in the number of cells in the basal forebrain nuclei (mainly the nucleus basalis of Meynert), from which the major portion of neocortical cholinergic terminals originate (Whitehouse et al). However, a 50 percent reduction in ChAT activity has been found in regions such as the caudate nucleus, which shows neither plaques nor tangles (see review by Selkoe). The specificity of the nucleus basalis cholinergic changes has been questioned for other reasons as well. For one, Alzheimer brain also shows a loss of monoaminergic neurons and a diminution of noradrenergic, gabanergic,

and serotonergic functions in the affected neocortex. The concentration of amino acid transmitters, particularly of glutamate, is also reduced in cortical and subcortical areas (Sasaki et al) and the concentration of several neuropeptide transmitters—notably substance P, somatostatin, and cholecystokinin are likewise low—but it has not been determined whether any of these biochemical abnormalities, including the cholinergic ones, are primary or secondary to heterogeneous neuronal loss. Nevertheless, the administration of cholinomimetics—either acetylcholine precursors (e.g., choline or lecithin), degradation inhibitors (e.g., physostigmine), or muscarinic agonists that act directly on postsynaptic receptors—have had a mild and unsustained therapeutic effect (see further under “Treatment”).

Chase and associates have demonstrated a 30 percent reduction in cerebral glucose metabolism in Alzheimer disease, greatest in the parietal lobes, but this seems most likely to be secondary to tissue loss in these regions. Even if not of pathogenic significance, it finds value as a diagnostic marker of the disease. The role of aluminum in the genesis of neurofibrillary tangles, as was once proposed, has never been validated. It has been suggested that the use of estrogen by postmenopausal women or of antiinflammatory agents in men or women delayed the onset of the disease or reduced its occurrence, but neither of these have been corroborated by other studies.

Genetic Aspects of Alzheimer Disease (Table 39-1)

Of great importance was the aforementioned series of discoveries in patients with inherited forms of Alzheimer disease, of defective genes that code for errant APPs localized to chromosome 21 near the β -amyloid gene (St. George-Hyslop et al). As mentioned, this also provided an explanation for the Alzheimer changes that characterize the brains of practically all patients with the trisomy 21 defect (Down syndrome) who survive beyond their twentieth year; they overproduce amyloid as a result of the triplication of the gene. But gene defects on chromosome 21 are responsible for only a small proportion of familial cases and a minuscule percentage of disease overall. Other kindreds with familial Alzheimer disease have been linked to rare dominant mutations of the presenilin genes on chromosome 14 (presenilin 1;

Sherrington et al), accounting in some series for up to 50 percent of familial cases, and on chromosome 1 (presenilin 2), which may account for many of the remaining ones (Levy-Lahad et al). These are summarized in Table 39-1. The age of onset of the disease in these familial forms, as in the Down cases, is earlier than that in sporadic forms. These cohorts of patients have provided great insight into long duration between the appearance of amyloid in the brain, approximately a decade, and the onset of clinical disease, and they suggest the potential use of imaging of chemical biomarkers for the disease (The Dominantly Inherited Alzheimer Network; see Bateman et al).

It has been clear for some time that an excess or aberrant amyloid alone is an incomplete explanation for the disease. Certain sequence variants in normal genes confer an increased risk of the disease. The one first discovered was Apo E, a regulator of lipid metabolism that has an affinity for $A\beta$ in Alzheimer plaques, has been found to modify the risk of acquiring Alzheimer disease. Of the several isoforms of Apo E, the presence of E4 (and its corresponding allele e4 on chromosome 19) is associated with a tripling of the risk of developing sporadic Alzheimer disease (Roses; Strittmatter et al; Polvikoski et al). This is the same allele that contributes to an elevated low-density lipoprotein fraction in the serum. Possession of two e4 alleles virtually assures the development of disease in those who survive to their eighties. The e4 allele also modifies the age of onset of some of the familial forms of the disease. In contrast, the e2 allele is underrepresented among Alzheimer patients. For these reasons it has been proposed that Apo E, by interacting with APP or tau protein in some way, modifies the formation of plaques. Indeed, possession of the e4 allele correlates with increased deposition of $A\beta$ in the brain (McNamara). As pointed out by Hardy, Apo E appears to act at a point in the pathogenesis that is after the various genetic mutations have influenced the cellular pathology that ostensibly causes Alzheimer disease. However, these statistical relationships do not invariably connect an allele to the disease in a particular individual. In other words, the e4 allele does not act as a mendelian trait but as a susceptibility (risk) factor. It follows that many, if not most, individuals who develop Alzheimer disease do not

Table 39-1

MUTATIONS AND MODULATING FACTORS ASSOCIATED WITH ALZHEIMER DISEASE

GENE	PROTEIN	INHERITANCE	AGE	CLINICAL FEATURES
APP	Amyloid precursor protein	AD	Early	Rare but clinically simulates sporadic Alzheimer disease
PS1	Presenilin 1	AD	Early	As above
PS2	Presenilin 2	AD	Early	As above
Apo E	Apolipoprotein E	Haplotype	Late	Modifies susceptibility to Alzheimer disease; e-4 allele represents risk
UBQLN1	Ubiquilin 1	SNP	Late	Familial cases only
TREM2	TREM2	SNP	Late	Modulating factor as for Apo E

AD, autosomal dominant; SNP, single nucleotide polymorphism.

have the risk allele. Moreover, many individuals with the e4 allele live into their seventies and eighties without developing Alzheimer disease. All that can be stated with certainty is that, on average, the presence of the e4 allele accelerates the appearance of Alzheimer disease by about 5 years.

Another polymorphism in TREM2 is quite rare in comparison to the aforementioned Apo E variants but confers an equivalent risk of Alzheimer disease that has been shown in several populations in (Guerreiro et al and Jonsson et al). In sporadic Alzheimer disease, the TREM2 polymorphism that is implicated in Alzheimer disease putatively causes inadequate phagocytic clearance of amyloid. Another rare modifying gene has been found in familial cases at the *UBQLN1* (ubiquilin 1) site, coding for a protein that interacts with PS1 and PS2 and participates in proteasomal degradation.

Diagnostic Studies

Studies with CT and MRI are useful, but not definitive ancillary tests (Fig. 39-3). In patients with advanced Alzheimer disease, the lateral and third ventricles are enlarged to about twice the normal size and the cerebral sulci are proportionately widened. Coronal MRI of the medial temporal lobes may reveal a disproportionate atrophy of the hippocampi and a corresponding enlargement of the temporal horns of the lateral ventricles. Early in the disease, however, the changes do not exceed those found in many mentally intact old persons. For this reason, one cannot rely solely on imaging procedures for diagnosis and CT and MRI are most valuable in excluding alternative causes of dementia such as brain tumor, subdural hematoma, cerebral infarction, and hydrocephalus. The EEG undergoes mild diffuse slowing, but only late in the course of the illness; it is useful again, in the exclusion of alternative causes of mental decline that manifest themselves in seizure activity or changes typical of metabolic encephalopathy. The CSF is also normal, although occasionally the total protein is slightly elevated. Using the constellation of clinical data, cerebral imaging in the context of the age of the patient and time course of the disease, the diagnosis of dementia of Alzheimer type is made correctly in 85 to 90 percent of cases.

Of considerable value have been studies of cerebral blood flow single-photon emission computed tomography [SPECT]) and metabolism (positron emission tomography [PET]), which early in the illness often, but not always, show diminished activity in the parietal association regions and the medial temporal lobes. In most cases, when such changes are evident, the diagnosis was already obvious on clinical grounds. Newer PET ligand agents that bind to amyloid, such as the "Pittsburgh compound" and tau-ligands are more sensitive in identifying and observing the course of Alzheimer disease. Their main utility may be in detecting changes before brain atrophy is evident and in identifying patients who have the earliest changes of Alzheimer disease, whose disease course may be amenable to alteration by medications.

Neuropsychologic tests in the typical case show disproportionate deterioration in memory and verbal access skills. Testing is particularly useful when there is

Figure 39-3. *Top:* Coronal T1-weighted MRI of a 74-year-old man with moderate Alzheimer-type dementia. Diffuse cerebral and hippocampal atrophy with ex vacuo ventricular and cortical sulcal dilation is noted. *Bottom:* Coronal T1-weighted MRI of a 70-year-old woman with behavioral variant frontotemporal lobar dementia. Atrophy of the right greater than left temporal lobes is out of proportion to atrophy of the frontal and parietal lobes.

a serial decline in ability. Certain aspects of attention and executive function in Alzheimer disease that also show changes in Alzheimer disease were reviewed by Perry and Hodges. The use of these examinations is described in Chap. 21.

There are no established biologic markers of Alzheimer disease with the possible exception of the ratio of $A\beta_{42}$ to tau, in the cerebrospinal fluid (the ratio is low in Alzheimer disease). This test is used in some clinics, but may not be well enough validated for routine use (Maddalena et al). Schoonenboom and colleagues have shown that the incorporation of CSF phosphorylated tau (p-tau) with the typical CSF amyloid/tau ratio may provide additional specificity in distinguishing Alzheimer from other dementing diseases.

Differential Diagnosis of Alzheimer Disease

(See also Table 21-3)

Formerly, when virtually all forms of dementia were untreatable, there was little advantage to either the patient or the family in ascertaining the cause of the cerebral disease. There are now adequate treatments for a number of diseases and conditions that cause cognitive decline, putting a premium on proper diagnosis.

The currently potentially treatable forms of dementia are those caused by normal-pressure hydrocephalus; chronic subdural hematoma; the dementia of AIDS; paraneoplastic and related autoimmune encephalitis; nutritional deficiencies (thiamine—Wernicke-Korsakoff syndrome, Marchiafava-Bignami disease, pellagra, vitamin B₁₂ deficiency); chronic intoxication (e.g., alcohol, sedatives); multiple cerebral infarctions; certain endocrine and metabolic disorders (myxedema, Hashimoto encephalopathy), neurosyphilis and other chronic meningitides, Cushing disease, chronic hepatic encephalopathy; frontal and temporal lobe tumors; vascular dementia, cerebral vasculitis; sarcoidosis; progressive multifocal leukoencephalopathy (PML), Whipple disease; multiple sclerosis; and sometimes neglected, the pseudodementia of depression. Exclusion of most of these diseases is readily accomplished by careful history, sequential clinical evaluations, and testing of blood and CSF, EEG, CT, MRI, and neuropsychologic testing can be undertaken. We have regularly but infrequently incorporated the results of metabolic brain imaging (both FDG-PET and amyloid-ligand imaging) as well as CSF amyloid-tau ratio. We anticipate that these tests or similar ones may find more frequent use. In exceptional situations, brain biopsy may be justified in the diagnosis of dementia, almost limited to rapidly progressive cases. A perspective, albeit from a sample that cannot be generalized to practice, has been given by Warren and colleagues of 90 consecutive brain biopsies performed between 1989 and 2003 for the evaluation of dementia. More than half provided a diagnosis, mostly Alzheimer, Creutzfeldt-Jakob disease, and inflammatory disorders. However, reasonable assurances must be given to the neurosurgeon that prion disease is unlikely.

One problem in differential diagnosis is the distinction between a late-life depression and a dementia, especially when some degree of both is present. Observation over several weeks or more, and the patient's demeanor, makes the distinction clearer. Multiinfarct dementia is usually not difficult to separate from Alzheimer dementia, as discussed further on. The dementia of normal-pressure hydrocephalus may also be confused with Alzheimer dementia (see Chap. 30). The problem of distinguishing Alzheimer disease from a more "benign" form of memory decline associated with aging comes up frequently in practice, as discussed further on. These treatable conditions are discussed in Chaps. 21, 30, and 34 and the important topic of depression is addressed in Chap. 52. Often we have been confident on clinical grounds that a patient had Alzheimer disease, only to have revealed at autopsy that progressive supranuclear palsy, Lewy-body disease, Pick disease, another non-

Alzheimer degeneration of the frontal lobes, or cortical-basal-ganglionic degeneration was the cause. All are discussed later in this chapter.

Treatment

There is no evidence that any of the formerly proposed therapies for Alzheimer disease—cerebral vasodilators, stimulants, L-dopa, massive doses of vitamins B, C, and E, ginkgo biloba, hyperbaric oxygen, intravenous immunoglobulin, and many others—have any salutary effect. Trials of oral physostigmine, choline, and lecithin have yielded mostly negative or uninterpretable results.

The effect of the currently used cholinergic precursors and agonists and acetylcholinesterase inhibitors, such as donepezil, is modest. With regard to the latter group of drugs, several large trials have demonstrated a slight prolongation of the patient's ability to sustain an independent life, but such evidence generally requires that the medications be taken for 6 to 12 months. For example, a meta-analysis of the drugs collectively demonstrated a mean improvement of 2 to 3 points on the 70-point Alzheimer Disease Assessment Scale and a slight delay in progression. Despite some trials that have failed to demonstrate benefit (c.f., AD 2000 Collaborative Group), the balance of evidence favors the use of these medications in practice, but only in mildly or moderately affected patients.

Side effects of the aforementioned class of drugs may include nausea and less often, vomiting. The families of our patients report from time to time that the medication caused insomnia or increased confusion. It is worth mentioning that when the acetylcholine receptor antagonist succinylcholine is used prior to general anesthesia, its effects may be prolonged in patients taking the above drugs. The use of trazodone, haloperidol, thioridazine, risperidone, and related drugs may suppress some of the aberrant behavior and hallucinations when these are problems, making life more comfortable for both patient and family, but several trials suggest that their general application causes more problems than it solves and they must often be discontinued in response to adverse effects. The randomized trial conducted by Schneider and coworkers found that olanzapine, quetiapine, and risperidone for the treatment of psychosis, aggression, or agitation with Alzheimer disease were approximately as good as placebo in relieving these symptoms, but largely because the drugs were not tolerated. Olanzapine was slightly preferable in those who continued taking the medication. The clinician is left with little recourse but to use this class of medications or haloperidol to control unmanageable behavior. Small doses of diazepam, such as lorazepam, are useful when sleep is severely disturbed, but they often increase confusion as well.

The *N*-methyl-D-aspartate (NMDA) glutamergic antagonists, specifically memantine (20 mg daily), have also been tried. In a study of memantine by Reisberg and colleagues of 252 patients (187 of whom completed the trial), there were better results on a few scales that reflected functional behavior compared to the use of placebo, but there was no change in 3 main measures of cognitive performance. Because the side effects were

ostensibly minor, this drug has been approved for use in late-stage Alzheimer disease and in conjunction with cholinergic drugs. Nevertheless, hallucinations or agitation may occur and require discontinuation. The combination of memantine and donepezil in moderately to severely affected patients offered no benefit over either drug alone (Howard et al). The effects of these drugs in later stages of the disease are, in any case, minimal.

A provocative series of studies using a small molecule inhibitors of the enzyme γ -secretase (semagacetat; see Doody et al, 2013), and a monoclonal antibody directed at soluble forms of amyloid (solanezumab; see Doody et al, 2014) have failed to demonstrate clear benefit in early Alzheimer disease. The presumption is that such agents might be useful if started in the presymptomatic stages of disease.

A series of animal experiments that demonstrated the possibility of removal of plaques by immunization against amyloid has led to human studies with a similar vaccination. One trial was stopped because of the occurrence of an immune encephalitis in a small number of patients, but in autopsy material there were indications that this novel approach may have had the desired effect of reducing amyloid deposition (Orgogozo et al). Revised vaccines are being formulated for further testing of this approach.

Given the state of therapeutics for Alzheimer disease, always important is the general management of the demented patient, which should proceed along the lines outlined in Chap. 21, keeping in mind that the physician's counsel is often the family's main resource for important medical and social decisions.

Associated Pathologic States

As indicated earlier, the histologic changes of Alzheimer disease have a number of interesting associations. Amyloid plaques and tangle deposition are far more common in the brains of patients with Parkinson disease (20 to 30 percent) than in the brains of age-matched controls (Hakim and Mathieson). These findings partly explain the high incidence of dementia in patients with Parkinson disease (see further on). As mentioned, with the advance of Alzheimer disease, extrapyramidal features may emerge. In such cases, Burns and colleagues have found changes in the substantia nigra including accumulation of synuclein and tau representative of Lewy bodies. Another association between the 2 diseases is apparent in the *Guamanian Parkinson-dementia complex*, which is also discussed below. In this entity, the symptoms of dementia and parkinsonism are related to neurofibrillary changes in the cerebral cortex and substantia nigra, respectively; senile plaques and Lewy bodies are unusual findings. What can be deduced from the crossover syndromes is that multiple degenerative changes can occur in these diseases and give rise to heterogeneity in clinical presentation.

The finding of neurofibrillary tangles (and to a lesser extent of plaques) in boxers ("*punch-drunk syndrome*, or *dementia pugilistica*") is another interesting ramification of the Alzheimer disease process in that trauma appears to be able to elicit one of the core features of the disease as discussed in Chap. 35. Some cases of *primary progres-*

sive aphasia (see further on) have Alzheimer change and amyloid plaque deposition as the primary pathologic change. There are other unusual and meaningful associations, such as dementia with motor neuron disease or the cases of familial dementia with spastic paraplegia reported by Worster-Drought and by van Bogaert and their associates (see later in this chapter). Here, neurofibrillary change is the most prominent feature whereas amyloid plaques are negligible in number or absent.

Another provocative connection is the already mentioned interrelationship between cerebrovascular disease and Alzheimer disease. This is a complex area that at one time, considered the 2 processes to be intimately related and later, was rejected, only to now be resurrected with clearer focus, as discussed Chap 34.

Lobar Atrophies (Frontotemporal Lobar Degeneration, Posterior Lobar Degeneration)

This broad category of disease has evolved and the nosology is confusing because type of selective atrophy of a cerebral lobe may be caused by several different histopathologic changes. The notion of lobar atrophy was introduced in 1892 when Arnold Pick of Prague described a special form of cerebral degeneration in which the atrophy was circumscribed (most often in the frontal or temporal lobes), with involvement of both gray and white matter; hence the term he applied was *lobar* rather than *cortical* sclerosis. In 1911, Alzheimer presented the first careful study of the microscopic changes, followed by even more complete analyses of the pathologic changes by the prominent neuropathologists of the age. As mentioned the pathologic change associated may be any one of several types: Pick inclusion bodies, neurofibrillary tangles, other inclusions, or with no characteristic changes except for neuronal loss. Contrariwise, gliosis and mild spongiform changes in the superficial layers of cortex, and even typical plaque and tangle pathology, have all been associated with syndromes of gross atrophy of the frontal or temporal lobes. What has emerged since his work is that the most common and important of the lobar atrophies is a group of frontotemporal degenerations that have diverse clinical and pathologic profiles.

In contrast to Alzheimer disease, in which the atrophy is relatively diffuse, the pathologic change in lobar atrophy is circumscribed and often asymmetrical. The parietal lobes are involved less frequently than the frontal and temporal lobes. The affected gyri become paper thin, resembling, in the advanced stages, the kernel of a dried walnut. The cut surface reveals not only a marked narrowing of the cortical ribbon but a grayish appearance and reduced volume of the underlying white matter. The corpus callosum and anterior commissure share in the atrophy but almost certainly as secondary phenomena. The overlying pia-arachnoid is often thickened, and the ventricles are enlarged. The pre- and postcentral, superior temporal, and occipital convolutions are relatively unaffected and stand out in striking contrast to the wasted parts.

The more common frontotemporal lobar degenerations (FTLDs) (to which Pick's name was attached) may

display any one of several pathologic changes and reflect different genetic causes. For example, the behavioral or the aphasic variants of FTD, which are described below, may be the result of the deposition of tau, progranulin, amyloid, or synuclein. It is not clear to us if the term "Pick disease" is worth retaining to denote a unique process aside from the unusual type that is due to deposition of argyrophilic intracytoplasmic inclusions (Pick bodies) and diffusely staining ballooned neurons (Pick cells). In other respects, it is simply one of the large group of FTLDs. It is the lobar atrophy and marked changes in the underlying white matter that provide the unifying elements of this group of diseases.

Clinical and Pathologic Features

The descriptive terms frontotemporal lobar atrophy and frontotemporal dementia are used by neurologists and neuropathologists to refer to a clinical syndrome that is associated with degeneration of the frontal and temporal lobes. Some of the clinical aspects of frontotemporal dementia were discussed in Chap. 21, but broadly speaking, there are 2 main types: a behavioral variant and a language variant, the latter being divided into semantic dementia, progressive nonfluent aphasia, and a logopenic variant, all described below.

Behavioral Variant FTLD Patients under consideration with behavioral changes present with personality and related abnormalities that include apathy, disinhibition, perseveration, poor judgment and limited ability for abstraction, loss of empathy, bizarre affect, eating disorders, and a general disengagement. Insight is almost always impaired and some subjects become euphoric or display repetitive compulsive behaviors. An initial diagnosis of depression has been common. Other psychiatric symptoms such as sociopathic and disinhibited behavior with aspects of hyperorality and hyperphagia may predominate late in the illness. Utilization behavior (the compulsive use of implements and tools put before the patient) is also displayed in advanced cases.

CT, MRI, and functional imaging demonstrate a disproportionate atrophy and hypofunction in the frontal lobes, usually asymmetric. A proportion of patients with this type of frontotemporal dementia have parkinsonian features. A form of motor neuron disease is also linked to frontotemporal dementia in a small number of cases. This is particularly the case in the Guamanian (now called *western Pacific*) variety and in the hereditary frontotemporal atrophy linked to a mutation on chromosome 17.

In some writings on this subject, the term frontotemporal dementia has come to be used in a highly restricted sense, being assigned to cases that show only tau-staining material in neurons. Most of the cases are sporadic, but the inherited variety linked to chromosome 17, in which parkinsonism is prominent, supports its distinction as a separate entity; it is in these cases that the intraneural deposition of tau is most striking, in both the frontotemporal cortex and the substantia nigra. In a few familial cases, this process is attributable to mutations in the gene on chromosome 17 that encodes the tau protein. These mutations alter the proportions of different isoforms of

this protein and lead both to tau accumulation and its hyperphosphorylation. Indeed, many cases of frontotemporal dementia are associated with tau gene mutations. However, abnormal aggregates of tau have been identified in practically all neurodegenerative atrophies and, of course, form the main constituent of the paired helical filaments (neurofibrillary tangles) of Alzheimer disease, and in progressive supranuclear palsy where they are abundant, although of slightly different structure. From the observations of Brun and Passant and of Neary and associates, pure tau-reactive cases outnumber Pick disease when the latter is strictly defined by the cortical white matter degeneration and Pick inclusions.

Nonetheless, a frontotemporal dementia identical to that of the tau-reactive cases has been observed in others without any tau or synuclein staining of neurons. Many of the frontally predominant cases have shown deposition of the protein progranulin, consisting mainly of a ubiquitin neuronal inclusion consisting of TDP-43 (TAR DNA-binding protein), the result of PGRN mutations.

Primary Progressive Aphasia (PPA) Focal disturbances, particularly aphasia and apraxia, occur early and prominently in certain patients with lobar degenerations, indicating a lesion in the left frontal or temporal lobes. Viewed from another perspective, a prominent language disorder has been described in almost two-thirds of all patients with temporal lobe atrophy.

Several types of this disturbance have been delineated. In the first, *progressive nonfluent aphasia*, the patient initially speaks less and has word-finding difficulty (anomia), but language structure is intact (Mesulam, 1982); later, he may forget and misuse words and soon fails to understand much of what is heard or read. Sentences are short and telegraphed. Later, dysarthria and apraxia become apparent and finally, the patient is virtually mute, seemingly without impulse to speak, and with an inability to form words (Snowden et al, 1992).

A second type, *semantic dementia*, is characterized by early difficulty naming items, people, and words, followed by verbal perseveration, but fluency is retained. There is considerable difficulty in generating lists of words of a given category, such as animals. These individuals are quite aware that they are having trouble finding words. Eventually the patient loses not just the use of names of people and objects, but also their meaning, or the conceptual knowledge of the word. Some may develop severe prosopagnosia, especially if the atrophy is predominantly right sided. Memory for day-to-day events is preserved.

A third type has been proposed, *logopenic aphasia*, that shares most aspects of nonfluent aphasia but in which the meaning of words is retained.

According to Mesulam (2003), who has studied the condition extensively, 60 percent of these cases show no characteristic pathologic change, 20 percent have Pick bodies, and a similar proportion show the typical changes of Alzheimer disease in the affected cortical region. A clear familial tendency has not been found. Chapter 23 can be consulted for details of the aphasic disorders.

Posterior Cortical Atrophy This regional variant of lobar degeneration has been slightly less frequent than

primary progressive aphasia in our practices. The fundamental feature is the progressive loss of the ability to understand and use visual information. The result is progressive and ultimately severe visuospatial difficulty with a relative preservation of memory. Prosopagnosia, achromatopsia, and dyslexia emerge, or, there may be difficulty with depth perception, reaching for objects and an inordinate sensitivity to bright light. Patients under our care have initially had a vague sense of visual disorientation followed over months by difficulty in seeing or recognizing objects in front of them. Many have alexia with agraphia while others have acalculia or the other elements of the Gerstmann syndrome. Several eventually become cortically blind. The syndrome is essentially that of an apperceptive visual disturbance that includes fragments of the Balint and the Gerstmann syndromes. The average age of onset is about 60 years. The most common pathologic change in most reports has been characteristic of Alzheimer disease.

Lewy-body Dementia (Diffuse Lewy-body Disease)

Next to Alzheimer disease, diffuse Lewy-body disease, or Lewy-body dementia, has been the most frequent pathologic diagnosis established in many series of globally demented patients. Reports of this condition have been increasing steadily since the original communication by Okazaki and colleagues in 1961 (see review by Kosaka). The disease is defined by the diffuse involvement of cortical neurons with Lewy-body inclusions and by an absence or inconspicuous number of neurofibrillary tangles and amyloid plaques. To some extent, increased recognition of this disorder is a result of improved histologic techniques, particularly the ability to detect ubiquitin and synuclein, main components of the Lewy body, by immunostaining. With this improved detection has come a better definition of the clinical syndrome and its distinctions from Alzheimer and other dementias. Because the Lewy bodies in cortical neurons are not surrounded by a distinct halo, as they are in the substantia nigra in cases of Parkinson disease (see further on for discussion and photomicrograph of a typical Lewy body) they were not readily appreciated. Aggregated α -synuclein is the main component of the Lewy body an observation that will prove important in understanding both Parkinson disease and Lewy-body dementia.

Clinical Features

The disease in its typical form is marked by parkinsonian features, dementia, and a tendency to episodic delirium, especially nocturnally, and rapid eye movement (REM) sleep behavior disorder (described below and in Chap. 19). Diagnostic criteria have been offered by a working group, requiring 2 of 3 of the following: a parkinsonian syndrome (usually symmetric), fluctuations in behavior and cognition, and recurrent hallucinations (McKeith et al). The latest recursion of this group's criteria emphasizes the presence of the REM sleep behavior disorder and severe neuroleptic sensitivity.

In an analysis of 34 cases of diffuse Lewy-body disease, Burkhardt and colleagues, found that the most char-

acteristic syndrome was one of progressive dementia in an elderly patient with the additional late onset of parkinsonism in many cases. In Lennox's summary of 75 cases, parkinsonism, particularly with limb and axial rigidity, was a prominent feature in 90 percent once the illness was fully developed, and almost half had tremor of the parkinsonian type (this is somewhat different from other series). Byrne and associates, as have many others, pointed out that episodic confusion, hallucinations, and paranoid delusions were features of Lewy-body dementia; such psychotic aspects are generally uncharacteristic of Alzheimer and lobar dementias, and only then, in advanced stages. In Lennox's review, one-third of patients had these swings in behavior, but as the illness advanced, amnesia, dyscalculia, visuospatial disorientation, aphasia, and apraxia differed little from those of Alzheimer disease. In the cases reported by Fearnley and coworkers, there was a supranuclear gaze palsy simulating that of progressive supranuclear palsy. These overlapping clinical features make diagnosis difficult unless the specific feature of episodic hallucinations is evident. Difficulty in diagnosis also arises because the parkinsonian disorder may be either mild or prominent and may occur as an early or a late manifestation.

The parkinsonian features can respond favorably to L-dopa, but only for a limited time and sometimes at the expense of causing an agitated delirium or hallucinations that would be uncharacteristic of early Parkinson disease (Hely et al); in others, the response to L-dopa is inconsistent or inapparent. Some patients also have orthostatic hypotension corresponding to cell loss and Lewy bodies in the intermediolateral cell column of the spinal cord or in the sympathetic ganglia, thereby simulating striatonigral degeneration or Shy-Drager syndrome (see further on). Others have commented on an extreme sensitivity of such patients to neuroleptic drugs, including increased confusion and greatly worsening parkinsonism or the development of the neuroleptic malignant syndrome.

In our experience with Lewy-body disease, the parkinsonian symptoms have been more prominent than they are in progressive supranuclear palsy, and the most characteristic feature besides the movement disorder and a slowly advancing dementia has been a vacuous, anxious state with intermittent psychotic or delirious behavior.

At least one randomized trial has described benefit from the anticholinesterase inhibitor, rivastigmine, in reducing delusions, hallucinations, and anxiety (McKeith and colleagues, 2000). With regard to diagnostic testing, the finding of reduced activity in the posterior parietal cortical regions on PET scans (as in Alzheimer disease) has been found as a relatively consistent, but not invariable, feature.

Other Degenerative Dementias

Argyrophilic Grain Disease

This obscure entity has been connected with a late-life dementia in which behavioral disturbances precede memory difficulty. Whether the finding of argyrophilic grains in the mediotemporal lobe, different from tau-laden neurofibrillary tangles and from the glial inclusions

(putatively a defining feature of multiple system atrophy), constitutes a specific entity is not clear to the authors. The finding overlaps with the deposition of other materials that are more closely associated with dementing diseases such as phosphorylated tau and Lewy bodies. Probst and Tolnay remarked that these small argyrophilic inclusions are not found in nondemented individuals. It is unlikely that the condition can be identified in life; if it is a genuine entity, it must be rare. The interested reader may consult the review by Ferrer.

Neuroserpinopathy

There have been infrequent case reports of dominantly inherited, adult-onset dementia with a fulminant evolution suggestive of encephalopathy and the special feature of seizures. The distinctive feature has been the presence at autopsy of large eosinophilic, PAS-positive intraneuronal inclusions that contain aggregates of neuroserpin, thus the initial description of "familial encephalopathy with neuronal inclusion bodies." The serpins are a family of protease inhibitors that include neuroserpin, a protein expressed exclusively in neurons, and α_1 -antitrypsin. The neuronal inclusions are dense in the deep layers of the cortex and in the substantia nigra. Missense mutations in the gene encoding neuroserpin have been identified as the cause. This entity is reviewed by Lomas and Carrell.

DEMENTING DISEASES IN WHICH OTHER NEUROLOGIC ABNORMALITIES ARE PROMINENT

Huntington Disease (Huntington Chorea)

This disease, distinguished by the triad of dominant inheritance, choreoathetosis, and dementia, commemorates the name of George Huntington, a medical practitioner of Pomeroy, Ohio. In 1872, his paper, read before the Meigs and Mason Academy of Medicine and published later that year in the *Medical and Surgical Reporter* of Philadelphia, gave a succinct and graphic account of the disease that was based on observations of patients that his father and grandfather had made in the course of their practice in East Hampton, Long Island. Reports of this disease had appeared previously (see DeJong for historical background) but they lacked the completeness of Huntington's description. In 1932, Vessie was able to show that practically all the patients with this disease in the eastern United States could be traced to about 6 individuals who had emigrated in 1630 from the tiny East Anglian village of Bures, in Suffolk, England. One remarkable family was traced for 300 years through 12 generations, in each of which the disease had expressed itself.

To quote Huntington, the rule has been that "When either or both of the parents have shown manifestations of the disease, one or more of the offspring invariably suffer of the disease, if they live to adult life. But if by any chance these children go through life without it, the thread is broken and the grandchildren and great grandchildren of the original shakers may rest assured that they are free

from disease." Davenport, in a review of 962 patients with Huntington chorea, found only 5 who had descended from unaffected parents. Possibly, in these 5 patients, a parent had the trait, in very mild form, or parentage was in question, because spontaneous mutations are rare.

In university hospital centers, this is a regularly observed type of hereditary nervous system diseases and the main cause of progressive chorea at most ages. Its overall frequency is estimated at 4 to 5 per million, and 30 to 70 per million among whites of northern European ancestry. The usual age of onset is in the fourth and fifth decades, but 3 to 5 percent begin before the fifteenth year and some even in childhood, where it takes on special form. In approximately 30 percent, symptoms become apparent after 50 years. The progression of the disease is generally slower in older patients for reasons noted below. Once begun, the disease progresses relentlessly, until only a restricted existence is possible and a medical disease terminates life.

Exhaustive genealogic documentation many years ago established the cause to be an autosomal dominant gene with complete penetrance. Koller and Davenport made the observation that young patients usually inherit the disease from their fathers and older patients from their mothers. It has been observed beginning at almost the same age in identical twins.

The first important achievement in respect to the biologic understanding of Huntington disease was the discovery by Gusella and colleagues of a marker linked to the Huntington gene and localized to the short arm of chromosome 4. Subsequently, these investigators and others identified the mutation as an excessively long repeat of the trinucleotide CAG within the Huntington gene, the length (number) of which determines not only the presence of the disease, but also the age of onset, longer repeat lengths being associated with an earlier appearance of signs. At the Huntington gene locus there are normally 11 to 34 (median: 19) consecutive repetitions of the CAG triplet, each coding for glutamine. Individuals with 35 to 39 triplets may eventually manifest the disease but it tends to be late in onset and mild in degree, or limited to the below-mentioned "senile chorea." Those with more than 42 repeats almost invariably acquire the signs of disease if they live long enough. The rare alternative mutation, termed HDL2 (Huntington disease-like-2), is associated with CATCG repeat expansion of the junctophilin-3 gene, but it is so infrequent that few clinicians will encounter it (Margolis et al).

These discoveries have made possible the development of a genetic test for the measurement of the repeat length that confirms the diagnosis in symptomatic patients and allows screening of asymptomatic individuals. Because there is no treatment for the disease, testing raises certain ethical considerations that must be resolved before its widespread utilization.

Clinical Features

The *mental disorder* assumes several subtle forms long before the more obvious deterioration of cognitive functions becomes evident. In approximately half the cases,

slight but annoying alterations of personality are the first to appear. Patients begin to find fault with everything, to complain constantly, and to nag other members of the family; they may be suspicious, irritable, impulsive, eccentric, untidy, or excessively religious, or they may exhibit a false sense of superiority. Poor self-control may be reflected in outbursts of temper, fits of despondency, slovenliness, alcoholism, or sexual promiscuity. Disturbances of mood, particularly depression, are common (almost half of the patients in some series) and may constitute the most prominent symptoms early in the disease. Invariably, sooner or later, the intellect begins to fail globally. The patient becomes less communicative and socially withdrawn. The emotional disturbances and changes in personality may reach such proportions as to constitute a virtual psychosis with persecutory delusions or hallucinations.

Diminished work performance, inability to manage household responsibilities, and disturbances of sleep may prompt medical consultation. There is difficulty in maintaining attention and concentration and in assimilating new material. Mental flexibility lessens. Simultaneously, there is loss of fine manual skills (see further on). The performance parts of the Wechsler Adult Intelligence Scale show greater loss than the verbal parts. Memory is relatively spared. This gradual dilapidation of intellectual function has been characterized as a "subcortical dementia," that is elements of aphasia, agnosia, and apraxia are observed only rarely and memory loss is not profound. Often the process is so slow, particularly in cases of late onset, that a fair degree of intellectual capacity seems to be retained for many years.

The *abnormality of movement* is subtle at first and most evident in the hands and face; often the patient is merely considered to be fidgety, restless, or "nervous." Slowness of movement of the fingers and hands, a reduced rate of finger tapping, and difficulty in performing a sequence of hand movements are early signs. Gradually these abnormalities become more pronounced until the entire musculature is implicated with chorea. The frequency of blinking is increased (the opposite of parkinsonism), and voluntary protrusion of the tongue, like other attempts at sustained posture, is constantly interrupted by unwanted darting movements. In the advanced stage of the disease the patient is seldom still for more than a few seconds. The choreic movements are slower than the brusque jerks and postural lapses of Sydenham chorea, and they involve many more muscles. They tend to recur in stereotyped patterns yet are not as stereotyped as tics. In advanced cases, they acquire an athetoid or dystonic quality. Muscle tone is usually decreased until late in the illness, when there may also be some degree of rigidity, tremor, and bradykinesia, elements suggestive of Parkinson disease. Parkinsonism with rigidity characterizes the Westphal or "rigid" variant, which is more common with a childhood onset, or the HDL2 genetic variant noted earlier. Tendon reflexes are exaggerated in one-third of patients, but only a few have Babinski signs. Voluntary movements are initiated and executed more slowly than normal, but there is no weakness and no ataxia, although speech, which becomes dysarthric and explosive because

of incoordination between tongue and diaphragm, may convey the impression of a cerebellar disorder. Inability to hold the tongue protruded is characteristic. In late-onset cases there may be an almost constant rapid movement of the tongue and mouth, simulating the tardive dyskinesia that follows the use of neuroleptic drugs. These disorders of movement that characterize Huntington chorea are described more fully in Chap. 4.

Oculomotor function is subtly affected in most patients (Leigh et al; Lasker et al). Particularly characteristic are impaired initiation and slowness of both pursuit and volitional saccadic movements and an inability to make a volitional saccade without movement of the head. Excessive distractibility may be noticed during attempted ocular fixation. The patient feels compelled to glance at extraneous stimuli even when specifically instructed to ignore them. Upward gaze is often impaired as the illness progresses.

As Wilson stated, the relation of the choreic to the mental symptoms "abides by no general rule." Most often the mental symptoms precede the chorea but they may accompany or follow it, sometimes by many years. Once the movement disorder is fully established, there is nearly always some degree of cognitive abnormality. Exceptional cases have been reported in which the movement disorder existed for 10 to 30 years without mental changes (Britton et al); this would be most characteristic of patients with fewer CAG repeats. More typically after 10 to 15 years of symptoms, most patients deteriorate to a vegetative state, unable to stand or walk and eating little; in this late stage, a mild amyotrophy may appear. Noteworthy is the high suicide rate, as pointed out by Huntington himself (see also Schoenfeld et al). Because there is a higher-than-normal incidence of head trauma, chronic subdural hematoma is another common finding at autopsy.

The first signs of the disease may appear in childhood, before puberty (even younger than the age of 4 years), and several series of such early-onset cases have been described (Farrer and Conneally; van Dijk et al). Mental deterioration at this early age is more often accompanied by cerebellar ataxia, behavior problems, seizures, bradykinesia, rigidity, and dystonia than by chorea (Byers et al). However, this rigid form of the disease (Westphal variant) also occurs occasionally in adults as mentioned above, in some cases because of HDL2. Functional decline is much faster in children than it is in adults (Young et al).

The dementia is generally more severe in cases of early onset and with correspondingly longer repeat lengths (15 to 40 years of age) than in those of later onset (55 to 60 years of age). In adult patients with early onset, the emotional disturbance tends to be more prominent initially and precedes the chorea and intellectual loss by years; with older age of onset, choreiform features are more often the initial components; in the middle years, dementia and chorea have their onset at nearly the same age. At the other extreme of age, the first features may become evident in the eighties, with orofacial or other dyskinesias that are mistakenly attributed to an exposure to neuroleptic drugs or called "senile chorea" (see Chap. 4).

Figure 39-4. Axial CT from a 54-year-old mildly demented woman with a 10-year history of Huntington chorea. The bulge in the inferolateral border of the lateral ventricle, normally created by the head of the caudate nucleus, is obliterated. There is also diffuse enlargement of the lateral ventricles.

Pathology and Pathogenesis

Gross atrophy bilaterally of the head of the caudate nucleus and putamen is the characteristic abnormality, usually accompanied by a moderate degree of gyral atrophy in the frontal and temporal regions. The caudate atrophy alters the configuration of the frontal horns of the lateral ventricles in that the inferolateral borders do not show the usual bulge formed by the head of the caudate nucleus. In addition, the ventricles are diffusely enlarged (Fig. 39-4); in CT scans, the bicaudate-to-cranial ratio is increased, which corroborates the clinical diagnosis in the moderately advanced case.

The early articles of Alzheimer and Dunlap and the more recent one of Vonsattel and DiFiglia contain the most authoritative descriptions of the microscopic changes. The latter authors have graded the disease into early, moderately advanced, and far advanced stages. In 5 early but genetically verified cases, no striatal lesion was found, which suggests that the first clinical manifestations are based on a biochemical or infrastructural change. This view is supported by the observation that Huntington patients studied with PET show a characteristic decrease in glucose metabolism in the caudate nuclei, which precedes the volumetric loss of tissue (Hayden et al). The striatal degeneration begins in the medial part of the caudate nucleus and spreads, tending to spare the

nucleus accumbens. Of the 6 cell types in the striatum (a differentiation based on size, dendritic arborizations, spines, and axon trajectories), the smaller neurons are affected before the larger ones. Loss of dendrites of the small spiny neurons has been an early finding, while the large cells are relatively preserved and exhibit no special alterations.

The anterior parts of the putamen and caudate are more affected than the posterior parts. Some observers have noted changes in the globus pallidus, subthalamic nucleus, red nucleus, cerebellum, and in the pars reticulata of the substantia nigra. In the cerebral cortex, there is slight neuronal loss in layers 3, 5, and 6, with replacement gliosis. Cases are reported with typical striatal lesions but normal cortices in which only chorea had been present during late life. Several neuropathologists have observed marked cell loss and gliosis in the subthalamic nuclei in Huntington-affected children or young adults with chorea and behavior disorders. However, Hadzi and colleagues have determined that the pathologic changes in the striatum and the cortex evolve differently and have separate relationships to the CAG repeat length.

Mechanism of Disease As mentioned above, there is a general relationship between the number of CAG repeats and the age of onset of symptoms. It has been found that it is the longer sequence on either of the 2 alleles that determines the age of onset, the size of the expansion of the normal allele exerting no influence (Lee et al, 2012). Earlier onset in successive generations (*anticipation*) is well described in the early writings on the subject and is now known to be attributable to increasing lengths of the CAG repeat sequence.

From the molecular perspective, the pathogenesis of this disease is a direct, but still poorly understood, consequence of the aforementioned expansion of the polyglutamine region of *huntingtin* (the protein product of the Huntington gene). It has been shown that the mutant huntingtin protein aggregates in the nuclei of neurons. Moreover, the protein accumulates preferentially in cells of the striatum and parts of the cortex affected in Huntington disease. Evidence, particularly that given by Wetz (cited in the review by Bates), suggests that these aggregates may be toxic to neurons, either directly or in their protofibrillary (unaggregated) form. The situation is, however, likely to be more complex, as the bulk of huntingtin deposition is found in cortical neurons, whereas the neuronal loss is predominantly striatal. One theory supports the concept that the polyglutamine complex renders certain cell types unduly sensitive to glutamate-mediated excitotoxicity. More recently, 2 mechanisms have been proposed based on an interruption of protein transcription by the binding of mutant huntingtin to transcription proteins or that mitochondrial dysfunction occurs directly or through the same transcriptional mechanism, as summarized by Greenamyre. Because polyglutamine expansions are implicated in several neurodegenerative diseases (reviewed in corresponding sections of this chapter), treatments that block their effects on cellular function may be broadly effective in several degenerative diseases.

Diagnosis

Once the disease has been observed in its fully developed form, its recognition requires no great clinical acumen. The main difficulty arises in patients who lack a family history but who display progressive chorea, emotional disturbance, and dementia. This problem has been largely overcome since the mutation was identified. It is now possible to confirm or exclude the diagnosis by analysis of DNA from a blood sample. The presence of more than 39 CAG repeats at the Huntington locus essentially confirms the disease and gives some indication of the expected time of onset; lesser numbers of repeat length leave room for equivocation and strings between 39 and 42 may not be manifest if the patient does not live long enough to express the illness.

Chorea that begins in late life with only mild or questionable intellectual impairment and without a family history of similar disease is a source of diagnostic difficulty. A few cases are the result of the earlier mentioned HDL2 mutation and others derive from alternative degenerative conditions discussed below. Referring to the problem as “senile chorea” does not solve the problem. Indeed, senile chorea has many causes. We have seen it appear with infections, hyperglycemia, drug therapy, strokes, and thyrotoxicosis, only to disappear after a few weeks. A few times we have been confronted with the problem of an older patient who displays orolingual dyskinesias that are most characteristic of exposure to neuroleptic drugs but in whom there was no such history of exposures; testing usually disclosed Huntington disease.

Chorea in early adult life always raises the question of a late form of Sydenham chorea, of lupus erythematosus with antiphospholipid antibodies, or of cocaine use, but neither familial occurrence nor mental deterioration is part of these processes. A “benign inherited chorea,” transmitted as an autosomal dominant trait without prolongation of a triplet sequence, has been traced to chromosome 14q. It is differentiated from Huntington disease by onset before age 5 years, progressing little, and having no associated mental deterioration (Breedveld et al). Other progressive neurologic disorders inherited as autosomal dominant traits and beginning in adolescence or adult life (e.g., polymyoclonus with or without ataxia, acanthocytosis with progressive chorea, and dentatorubropallidolusian degeneration) can closely mimic Huntington disease, as described further on; sometimes only the genetic and pathologic findings settle the matter. A midlife progressive chorea without dementia (after more than 25 years of followup) that does not display the Huntington genotype has been reported. In at least one family in which this clinical picture is dominantly inherited, the fundamental defect is a mutation in the gene encoding the light chain of ferritin (Curtis). Affected individuals have axonal changes in the pallidum with swollen, ubiquitin- and tau-positive aggregates; serum ferritin levels may be depressed. The implication of this mutation is that perturbations of iron metabolism may be toxic to neurons, a feature that also characterizes Hallervorden-Spatz disease.

Dentatorubropallidolusian atrophy (DRPLA), sometimes mistaken clinically for Huntington chorea, was

described in European families by Warner and associates and is discussed further on. The extrapyramidal manifestations include chorea, myoclonus, and rigidity. Adult-onset chorea and dementia has been described with *propionic acidemia*; propionic acid is elevated in the plasma, urine, and CSF. This disorder must be added to other metabolic diseases described in Chap. 37 as causes of childhood chorea and dyskinesia—such as glutaric acidemia, keratin sulfaturia, calcification of basal ganglia, phenylketonuria, and Hallervorden-Spatz disease, now called PANK (Hagberg et al).

Other problems in differential diagnosis include prion disease, Wilson disease (see Chap. 37), acquired hepatocerebral degeneration (see Chap. 40), paraneoplastic chorea (see Chap. 31), and most often and especially, tardive dyskinesia (see Chap. 41). Many drugs in addition to the toxic effects of L-dopa and antipsychotic medications occasionally cause chorea (amphetamines, cocaine, tricyclic antidepressants, lithium, isoniazid, linezolid). The hyperglycemic-hyperosmolar state is known for producing a variety of generalized or local movement disorders, prominent among them being chorea.

Treatment

The dopamine antagonist haloperidol, in daily doses of 2 to 10 mg, is effective partially in suppressing the movement disorder. Because of the danger of superimposing tardive dyskinesia on the chronic disorder, the chorea should be treated only if it is functionally disabling, using the smallest possible dosages. Haloperidol may also help alleviate abnormalities of behavior or emotional lability, but it does not alter the progress of the disease. The authors have not been impressed with the therapeutic effectiveness of other currently available drugs. Levodopa and other dopamine agonists make the chorea worse and, in the rigid form of the disease, evoke chorea. Drugs that deplete dopamine or block dopamine receptors—such as reserpine, clozapine, and particularly tetrabenazine, which has been validated in a controlled study (Huntington Study Group)—suppress the chorea to some degree, but their side effects (drowsiness, akathisia, and tardive dyskinesia) usually outweigh their desired effects. They may be tried in difficult cases. The juvenile (rigid) form of the disease is probably best treated with antiparkinsonian drugs. Preliminary studies of the transplantation of fetal ganglionic tissue into the striatum have achieved mixed results. The psychologic and social consequences of the disease require supportive therapy, and genetic counseling is essential. Antidepressant drugs are widely implemented because of the high incidence of depression and suicidality but their efficacy is not clear. Huntington disease pursues a steadily progressive course and death occurs as mentioned, on average 15 to 20 years after onset, sometimes much earlier or later.

Acanthocytosis With Chorea

There are 2 categories of neurologic disease associated with red blood cell acanthocytosis; one with a defect in the red cell lipid membrane (represented by Bassen-Kornzweig

disease and the HARP [hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration] syndrome [see Chap. 37]) and a second group that lacks a lipid abnormality. This latter type of neuroacanthocytosis enters into the differential diagnosis of Huntington chorea or unexplained progressive choreas and has the following characteristics: (1) onset in adolescence or early adult life of generalized involuntary movements (described as chorea but including dystonia and tics), usually beginning as an orofacial dyskinesia and spreading to other parts of the body and to other neural systems; (2) mild to moderate mental deterioration with behavioral disturbance in some but not all cases; (3) decreased or absent tendon reflexes and evidence of chronic axonal neuropathy and denervation atrophy of muscles; and (4) the defining feature of acanthocytosis (thorny or spiky appearance of erythrocytes). The main syndrome, and the one to which the term *neuroacanthocytosis* had for a long time been applied, is caused by an autosomal recessive mutation. However, there are now 4 additional subtypes, one dominantly transmitted and another X-linked (McLeod type), which is discussed below. These are all in distinction to Bassen-Kornzweig disease that is caused by an inherent defect in the lipid layer of the red cell membrane (see further on).

In the series of 19 cases reported by Hardie and colleagues, the manifestations included dystonia, tics, vocalizations, rigidity, and lip and tongue biting; more than half had cognitive impairment or psychiatric features. The average age of onset was 32 years; 7 of the 19 cases were sporadic. The disease has been linked in almost all families to chromosome 9q, where there is a mutation in the gene encoding a large (3,100-amino-acid) protein designated *chorein* that is involved in cellular protein sorting and trafficking (Rampoldi). Some of the families with dominantly inherited neuroacanthocytosis have mutations in the chorein gene. There is atrophy and gliosis of the caudate nuclei and putamens but no neuronal loss in the cerebral cortex or other parts of the brain.

According to Sakai and coworkers, the acanthocytosis is the result of an abnormal composition of covalently (tightly) bound fatty acids in erythrocyte membrane proteins (palmitic and docosahexanoic acids increased and stearic acid decreased). The cells should be examined in a fresh preparation of blood and isotonic saline; it is likely to be overlooked in a conventional Wright stain. More than 5 percent of the red cells have the characteristic structural abnormality in affected individuals. The acanthocytosis may also be detected by scanning electron microscopy. The latter may be necessary to undertake in cases of unexplained chorea that have the other features of this disease as genetic testing for the gene (see below) is not widely available.

McLeod disease, another disorder with acanthocytosis and the gradual development of chorea in middle to late life, is characterized by degeneration of the caudate and putamen and a myopathy (elevated serum creatine phosphokinase [CPK]). These individuals have fewer facial tics and orofacial features than those with neuroacanthocytosis. McLeod syndrome arises from mutations

in a gene on the X-chromosome that encodes the KX protein, which binds to surface Kell antigens on red cells. In addition to the primary KX gene mutations, these individuals show diminished Kell antigen expression on the red-cell surface.

Corticostriatospinal Degenerations

Included in this category are a heterogeneous group of degenerative diseases in which the symptoms of parkinsonism and corticospinal degeneration are present in various combinations. Some of the diseases that make up this group have not been sharply delineated and are difficult to separate from one another.

Variants of this category of disease continue to appear, all rare. The authors have observed several patients in whom extreme rigidity, corticospinal signs but no dementia, have developed over a period of several years. In the later stages of the disease, the patient, while alert, is totally helpless and unable to speak, swallow, or move the limbs. Only eye movements are retained, and even these are hampered by supranuclear gaze palsies in advanced cases. Intellectual functioning appears to be better preserved than movement but is difficult to assess. Other bodily functions are intact. The course is slowly progressive and ends fatally in 5 to 10 years. There is no family history of similar disease, and there are no clues as to causation. Gilbert and colleagues have described similar cases with signs of Parkinson disease, motor neuron disease, and dementia; in their cases, there were no senile plaques or Lewy bodies. The concurrence of typical motor neuron disease and Parkinson disease may be coincidental, but Qureshi and colleagues described 13 patients in whom both clinical phenomena began within a short time and they considered them to be related. In the variant described by Tandan and colleagues, an autosomal dominant syndrome of Charcot-Marie-Tooth polyneuropathy was combined with ptosis, parkinsonism, and dementia, again without Lewy bodies or amyloid plaques. Other variants have been described by Schmitt and coworkers and by Mata and colleagues. Hudson reviewed 42 sporadic cases in which ALS-parkinsonism-dementia were combined.

Under the title "Spastic Pseudosclerosis," Jakob, in 1921, described a chronic disease of middle to late adult life, characterized by abnormalities of behavior and intellect; weakness, ataxia, and spasticity of the limbs (chiefly the legs); extrapyramidal symptoms such as rigidity, slowness of movement, tremors, athetotic postures, and hesitant, dysarthric speech; and normal spinal fluid. The pathologic changes were diffuse and consisted mainly of an outfall of neurons in the frontal, temporal, and central motor gyri, striatum, ventromedial thalamus, and bulbar motor nuclei. In one of Jakob's cases, there were also prominent changes in the anterior horn cells and corticospinal tracts in the spinal cord like those of ALS. The latter finding gave rise to Wilson's concept of the disease as a *corticostriatospinal degeneration*. Some restricted cases bear a resemblance to the type of frontotemporal dementia that occurs with motor neuron disease.

A degenerative and probably familial disorder that had been described earlier by Creutzfeldt was considered by Spielmeyer to be sufficiently similar to the one of Jakob to warrant the designation *Creutzfeldt-Jakob disease*. As discussed in Chap. 33, the disorder originally described by Creutzfeldt and Jakob has been a source of endless controversy because of its indeterminate character. It has been confused with the subacutely evolving myoclonic dementia, or subacute spongiform encephalopathy, which is now known to be an infection caused by a prion agent. The latter disease bears at best only a superficial resemblance to the one described by Creutzfeldt and Jakob, and the 2 disorders should be separated. Unfortunately, the use of the eponym for the prion-related disease is so entrenched that attempts to delete it are futile and probably unnecessary. However, the term *Jakob disease* has been used for the degenerative type of corticostriatal degeneration.

The *Guamanian Parkinson-dementia-ALS* complex deserves separate comment because there have been many carefully studied cases with almost uniform clinical and pathologic features. The disease occurs in the indigenous Chamorro peoples of Guam and the Mariana islands, predominantly in men between the ages of 50 and 60 years. Progressive parkinsonism and dementia are combined with upper or lower motor neuron disease (ALS is also common among the Chamorro) leading to death in 5 years. The pathologic changes, described by Hirano and associates, consist of severe cortical atrophy with neurofibrillary tangles and a depopulation of the substantia nigra, but notably no Lewy bodies or amyloid plaques, even with sensitive neurochemical staining. Cases with amyotrophy show a loss of anterior horn cells. The cause of the Guamanian multisystem degeneration is not known, although several studies have incriminated one or more putative neurotoxins in the food supply (see Chap. 43). There are some clinical and pathologic similarities to the form of frontotemporal dementia with motor neuron disease.

Familial Dementia With Spastic Paraparesis

Occasionally, the authors have encountered families in which several members developed a spastic paraparesis and a gradual failure of intellectual function during the middle adult years. The patient's mental horizon narrowed gradually, and the capacity for high-level thinking diminished; in addition, the examination showed exaggerated tendon reflexes, clonus, and Babinski signs. In one such family, the illness had occurred in 2 generations; in another, 3 brothers in a single generation were afflicted. Skre described 2 recessive types of hereditary spastic paraplegia in Norway, 1 with onset in childhood, the other with onset in adult life. In contrast to the dominant form (see further on), the recessive types displayed evidence of more widespread involvement of the nervous system, including dementia, cerebellar ataxia, and epilepsy. Also, Cross and McKusick have observed a recessive type of paraplegia accompanied by dementia beginning in adolescence. They named it the *Mast syndrome*, after the afflicted family.

Worster-Drought and others reported the pathologic findings in 2 cases of this type. In addition to plaques and neurofibrillary changes, there was demyelination of the subcortical white matter and corpus callosum and a "patchy but gross swelling of the arterioles," which gave the staining reactions for amyloid ("Scholz's perivascular plaques"). van Bogaert and associates published an account of similar cases that showed the characteristic pathologic features of Alzheimer disease.

Another interesting association of familial spastic paraplegia is with progressive cerebellar ataxia. Fully one-third of the cases that we have seen with such a spastic weakness were also ataxic and would fall into the category of spinocerebellar degenerations. Yet another variant of this group of diseases has been described by Farmer and colleagues; the inheritance in their cases was autosomal dominant, and the main clinical features were deafness and dizziness, ataxia, chorea, seizures, and dementia, evolving in that order. Postmortem examinations of 2 patients disclosed calcification in the globus pallidus, neuronal loss in the dentate nuclei, and destruction of myelinated fibers in the centrum semiovale.

Adult Polyglucosan Body Disease

Under this title, Robitaille and colleagues have described a progressive neurologic disease in adults characterized clinically by spasticity, chorea, dementia, and a predominantly sensory polyneuropathy that is reviewed in more detail in Chap. 39. Structures that closely resembled Lafora bodies and corpora amylacea were found in large numbers in both central and peripheral neural processes (mainly in axons) and also in astrocytes. These basophilic PAS-positive structures were composed of glucose polymers (polyglucosans) and were readily demonstrated in sural nerve biopsies and therefore probably best termed *polyglucosan bodies*. Some of these structures were also found in the heart and liver.

More recently, Rifaal and associates reviewed the findings in 25 cases of this disease—one observed by them and 24 reported previously. The dementia was relatively mild, consisting of impairment of retentive memory, dysnomia, dyscalculia, and sometimes nonfluent aphasia and deficits of "visual integration"; this was overshadowed by rigidity and spasticity of the limbs and the peripheral nerve disorder. Bladder dysfunction has been an early sign in many patients including a middle-aged woman under our care who had only diffuse white matter changes in the cerebral MRI and a moderate sensory neuropathy. Nerve conduction velocities were diminished and the leg muscles were denervated. Moderate degrees of generalized cerebral atrophy, multifocal areas of white matter rarefaction, and degeneration of the corticospinal system, disclosed by MRI. Some cases simulate motor neuron disease. The finding of polyglucosan axonal inclusion in biopsied nerves confirms the diagnosis. The disease has sometimes been misinterpreted as adrenoleukodystrophy. The disorder appears to be a glycogenosis that is allied with Anderson disease, as discussed in Chaps. 38 and 48.

Adult forms of metachromatic leukodystrophy, adrenoleukodystrophy, Krabbe disease, and neuronal ceroid

lipofuscinosis (Kufs disease) may be present with a similar clinical picture of progressive dementia (see Chap. 37) as may Whipple disease or the Wernicke-Korsakoff disease. Quite rare instances of the same syndrome with adult onset have proved to be caused by phenylketonuria or other aminoacidopathies (see Chap. 37).

DISEASES CHARACTERIZED BY ABNORMALITIES OF POSTURE AND MOVEMENT

Parkinson Disease

This common disease, known since ancient times, was first cogently described by James Parkinson in 1817. In his words, it was characterized by “involuntary tremulous motion, with lessened muscular power, in parts not in action and even when supported; with a propensity to bend the trunk forward, and to pass from a walking to a running pace, the senses and intellect being uninjured.” Strangely, his essay contained no reference to rigidity or to slowness of movement and it stressed unduly the reduction in muscular power. The same criticism can be leveled against the term *paralysis agitans*, which appeared for the first time in 1841 in Marshall Hall’s textbook *Diseases and Derangements of the Nervous System* and has fallen out of use, but was such a common term in the literature that it is included here.

The natural history of the disease is of interest. As a rule, it begins between 45 and 70 years of age, with the peak age of onset in the sixth decade. It is infrequent before 30 years of age, and most series contain a somewhat larger proportion of men. Trauma, emotional upset, overwork, exposure to cold, “rigid personality,” and so on, were among many factors that had been suggested over the years as predisposing to the disease, but there is no evidence to support any such claims. Idiopathic Parkinson disease is observed in all countries, all ethnic groups, and all socioeconomic classes, although the incidence in African Americans is only one-quarter that in whites. There may be an increased incidence in rural compared to urban areas. In Asians, the incidence is one-third to one-half that in whites. The disease is frequent in North America, where there are approximately 1 million affected patients, constituting about 1 percent of the population over the age of 65 years. The incidence in European countries where vital statistics are kept is similar. A possible relationship to repeated cerebral trauma and to the “punch-drunk” syndrome (dementia pugilistica; chronic traumatic encephalopathy) has been particularly problematic and is unresolved despite several celebrated cases (Lees). A protective effect of smoking and coffee drinking has emerged in some epidemiologic studies but is marginal.

Clinical Features

A tetrad of hypo- and bradykinesia, resting tremor, postural instability, and rigidity are the core features of Parkinson disease. These are evident as an expressionless face, poverty and slowness of voluntary movement, “resting”

Table 39-2

INITIAL SYMPTOMS IN PATIENTS WITH PARKINSON DISEASE

Tremor	70%
Gait disturbance	11%
Stiffness	10%
Slowness	10%
Muscle aches	8%
Loss of dexterity	7%
Handwriting disturbance	5%
Depression, nervousness, other psychiatric disturbance	4%
Speech disturbance	3%

Source: Adapted from Hoehn and Yahr’s study of 183 idiopathic cases, 1967.

tremor, stooped posture, axial instability, rigidity, and festinating gait. Much can still be gained from perusal of the often-cited study by Hoehn and Yahr, published in 1967 before the widespread use of L-dopa. Table 39-2 is reproduced from that paper. The manifestations of basal ganglionic disease are fully described in Chap. 4, and only certain diagnostic problems and variations of the clinical picture need be considered here.

The early symptoms may be difficult to appreciate and are often overlooked by family members because they evolve slowly and tend to be attributed to the natural changes of aging. Speech becomes soft, monotonous, and cluttered. For a long time the patient may not be conscious of the inroads of the disease. At first the only complaints may be of aching of the back, neck, shoulders, or hips and of vague weakness. Slight stiffness and slowness of movement or a reduction in the natural swing of one arm during walking are ignored until one day it occurs to the physician or to a member of the family that the patient has the overall cast of Parkinson disease. Infrequency of blinking, as originally pointed out by Pierre Marie, is an early sign. The usual blink rate (12 to 20/min) is reduced in the parkinsonian patient to 5 to 10/min, and with it there is a slight widening of the palpebral fissures, creating a stare. A reduction in movements of the small facial muscles imparts the characteristic expressionless “masked” appearance (hypomimia). When seated, the patient makes fewer small shifts and adjustments of position than the normal person (hypokinesia), and the fingers straighten and assume a flexed and adducted posture at the metacarpophalangeal joints.

The characteristic tremor, which usually involves a hand, is often listed as the initial sign; but in at least half the cases observant family members will already have remarked on the patient’s relative slowness of movement. In about one-quarter of cases the tremor is mild and intermittent, or evident in only one finger or one hand. The tremor of the fully developed case takes several forms, as was remarked in Chap. 6. The 4-per-second “pill-rolling” tremor of the thumb and fingers, although most characteristic, is seen in only about half the patients. It is typically

present when the hand is motionless, that is not used in voluntary movement (hence the commonly used term *resting tremor*). Complete relaxation, however, reduces or abolishes the tremor, so that the term *tremor in the position of repose* is actually a more accurate description. Volitional movement dampens it momentarily. The rhythmic beat coincides with an alternating burst of activity in agonist and antagonist muscles in the electromyogram (EMG); hence the description *alternating tremor* is applied. The arm, jaw, tongue, eyelids, and foot are less often involved. Even the least degree of tremor is felt during passive movement of a rigid part (cogwheel phenomenon, or Negro sign, or at least this is the ostensible explanation for cogwheeling). The tremor shows surprising fluctuations in severity and is aggravated by walking and excitement, but its frequency remains constant (Hunker and Abbs). *It bears repetition that one side of the body is typically involved before the other with tremor and rigidity*, and the tremor in particular remains asymmetrical as the illness advances.

Lance and associates have called attention to the high incidence of a second essential type of tremor in Parkinson disease—a fine, 7- to 8-per-second, slightly irregular, action tremor of the outstretched fingers and hands. This tremor, unlike the slower one, persists throughout voluntary movement, is not evident with the limb in a resting position, and is more easily suppressed by relaxation. Electromyographically, it lacks the alternating bursts of action potentials seen in the typical tremor and resembles, if not equates with, essential tremor (see Table 6-1). It is subject to modulation by different medications than those used for the alternating Parkinson tremor. The patient may have either type of tremor or both.

Rigidity is less often an early finding. Once rigidity develops, it is constantly present and can be felt by the palpating fingers and as a salience of muscle groups even when the patient relaxes. When the examiner passively moves the limb, a mild resistance appears from the start (without the short free interval that characterizes spasticity) and it continues evenly throughout movement in both flexor and extensor groups, being interrupted to a variable degree only by the cogwheel phenomenon. Rigidity and its cogwheel component are elicited or enhanced by having the patient engage the opposite limb in a motor task requiring some degree of concentration, such as tracing circles in the air (termed *Froment sign*, or *Noïka-Froment sign* when the patient is asked to raise the other arm as high as possible, but this maneuver was actually utilized first to bring out cogwheeling in essential tremor) or touching each finger to the thumb. In the muscles of the trunk, postural hypertonus predominates in the flexor groups and confers on the patient the characteristic flexed posture. Other particulars of the parkinsonian appearance of muscle tone, stance, and gait are discussed in detail in Chaps. 4 and 7. There should be no pyramidal signs in Parkinson disease.

Here, a few additional points should be made regarding the quality of volitional and postural movements. The patient is slow and ineffective in attempts to deliver a quick hard blow; he cannot complete a rapid (ballistic) movement. On the EMG, the normal single burst of agonist-antagonist-agonist sequence of energizing activity

is replaced by several sequential brief bursts, according to Hallett and Khoshbin. Alternating movements, at first successful, become progressively impeded if performed repetitively and, finally, they are blocked completely or adopt the rhythm of the patient's alternating tremor. The patient has great difficulty in executing 2 motor acts simultaneously. In the past the impaired facility of movement had been attributed to rigidity, but the observation that certain surgical lesions in the brain abolished rigidity without affecting movement refuted this interpretation. Thus slowness and lack of natural movements (bradykinesia and hypokinesia, respectively) are not derived from rigidity but are independent manifestations of the disease. The bradykinetic deficits underlie the characteristic poverty of movement, reflected also by infrequency of swallowing, slowness of chewing, a limited capacity to make postural adjustments of the body and limbs in response to displacement of these parts, a lack of small "movements of cooperation" (as in arising from a chair without first adjusting the feet), absence of arm swing in walking, and most of the other aspects of the parkinsonian countenance. Despite a perception of muscle weakness, the patient is able to generate normal or near-normal power, especially in the large muscles; however, in the small ones, strength is slightly diminished.

As the disorder of movement worsens, all customary activities show the effects. Handwriting becomes small (micrographia), tremulous, and cramped, as first noted by Charcot. Speech softens and seems hurried, monotonous, and mumbling (cluttered): The voice becomes less audible and, finally, the patient only whispers. Caekebeke and coworkers refer to the speech disorder as a *hypokinetic dysarthria* and attribute it to combined respiratory, phonatory, and articulatory dysfunctions. There is a failure to fully close the mouth. The consumption of a meal takes an inordinately long time. Each morsel of food must be swallowed before the next bite is taken.

Walking becomes reduced to a shuffle; the patient frequently loses balance, and in walking forward or backward seems to be "chasing" the body's center of gravity with a series of increasingly rapid short steps in order to avoid falling (festination). Defense and righting reactions are faulty. Falls do occur, but surprisingly infrequently given the degree of postural instability. Gait is improved by sensory guidance, as by holding the patient at the elbow. Obstacles such as door thresholds have the opposite effect, at times causing the patient to "freeze" in place. Getting in and out of a car or elevator or walking into a room or in a hall becomes particularly difficult. Difficulty in turning over in bed is a similarly characteristic feature as the illness advances, but the patient rarely volunteers this information. Several of our patients have fallen out of bed at a frequency that suggests a connection to their reduced mobility combined with slowed corrective or defensive postural movements. Shaving or applying lipstick becomes difficult, as the facial muscles become more immobile and rigid.

Persistent extension or clawing of the toes, jaw clenching, and other fragments of dystonia, often quite painful, may enter the picture and are sometimes early findings. (These are particularly resistant to treatment.)

A special problem of camptocormia occurs in some Parkinson patients wherein an extreme forward flexion of the spine and correspondingly severe stooping occur. It appears to be a type of axial dystonia when it occurs with Parkinson disease. The deformity resolves when the patient is supine or pushes upward on the handles of a walker. This symptom is associated with a variety of other diseases, some of them muscular. We have not been impressed that it is ameliorated by L-dopa. Why some patients with Parkinson disease are extremely bent over and others are not at all affected is unknown.

As noted above, these various motor impediments and tremors characteristically begin in one limb (more often the left) and spread to one side and later to both sides until the patient is quite helpless. Yet in the excitement of some unusual circumstance (as escaping from a fire, for example), the patient with all but the most advanced disease is capable of brief but remarkably effective movement (*kinesis paradoxica*).

Regarding elicitable neurologic signs, there is an inability to inhibit blinking in response to a tap over the bridge of the nose or glabella (Myerson sign) but grasp and suck reflexes are not present unless dementia supervenes and buccal and jaw jerks are rarely enhanced. Commonly there is an impairment of upward gaze and convergence; if prominent or noted early in the disease, this sign suggests more the possibility of progressive supranuclear palsy. Bradykinesia may extend to eye movements, in that there is a delay in the initiation of gaze to one side, slowing of conjugate movements (decreased maximal saccadic velocity), hypometric saccades, and breakdown of pursuit movements into small saccades.

There are no sensory findings, but a wide variety of paresthetic and other sensory complaints and discomforts are common. These affect mainly the calves and abdomen and are among the most distressing of the *nonmotor parkinsonian symptoms*. Drooling is troublesome; an excess flow of saliva has been assumed, but actually the problem is probably one of failure to swallow with normal frequency. Seborrhea and excessive sweating are claimed to be secondary as well, the former due to failure to cleanse the face sufficiently, the latter to the effects of the constant motor activity but this explanation seems lacking to us; an autonomic disturbance is more plausible. Other nonmotor features are mostly in the category of autonomic disturbances and include most prominently constipation, abdominal pains and cramps, erectile dysfunction, joint aches, and various other sensory experiences that may be difficult for the patient to describe. There is a tendency in some patients to have orthostatic hypotension and sometimes syncope; this has been attributed by Rajput and Rozdilsky to cell loss in the sympathetic ganglia. However, these features are not as prominent as in multiple system atrophy (Shy-Drager syndrome). It is worth mentioning that several of our younger Parkinson patients with recurrent syncope proved to have cardiac arrhythmias; hence other causes of fainting must be considered.

Postural instability is a core feature of the illness; it can be elicited by tugging at the patient's shoulders from behind and noting the lack of a small step backward to

maintain balance often with a fall or the initiation of backward festination. The tendon reflexes vary, as they do in normal individuals from being barely elicitable to brisk. Even when parkinsonian symptoms are confined to one side of the body, the reflexes are usually equal on the two sides, and the plantar responses are flexor. Exceptionally, the reflexes on the affected side are slightly brisker, which raises the question of corticospinal involvement, but the plantar reflex remains flexor. In these respects, the clinical picture differs from that of corticobasal ganglionic degeneration, in which rigidity, hyperactive tendon reflexes, and Babinski signs are combined with apraxia (see further on).

As mentioned earlier, Parkinson disease may be complicated by dementia, a feature described by Charcot. The reported frequency of this combination varies considerably based on the selection of patients and type of testing. An estimate of 10 to 15 percent (Mayeux et al) is the generally accepted figure and matches our experience. The incidence increases with advancing age and duration of disease, approaching 65 percent in Parkinson patients older than 80 years of age, but mental decline may become apparent in patients in their late fifties. The pathologic basis of the dementia is discussed below.

The overall course of the disease is quite variable. In the majority of patients, the mean period of time from inception of the disease to a chairbound state is 7.5 years, but with a wide range (Hoehn and Yahr; Martilla and Rinne). As much as 10 percent of cases remain relatively mild and only very gradually progressive, and such patients may remain almost stable for 10 years or more. These trajectories have been altered somewhat by modern therapies.

Hemiparkinson–Hemiatrophy Syndrome Mentioned here is a rare syndrome described by Klawans and elaborated in a series of 30 patients by Wijemanne and Jankovic. The typical case shows atrophy in one or more body parts, including at times the face, often since childhood, and usually quite subtle. Signs of progressive parkinsonism or dystonia begin in midlife on the atrophic side and, for the most part, are responsive to L-dopa, but some, such as Klawans' original patients, are resistant. Several types of early life cerebral injury underlie the syndrome, but half of patients have no such lesion evident. Understanding of the idiopathic cases is limited. Those with deep brain lesions may be experiencing a slow degeneration of basal ganglia pathways.

Diagnosis

The 2 main difficulties are to distinguish typical Parkinson disease from the many parkinsonian syndromes caused by other degenerative conditions and by medications or toxins, and to distinguish the Parkinson tremor from other types, especially essential tremor. It is worth noting that Parkinson disease is far more common than any of the degenerative syndromes that resemble it. Bradykinesia and rigidity of the limbs and axial musculature are symptoms shared with other forms of parkinsonism, but it is mainly in Parkinson disease that one observes an early sign of "resting" alternating tremor that is more prominent in one arm.

When not all the typical signs are evident, there is no alternative but to reexamine the patient at several-month intervals until it is clear that Parkinson disease is present or until the characteristic features of another degenerative process become evident; these include early falls and vertical gaze impairment in progressive supranuclear palsy; dysautonomia with fainting, bladder, or vocal cord dysfunction in multiple system atrophy; early and rapidly evolving dementia or intermittent psychosis in Lewy-body disease; or apraxia in corticobasal ganglionic degeneration. Very symmetrical findings, particularly tremor, suggest an alternative to idiopathic Parkinson disease. Also, the constellation of features termed "*lower half parkinsonism*" consisting of difficulty purely with gait and stability, as discussed below and in Chap. 7, suggest a process other than Parkinson disease.

If the symptoms warrant, a beneficial and sustained response to levodopa or a dopamine agonist also gives a reasonably secure, although not entirely conclusive, indication of the presence of Parkinson disease (see further on). The other parkinsonian syndromes are for the most part changed only slightly or only for a few weeks or months by the drug. Conversely, although some experts disagree, we have adhered to the notion that complete resistance of the symptoms to L-dopa early in the illness makes the diagnosis unlikely. Furthermore, almost all patients with idiopathic Parkinson disease eventually acquire dyskinesias in response to L-dopa and the absence of this sign after approximately 3 to 5 years of use of the drug brings the diagnosis into question.

The epidemic of encephalitis lethargica (von Economo encephalitis) that spread over Western Europe and the United States after the First World War left great numbers of parkinsonian cases in its wake. No definite instance of this form of encephalitis had been recorded before the period 1914 to 1918, and very few have been seen since 1930; hence, this type of postencephalitic parkinsonism is no longer a diagnostic consideration. However, a Parkinson-like syndrome has been described following other forms of encephalitis, particularly with Japanese B virus, West Nile virus, and eastern equine encephalitis. In the few cases caused by these viruses that we have observed, there has been fairly symmetrical rigidity, hypokinesia, and little or no tremor.

An "arteriopathic" or "arteriosclerotic" form of Parkinson disease was at one time much diagnosed but we have never been entirely convinced of its reality, referring to damage to the substantia nigra as a result of vascular disease or to a syndrome that closely resembles Parkinson disease as a result of atherosclerotic white matter damage. Nonetheless, a number of authoritative clinicians are of the opinion that patients with a vascular cause have a predominantly "lower half" parkinsonism in which shuffling gait, stickiness on turning, and falling are disproportionate to other features. There is no tremor, and little or no response to L-dopa (see Winikates and Jankovic). MRI in such cases has shown substantial white matter changes in both cerebral hemispheres. In the few cases attributable to vascular parkinsonism that have come to our attention with autopsy material, there have been Lewy bodies in the appropriate locations.

Pseudobulbar palsy from a series of lacunar infarcts or from Binswanger disease can cause a clinical picture that simulates certain aspects of Parkinson disease, but unilateral and bilateral corticospinal tract signs, hyperactive facial reflexes, spasmodic crying and laughing, and other characteristic features distinguish spastic bulbar palsy from Parkinson disease. Of course, the elderly parkinsonian patient is not impervious to cerebrovascular disease, and the 2 conditions overlap, but differentiating the predominantly gait or dementing disorders of widespread vascular brain damage from idiopathic Parkinson disease is not difficult.

Normal-pressure hydrocephalus can undoubtedly produce a syndrome resembling Parkinson disease, particularly in regard to gait and postural instability, and at times extending to bradykinesia; but rigid postures, slowness of alternating movements, hypokinetic ballistic movements, and resting tremor are not part of the clinical picture. The gait tends to be short-stepped but not shuffling and there is more of a tendency to retropulsion than there is in Parkinson disease. Sometimes a lumbar puncture gives surprising benefit, indicating hydrocephalus as the cause of the motor slowing and gait disorder.

Essential tremor is distinguished by its fine, quick quality, its tendency to become manifest during volitional movement and to disappear when the limb is in a position of repose, and the lack of associated slowness of movement or of flexed postures. Cogwheeling of minor degree may be associated. The head and voice are more often truly tremulous in essential tremor than in Parkinson disease. Some of the slower, alternating forms of essential tremor are difficult to distinguish from parkinsonian tremor; one can only wait to see whether it is the first manifestation of Parkinson disease. A markedly asymmetrical or unilateral tremor favors Parkinson disease. Also as noted, a faster oscillation is often mixed with the slow alternating Parkinson tremor, but the fast-frequency tremor is only occasionally an opening feature of the disease as discussed in Chap. 6.

Progressive supranuclear palsy (discussed in a section further on) is characterized by rigidity and dystonic postures of the neck and shoulders, a staring and immobile countenance, and a tendency to topple when walking—all of which are vaguely suggestive of Parkinson disease. Early and frequent falls are particularly suggestive of this disease, not being atypical of Parkinson disease until its late stages. Inability to produce vertical saccades and, later, paralysis of upward and downward gaze and eventual loss of lateral gaze with retention of reflex eye movements establish the diagnosis of PSP in most cases.

Paucity of movement, unchanging attitudes and postural sets, and a slightly stiff and unbalanced gait may be observed in patients with an anergic or hypokinetic type of depression. Because a fair proportion of parkinsonian patients are depressed, the separation of these 2 conditions is at times difficult. The authors have seen patients who were called parkinsonian by competent neurologists but whose movements became normal when antidepressant medication or electroconvulsive therapy was given. Several such patients have nonetheless insisted that levodopa helps them in some nondescript way.

The rapid onset of parkinsonism should suggest exposure to neuroleptic medications (used at times as antiemetics and gastric motility agents [metoclopramide]), a variant of Creutzfeldt-Jakob disease, an unusual postinfectious or paraneoplastic illness, or viral encephalitis. The implicated drugs may also evoke an inner restlessness, a “muscular impatience,” an inability to sit still, and a compulsion to move about much like that which occurs at times in the parkinsonian patient (akathisia). Even the newer antipsychosis medications, favored specifically because of a putative lack of extrapyramidal effects, may be at fault.

Strict adherence to the diagnostic criteria for Parkinson disease also permits its differentiation from corticostriatal, striatonigral, and corticobasal ganglionic degeneration, calcification of the basal ganglia, Wilson disease, the acquired hepatolenticular degeneration of repeated hepatic coma, manganese poisoning, as well as Machado-Joseph disease, all of which are discussed in other parts of this chapter.

All in all, if one adheres to the standard definition of Parkinson disease—bradykinesia, hypokinesia “resting” tremor, postural changes and instability, cogwheel rigidity, and response to L-dopa—errors in diagnosis are few. Yet in a series of 100 cases, studied clinically and pathologically by Hughes and associates, the diagnosis was inaccurate in 25 percent. The ostensible explanation for this difficulty is that approximately one-quarter of Parkinson patients fail to display the characteristic tremor and approximately 10 percent are said to not respond to L-dopa. These authors noted that early dementia and autonomic disorder and the presence of ataxia or corticospinal signs were reliable guides to an alternate diagnosis.

Pathology and Pathogenesis

The most constant and pertinent finding in both idiopathic and postencephalitic Parkinson disease is a loss of pigmented cells in the substantia nigra and other pigmented nuclei (locus ceruleus, dorsal motor nucleus of the vagus). The substantia nigra is visibly pale to the naked eye; microscopically, the pigmented nuclei show a marked depletion of cells and replacement gliosis, and some of the remaining cells have reduced quantities of melanin, findings that enable one to state with confidence that the patient must have suffered from Parkinson disease. Also, many of the remaining cells of the pigmented nuclei contain eosinophilic cytoplasmic inclusions, surrounded by a faint halo, called *Lewy bodies* (Fig. 39-5). These are seen in practically all cases of idiopathic Parkinson disease. They were generally absent in postencephalitic cases, but there were neurofibrillary tangles within nigral cell in that disorder. Both these cellular abnormalities appear occasionally in the substantia nigra of aged, nonparkinsonian individuals. Possibly the individuals with Lewy bodies would have developed Parkinson disease had they lived a few more years. Many of the inherited forms of Parkinson disease also lack Lewy bodies.

Noteworthy is the finding by McGeer and colleagues that nigral cells normally diminish with age, from a maximal complement of about 425,000 to 200,000 at age 80 years.

Figure 39-5. Photomicrograph of a round Lewy-body inclusion in the cytoplasm of a nigral neuron. (Hematoxylin and eosin [H&E] staining.) (Courtesy of Matthew Frosch, MD, PhD.)

Tyrosine-hydroxylase, the rate-limiting enzyme for the synthesis of dopamine, diminishes correspondingly. However, these authors and others have found that in patients with Parkinson disease the number of pigmented neurons is reduced to 30 percent or less of that in age-matched controls. Using more refined counting techniques, Pakkenberg and coworkers estimated the average total number of pigmented neurons to be 550,000 and to be reduced in absolute numbers by 66 percent in Parkinson patients. (The number of nonpigmented neurons was reduced in Parkinson cases by only 24 percent.) Thus aging contributes importantly to nigral cell loss, but the cell depletion is so much more marked in Parkinson disease that some factor other than aging must also be operative.

Other regions of neuronal loss are widespread as mentioned, but their significance is less clear. There is neuronal loss in the mesencephalic reticular formation, near the substantia nigra. These cells project to the thalamus and limbic lobes. In the sympathetic ganglia, there is slight neuronal loss and Lewy bodies are seen. This is also true of the pigmented nuclei of the lower brainstem as well as of neuronal populations in the putamen, caudatum, pallidum, and substantia innominata. On the other hand, dopaminergic neurons that project to cortical and limbic structures, to caudate nucleus and nucleus accumbens, and to periaqueductal gray matter and spinal cord are affected little or not at all. The lack of a consistent lesion in either the striatum or the pallidum is noteworthy. An alternative hypothesis offered by Braak and Tredici, mentioned in an earlier section of this chapter and attributed to Braak and Braak, is that the substantia nigra compacta is affected only late in the pathobiology of Parkinson disease. Their study found that the earliest changes in the brain occur in the dorsal glossopharyngeal-vagal and anterior olfactory nuclei, and only later did they appear in the midbrain nuclei. This theory

accommodates a variety of clinical features and potential environmental triggers to the disease. Lang has suggested that this distribution of cell loss explains some of the nondopaminergic features of the disease and offers other avenues for therapy.

Statistical data relating Parkinson and Alzheimer diseases are difficult to assess because of different methods of examination from one series to another. Nevertheless, the overlap of the 2 diseases is more than fortuitous, as indicated earlier in this chapter. The majority of the demented Parkinson patients show some Alzheimer-type changes but there are some in whom few plaques or neurofibrillary changes can be found and instead display cortical neuronal loss accompanied by widespread distribution of Lewy bodies, marking the process as Lewy-body dementia and not Parkinson disease.

Of interest had been the observation, both in humans and in monkeys, that a neurotoxin (known as MPTP [1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine]) produces irreversible signs of parkinsonism and selective destruction of cells in the substantia nigra. The toxin, an analogue of meperidine, which was self-administered by addicts, binds with high affinity to monoamine oxidase, an extraneural enzyme that transforms MPTP to a toxic metabolite, pyridinium MPP (1-methyl-4-phenylpyridinium). The latter is bound by the melanin in the dopaminergic nigral neurons in sufficient concentration to destroy the cells. The mechanism by which MPTP produces the clinical aspects of the Parkinson syndrome is unsettled. One hypothesis is that the inner segment of the globus pallidus is rendered hyperactive because of reduction of the influence of gamma-aminobutyric acid (GABA) of the subthalamic nucleus. The notion of some other environmental toxin as a cause of Parkinson disease has been stimulated

by the MPTP findings (see Uhl et al; also the review by Snyder and D'Amato). For example, Parkinson disease is slightly more frequent in industrialized countries and in agrarian regions where organophosphates are commonly used, but its universal occurrence would argue against this hypothesis. Despite extensive study, no chemical toxin, heavy metal, or infection has been causally related to the disease. Some plausible theories hold that a toxin might be implicated only on a genetic background predisposing to the disease. The MPTP disease serves as a model for the neurophysiologic and neurochemical changes of Parkinson disease because of destruction of the substantia nigra, but in most other respects it does not reflect the naturally occurring disorder (including the absence of Lewy bodies).

Genetic Aspects

Considering its frequency, coincidence in a family on the basis of chance occurrence might be as high as 5 percent. However, careful epidemiologic studies suggest that a familial occurrence may be as high as 15 percent. A lack of concordance of Parkinson disease in twins was at first thought to negate the role of genetic factors, but a study of dopamine metabolism using PET scanning showed that 75 percent of asymptomatic twins of Parkinson patients had evidence of striatal dysfunction, whereas only a small portion of dizygotic twins showed these changes (Piccini et al). These data indicate a substantial role for inherited traits, even in cases of ostensibly sporadic Parkinson disease (see below regarding the better defined inherited forms). Some mutations and polymorphisms are more clearly modifying factors in producing the disease, but others act as dominant disease genes. These are summarized in Table 39-3. We have chosen to

Table 39-3

MAIN GENETIC DEFECTS ASSOCIATED WITH PARKINSON DISEASE

NOTATION	GENE (PROTEIN)	INHERITANCE	AGE OF ONSET	LEWY BODIES	SPECIAL FEATURES
Park1 & Park4	SCNA (α -synuclein)	AD	30–40 years	+	Two main mutations—A53T, A30P—promote oligomerization of α -synuclein.
Park2	PARK2 (parkin)	AR	20–40 years	–	Accounts for 50% of early-onset inherited PD; 20% of “sporadic” early-onset cases.
Park3	PARK3	AD	Late onset	+	Resembles idiopathic PD.
Park5	UCHL-1 (ubiquitin esterase)	SNP	50’s	+	Two different polymorphisms confer risk of PD. Mutations decreased recycling of ubiquitin monomers.
Park6	PINK1 (PTEN-induced putative kinase 1)	AR	Varies		Mitochondrial gene.
Park7	PARK7 (DJ-1)	AR	30’s	?	Slow progression; gene plays role in cellular response to oxidative stress.
Park8	LRRK2 (leucine-rich repeat kinase 2)	AD	Late	±	Ashkenazic Jews. Protein also called dardarin; related to Gaucher disease.
Park14	PLA2G6 (phospholipase A2)	?	Late	–	Dystonia-parkinsonism; late onset; other mutations cause neuroaxonal dystrophy.
NR4A2	NURR1 (nuclear receptor related protein 1)	AD	Confers susceptibility to PD	?	Gene is implicated in the formation and identity of dopaminergic neurons.

AD, autosomal dominant; AR, autosomal recessive; PD, Parkinson disease.

retain the nomenclature of the *PARK* genes for ease of exposition but, as the genes are sequenced, their names have replaced this generic notation in many summaries of the genetics of the disease.

Numerous observations have implicated the nuclear and synaptic protein α -synuclein, the main component of Lewy bodies in both the sporadic and inherited forms of Parkinson disease, as well as in Lewy-body disease. Synuclein, a normal component of the synapse, exists in a soluble unfolded form, but in high concentrations it aggregates into filaments, which are the main (but not the only) constituent of the Lewy body. Immunostaining techniques disclose additional less-specific proteins, such as ubiquitin and tau within the Lewy bodies. Furthermore, in families with a rare autosomal dominant form of Parkinson disease, several different mutations on chromosome 4 code for an aberrant form of synuclein that decreases its stability and promotes its aggregation (Polymeropoulos et al). A family has also been described in which the cause of Parkinson disease is an extra nonmutant copy of the α -synuclein gene (Singleton et al), comparable to the circumstance or triplication of chromosome 21 in

the Alzheimer disease of Down syndrome. Additionally, some cases of familial parkinsonism result from mutations that control the removal of α -synuclein from the cell via proteasomal pathways. Together, these findings indicate that instability or misfolding of α -synuclein or its deficient removal may be a primary defect in the disease. The protofibrillary form of the protein (i.e., a soluble protein in the cytosol) is also toxic to dopaminergic neurons. These processes are accelerated by defects in heat shock proteins that chaperone α -synuclein into and out of the cell. Curiously, Lewy bodies are not found in patients with most of the parkin mutations.

Parkin is a ubiquitin protein ligase that participates in the removal of unnecessary proteins from cells through the proteasomal system (Fig. 39-6). Attachment of parkin and ubiquitin to cytosolic proteins is understood to be an obligatory step in the disposal of proteins by proteasomes. Mutations in the parkin gene lead either to an inadequacy or misfolding of synuclein, resulting in its accumulation, or to the disruption of disposal of proteins in dopamine-producing cells. The importance of the ubiquitination pathway in this disease is further highlighted

Figure 39-6. Schematic diagram of proposed mechanisms of α -synuclein toxicity in Parkinson disease. In this model, α -synuclein levels are elevated by (a) duplication of one copy of the α -synuclein gene; (b) point mutations in the α -synuclein gene that generate excessive accumulations of synuclein; or (c) mutations in parkin and *UCH-L1* genes that reduce normal removal of synuclein by the proteasomes. The excess of synuclein polymerizes to form protofibrils, a process that is enhanced by defects in heat shock proteins (Hsps) or by the action of dopamine, which binds to synuclein. In turn, this leads to formation of Lewy bodies. This model attributes the neurotoxicity to either the protofibrils or the Lewy bodies. (Adapted by permission from Eriksen JL, Dawson TM, Dickson DW, Petrucelli L: Caught in the act: α -Synuclein is the culprit in Parkinson's disease. *Neuron* 40:453–456, 2003.)

by the report that parkinsonian features are present in a family with mutations in ubiquitin carboxyterminal hydrolase L1 (*Park5*, *UCHL-1*; Table 39-3). Figure 39-6 illustrates these relationships and the processing of synuclein in the cell. It must be emphasized that most of the mechanisms illustrated are speculative or are derived from the molecular study of familial Parkinson disease and therefore may not apply to the sporadic process.

A mutation that has received much attention has been at the *LRRK2* (leucine-rich repeat kinase 2) site. It is implicated in both genetic and sporadic forms of the disease, particularly among those of Ashkenazic Jewish or North African origin. The *LRRK2* protein (dardarin) is a cytoplasmic component that is widely distributed in the brain and peripheral nerves. It has been estimated that mutations in the gene (mainly one common one, G20195) are responsible for 1 percent of sporadic cases and are found in 5 to 8 percent of individuals with a first-degree relative who has the disease. The gene acts as a dominant trait but penetrance of the defect increases with age, being 85 percent at 70 years. Therefore, there may not be a family history. The clinical syndrome in most respects simulates the sporadic form of the disease according to Papapetropoulos and colleagues, but several other series have noted the absence of tremor. The genetics of this disorder, also called *Park8*, are reviewed by Brice.

Several other gene defects are of interest in familial parkinsonism. One is a dominantly inherited mutation in the gene *Nurr1*, whose normal function is to specify the identity of dopaminergic neurons. Another is in recessively inherited parkinsonism caused by defects in the gene *DJ-1*, a protein that is essential for the normal neuronal response to oxidative stress. Also, a disease-causing mutation in the gene termed *PINK*, corresponding to *Park6*, codes for a mitochondrial kinase, therefore implicating this cellular structure in some forms of Parkinson disease (Valente et al). Presumably, dopaminergic neurons are compromised in some manner by these defects.

There has also been emphasis on mutations on 1 of 12 exons in the so-called *Park2* gene, which codes for the protein parkin (see Table 39-3). The most common types are point mutations or deletions in exon 7, but abnormalities of the other exons evince similar syndromes. Homozygous mutations generally give rise to early-onset disease, but certain hemizygous changes (in exon 7) are associated with a later onset. The resultant syndromes have been termed *parkin disease* to distinguish them from the idiopathic variety. It has been estimated by Khan and colleagues that 50 percent of families that display an early onset of Parkinson disease and 18 percent of sporadic cases with early onset (before age 40 years) harbor mutations in this gene. Perhaps of greater clinical interest is finding that up to 2 percent of late-onset cases are associated with parkin mutations, and 1 percent due to changes in the aforementioned *LRRK2* gene. Sequencing of these genes is now available in commercial laboratories for the purposes of detecting mutations and polymorphisms.

From a clinical perspective, the presentation of the late-onset cases with parkin mutations has been quite variable. Collectively, they can often be identified by an extreme sensitivity to L-dopa, maintaining an almost complete suppression of symptoms over decades with only small doses of medication; also, they have a low threshold for dyskinesias induced by L-dopa. We can also corroborate from experience with our own patients an excellent response of tremor, postural changes, and bradykinesia to anticholinergic drugs. A second feature has been that most of these patients may enjoy a remarkable restorative benefit from sleep, which creates a diurnal pattern of symptoms. Several series, particularly those of Lohmann and associates and of Khan and colleagues, have indicated that there may be a wide variety of additional features: hyperreflexia, cervical, foot, or other focal dystonias, sometimes induced by exercise; and, less often, autonomic dysfunction, peripheral neuropathy, and psychiatric symptoms. The sensitivity to medication and sleep benefit have long been known as the distinguishing components of juvenile-onset parkinsonism with dopa-responsive dystonia (Segawa disease), which is discussed later in the chapter.

Of similar interest as a modulating factor in the development of the disease is strong association between mutations in the glucocerebrosidase gene (other mutations of which causes Gaucher disease) among Ashkenazi Jews (Sidransky et al), the same population predominantly affected by polymorphisms of *LRRK2*. Although population studies allow only limited conclusions about clinical correlations, the glucocerebrosidase mutation is present more often in patients with a family history of the disease, have an earlier onset than in patients with a normal gene and a lower incidence of resting tremor. Mutations have been present in 7 percent of Parkinson patients who had their genes fully sequenced, making it so far the most common genetic factor for the disease, and certainly in this ethnographic population.

It is hoped that the genetic mutations that give rise to Parkinson disease will expose the molecular pathophysiology of the disease. As discussed earlier, several sites are implicated in the familial forms of Parkinson disease, some related to the gene that codes for synuclein, the main component of the Lewy body.

Treatment

Although there is no current treatment that clearly halts or reverses the neuronal degeneration underlying Parkinson disease, methods are now available that afford considerable relief from symptoms. Treatment can be medical or surgical, although reliance is placed mainly on drugs, particularly on L-dopa (Table 39-4). The following sections are necessarily detailed so as to give the clinician a full comprehension of the use and side effects and interactions of these drugs.

L-Dopa and L-Dopa-Modifying Drugs At present, L-dihydroxyphenylalanine (L-dopa) is unquestionably the most effective agent for the treatment of Parkinson disease and the therapeutic results, even in those with

Table 39-4

DRUGS COMMONLY USED IN THE TREATMENT OF PARKINSON DISEASE

MEDICATION	STARTING DOSE	TARGET DOSE	MAIN BENEFIT	SIDE EFFECTS
L-Dopa				
Carbidopa-L-dopa	25/100 mg tid	Up to 50/250 mg q3h	Reduction of tremor and bradykinesia; less effect on postural difficulties	Nausea, dyskinesias, orthostatic hypotension, hallucinations, confusion
Controlled release carbidopa-L-dopa	25/100 mg tid	Up to 50/200 mg q4h	May prolong L-dopa effects	
Dopamine agonists				
Ropinirole	0.25 mg tid	9 to 24 mg/d	Moderate effects on all aspects; reduced motor fluctuations of L-dopa	Orthostatic hypotension, excessive and abrupt sleepiness, confusion, hallucinations
Pramipexole	0.125 mg tid	0.75 to 3 mg/d	As above	
Glutamate antagonist				
Amantadine	100 mg/d	100 mg bid–tid	Smoothing of motor fluctuations	Leg swelling, congestive heart failure, prostatic outlet obstruction, confusion, hallucinations, insomnia
Anticholinergics				
Benztropine	0.5 mg/d	Up to 4 mg/d	Tremor reduction, less effect on other features	Atropinic effects: dry mouth, urinary outlet obstruction, confusion, and psychosis
Trihexyphenidyl	0.5 mg bid	Up to 2 mg tid	As above	As above
COMT inhibitors				
Entacapone	200 mg with L-dopa		Prolonged effect of L-dopa	Urine discoloration, diarrhea, increased dyskinesias
MAO-inhibitors				
Rasagiline	0.5 mg	1 mg daily	Reduced “off” time, Potential neuroprotection	Hypertensive crisis with tyramine-rich foods and sympathomimetics
Selegiline	5 mg	5 mg bid	Potential neuroprotection	

far advanced disease, are much better than have been obtained with other drugs. The levodopa, or a dopamine agonist preparation as described below, is introduced when the symptoms begin to interfere with work and social life or falling becomes a threat, and then these drugs are used at the lowest possible dose. The theoretical basis for the use of this compound rests on the observation that striatal dopamine is depleted in patients with Parkinson disease but that the remaining diseased nigral cells are still capable of producing some dopamine by taking up its precursor, L-dopa. The number of neurons in the striatum is not diminished and they remain receptive to ingested dopamine acting through the residual nigral neurons. Over time, however, the number of remaining nigral neurons becomes inadequate and the receptivity to dopamine of the striatal target neurons becomes excessive, possibly as a result of denervation hypersensitivity; this results in both a reduced response to L-dopa and to paradoxical and excessive movements (dyskinesias) with each dose. The drug has an interesting history that includes many early trials that failed to persuade neurologists of its

effectiveness; Barbeau's paper on this historical subject may be consulted by the interested reader.

Most patients tolerate the drug initially, experiencing few serious adverse effects and showing various degrees of improvement, sometimes dramatic, especially in hypokinesia and tremor after several days or sooner. However, the side effects and limitations of L-dopa become considerable as the drug therapy continues and the disease progresses, as discussed below.

By combining L-dopa with a decarboxylase inhibitor (carbidopa or benserazide), which is unable to penetrate the central nervous system (CNS), decarboxylation of L-dopa to dopamine is greatly diminished in peripheral tissues. This permits a greater proportion of L-dopa to reach nigral neurons and, at the same time, reduces the peripheral side effects of L-dopa and dopamine (nausea, hypotension, confusion). Combinations of carbidopa-levodopa are available in a 1:10 or 1:4 ratio and the benserazide-levodopa combination is available in a 1:4 ratio. The initial dose of carbidopa-levodopa is typically one-half to one of a 25/100-mg tablet given bid

or tid and increased slowly until optimum improvement is achieved, usually up to 4 tablets administered 5 or more times daily as the disease advances, or a similar dose of the 25/250-mg combination.

A class of catechol-*O*-methyltransferase (COMT) inhibitors, typified by entacapone, extends the plasma half-life and the duration of L-dopa effect by preventing its breakdown (as opposed to increasing its bioavailability, as in the case of carbidopa). A combination of L-dopa, carbidopa, and a COMT inhibitor is available in a single pill.

Long-acting preparations of levodopa-carbidopa may provide slightly longer effect and reduce dyskinesias in some patients (Hutton and Morris) in the advanced stages of disease, but our experience with these drugs given earlier in the course of disease has given less-predictable results. The absorption of the long-acting drug, however, is approximately 70 percent and may be inconsistent, often necessitating a slight increase in total dose. To facilitate the treatment of morning rigidity and tremor, the long-acting tablet can be given late in the previous evening.

For patients who require very frequent but small doses of the drug because of severe motor fluctuations and dyskinesias, an oral suspension may be formulated that allows precisely measured doses to be delivered orally or through a nasogastric tube. The typical composition is 500 mg L-dopa (of carbidopa-L-dopa 10/100 or 25/100), 500 mg of ascorbic acid to stabilize the drug, and 250 mL of water, resulting in a concentration of L-dopa of 2 mg/mL, which is administered in small amounts. A gel preparation is also available for delivery through a duodenal tube.

Each patient requires empirical adjustment of the dose and timing of medication and then generally does well by maintaining a relatively regular medication schedule, supplemented by small intercalated doses when needed. The effect of L-dopa may be virtually immediate (i.e., after absorption, which occurs over 30 to 40 min) but there is a further cumulative effect over several days of consistent dosing. The principles that guide the adjustment of dosing (end-of-dose wearing off, dyskinesias, freezing, confusion) are discussed further on.

Dopamine Agonists These drugs have a direct dopaminergic effect on striatal neurons, thereby partially bypassing the depleted nigral neurons. They have found a place both as the initial treatment, replacing L-dopa in this role, and in modulating the effects of L-dopa later in the illness. However, dopamine agonists are consistently less potent than L-dopa in managing the main features of Parkinson disease and, in higher doses and in older individuals, they produce undesirable motor and cognitive side effects (see further on). They are favored because they are associated with fewer dyskinetic motor complications, or at least, delay the need for L-dopa and its dyskinetic effects. *Bromocriptine* and *lisuride* are synthetic ergot derivatives whose action in Parkinson disease is explained by their direct stimulating effect on dopamine (D₂) receptors located on striate neurons. The nonergot dopamine agonists *ropinirole* and *pramipexole* have a similar type and duration of effectiveness and are used

more widely because of their minimal ergot-like effects. Pergolide and the related drug cabergoline are no longer used because of the risk of cardiac valvular damage, particularly at higher dose levels.

The dopamine agonists are introduced gradually. For example, the initial dose of pramipexole is 0.125 mg tid, following which the dosage is doubled weekly to a total of 3 to 4.5 mg/d if the medication is used without L-dopa. If an individual is already taking L-dopa, these drugs usually permit a gradual reduction in levodopa-carbidopa dose by approximately 50 percent. Their duration of action is slightly longer than that of L-dopa and they cause less nausea. These medications may be also useful in reducing the motor fluctuations of L-dopa.

Our experience is in general agreement with that of Marsden, who found that of 263 patients given dopamine agonists as the sole treatment, 181 had abandoned medication after 6 months because of lack of effect or adverse reactions. Nevertheless, the fact that a large enough proportion of patients continue to benefit for up to 3 to 5 years indicates that the initial use of dopamine agonists has merit (see also Rascol et al). A recent development of some interest is a transdermally absorbed dopamine agonist such as rotigotine. Several trials suggest that the transdermal system can maintain a stable plasma level of the drug. In the study by LeWitt and associates, the main effect was a doubling of "on" time without unwanted dyskinesias. The effects on the quality of life in Parkinson patients appear to be positive but minor in degree. Skin reactions are common and the sulfites used in the patch formulation can cause severe systemic reactions in sensitive individuals.

Even small doses of dopaminergic drugs, when first introduced, may induce orthostatic hypotension, but most patients are tolerant of them. They may also produce abrupt and unpredictable sleepiness, and patients should be warned of this possibility in relation to driving. In some individuals, particularly the elderly, dopamine agonists may produce hallucinosis or confusion; these problems are most profound in patients who are later determined to have Lewy-body disease (see further on). More data are required to judge the efficacy of the current trend of initiating therapy with a dopamine agonist rather than with L-dopa.

Many clinicians initiate treatment with small amounts of a dopamine agonist, at least as much for the putative delay of dyskinesias that they offer in comparison to starting L-dopa. Alternatively, carbidopa/L-dopa tid can be initiated and supplemented over a month with a dopamine agonist. The side effects and subtleties of dosing are explained in the sections above on each of these classes of drug. The issue of also starting an MAO inhibitor such as rasagiline early in the illness is discussed below.

Adjunctive Medications Because of the side effects of levodopa and of dopaminergic agents, some neurologists avoid pharmacotherapies if the patient is in the early phase of the disease and the parkinsonian symptoms are not troublesome. When the predominant manifestation is tremor, very satisfactory results can be obtained in some patients for up to several years with anticholinergic agents alone. The anticholinergic drugs have limited effect on the

postural, hypokinetic, and other manifestations of disease. Koller's study, which quantified the effect of anticholinergic medication on tremor and compared it to L-dopa, concluded that there was considerable variability in response between patients but that L-dopa was on average more effective. Nonetheless, anticholinergic agents have long been in use for the treatment of tremor in younger patients and we still use them occasionally, either in conjunction with L-dopa or in patients who cannot tolerate the latter drug. The optimum dosage level is the point at which the greatest relief from tremor is achieved within the limits of tolerable side effects, mainly dry mouth. In older patients, one must be alert to changes in cognitive function, hallucinations, and urinary outflow obstruction.
